There is a solid evidence base for treatment of psychosis in PD. The gold standard is clozapine; it is effective even at low doses (<25 mg), does not block D2 receptors, and has been evaluated in several controlled trials. Because of the requisite blood monitoring with clozapine, quetiapine is usually the initial drug of choice, but some patients eventually experience worsened motor function and patients with dementia may be especially vulnerable. Controlled trials of quetiapine, however, have not been shown to be efficacious. Orthostatic hypotension, headache, and nausea also contribute to its intolerance. Other “atypical” neuroleptic agents (olanzapine and risperidone) reduce or eliminate psychosis at low doses, but their effects on striatal D2 receptors are frequently associated

Telegram: @medical_k

www.konkur.in

with significant motor deterioration. Case reports and open-label studies demonstrate that aripiprazole, a partial agonist at serotonergic and dopaminergic receptors, has variable effects on psychotic symptoms but its propensity to worsen motor function indicates it is not suitable for use in PD. Controlled trials of ziprasidone are needed to evaluate its efficacy and safety, though case reports and case series report psychiatric benefits without significant adverse effects. Pimavanserin, a selective serotonin 5-HT2A inverse agonist without adverse motor effects, is FDA approved for treating PD psychosis, including both hallucinations and delusions. Pimavanserin may also improve cognition and sleep, even before the antipsychotic effect, which may not be evident for 3 to 4 weeks. ECT is effective for major depression with psychosis and nonpsychotic depression; it also benefits parkinsonism and can be used for dopamine-induced psychosis. Cholinergic agents can also have antipsychotic effects.

Other Parkinsonian Conditions

Progressive Supranuclear Palsy

EPIDEMIOLOGY AND ETIOLOGY. PSP, an important cause of parkinsonism, was first described in 1964 and accounts for 4% of all cases with parkinsonism. Prevalence of the classic PSP–Richardson syndrome (PSP-RS) is five to six cases per 100,000 with onset of symptoms usually after age 60 in all races and both genders, but men tend to be affected more often than women. Disease duration is approximately 6 years. Recognition that there is spectrum of clinical phenotypes corresponding to PSP pathology. There are rare familial cases of PSP, but its development is usually sporadic. PSP is classified as a tauopathy, a term referring to neurodegenerative disorders characterized by intracellular aggregations of abnormally phosphorylated tau protein. Tau normally stabilizes microtubules and its aggregation leads to formation of abnormal cytoskeletal fibrils. The cause of the tauopathy in PSP, and its role in neurodegeneration, remains uncertain.

CLINICAL FEATURES. The defining features of PSP-RS are of a gradually progressive neurodegenerative condition that is manifest in affected individuals over age 40 years as ocular motor dysfunction (vertical supranuclear gaze palsy) or postural instability and falls within the initial

Telegram: @medical_k

www.konkur.in

year of onset. More recent criteria by the Movement Disorder Society also include akinesia (progressive gait freezing) and cognitive dysfunction as core features. In contrast to PD, the parkinsonism progresses with symmetric bradykinesia and axial rigidity along with paralysis of downward vertical gaze. The problems with ocular motility may not be evident for several years, but cause problems with walking downstairs. Dysphagia develops over the course of the illness. Unlike PD, postural instability leading to falls and dysarthria are early and often presenting features. Also, there is a poor response to levodopa, tremor is uncommon and stride length is erratic. Posture tends to be upright or sometimes opisthotonic because of axial rigidity. Instead of a lack of facial expression (hypomimia), patients appear “worried” or “astonished,” resulting from dystonic contractions of facial muscles between the eyebrows, reduced blinking, lid retraction, and gaze palsy.

The clinicopathologic complexity of PSP is notable, leading to recognition of its phenotypic variability, in which initial phenomena are atypical for PSP. With progression, the typical motor features, that is, postural instability and vertical gaze palsy, emerge and the ultimate diagnosis of “definite” PSP is based on evidence of PSP neuropathology. However, the varied initial presentations confound early and accurate diagnosis, underscoring the need for specific biomarkers that facilitate diagnosis. Examples of phenotypic variability include PSP presenting with apraxia of speech (PSP-AOS), as Parkinson disease like (PSP-P) with a jerky postural tremor and levodopa response, as the corticobasal syndrome (PSB-CBS), with cerebellar ataxia (PSP-C), with exclusive ocular motor dysfunction (PSP-OM), with primary lateral sclerosis (PSP-PLS); with progressive akinesia and gait freezing (PSP-PAGF), and with the behavioral variant of frontotemporal dementia (PSP-F).

Cognitively, there is also phenotypic variability, with features of a subcortical dementia with bradyphrenia, memory deficits, and predominant frontal lobe dysfunction with executive, attentional deficits, memory, visuospatial, and language and social cognitive deficits. Approximately 10% present with cognitive symptoms and up to 70% develop a dementia over the disease course. Speech and language dysfunction presenting as a nonfluent/agrammatic variant of primary progressive aphasia (naPPA) or progressive apraxia of speech increases diagnostic certainty for PSP. Aphasia, apraxia, and agnosia, the classic features of “cortical dementias,” are not evident. Apathy, irritability,

Telegram: @medical_k

www.konkur.in

childishness, impulsivity, perseveration, and disinhibition are compatible with damage to orbitofrontal and medial frontal circuits and are the most common psychiatric or behavioral features. There are also sleep disturbances, depression, emotional lability including abrupt laughter or crying episodes that are usually inappropriate or mood incongruent (also referred to as pseudobulbar affect or emotional incontinence), and occasionally schizophreniform psychotic symptoms.

PATHOLOGY AND LABORATORY EXAMINATION. Neuropathologically, there is broader involvement of the basal ganglia in PSP than in PD. PSP affects the substantia nigra as well as the striatum, thalamus, subthalamus, other brainstem nuclei, and periaqueductal gray matter. The main pathologic findings are abnormal accumulations of tau in what are described as “tufted” astrocytes, globose high-density tau-positive neurofibrillary tangles composed solely of the 4R tau isoform, coiled bodies in oligodendrocytes in white matter, neuronal loss, and gliosis. There is pronounced dopamine depletion in the striatum, decreased density of striatal D2 receptors, widespread cholinergic neuronal damage, and effects on serotonergic and GABAergic systems. Structural imaging studies initially reveal midbrain atrophy followed by third ventricular enlargement and pontine and frontotemporal atrophy. Diffusion tensor imaging studies demonstrate white matter tract degeneration connecting the cerebellum, midbrain, thalamus, and premotor cortex. PET studies show decreased striatal dopamine binding and fluorodopa uptake and bilateral premotor hypometabolism extending into prefrontal cortex, supplementary motor area, and midbrain. A recent GWAS of autopsy-confirmed PSP implicates three genes, STC6, EIF2AK3, and MOBP, as associated with PSP. However, PSP is rarely associated with a family history and is considered sporadic at this point.

DIFFERENTIAL DIAGNOSIS. After PD, which is at least 10 times more prevalent, PSP is the second most common parkinsonian syndrome. Frontotemporal dementia (FTD) and corticobasal ganglionic degeneration manifest similar clinical and pathologic features, including parkinsonism, frontal executive impairments, apathy, and tau-positive inclusions. While profound apathy is the predominant psychiatric feature, it can be misdiagnosed as depression, which occurs with apathy in a minority of cases.

Telegram: @medical_k

www.konkur.in

COURSE AND PROGNOSIS. PSP is a rapidly progressive and devastating degenerative disease. Life expectancy is generally 5 to 7 years after onset, with death often related to dysphagia.

TREATMENT. There are no specific treatments for the motor or cognitive aspects of PSP and care is largely supportive and symptomatic. Occupational, physical, and speech therapy interventions address safety and function as the disease progresses. Clinical trials targeting tau represent significant progress and antibody and gene therapies are under development. Both tideglusib, a glycogen synthase kinase 3 inhibitor, and davunetide, which affects microtubule stability, were safe and well tolerated, but did not demonstrate clinical efficacy on the PSP rating scale. Levodopa is ineffective in PSP, probably because of the reduced number of postsynaptic striatal D2 receptors, although there can be an initial response in some patients. Despite extensive cholinergic damage, cholinergic enhancing agents provide little or no benefit for cognition and can be poorly tolerated. Psychiatric symptoms in PSP can be difficult to treat, but include standard targeted pharmacologic and psychosocial approaches aimed at reducing apathy, irritability, agitation, mood lability, etc., in neuropsychiatric populations.

Corticobasal Degeneration

Originally termed corticodentatonigral degeneration with neuronal achromasia, corticobasal degeneration (CBD) was first described in 1968 as a syndrome of involuntary movements and slowed voluntary movements. CBD is classified as a sporadic tauopathy characterized by deposition of hyperphosphorylated 4-repeat tau in neurons and glia, referred to as astrocytic plaques. CBD also shares clinical and pathologic features with other tauopathies, including PSP and certain forms of FTD. Although numerous clinical criteria have been applied to CBD, these predict pathologic CBD in 25% to 56% of cases and diagnostic criteria are evolving. Review of pathologically confirmed cases of CBD suggest four CBD phenotypes: the initially reported phenotype, now referred to as CBS, a frontal behavioral–spatial syndrome (FBS), naPPA, and progressive supranuclear palsy syndrome (PSPS). To facilitate development of potential neuroprotective therapies for tauopathies, two sets of clinical diagnostic criteria comprising these phenotypes for CBD have been proposed, one for probable CBD and a second broader set of

Telegram: @medical_k

www.konkur.in

criteria for possible CBD with less specificity for CBD pathology, but still likely representing tau pathology.

CBD affects adults with gradual onset usually after age 40 and steady progression until death within 2 to 12 years. Mean age of disease onset is reported as 64 years and the median survival is around 6 to 7 years. The pathologic findings include ballooned achromatic neurons, frontoparietal atrophy, pronounced cortical neuronal loss, cortical astrocytic plaques, and tau inclusions in the substantia nigra, basal ganglia, and along dentatorubrothalamic tracts. Neuroimaging studies show asymmetric frontoparietal atrophy and subcortical hypometabolism contralateral to the more affected side along with bifrontal–parietal hypometabolism.

The clinical manifestations reflect both basal ganglia and cortical dysfunction. Motor signs almost invariably include highly asymmetric or unilateral progressive motor signs of levodopa-resistant parkinsonism (rigidity, brady/akinesia, and postural or action tremor). There is also postural instability, focal reflex myoclonus, and limb dystonia, which is present in about 40% of patients. Oculomotor motility may be impaired, similar to PSP. The most prominent neuropsychiatric features and clinical hallmarks of CBS are lateralized ideomotor and ideational apraxia and the “alien hand syndrome.” Cognitive deficits, originally regarded as late-stage phenomena, are evident in most patients early in the disease course, along with behavioral features. These may be overlooked, however, when there is prominent motor dysfunction. As with other subcortical motor disorders, there are multiple cognitive deficits, including predominantly executive, memory, and attentional dysfunction that may be severe enough to amount to dementia. Parietal lobe dysfunction, manifest as sensory or visual neglect and visuospatial deficits, is apparent on cognitive testing, as are deficits in social cognition. Aphasia may also be present.

Depression is much more common in CBD relative to PSP, which is characterized by apathy. In CBD, apathy, disinhibition, and delusions are also common and may co-occur, but appear distinct from depression, suggesting different underlying mechanisms. There are no definitive treatments for the motor or cognitive symptoms in CBD, but the parkinsonism may have a limited response to levodopa. Antidepressants are used for depression and anxiety but are not always effective. Caregiver education and assessment for depression are important

Telegram: @medical_k

www.konkur.in

aspects of patient care. Physical therapy interventions address daily functioning, improve rigidity, and prevent contractures.

PRIMARY DEMENTIA SYNDROMES WITH PARKINSONIAN SIGNS

Frontotemporal Dementia

Social cognition is one of the six cognitive domains assessed in the diagnosis of major neurocognitive disorder in the DSM-5. FTD is a clinical syndrome characterized by prominent behavioral or personality changes involving social cognition, language dysfunction, and neuronal loss, spongiosis, and gliosis in the frontal and temporal cortices. Onset of FTD is usually after age 50, but ranges from 35 to 75 years. Life expectancy after diagnosis is 3 to 15 years.

FTD is neuropathologically, clinically, and genetically heterogenous, with approximately 30% to 50% of cases having a positive family history. FTD also overlaps clinically and neuropathologically with CBD, PSP, and motor neuron disease/amyotrophic lateral sclerosis (MND/ALS), which are often considered part of the FTD complex. The characterization and genetics of the FTDs have evolved rapidly over the last decade. Neuropathologic consensus criteria include three major subgroups based on protein pathology: tau, transactive response DNA-binding protein 43 (TDP-43), and fused in sarcoma (FUS) and there are three major FTD disease genes (microtubule-associated protein tau [MAPT], progranulin [GRN], and C9*orf*72) and many other rarer disease genes. Mutations in MAPT, located on chromosome 17, are typically associated with bvFTD and parkinsonism, and are generally referred to as FTD and parkinsonism linked to chromosome 17 (FTDP-17).

Symptom onset in FTD is insidious and many patients with FTD are initially misdiagnosed with a primary psychiatric illness. The behavioral variant (bvFTD) involves prominent and altered social behavior and personality changes such as profound apathy, impulsivity, disinhibition (e.g., shoplifting or grabbing food off another person's plate), loss of personal awareness (e.g., neglect of personal grooming), stereotyped and perseverative behaviors, delusions, depression, affective lability, overeating and other signs of hyperorality, social inappropriateness, and lack of tact or empathy. The most striking cognitive change is

Telegram: @medical_k

www.konkur.in

anosognosia and indifference toward their cognitive and social deficits. Otherwise, cognitive testing reveals profound impairment on tests of executive function, but relative preservation of other cognitive domains, including memory. Two other variants, progressive nonfluent aphasia (PNFA) and semantic dementia (SD) present with gradual language deterioration and can be difficult to distinguish from one another early in their course. However, the insidious onset of language deficits in PNFA and SD distinguishes them from an acute aphasia caused by a cerebrovascular accident. In PNFA, there are deficits in expressive language and articulation, with effortful nonfluent spontaneous speech, agrammatism, phonemic paraphasias, and marked word-finding deficits. Language comprehension, memory, and other cognitive domains are relatively preserved. A third variant, SD, involves profound language dysfunction and a fluent aphasia notable for its spontaneous, circumlocutory, empty speech resulting from loss of semantic memory in both and the ability to link words and objects to their meanings. Both verbal and nonverbal domains are affected and there is pronounced anomia. With disease progression, behavioral and personality changes akin to bvFTD may develop.

Motor deficits may include symptoms of MND or parkinsonism of the akinetic-rigid type that is common in bvFTD or PNFA and rarely seen in SD. Structural imaging studies may show frontal and anterior temporal atrophy; functional imaging typically reveals hypoperfusion in the same regions, though there may be pronounced asymmetry. More widespread involvement of parietal regions is suggestive of AD. The electroencephalogram may be normal in early stages. The differential diagnosis in younger persons includes schizophrenia, mood disorders, addictions, and personality disorders. When onset is later, the diagnosis is often confused with AD, late-life depression, and, when there are prominent motor features, CBD and PSP. These conditions resemble one another in their advanced stages, but are distinguished by the course of the disease prior to the advanced stage. There are no treatments for the underlying disease process, and no definitive evidence supporting the use of cholinergic treatments. The behavioral symptoms may improve with serotonin reuptake inhibitors. Aggressive behaviors can be managed with low doses of atypical antipsychotics or trazodone and antiseizure medications can reduce agitation and aggression. Family counseling is a critical part of treatment so that the safety of the patient and others is

Telegram: @medical_k

www.konkur.in

maintained in the setting of their poor judgment and to provide caregiver support and assist with psychosocial issues.

Dementia with Lewy Bodies

DLB is a dementia syndrome with Lewy bodies in the cerebral cortex, brainstem, thalamus, and striatum. It is now regarded as the second most common form of dementia after AD and second most common synucleinopathy after PD. Symptom onset is usually after age 50 and the disease is more common in men. Average survival is less than 10 years. There are both genetic and sporadic forms of DLB, and there is overlap in the clinical and pathologic findings of DLB, AD, and PD and other α-synucleinopathies. About half of the patients with DLB also have Alzheimer pathology. Up to one-third of cases show microvascular ischemic pathology. Neurochemically, there is evidence of a marked cholinergic deficit.

While the defining feature of DLB is progressive cognitive impairment, its association with basal ganglia signs and hallucinations leads to its inclusion in the differential diagnosis of parkinsonian movement disorders with psychiatric presentations. For the diagnosis of probable DLB, the most recently updated consensus criteria require (1) progressively disabling cognitive deficits in which the domains of attention, executive function, and visual processing are disproportionately affected relative to memory and naming and (2) at least two of the four core clinical features: delirium-like cognitive fluctuations, recurrent complex visual hallucinations, parkinsonism, and REM sleep behavior disorder. Early cognitive deficits often involve attentional, visuospatial, or frontal–subcortical skills, and memory impairment may only become apparent with progression. With progression, there are the usual cortical features of dementia (aphasia, apraxia, and agnosia). The psychiatric symptoms present early in the course and often include dramatic well-formed visual hallucinations, depression, or paranoid delusions. Motor features include myoclonus and parkinsonian signs of bradykinesia, rigidity, and gait difficulties with early falls in about two-thirds of patients. Resting tremor is uncommon. There may be an early but limited response to levodopa. As a general rule, the occurrence of psychosis unrelated to medications and early dementia with spontaneous parkinsonism, especially within the first year, should lead to consideration of DLB.

Telegram: @medical_k

www.konkur.in

The diagnosis of DLB remains clinically based and neuroimaging studies are not especially helpful in distinguishing DLB from AD. Treatment of DLB requires a targeted approach. Motor symptoms can be treated with antiparkinsonian therapies, though this may aggravate psychiatric symptoms, especially psychosis. Atypical neuroleptics can reduce psychosis, but are often not tolerated and cases of neuroleptic malignant syndrome are reported. The most promising treatments include cholinergic therapies, which can benefit cognitive and psychiatric symptoms. Antidepressants and stimulants can also be helpful.

Multiple System Atrophy

The term MSA was introduced in 1969 and operationally defined in 1999 as a clinically heterogeneous neurodegenerative disorder with variably present parkinsonism, early autonomic dysfunction, cerebellar, and pyramidal symptoms. These are manifested as rapidly progressive parkinsonism, gait ataxia with cerebellar dysarthria, limb ataxia, cerebellar oculomotor dysfunction, Babinski sign with hyperreflexia, postural instability, and dysphagia. At least one sign of autonomic dysfunction should be evident. MSA is now used in place of three older diagnoses, olivopontocerebellar atrophy (OPCA), Shy–Drager syndrome, and striatonigral degeneration, which could not be reliably distinguished from each other. The two MSA subtypes are autonomic dysfunction with predominant cerebellar findings (MSA-C) and autonomic dysfunction with predominant parkinsonian findings (MSA-P). The disease is rare and affects both sexes equally. It typically begins in late middle age, with a median survival of about 9 to 10 years after symptom onset. The cause is unknown, but almost all cases are sporadic. The neuropathology consists of glial cytoplasmic inclusions (containing tau, synuclein, and ubiquitin, among other proteins) in the presence of neurodegeneration in a variable combination of CNS structures, potentially including the putamen, caudate, globus pallidus, substantia nigra, inferior olives, brain stem nuclei, cerebellum, and spinal cord. MRI may reveal typical signs (hyperintense portions of the putamen, “hot cross bun” sign in the basis pontis), but diagnosis is essentially made clinically or neuropathologically.

A prodromal premotor phase is evident in up to 75% of cases and, consistent with multisystem pathology, includes sexual and urinary dysfunction, orthostatic hypotension, respiratory disturbances, and RBD. Initial parkinsonism in MSA is often difficult to distinguish from PD.

Telegram: @medical_k

www.konkur.in

Psychiatric and cognitive manifestations of MSA have received little systematic attention. Dementia and visual hallucinations are considered nonsupportive diagnostic criteria and suggestive of DLB. However, more recent data from patients surviving longer than 8 years show evidence for significant cognitive impairment in up to 50% of cases, with a profile of cognitive deficits similar to other parkinsonian disorders and dementia in up to one-third of cases. Executive dysfunctions are most commonly seen, more so in MSA-P, whereas learning and visuospatial impairments are more prominent in MSA-C. Pathologic laughter and crying, depression, anxiety, panic attacks, and suicidal ideation are also reported. Treatment is symptomatic. A transient response to levodopa is seen in up to 40% of patients in the early disease stage. Orthostatic hypotension and urinary symptoms may respond to both pharmacologic agents and environmental manipulations, and such treatment may substantially improve patient and caregiver quality of life. There are no clear guidelines for treating psychiatric disorders in MSA; it is likely that strategies useful for PD, HD, or cerebellar disease will also prove of value in MSA. A small case series demonstrated the usefulness and safety of ECT in patients with MSA.

Encephalitis Lethargica

Encephalitis lethargica, described by Constantin von Economo, presented as a worldwide epidemic between 1917 and 1929. While putative sporadic cases continue to be reported, encephalitis lethargica is important historically as an early example of the relationship between brain disease and psychopathology. The acute phase was characterized by profound lethargy, hence its name, along with other mental status changes such as psychosis or catatonia and various movement abnormalities, including parkinsonism, choreoathetosis, and myoclonus. The mortality rate was approximately 30% during the acute phase. Survivors returned to normal for several months to years, then many developed a chronic postencephalitic syndrome characterized most commonly by parkinsonism (usually without tremor), and less commonly by hyperkinetic movements resembling tardive dyskinesia and episodic oculogyric and respiratory crises. Psychiatric manifestations included disinhibition, mania, attentional deficits, apathy, narcolepsy, verbal tic-like behaviors, executive dysfunction, and bradyphrenia. Hyperactivity and oppositional behaviors developed in children. Postmortem studies of acute victims showed

Telegram: @medical_k

www.konkur.in

inflammatory changes in the substantia nigra, globus pallidus, and subthalamic, red, and brainstem nuclei. Postencephalitic cases showed degenerative changes and depigmentation of the same subcortical areas, with neurofibrillary tangles but without Lewy bodies. The etiology remains unknown.

Huntington Disease

Introduction and Definition. HD (formerly Huntington chorea) is an autosomal dominant neurodegenerative disorder characterized by midlife onset, a relentlessly progressive course, and a combination of motor, psychiatric, and cognitive symptoms. The disease is caused by a CAG repeat expansion mutation in the huntingtin (HTT) gene on chromosome 4. For 130 years, HD has been recognized as one of the most terrible yet enlightening of all medical disorders, and now, as in the past, the approach to HD provides a model for the development of clinical, scientific, and ethical strategies in other genetic diseases of the brain. HD remains an important example of subcortical dementia and the prominence of the psychiatric consequences of neurodegenerative disorders.

History. George Huntington first described the disease that now bears his name in 1872. His original paper, which noted the salient features that still define HD, remains a model of clarity and clinical observation. After serving as the textbook case of dominant inheritance for 100 years, HD again made news in 1983 as the first disorder mapped to a specific chromosomal locus using anonymous DNA markers, and then again in 1993 when the genetic etiology was discovered to be a member of a new class of mutations referred to as repeat expansion or dynamic mutations. Current research focuses on understanding HD pathogenesis and the use of this knowledge to develop rationale therapeutics for the underlying disease process.

Epidemiology. The prevalence of HD in the United States is about five cases per 100,000 individuals, with similar rates found in most European countries. The prevalence in Japan is about 10-fold less, and prevalence also appears to be low in China, Finland, and Africa. As with many rare autosomal disorders, pockets of high prevalence exist. The most famous concentration is in the villages surrounding Lake Maracaibo in Venezuela;

Telegram: @medical_k

www.konkur.in

analysis of this population led to the discovery of the HD mutation and has contributed greatly to the clinical understanding of HD.

Etiology. HD is one of a group of 13 neurodegenerative diseases caused by a mutation in which repeating units of DNA consisting of the nucleotides cytosine, adenine, and guanine (a so-called CAG repeat; cytosine, thymine, guanine—CTG—on the opposite strand) increase in number. This is referred to as a CAG, or CAG/CTG, trinucleotide repeat expansion mutation. In most of these disorders, including HD, the CAG repeat is in-frame to encode for the amino acid glutamine. Genes containing this type of expansion, therefore, express an RNA transcript with an expanded CUG repeat, which in turn is translated into a protein with an excessively long stretch of glutamine residues. The CAG repeat expansion occurs in different and unrelated genes in each of the CAG repeat diseases. The only similarity among the genes is the repeat itself. This and other lines of evidence have led most investigators to conclude that proteins with stretches of more than about 35 to 40 consecutive glutamine residues become neurotoxins, though there is increasing recognition that RNA transcripts with long CUG or CTG repeats may also have toxic properties. The differences among the CAG repeat expansion diseases, particularly concerning which brain regions are most prominently affected and the precise threshold for toxicity, are thought to derive from other aspects of protein expression and structure.

Telegram: @medical_k

www.konkur.in

FIGURE 2.6–3. Repeat length as an important variable in Huntington disease. **A:** Repeat length increases in paternal transmission of the expanded allele. Points above the diagonal line represent cases in which the repeat length increases during paternal transmission. Expansion occurs in most cases, and in some instances the expansion is substantial. N = 84 pairs, mean +/− SD increase of repeat length = 4.2 +/− 0.8 triplets. **B:** Correlation of repeat length with a younger age of onset. As repeat length increases, age at disease onset decreases. N = 480, r^2 = 0.57. **C:** Anticipation in HD. The age at which affected parents and their affected offspring first develop disease symptoms is depicted as a survival curve. The younger generation develops the disease at a substantially younger age, a result of increasing repeat length during paternal transmission and the correlation of repeat length with younger age of onset. N = 61 parents, 82 offspring. (All data from the Baltimore Huntington Disease Center, courtesy of Drs Adam Rosenblatt and Christopher A. Ross.)

The CAG repeat expansion in HD is located in exon 1 of the *HTT* gene (formerly referred to as *IT15*) on the short arm of chromosome 4. Like the genes associated with other polyglutamine disorders, HTT is widely expressed, and is not limited to the CNS. The normal function of HTT is only partially understood, though it has been associated with embryogenesis, intracellular organelle transport, and regulation of growth factors. Like many of the other repeat expansion diseases, the

Telegram: @medical_k

www.konkur.in

phenomenon of anticipation (younger age of onset in subsequent generations of a family) occurs in HD. The explanation derives from a strong correlation between repeat length and younger age of onset and a tendency for repeat length to increase during paternal transmission of the gene (Fig. 2.6–3A, B). There is also increasing recognition that understanding disease pathogenesis requires understanding of the molecular complexity of CAG/CTG repeat regions of the human genome, including the HD locus, in which an RNA transcript is encoded by the DNA strand antisense to HTT. The antisense transcript may regulate HTT expression, and could also independently contribute to disease pathogenesis.

The investigation into the pathway that leads from the CAG repeat expansion to clinical phenotype in HD and related diseases had led to dozens of candidate pathogenic pathways. Early pathogenic steps appear to include abnormal phosphorylation and cleavage of the HTT protein into small fragments by cellular enzymes, and subsequent misfolding of fragments with long glutamine tracts. Small fragments of HTT may also be generated by abnormal splicing during the transcriptional process. These fragments eventually aggregate into structures that can be visualized with immunohistochemical stains in postmortem brain from patients with HD (Fig. 2.6–4A). Many mechanisms have been invoked to explain subsequent steps in pathogenesis. For instance, proteins with long glutamine stretches sequester other proteins, including transcription factors. These proteins become unavailable to perform their normal cellular duties, with potentially lethal consequences. Alternatively, proteins with long polyglutamine expansions, or aggregates of these proteins, may interfere with the process of autophagy, through which cells degrade abnormal protein and recycle organelles. Failure of this system might lead to an accumulation of a variety of toxic proteins. Other proposed pathogenic mechanisms include interference with mitochondrial energy metabolism, polyglutamine-induced vulnerability to excitotoxicity and oxidative stress, loss of brain-derived neurotrophic factor (BDNF) release, and abnormalities in the nucleocytoplasmic transport system. Recent work has also detected cell-to-cell spread of mutant HTT protein, with some similarities to the action of prion proteins. Further, a powerful convergence of genetic evidence and cell biology has demonstrated that neuronal repeat length in HD patients may increase over time, as normal DNA repair mechanisms go awry at the site of the expanded repeat in *HTT*. It is

Telegram: @medical_k

www.konkur.in

hypothesized that neurotoxicity arises once repeat length reaches an as yet undetermined threshold. This concept may explain why rare individuals with expansion mutations in both copies of their *HTT* gene do not have an unusually severe course of illness.

FIGURE 2.6–4. Huntington disease neuropathology. **A:** Gross pathology. HD case on the right, control brain on the left. Note the enlarged lateral ventricle, nearly absent caudate and putamen, and atrophy of the cerebral cortex. **B:** Intranuclear inclusions in HD. Immunohistochemical staining of cerebral cortex from an HD patient with an antibody that labels the huntingtin protein demonstrates prominent intranuclear inclusions in neurons. (Photographs courtesy of Dr Christopher A. Ross.)

Diagnosis and Clinical Features. Typically, the diagnosis of HD is made by a genetic test in the setting of motor signs and symptoms in an individual with a family history of HD. The advent of genetic testing now makes diagnosis possible in individuals with a family history of HD who do not yet have symptoms themselves, or in patients with unusual presentations or HD-like symptoms in the absence of a known family history of a movement disorder.

MOTOR MANIFESTATIONS. The primary *involuntary* movement abnormality is chorea or choreoathetosis, continuous and irregular writhing and jerking movements. The limbs and trunk are most prominently affected, but respiratory, laryngeal, pharyngeal, oral, and nasal musculature may also be involved. Chorea may be among the early symptoms, but often plateaus and may even diminish during the course of the disease. Voluntary movement abnormalities typically affect visual tracking (slow hypometric saccades and catchy pursuit), fine motor movements (slow,

Telegram: @medical_k

www.konkur.in

poorly coordinated, arrhythmic), speech and swallowing, tone (rigidity), and gait. The voluntary motor problems are most associated with functional disability and are most likely to lead to serious illness or death. Unlike chorea, voluntary movement abnormalities progressively worsen.

COGNITIVE MANIFESTATIONS. Cognitive decline generally parallels development of movement abnormalities. For example, when examined an average of 24 years before the predicted age of onset of clinical HD (as predicted by their repeat length and age), carriers of the HD gene in a systematic study had no detectable cognitive deficits. Carefully controlled studies indicate that detectable cognitive abnormalities likely emerge at about 10 years prior to clinical onset of disease, though these will progress slowly and may be difficult to detect in an individual patient. Early cognitive changes, which may be subtle, often affect cognitive flexibility and speed, such that switching from one task to another, or tracking multiple tasks simultaneously, becomes difficult or slow. Work or school performance may suffer to the point that colleagues notice. A four-domain model of cognitive deficits suggests that in early- to middle-stage HD, visuospatial deficits are the most pronounced deficits, followed by executive dysfunction, and then less prominent memory and verbal deficits. The dementia becomes more global as the disease progresses, but, as in other subcortical dementias, aphasia and agnosia are less evident than in AD. MMSE scores typically decline by 1 to 2 points/year.

PSYCHIATRIC MANIFESTATIONS. As many as 80% of patients with HD develop some form of noncognitive psychiatric disorder within 10 to 15 years of disease onset, and up to 20% may present with psychiatric symptoms. Since it is the psychiatric aspects of HD that are most amenable to treatment at present, psychopathology should be sought diligently. The consequences of these disorders may be devastating to the patient and family, perhaps more so than either the cognitive or motor dysfunction. The suicide rate is much higher than in the general population. Lifetime history of suicide ideation has been estimated at 20%, with a 6.6% lifetime rate of completed suicide. Data from the ENROLL-HD study revealed an incident rate of suicide and suicide attempts in HD gene carriers of 72 per 100,000 person-years and 306 to 375 per 100,000 person-years, respectively, approximately 10 times greater than non–HD gene carriers. The lifetime prevalence of psychotic phenomena is 11% to

Telegram: @medical_k

www.konkur.in

13%, and perhaps higher in some populations. Thirty to 40% of patients with HD will develop major depression, and another 10% to 20% will have a different depressive syndrome. Up to 10% of patients with HD develop mania, though this diagnosis may be confused with disinhibition and other personality changes. Less frequently, patients with HD develop disorders that are clinically indistinguishable from idiopathic obsessive-compulsive disorder, schizophrenia, or delusional disorder. The overall prevalence of sleep disorder in HD is 15%, but increases with disease duration, so that by midcourse 27% of patients are affected. As in patients with other types of brain damage, patients with HD are vulnerable to delirium from pharmacologic or medical illness.

Personality change is very common, occurring in up to 50% of patients with HD by midcourse. Most patients with HD with personality change also have cognitive impairment or dementia, but cognitive deficits and personality change do not always occur together. Other patients may develop a naive, superficial, child-like personality that does not fit into current DSM terminology. Apathy and irritability are particularly common and troublesome states, may occur prior to overt clinical disease, and may exist as either separate syndromes or as symptoms of other disorders.

The many psychosocial issues that accompany HD increase the chance for adjustment disorders, relationship disorders, and other behavioral disorders. Caring for a cognitively impaired, irritable, or apathetic family member may result in emotional turmoil and financial hardship. Frequent additional stressors include social stigma (real or feared), parental guilt over passing the disease gene on to children, a family legacy of secrecy, and the burden faced by young gene-positive adults who can predict their own future in light of the progressive decline of a parent or other relative. These issues and their consequences must be recognized and treated, but should not be used to “explain away” other psychiatric disorders for which other treatments may be more appropriate.

Pathology and Laboratory Examination

Pathologic Examination. Gross pathology of HD (Fig. 2.6–4B) is limited to the brain, though microscopic or metabolic involvement has been detected in other tissue, including muscle, liver, adipocytes, and lymphocytes. In advanced cases, brain weight may be reduced by 25% to 30%. The most prominent atrophy involves the caudate and putamen, which is readily apparent on MRI scans or on gross pathology, along with

Telegram: @medical_k

www.konkur.in

accompanying hydrocephalus ex vacuo. The cerebral cortex becomes quite atrophied, with less pronounced atrophy in other regions of the basal ganglia (especially the globus pallidus and STN) and to a lesser and more variable extent in other brain regions.

On the microscopic level, selective neuronal vulnerability is striking. Striatal cell loss primarily affects medium spiny projection neurons, and in a gradient such that the earliest and most severe loss is in the dorsomedial region. Cortical cell loss consists mostly of large neurons in layers III, IV, and V. Surviving neurons in the striatum and cortex may have an increased number of dendrites and dendritic spines, but some cells will have evidence of dystrophic processes. Gliosis is present in regions with significant cell loss. Intranuclear inclusions are evident in striatum and other brain regions (Fig. 2.6–4B). The inclusions consist of amyloid-like fibrils that contain, among other proteins, mutant HTT, ubiquitin, and synuclein, but not tau. Inclusions may also be detected in neuronal cytoplasm and processes.

Laboratory Evaluation. It has been possible to directly test for the HD repeat expansion since the discovery of the gene in 1993, using a simple PCR-based assay on DNA obtained from a blood sample. The test is available from a number of commercial and academic centers. Interpretation of results is shown in Table 2.6–3. While the test is generally reliable, ambiguity may arise if a repeat length is on the borderline of one of the categories, since the results of even the best laboratories have an error of +/− 1 triplet. Also, occasionally, only a single allele of normal length is detected. This usually means that both alleles contain a repeat of the same length, but the possibility exists that an expanded allele went undetected, which requires additional assays.

Telegram: @medical_k

www.konkur.in

Table 2.6–3.
Interpretation of HD Repeat Length (Longest of the Two Alleles)

Repeat Length (CAG Triplets)	Interpretation	Comments
<29	Not at risk	Repeat length stable
29–35	Not at risk	Reports of a few HD cases
36–39	May develop HD	Increasing risk with longer repeats
40 and greater	Will develop HD	Earlier age of onset with longer expansions

Ancillary Tests. MRI, CT, SPECT, and PET were previously of diagnostic importance, but are now mainly used to exclude strokes, tumors, and subdural hematomas, etc., that may coexist with HD. MRI scans should be considered if the patient's course rapidly deteriorates or in the presence of signs and symptoms not typical for HD, as falls are common in HD, and the risk of a complicating but treatable brain injury is relatively high.

Premanifest Testing. The availability of a diagnostic test for HD has made testing of individuals who are at risk but do not yet have clinical disease testing possible. So far, only a minority of individuals at risk of HD request testing, often for psychological and practical reasons related to childbearing, long-term planning about caring for a relative with HD, and finances. Perhaps because of the self-selected nature of those seeking premanifest testing and the exclusion from testing of those who are suffering from major depression, most patients feel relieved to learn of their status, whether testing positive or negative. Careful protocols for pre- and post-test counseling have been developed to assure that patients understand the potential psychological risks and risks of discrimination (employment and insurance) that may arise from the test results. Expert counseling is mandatory before premanifest testing is obtained. For known gene carriers, it is possible to obtain prenatal diagnosis early in pregnancy. A few centers offer preimplantation testing of embryos generated by in vitro fertilization. Premanifest testing is likely to increase

Telegram: @medical_k

www.konkur.in

in the future, as the availability of clinical trials for premanifest individuals will increase incentive for learning about gene status.

Differential Diagnosis. The availability of a definitive diagnostic tests leaves two issues in HD differential diagnosis: when to consider a diagnosis of HD and what diagnoses to consider if a patient with HD-like symptoms tests negative for HD. HD may occasionally present with rigidity, dystonia, athetosis, or tic-like movements rather than chorea, sometimes in every member of a pedigree. At other times, patients present with typical clinical manifestations, but they have no known family history of HD. This may arise when disease onset occurs earlier in a child than their parent, a parent carrying the mutation has died from other causes prior to the onset of clinical HD, there is nonpaternity or adoption, or, in very rare cases, a new mutation arises that is not present in previous generations. Genetic testing should be considered in either situation. Table 2.6–4 lists some of the disorders that present with HD-like symptoms. Notably, any disease or insult that affects the basal ganglia might lead to chorea or dystonia. Very few diseases fully mimic the clinical features of HD coupled with autosomal dominant inheritance; examples include Huntington disease-like 2 (HDL2), which is not clinically distinguishable from HD, and spinocerebellar ataxia type 17.

Course and Prognosis. HD is relentlessly progressive and fatal (Fig. 2.6–3C). Onset is typically insidious, with early complaints of clumsiness, jerks, and tremor. While the chorea tends to plateau and may even decline later in the course, the voluntary motor abnormalities progress, paralleled by cognitive decline. Patients with late-stage HD require complete care for all activities of daily living. They are mostly nonverbal, rigid, and akinetic, but may make whole-body movements resembling myoclonic jerks when disturbed. Dementia is global and severe, but may be less severe than the patient's appearance would suggest. Death usually occurs 15 to 20 years after disease onset, often from the consequences of swallowing difficulties (suffocation or aspiration pneumonia) or general debilitation. Juvenile-onset HD often presents with bradykinesia, rigidity, dystonia, and sometimes seizures or myoclonus. Chorea may be minimal or absent. The course seems to be more rapid and severe than typical HD. Large-scale longitudinal studies in Europe and the United States, including ENROLL, PREDICT, and PHAROS, have attempted to define the course of HD in sufficient detail that the

Telegram: @medical_k

www.konkur.in

effectiveness of interventions can be precisely measured against the anticipated course of disease in any given individual.

Telegram: @medical_k

www.konkur.in

Table 2.6–4.
Differential Diagnosis of Choreiform Disorder

Telegram: @medical_k

www.konkur.in

Genetic Causes of Chorea	Comment
Dentatorubralpallidoluysian atrophy (DRPLA)	Autosomal dominant, rare in United States, more common in Japan, variable presentation
Huntington disease-like 2	Rare autosomal dominant disorder clinically indistinguishable from HD
Autosomal dominant spinocerebellar ataxias	Most commonly in SCAs 2,3, but also in others
Hereditary Creutzfeldt–Jakob disease	Autosomal dominant; 85% of cases are sporadic
Wilson disease	Autosomal recessive, distinguished by eye and liver abnormalities, abnormal copper metabolism
Ceroid neuronal lipofuscinoses	Usually childhood onset autosomal recessive, rarely adult-onset autosomal dominant
Neuroacanthocytosis	Recessive and dominant forms, distinguished by abnormal red blood cells (acanthocytes)
Benign hereditary chorea	Usually childhood onset
Pantothenate kinase-associated neurodegeneration	Childhood onset, recessive
Fahr disease	Basal ganglia calcification, usually autosomal dominant, adult onset
Mitochondrial diseases	Maternal inheritance, heterogenous phenotypes
Paroxysmal dyskinesias	Induced by external factors, multiple genetic subtypes, some sporadic forms
Lesch–Nyhan syndrome	Boys only, self-mutilation
Other metabolic disorders	Phenylketonuria, guaric acidemia type I, methylglutaconic aciduria type III, various aminoacidopathies

Telegram: @medical_k

www.konkur.in

C9ORF72 disease	Reports of prominent chorea in some mutation carriers
Neuroferritinopathy	Middle-age onset, associated with brain iron accumulation
Sporadic forms of chorea	Comment
Tardive dyskinesia	Common
Sydenham chorea	Poststreptococcal complication
Systemic lupus erythematosis	May occur in 1–7% of cases, chorea also seen in other autoimmune disorders
HIV	Direct encephalitis or secondary lesions
Thyroid disease	Typically hyperthyroidism
Neurosyphilis	May also complicate HIV
Paraneoplastic syndromes	Mechanism appears to be autoantibodies
Drug induced	Anticonvulsants, lithium, stimulants, levodopa

Treatment. There is currently no treatment of the underlying neurodegeneration of HD. Large-scale clinical trials of creatine and co-enzyme Q10 were both terminated early based on strong evidence that the drugs had no beneficial effect. Multiple other drugs have shown some promise only to fail at phase III trials. As of 2021, drugs under active investigation include the sigma-1 receptor agonist pridopidine, and the RNA splicing regulator branapram. Surgical treatments, either via DBS or fetal striatal transplantation, remain in early stages. Perhaps the most promising therapeutic approach is to suppress expression of the mutant HTT gene, using one of several methods that prevent gene transcription or translation. Many hurdles to this strategy must be overcome, including sufficient delivery to the necessary brain regions, off-target effects (i.e., incidental suppression of other genes), the amount of mutant *HTT* suppression that must be achieved to obtain a clinical effect, dosing, and time course of treatment. Indeed, the first phase III trial of a suppression strategy, in which an oligonucleotide (a short piece of DNA) that targeted *HTT* RNA for degradation was infused into CSF via lumbar puncture, was not successful. Nonetheless, multiple other suppression strategies are under investigation, and there remains considerable optimism in the field

Telegram: @medical_k

www.konkur.in

for the ultimate success of this strategy. In the meantime, more sophisticated study design, and improved measures of treatment outcome including highly sensitive cognitive, motor, and neuroimaging techniques, will likely increase the sensitivity and throughput of clinical trials.

Despite the absence of treatments to modify the fundamental course of the disease, the quality of life for the patient and their family can be substantially improved by medical intervention. Some patients are concerned about the social implications of chorea and others may find chorea functionally impairing. Chorea may be effectively treated by tetrabenazine or its derivatives deutetrabenazine and valbenazine which block dopamine release via action at the vesicular monoamine transporter 2. Chorea may also respond to low doses (0.5 to 2.0 mg/day) of typical high-potency antipsychotics such as haloperidol or fluphenazine, other neuroleptics, benzodiazepines, or other dopamine-depleting agents such as reserpine or amantadine. Care must be taken, since dopamine-depleting agents increase the risk of depression, and other agents may worsen voluntary movement abnormalities or apathy, or cause akathisia or excess sedation. The simple mechanical strategy of weights strapped to the wrists can often prove of considerable value without causing side effects. Environmental interventions, such as removal of throw rugs, adding grab bars in bathrooms, and avoidance of stairs, are always essential to reduce falls.

Other common symptoms can also be at least partially ameliorated. Swallowing abnormalities can be assessed by pharyngeal esophogram and treated with thickened liquid and softened solid diet. Botulinum injections may be useful for dystonia. Myoclonus has been successfully treated with valproate and clonazepam and valproate may also be effective for seizures.

There are no established pharmacologic treatments for cognition. In particular, there is little evidence for an effect of anticholinesterase inhibitors. Simple education interventions may prove helpful, as in other forms of dementia. Early in the disease, patients can be taught to write down notes and to limit the number of tasks undertaken at once. Patients, and especially family members and care providers, need to be told about the progressive cognitive decline, so that they can learn to phrase questions more simply, provide cues for recall, and keep cognitive demands on the patient at a level commensurate with cognitive capacity. The topic of guardianship or power of attorney for legal and medical

Telegram: @medical_k

www.konkur.in

matters should be raised before the patient is too incapacitated to participate in the discussion.

Depression may be treated with any of the standard antidepressants, with the caveat that as in any patient with brain damage, starting doses should be low and doses should be increased slowly, along with careful monitoring for delirium. SSRIs are often useful and, given the higher suicide risk in patients with HD, are notably less toxic in overdose than tricyclic antidepressants or MAOIs. SSRIs may occasionally cause akathisia, insomnia, or dyskinesias. Other antidepressants have been used successfully. ECT has been used quite successfully to treat life-threatening or intractable depression, and other than an increased risk of delirium, is generally well tolerated. Mild mood elevations may not warrant treatment, but mania, like depression, can be treated with standard pharmacologic agents; limited data and anecdotal accounts suggest that divalproex sodium or carbamazepine is better tolerated and more effective than lithium. Benzodiazepines or antipsychotics (the atypical agents may have fewer negative effects on movement than the typical agents) may be helpful adjuncts.

Aggression and irritability stem from multiple causes, including psychiatric syndromes, cognitive and personality changes, and environmental precipitants such as hunger, thirst, pain, frustration over an inability to communicate, boredom, or unexpected change in routine. Treatment of any underlying psychiatric disorder and careful attention to possible precipitants is the first approach. When necessary, anecdotal evidence supports the effectiveness, in some patients, of SSRIs, antipsychotics, anticonvulsants, β-blockers, and benzodiazepines. Apathy probably responds best to family education combined with a structured and stimulating environment. SSRIs, stimulants, and dopaminergic agents such as amantadine and bromocriptine may be of value, though the latter agents may increase chorea.

Wilson Disease

Introduction and Definition. WD, also named hepatolenticular degeneration, is an autosomal recessive disorder in which mutations in the copper-transporting gene ATP7B result in abnormal copper accumulation in the liver, brain, and other tissues, with consequent hepatic cirrhosis and neuronal degeneration. Psychiatric and movement abnormalities are common, and patients may present to a psychiatrist

Telegram: @medical_k

www.konkur.in

first. WD can be effectively treated in acute and chronic stages, yet fatal without treatment. Earliest recognition of the characteristic signs, symptoms, and laboratory abnormalities is therefore essential.

History. The disease was named after Kinnear Wilson, who first recognized the syndrome, including a high rate of psychiatric abnormalities, in 1912. In 1948, Cummings recognized the role of copper in disease pathogenesis; Schenberg and Gitlin, in 1952, discovered the deficiency of ceruloplasmin in patients with WD (establishing a test that is still in use), and, in 1960, Bearn definitively established the recessive nature of the disorder. The molecular basis of the disease emerged first with linkage to the esterase D locus on chromosome 13 in 1985, and then, in 1993, with the discovery of causative mutations in ATP7B.

Epidemiology. WD is found worldwide, with a frequency estimated at about 1/30,000. Approximately 1 in 90 individuals are heterozygous carriers.

Etiology. Over 600 disease-causing mutations have been identified in ATP7B. A few mutations are common (H1069Q accounts for more than 40% of mutations in Northern European populations), while most are rare. The result is that most individuals with WD are compound heterozygotes, carrying a different mutation on each allele. The Wilson protein, an ATPase involved in copper transport, functions to maintain copper homeostasis by facilitating excretion of copper from hepatocytes into bile. In patients with WD, this function fails, resulting in accumulation of copper in the liver, brain, and other tissues, eventually leading to hepatic failure and neurologic and psychiatric signs and symptoms. In the brain, the basal ganglia appear to be particularly affected.

Clinical Features. About 40% of patients first present with liver abnormalities, 40% with neurologic abnormalities, and up to 20% with primarily psychiatric abnormalities. Liver dysfunction, the most common childhood presentation of WD, may be manifest as mild elevations of serum transaminases, chronic active hepatitis, cirrhosis, or acute and fulminant liver failure. Copper toxicity may also lead to cardiac arrhythmias, renal disease, rhabdomyolysis, joint disease, anemia, and thyroid and parathyroid dysfunction. Neurologic signs and symptoms, which strongly correlate with brain and CSF copper levels, generally

Telegram: @medical_k

www.konkur.in

reflect the multiple brain regions involved, and include dysdiadokinesis, dysarthria, tremor, dystonia, rigidity, choreoathetosis, bradykinesia, masked facies, and micrographia. Seizures occur in 6% of patients.

Cognition in WD has not been well studied. A relatively mild degree of cognitive impairment akin to other basal ganglia diseases is thought to be present in about 25% of patients, worsening with time and in conjunction with accumulating neurologic symptoms.

Two-thirds of patients may have psychiatric symptoms by first presentation, and 10% to 20% of patients seek psychiatric treatment before WD is diagnosed (a stage at which, tragically, the diagnosis is often missed). Eventually, psychiatric manifestations affect nearly all patients with WD and the psychiatric profile generally resembles HD. The most common symptoms are personality changes (often described as irritability, aggressiveness, and emotional lability) and depression (ranging from subsyndromal mood changes to major depression, at times with suicidality). Anxiety disorders, psychotic disorders (and individual psychotic symptoms), and catatonia appear at higher rates than in the general population. About 10% of patients present with psychosis and are frequently misdiagnosed with primary schizophrenia or bipolar disorder. Psychiatric symptom severity correlates more strongly with neurologic deficits than to liver disease, indicating that the psychiatric phenomena arise from brain damage versus psychological reactions to the illness.

Diagnosis. Since the hepatic, neurologic, and psychiatric manifestations of copper toxicity are only partially reversible, prompt diagnosis of WD is essential. The key step is considering the diagnosis. Elevated liver transaminases are nonspecific, but maybe the first diagnostic clue. Kayser–Fleischer rings, copper deposits in the limbus of the cornea, may be detected by inspection or with a slit lamp examination, but are often absent early in the disease. Serum ceruloplasmin is below normal in 95% of patients with WD, but is also low in newborns and 20% of heterozygous WD carriers, and may be misleadingly normal in the setting of infection or inflammation. The absence of serum ceruloplasmin oxidase activity is a useful test in the latter cases. Elevated 24-hour urinary copper concentration is generally considered diagnostic of WD. Liver biopsy, the gold standard for diagnostic confirmation, may also be required and show increased hepatic copper concentration and evidence of hepatitis or cirrhosis. Genetic testing with sequencing of the ATP7B

Telegram: @medical_k

www.konkur.in

gene is confirmatory when the disease-causing mutations are identified, but negative genetic testing, in the absence of supportive laboratory data, does not exclude WD because of heterogeneity of ATPB7 mutations.

In patients with neurologic or psychiatric disorders, and sometimes in patients without clinical evidence of brain disease, head MRI will reveal generalized atrophy and increased T2-weighted signal in the basal ganglia secondary to copper deposition. The midbrain “panda sign,” common in WD but nonspecific, is the result of hyperintense signal around the red nucleus and putamen. Atrophy may be present in cerebral cortex (especially the frontal lobe), brainstem, and cerebellum. PET, SPECT, and MR spectroscopy are used to evaluate functional abnormalities; on SPECT, functional assessment of dopaminergic innervation shows deficits in both pre- and postsynaptic markers, which is relatively specific for WD versus other causes of striatonigral degeneration. The most prominent pathologic changes involve cavitary degeneration of the basal ganglia, with neuronal loss, gliosis, and high levels of copper.

Differential Diagnosis. Elevated hepatic copper may also result from cholestatic liver disease (normal or elevated ceruloplasmin) or idiopathic childhood cirrhosis (elevated ceruloplasmin). Aceruloplasminemia may result in neurologic symptoms but results in elevated liver iron rather than copper. Urine copper excretion may be elevated secondary to metal chelation therapy or in the presence of acute liver failure or cirrhosis with cholestasis or nephrotic syndrome.

Course, Prognosis, and Treatment. Onset of WD is usually in the second or third decade with mean age of onset at 17 years. Atypical late-onset cases are reported in individuals over the age of 60. Without treatment, death may occur within 5 years, and sooner with CNS disease. As WD is one of the few neurodegenerative diseases in which the fundamental pathogenic process, copper accumulation, is amenable to treatment, early consideration of WD, including in older patients, is essential; treatment outcomes are best when treatment begins within 1 month after symptom onset. Unfortunately, average symptom duration before correct diagnosis and treatment is about 1 year. Treatment involves either removing copper (chelation therapy) using D-penicillamine, trientine, and tetrathiomolybdate or blocking copper absorption by zinc salts. Except in areas with high levels of copper in the drinking water, dietary restrictions are inadequate to prevent copper overload. D-

Telegram: @medical_k

www.konkur.in

penicillamine, which is poorly tolerated by some patients, is prone to induce hypersensitivity reactions, and trientine can paradoxically increase neurologic and psychiatric symptoms acutely, as hepatic copper is mobilized and deposited in the brain. For patients with end-stage liver disease, orthotopic liver transplantation has proven successful. All treatment modalities appear to improve neurologic and psychiatric symptoms, but response may be partial if therapy began at an advanced stage.

There are no controlled trials regarding symptomatic treatment of psychiatric manifestations of WD. Anecdotal evidence suggests that patients with WD may be particularly vulnerable to motor side effects of antipsychotic medications. It seems prudent to treat psychiatric syndromes with standard psychiatric treatment modalities, both pharmacologic and psychotherapeutic, but to choose lower doses of medications, increase doses slowly, and avoid high-potency antipsychotics.

CEREBELLAR DISORDERS

Introduction

The cerebellum has long been considered a modulator of motor function. As the cerebellum also modulates cognition and affect, damage to the cerebellum from many different causes can result in cognitive deficits and psychiatric syndromes.

History

A role for the cerebellum in regulating motor function was established early in the 19th century, beginning with the studies of Luigi Rolando. By the early 20th century, the effect of cerebellar degenerative disease on coordination of the limbs, gait, posture, and speech was appreciated. By 1939, the work of Holmes established much of the terminology and methods of examination of the cerebellum still in use. Simultaneously, diseases that affect the cerebellum were delineated, including hereditary disorders described by Friedreich in 1863 and Marie in 1893. Anecdotal reports of cognitive and psychiatric disorders arising from cerebellar damage were noted in early cerebellar research; systematic investigation of this link is more recent, stimulated by a series of neuroanatomical

Telegram: @medical_k

www.konkur.in

studies that demonstrated connections between the cerebellum and multiple other brain regions, and frequent observations of odd behavior and mutism in patients following resection of posterior fossa tumors. Substantial evidence now supports an important role of the cerebellum in normal cognition and emotion and that cerebellar damage leads to neuropsychiatric phenomena, including those seen in common psychiatric disorders as major depression, schizophrenia, and autism.

Epidemiology

The overall prevalence of cerebellar disorders is difficult to determine, since many different diseases may affect the cerebellum. As many as 50% of patients who have alcohol dependence syndromes develop clinical or histologic evidence of cerebellar pathology; this may be the single most common cause of cerebellar damage worldwide. The cerebellum is affected in 1.5% to 8% of all strokes, so this is probably the second most common cause of cerebellar damage. In children, the annual incidence of tumors affecting the cerebellum is between 0.25 and 1/100,000/year. In adults, primary cerebellar tumors are rarer and metastases more common. Prevalence of recessive (primarily Friedreich ataxia), dominant, and sporadic neurodegenerative diseases that primarily affect the cerebellum is, in each case, about 2/100,000. Other causes of cerebellar lesions are rare.

Etiology

Table 2.6–5 lists many of the diseases that cause permanent injury to the cerebellum. With the exception of some strokes, tumors, and degenerative conditions, most of these disorders are unlikely to affect the cerebellum in isolation. Therefore, their cognitive and psychiatric manifestations likely derive from damage to multiple brain regions. However, established neuroanatomical links between cerebellum and other regions of the brain plus analysis of focal cerebellar lesions make it clear that damage to the cerebellum itself is sufficient to cause cognitive and emotional disturbance.

The pathway from the cerebral cortex to the cerebellum originates with projections from neurons in cortical layer Vb in motor, somatosensory, association, and paralimbic regions, including posterior parietal association cortex, portions of the superior temporal sulcus and gyrus, parastriate and parahippocampal regions, and dorsolateral, medial, and,

Telegram: @medical_k

www.konkur.in

to a lesser extent, ventral lateral prefrontal regions. After synapse in the pons, where topographical distinctions among the different sources of input are maintained, the pathway continues as projections into the cerebellar cortex. Feedback to the cortex begins with axons projecting from cerebellar Purkinje cells to the deep cerebellar nuclei, where the pathway again remains topographically defined. These nuclei then project to both “motor” and “nonspecific” nuclei of the thalamus. Axons in neurons from both types of thalamic nuclei project to posterior parietal, superior temporal, and prefrontal association regions, and the intralaminar nuclei also project to limbic regions. This cerebrocerebellar pathway appears to consist of a series of discrete and relatively closed loops, similar to the loops connecting the basal ganglia and the cerebral cortex. Other pathways of potential relevance include reciprocal connections between the cerebellum and brainstem catecholaminergic (locus coeruleus) and serotoninergic nuclei (dorsal raphe), the hypothalamus, and the brainstem reticular formation. fMRI studies now suggest that anterior cerebellar regions subserve sensorimotor processing, while more posterior regions subserve emotional and cognitive processing, with a specific functional association of different regions to relevant areas of cerebral cortex.

Hereditary Degenerative Autosomal Dominant
Spinocerebellar ataxia types 1–42+
Dentatorubropallidoluysian atrophy
Huntington disease (uncommonly)
Hereditary prion diseases
Episodic ataxias types 1–7

Hereditary Autosomal Recessive (Complex Pathogenesis)
Friedreich ataxia (most common autosomal recessive cerebellar ataxia)

Hereditary Autosomal Recessive (Metabolic)
Abetalipoproteinemia
Niemann–Pick type C
Hexosaminidase A deficiency (Tay–Sachs)
Glutamic aciduria
Hydroxyglutaric aciduria
Cholestanolosis (cerebrotendinous xanthomatosis)
Metachromatic leukodystrophy
Galactocereberosidase deficiency (Krabbe disease)
Alpha-tocopherol deficiency (Vitamin E deficiency)
Hartnup disease
Refsum disease (phytanic acid oxidase deficiency)
Biotinidase deficiency

Hereditary Autosomal Recessive, DNA Repair
Ataxia-telangiectasia
Xeroderma pigmentosum
Cockayne syndrome

Hereditary X-Linked
Pelizaeus–Merzbacher disease
Adrenoleukodystrophy
Rett syndrome
Fragile X–associated tremor/ataxia syndrome.

In addition to its connections to multiple other brain regions, the other aspect of cerebellar anatomy important to affect and cognition are the "cerebellar cortical modules." These modules exist as radially oriented, structurally identical units that comprise the cerebellar cortex. Each module consists of a Purkinje cell (numbering about 15 to 30 million in the human cerebellum), granule cells that receive input from outside of the cerebellum and innervate the Purkinje cell, and inhibitory interneurons (basket, stellate, and Golgi cells). The Purkinje cell thus serves to integrate excitatory and inhibitory input.

It is generally believed that these units perform the same type of transform for all information coming into the cerebellum, with the specificity of information processing provided by the unique connections of each region of the cerebellum to other brain structures. Schmahmann has therefore proposed that just as the "cerebellum regulates the rate, force, rhythm, and accuracy of movements, so may it regulate the speed, capacity, consistency, and appropriateness of mental or cognitive processes." He has termed this the "dysmetria of thought" hypothesis and suggests that damage to the cerebellum will lead to an "unpredictability and illogic to social and societal interaction" just as it leads to poorly coordinated and misjudged movements, using the term "cerebellar cognitive affective syndrome" to broadly define the clinical phenotype. He has suggested the cerebellar cognitive affective syndrome includes five axes: attention control, emotional control, autism spectrum disorders, psychotic disorders, and social skills. While intriguing, it remains uncertain to what extent this hypothesis can explain the multitude of cognitive and psychiatric phenomena that accompany cerebellar disease.

Diagnosis and Clinical Features

The diagnosis of cerebellar disorders involves narrowing the complicated differential: Is onset age at birth (congenital), childhood (metabolic, oncologic, Friedreich ataxia), middle age (spinocerebellar ataxias), or older adults (oncologic, vascular)? What other organ systems or regions of the nervous system are affected? Is the process acute (vascular, toxic, infectious), subacute (infectious, oncologic), chronic (hereditary, toxic, nutritional), or episodic? Is there progression or have symptoms remained static? Is there a family history of a similar disorder? Have there been exposures to drugs, alcohol, or toxins? The history and examination, followed by an MRI scan (and potentially other imaging modalities such as

Telegram: @medical_k

www.konkur.in

PET, SPECT, or angiography) and then specific genetic or metabolic tests will often, but by no means always, provide a final diagnosis.

Motor Features. Problems with balance and speech are often the presenting complaints in disorders with primarily cerebellar involvement. The “cerebellar gait” is wide based and staggering. Patients may complain of walking as if they were drunk, and stairs are particularly difficult. On examination, patients are unable to perform a tandem walk and may sway or display titubation, a low-frequency tremor of the body. The dysarthria is characterized by slurred speech of irregular rhythm and with incorrect emphasis of syllables. Speech may be slowed and monotonic (scanning speech) in compensation.

Cerebellar damage is also manifest in other ways. Eye movement abnormalities vary, and may include nystagmus, square wave jerks (inability to maintain fixation when gazing at a specified point), dysmetria (over- or undershoot when making rapid eye movements from one target to another), and uneven smooth pursuit. Limb incoordination may be manifest as trouble with fine motor tasks. Tremor may be either postural or kinetic; the latter is often observable as an intention tremor during finger-to-nose testing. The presence of other signs or symptoms signals the possibility that other regions of the CNS are also involved, more the rule than the exception with diseases affecting the cerebellum.

Cognitive Features. The cerebellum is involved in a variety of cognitive tasks, including procedural learning, executive function, language processing, visual–spatial orientation, sensory processing, timing, and attention. Within 10 to 15 years of disease onset, about 20% of patients with cerebellar degeneration will meet criteria for cognitive decline or dementia, and the rate presumably increases significantly later in the disease course. The pattern of deficits is consistent with a subcortical dementia, with deficits in verbal and nonverbal intelligence and especially executive function in the absence of aphasia, apraxia, or agnosia. Cognitive deficits in these patients, particularly when subtle, may not be detected on simple clinical mental state examinations that focus on language and memory. Executive functions impaired in cerebellar degeneration include attention, sequencing, and timing. Executive, visuospatial, verbal and visual memory, and language deficits also frequently follow focal lesions of the cerebellum. It has been suggested

Telegram: @medical_k

www.konkur.in

that cognitive deficits are more likely to follow lesions of the cerebellar hemisphere, while vermal lesions result in psychiatric disturbances.

Psychiatric Features. The frequency and nature of psychiatric syndromes in patients with cerebellar disease was initially noted in case reports and a few small studies. The findings of these studies have now been replicated and expanded in more systematic investigations. Following strokes restricted to the posterior circulation (cerebellum and brainstem), about 35% of patient develop either a major or minor depression acutely, with the frequency declining to about 20% 6 months after the stroke and 10% 12 to 24 months later. Personality changes, particularly blunted affect and disinhibition, may be prominent in patients with large posterior circulation infarcts, and potentially other lesions, while anterior lobe or very small cerebellar infarcts elsewhere are less likely to produce personality change.

In degenerative disorders predominately limited to the cerebellum, about 75% of patients develop one or more psychiatric syndromes within 10 to 15 years of disease onset. As many as one-third experience at least one episode of major depression and another third experience other forms of depression (including brief recurrent depression, minor depressive disorder, and dysthymia). Suicidality may be high, with The Clinical Research Consortium for Spinocerebellar ataxias reporting a rate of suicidal ideation as high as 65% in spinocerebellar ataxia type 3. Self-awareness of depression is frequently absent. About 25% develop persistent personality changes, similar in type to those found in HD, and, as in HD, not limited to patients with cognitive decline. The frequency of mania, anxiety syndromes, and psychotic syndromes may all be somewhat elevated. The neuropsychiatric findings in disorders in which cerebellar degeneration is accompanied by degeneration in other brain regions may be particularly severe. For instance, neuropsychiatric findings in the late-onset autosomal dominant disorder spinocerebellar ataxia type 2 (loss of cerebellar Purkinje and granule cells, loss of inferior olive, pontocerebellar nuclei, substantia nigra, and motor neurons, and white matter tract degeneration) include executive dysfunction, impaired memory, apathy, depression, and potentially psychosis.

Pathology and Laboratory Examination. The pathology of cerebellar disorders depends on the underlying disease. Even with isolated cerebellar diseases, pathologic examination is likely to reveal

Telegram: @medical_k

www.konkur.in

noncerebellar findings. The choice of laboratory evaluation, including genetic testing for hereditary disorders, metabolic screens for metabolic disorders, and immunologic screens for immune-related disorders (especially of paraneoplastic origin) will be based on clinical and MRI findings. Neuropsychological testing may help detect subtle cognitive difficulties of considerable clinical relevance. In addition to the diagnostic workup, imaging studies are important if the nature or severity of signs and symptoms change unexpectedly, to exclude the presence of new subdural hematomas, infarcts, or tumors.

Differential Diagnosis. The differential diagnosis of the underlying disease for a patient presenting with cerebellar signs and symptoms is complex. Various schemes are proposed for either nosologic purposes or for the differential diagnosis in an individual patient. One practical and logical approach is to divide disorders into nonhereditary and hereditary, and to further classify each of these broad groups into subcategories. This approach is depicted in Table 2.6–5. Similar to other movement disorders, the differential diagnosis of affective symptoms is perhaps the most important issue facing the psychiatrist. Delirium must always be considered, regardless of whether criteria for DSM-5 major depressive disorder are met. Isolated affective symptoms in the absence of delirium and major depression may reflect a subsyndromal depressive disorder, but could also be manifestations of a personality change or cognitive deficits either resulting in affective change (particularly apathy or irritability) or fueling demoralization.

Course and Prognosis. The course of cerebellar diseases varies widely by etiology, ranging from steadily progressive to intermittent to completely static. Personality and cognitive change are likely to follow the underlying disease course, while major depression may be more intermittent, suggesting differences in pathophysiology among these disorders.

Treatment. Determining the cause of the underlying disorder is essential, since cerebellar degeneration secondary to nutritional, dietary, and some metabolic disorders may be treatable and at least partially reversible. Cognitive treatments are supportive and educational, as described for HD. Little is known about the treatment of psychiatric disorders. Anecdotal accounts indicate that patients respond to standard

Telegram: @medical_k

www.konkur.in

treatments, including various classes of antidepressants and ECT. Treatable conditions, especially mood disorders, are likely under-recognized and undertreated. Caution is necessary with agents that may increase ataxia. Large-scale international registries of patients with specific disorders (e.g., European Friedreich ataxia database registry) may help elucidate disease course, establish biomarkers, and facilitate clinical trials of likely agents.

Essential Tremor

ET has been well characterized since 1887, but controversy remains over its definition, whether it represents a symptom, syndrome, or disease entity, and the basis for associated neuropsychiatric abnormalities. ET affects 1% of the population and increases at least fivefold with age, making it the most common movement disorder. Age onset is bimodal. Early onset has a male predominance and is typically in children and before age 25 years; it may even be evident at birth. Older onset begins around age 45 or older and a male predominance is not definitive. In 50% to 70% of patients, ET is a familial disorder, and genetic factors are important, but no causative gene mutations have been consistently reproduced. Growing evidence demonstrates the heterogeneity of ET with respect to its clinical presentation, age onset, progression, pharmacologic response, genetics, pathology, and relationships with other diseases.

The main clinical sign in ET is gradual evolution of a bilateral postural and kinetic (action) tremor affecting the upper limbs. Tremor of the head, voice, or lower limbs may also be present. ET is either sporadic or genetic in origin and is not associated with other known causes of tremor. Activities of daily living can be significantly affected.

The etiology and pathophysiology of ET are unclear. Traditionally, ET was regarded as a benign condition presenting as a monosymptomatic disorder without other neurologic involvement or nonmotor effects. Whether the heterogeneity of ET represents a complex neurodegenerative disorder or a functional reversible disorder of neuronal oscillation is debated. Recent postmortem studies suggest that ET may be a cerebellar disease affecting Purkinje cells. This is supported by increasing evidence that ET is associated with development of other motor abnormalities, including comorbid PD, dystonia, and myoclonus, cognitive and psychiatric features, and olfactory and oculomotor deficits. The kinetic component of ET plus subtle signs of ataxia suggest

Telegram: @medical_k

www.konkur.in

cerebellar involvement and neuroimaging studies suggest nigrostriatal damage. Other studies identified higher prevalence of MCI or selective cognitive deficits indicative of frontocerebellar dysfunction in association with ET, including executive dysfunction, and impairment in attention, verbal fluency, verbal learning, and verbal memory. Higher rates of depressive and anxiety symptoms, sleep disturbances, and fatigue are reported in ET, but the epidemiology and features of discrete psychopathologic syndromes have not been examined. Self-consciousness and embarrassment about symptoms are common. The sensation of internal tremor can be experienced as anxiety. No studies have addressed specific treatment of neuropsychiatric features in ET.

Treatment of ET is usually initiated when symptoms are socially problematic or interfere with daily functioning. The first-line medication treatments used are β-blockers and antiseizure medications, but response is often suboptimal. Chemodenervation with botulinum toxin injections, customized to the muscles associated with the tremor, can improve function and tremor. DBS and FUS, typically targeting the thalamic ventral intermediate nucleus (ViM), can improve action tremor and associated daily functioning for several years, but data on the duration of FUS effects is limited given the technique is relatively new.

Dystonias

Dystonia is characterized by involuntary, sustained muscle contractions that result in twisting, torsional, repetitive movements of one or more body parts and frequently appear as abnormal and sometimes painful or awkward positions and postures. It is the third most common movement disorder after PD and ET. Like ET, it can present as a monosymptomatic condition or as a feature of broader syndrome. Any part of the body can be affected, including the limbs, trunk, neck, eyelids, face, or vocal cords. In 2013, an international consensus committee developed a new classification system for the dystonias based on two axes: Axis 1, the clinical characteristics (age of onset, body distribution of symptoms, temporal pattern of symptoms, and associated features) and Axis 2, the etiology based on shared biologic mechanisms (e.g., neuropathology, inherited, acquired, idiopathic). Age onset is defined as childhood, adolescence, or adulthood (>28 years) and is an important predictor of whether symptoms will spread to other body parts. Distribution of dystonia is categorized as generalized, focal, segmental, multifocal, or

Telegram: @medical_k

www.konkur.in

hemidystonic and is one indicator of disease severity. The etiologic classification scheme is evolving with ongoing discovery of different genetic forms of dystonia. Isolated dystonias are defined by the existence of dystonia as the major symptom and include both hereditary and sporadic forms. In combined syndromes, dystonia is accompanied by other prominent neurologic features, such as parkinsonism or myoclonus, or other systemic features, including psychiatric symptoms. At least 10 genes or chromosomal locations are associated with isolated and combined dystonias, including early-onset generalized dystonia, dopa-responsive dystonia, paroxysmal dystonia, X-linked dystonia-parkinsonism (Lubag), myoclonic dystonia, and rapid-onset dystonia-parkinsonism. Acquired dystonias can be attributed to cerebral insults, including perinatal injury, trauma, toxins, or infarction or as a dopaminergic medication-related effect in PD or schizophrenia. Dystonia also occurs in neurodegenerative conditions, such as WD and PD. Neurophysiologic dysfunction in dopaminergic neurotransmission and basal ganglia output activity is thought to underlie dystonic disorders in which there is no evidence of nerve cell loss.

Dystonic movements begin with a particular motor action, but eventually generalize to multiple actions and are then present at rest. The contractions may be extreme, usually resulting in muscle hypertrophy and often pain or an oppositional tremor. Certain postures or sensory tricks can reduce dystonic contractions. Anticholinergic medications used to treat dystonia can affect memory, but cognitive impairment is not a general feature of dystonias.

Increased attention is being paid to the neuropsychiatric features of dystonia. Until 1997, with evidence that dystonia was an inherited neurologic disorder, it is noteworthy that there was sustained controversy as to whether dystonia was a primary psychiatric condition (a “motor neurosis”) versus a neurologic condition related to basal ganglia dysfunction. Pain, sleep disturbances, psychiatric symptoms, fatigue, and cognitive impairment impact quality of life and aggravate dystonia-associated disability and motor symptoms. Compared to healthy controls, patients with focal dystonia have over twice the rate of psychiatric disorders, with increased lifetime and point prevalence for major depression and anxiety disorders, particularly social phobia (71% in a series of patients with cervical dystonia) and panic disorder. Akin to PD, the psychiatric disturbance begins many years before onset of dystonia

Telegram: @medical_k

www.konkur.in

and there is not a clear correlation between psychiatric and dystonia symptom severity, indicating that the mood disturbance emerges from underlying brain pathology and is not solely an emotional reaction to motor symptoms. Similarly, obsessive-compulsive disorder may be over-represented in families with myoclonic dystonia. Shared pathophysiologic mechanisms in dystonia and psychiatric disturbances are further supported by recent transcriptome analyses showing gene co-expression in specific brain areas significantly enriched for dystonia genes and for depression, obsessive-compulsive disorder, and schizophrenia heritability. A reactive element, nonetheless, also exacerbates psychiatric distress, and can be a result of visible and painful motor symptoms. Alcohol may be misused to self-treat motor symptoms. The differential diagnosis of the various dystonias also includes functional movement disorders, including functional dystonias, which, not infrequently, may co-occur with other dystonias.

The prognosis of dystonia and rate of progression vary with the underlying condition and age of onset. Often, it stabilizes within 5 years of onset, but stressful circumstances provoke symptoms. Most therapy is symptomatic. Strategies include medications to reduce spasms and pain (e.g., anticholinergics, benzodiazepines, and muscle relaxants). Dopamine and dopamine-blocking agents have either negative or beneficial effects on dystonias. Botulinum toxin injections into selected muscles are used extensively to treat the various forms of dystonia. Exercise programs are an important component of therapy. When medical approaches are inadequate, surgery includes thalamotomy, pallidotomy, and DBS procedures. There are no studies on treatment of psychiatric disorders associated with dystonia, but care must focus on the identifying and treating psychiatric disorders or psychological distress. For example, botulism injections may reduce torticollis and depressive symptoms, but self-perceptions remain impaired. SSRIs can precipitate, aggravate, or improve dystonia. ECT may benefit motor and mood symptoms. Initial studies indicate that DBS procedures for dystonia do not have adverse (or positive) effects on rates of cognitive or psychiatric disturbances. Persistent anxiety after DBS-related improvement in dystonia suggest that anxiety is modulated by different networks.

2.7 Neuropsychiatric Aspects of Multiple Sclerosis and Other Demyelinating Disorders

JOSHUA J. RODGERS, M.D.

The higher brain functions referred to as "neuropsychiatric," including complex processes such as emotion, cognition, and behavior, are resultant of distributed cortical–cortical networks modulated by cortical–subcortical and cerebellar–subcortical circuits, all of which depend on

Telegram: @medical_k

www.konkur.in

myelin-insulated axonal connections (i.e., white matter) for efficient functioning. As such, these neuropsychiatric functions are, more often than not, disrupted in the setting of white matter disorders, including demyelinating disorders. The cerebral white matter consisting of neuronal axons and glial cells—one type of which, oligodendrocytes, creates the myelin sheath around axons—comprises half of the volume of the human brain and can be vulnerable to a wide array of afflictions of which the reader should be aware (Table 2.7–1). Many of these disorders from the various categories can cause damage to myelin and thus be said to be demyelinating.

The demyelinating disorders are heterogeneous in etiology and phenomenology (depending largely on lesion location and what networks are disrupted) but broadly share a common basic pathology, namely, the partial or complete loss of the myelin sheath surrounding axons in the white matter of the brain and spinal cord. As white matter tracts are also essential for the proper functioning of motor and sensory functions (e.g., the corticospinal tract, optic nerve, spinothalamic tract, etc.), demyelinating disorders can also disrupt these neurologic functions as well and result in abnormalities in standard neurologic examination (e.g., weakness, vision loss, somatosensory loss, etc.). However, while these motor and sensory abnormalities are easily assessed by the standard neurologic examination and are often the focus of assessments, the neuropsychiatric sequelae of demyelination account for the majority of the disability in these disorders, and thus psychiatrists and neurologists should be skilled in assessing and treating these aspects as well.

Telegram: @medical_k

www.konkur.in

Table 2.7–1.
Classification of Select White Matter Disorders

Telegram: @medical_k

www.konkur.in

1. Demyelinating diseases	Multiple sclerosis, neuromyelitis optica spectrum disorders (Devic syndrome), acute disseminated encephalomyelitis, acute hemorrhagic leukoencephalitis, Schilder disease, Marburg disease, Balò concentric sclerosis
2. Genetic disorders	Leukodystrophies, aminoacidurias, phakomatoses, mucopolysaccharidoses, muscular dystrophy, callosal agenesis
3. Infectious diseases	Acquired immunodeficiency syndrome dementia complex or HIV-associated neurodegeneration, progressive multifocal leukoencephalopathy, subacute sclerosing panencephalitis, progressive rubella panencephalitis, varicella zoster encephalitis, cytomegalovirus encephalitis, Lyme disease, COVID-19 encephalitis
4. Inflammatory diseases	Systemic lupus erythematosus, Behçet disease, Sjögren syndrome, Wegener granulomatosis, temporal arteritis, polyarteritis nodosa, scleroderma, isolated angiitis of the central nervous system, sarcoidosis
5. Toxic leukoencephalopathies	Irradiation toxicity, chemotherapy and other therapeutic drug toxicity, drugs of abuse, environmental toxins
6. Metabolic disorders	Cobalmin (B_{12}) deficiency, folate deficiency, central pontine myelinolysis, hypoxia, hypertensive encephalopathy, eclampsia, high-altitude cerebral edema
7. Vascular diseases	Migraine, stroke and Binswanger disease, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy, leukoaraiosis, cerebral amyloid angiopathy, prematurity, and birth trauma–associated disorders

Telegram: @medical_k

www.konkur.in

	(periventricular leukomalacia, periventricular hemorrhage—cerebral palsy)
8. Traumatic disorders	Traumatic brain injury, shaken baby syndrome, corpus callosotomy
9. Neoplasms	Gliomatosis cerebri, gliomas, primary cerebral lymphoma
10. Hydrocephalus	Congenital hydrocephalus, acute hydrocephalus, normal pressure hydrocephalus

Data from Filley CM. *The Behavioral Neurology of White Matter*. 2nd ed. Oxford University Press. 2012.

By far, the most common and well-studied demyelinating disorder is multiple sclerosis (MS). In fact, MS is the most common nontraumatic neurologic disease of young and middle-aged adults and, in the majority of cases, will manifest with neuropsychiatric symptoms either on presentation or over the disease course.

MS has been described in the literature for more than a century and a half, and over this time, the emotional, cognitive, and behavioral disturbances of MS have been recognized along with the motor and sensory dysfunction, and substantial efforts have been made to characterize the full spectrum of MS-related neuropsychiatric sequelae since. This interest has been sustained by an increasing awareness that different forms of psychopathology are very common in these disorders and that the prevalence exceeds what would be expected to occur in other similar chronic and disabling conditions. Moreover, it has also been hoped that these disorders, especially MS, may represent a biologic model for primary mood disorders, which may facilitate the elucidation of the etiology and neuroanatomy of primary mood and other psychiatric disorders. Indeed, these findings have led to research into the role of white matter abnormalities in the pathophysiology underlying primary psychiatric disorders, including schizophrenia, depression, bipolar disorder, attention deficit hyperactivity disorder, and autism.

MULTIPLE SCLEROSIS

Telegram: @medical_k

www.konkur.in

MS is a chronic, as of yet, incurable disease of the central nervous system (CNS), which can have an onset at nearly any age and is a highly variable course. MS has a complex and not fully known etiopathogenesis characterized pathologically by inflammation and demyelination as well as neuronal degeneration and cortical involvement thought to be due to autoimmune attack of oligodendrocytes and the myelin sheath they create. The lesions appear to occur at random locations, mostly in frontal periventricular white matter, and thus result in high variability in the clinical presentation.

Epidemiology

Nearly 3 million people worldwide are afflicted by MS, and its prevalence is increasing. The highest prevalence rates appear to occur in Caucasians of northern European descent, and in the United States, a clear north–south gradient of prevalence has been demonstrated. The disease is less common in certain Asian populations, such as Uzbekistanis, native Siberians, North and South Native Americans, Chinese, and Japanese, as well as African Americans and New Zealand Maoris. The data suggest more than just a geographical vulnerability but also strong genetic influences. The disease is far more common in women, as are other autoimmune disorders. MS is most commonly diagnosed in the age group of 20 to 50 years of age, but the prevalence of pediatric-onset appears to be increasing dramatically.

Clinical Features and Diagnosis

The French neurologist Jean-Martin Charcot first established diagnostic criteria for MS in the middle of the 19th century. His original diagnostic triad is now known not to be specific, and in fact, over the years, numerous other diagnostic criteria were developed, all of which had a lack of specificity for the illness, thus including many false positives. The chief components of the diagnostic criteria have remained (1) dissemination of distinct attacks of focal neurologic deficits in time (relapsing/remitting features separated by a period of at least 1 month) and space (distinct CNS lesions and deficits) and lasting a minimum of 24 hours, and (2) exclusion of other causes. The 2010 McDonald criteria, consisting largely of clinical and radiographic (magnetic resonance imaging [MRI]) proof of dissemination of disease in time and space, were revised in 2017 to include the latest research and improve specificity. These revisions

Telegram: @medical_k

www.konkur.in

include expanding the possible evidence of disease dissemination in time (such as the presence of intrathecal oligoclonal bands) and space (such as the inclusion of both symptomatic and asymptomatic lesions and the inclusion of cortical lesions as equivalent to juxtacortical lesions) (see Table 2.7–2).

The clinical diagnostic criteria specified allow one to distinguish MS from disseminated encephalomyelitis, which is most commonly a single episode of illness, with all lesions occurring within a few weeks, although multiple separate lesions do sometimes occur. Once believed to be a subtype of MS, the evolving concept of neuromyelitis optica spectrum disorders (NMOSD) is an important clinical entity to distinguish from MS along with other disorders in the broad differential diagnoses (see below).

The diagnosis of MS remains largely clinical. The initial symptoms of MS are nonspecific and heterogeneous and may include a broad range of somatosensory, ocular, motor symptoms, and neuropsychiatric syndromes. The motor symptoms could include transient hemiparesis and various forms of seizure, among others. Symptoms of cerebellar dysfunction may occur, including scanning speech, gait ataxia, and various tremors. Although these mentioned symptoms and signs are common in the initial presentation, almost any neurologic symptom or sign can be the first presentation of MS.

Telegram: @medical_k

www.konkur.in

Table 2.7–2.
The 2017 McDonald Criteria for Diagnosis of Multiple Sclerosis in Patients with an Attack at Onset

	Number of Lesions with Objective Clinical Evidence	Additional Data Needed for a Diagnosis of Multiple Sclerosis
≥2 clinical attacks	≥2	None*
≥2 clinical attacks	1 (as well as clear-cut historical evidence of a previous attack involving a lesion in a distinct anatomical location†)	None*
≥2 clinical attacks	1	Dissemination in space demonstrated by an additional clinical attack implicating a different CNS site or by MRI‡
1 clinical attack	≥2	Dissemination in time demonstrated by an additional clinical attack or by MRI§ OR demonstration of CSF-specific oligoclonal bands¶
1 clinical attack	1	Dissemination in space demonstrated by an additional clinical attack implicating a different CNS site or by MRI‡ AND Dissemination in time demonstrated by an additional clinical attack or by MRI§ OR demonstration of CSF-specific oligoclonal bands¶

If the 2017 McDonald Criteria are fulfilled and there is no better explanation for the clinical presentation, the diagnosis is multiple sclerosis. If multiple sclerosis is suspected by virtue of a clinically isolated syndrome but the 2017 McDonald Criteria are not

Telegram: @medical_k

www.konkur.in

completely met, the diagnosis is possible multiple sclerosis. If another diagnosis arises during the evaluation that better explains the clinical presentation, the diagnosis is not multiple sclerosis. An attack is defined in panel 1.

*No additional tests are required to demonstrate dissemination in space and time. However, unless MRI is not possible, brain MRI should be obtained in all patients in whom the diagnosis of multiple sclerosis is being considered. In addition, spinal cord MRI or CSF examination should be considered in patients with insufficient clinical and MRI evidence supporting multiple sclerosis, with a presentation other than a typical clinically isolated syndrome, or with atypical features. If imaging or other tests (e.g., CSF) are undertaken and are negative, caution needs to be taken before making a diagnosis of multiple sclerosis, and alternative diagnoses should be considered.

†Clinical diagnosis based on objective clinical findings for two attacks is most secure. Reasonable historical evidence for one past attack, in the absence of documented objective neurological findings, can include historical events with symptoms and evolution characteristic for a previous inflammatory demyelinating attack; at least one attack, however, must be supported by objective findings. In the absence of residual objective evidence, caution is needed.

‡The MRI criteria for dissemination in space are described in panel 5.

§The MRI criteria for dissemination in time are described in panel 5.

¶The presence of CSF-specific oligoclonal bands does not demonstrate dissemination in time per se but can substitute for the requirement for demonstration of this measure.

Reprinted from Thompson AJ, Banwell BL, Barkhof F, et al. Diagnosis of multiple sclerosis: 2017 revisions of the McDonald criteria. *Lancet Neurol.* 2017;17(2)162–173. © 2017, with permission from Elsevier. doi:10.1016/S1474-4422(17)30470-2.

MRI can greatly aid the diagnosis through the demonstration of characteristic T2 hyperintensities (see MRI below) but does not supersede the clinical diagnosis. MRI is not always specific for the diagnosis of MS and may lead to a false-positive diagnosis if it is relied on exclusively.

Laboratory support for the diagnosis of MS consists of demonstration in the cerebrospinal fluid (CSF) of at least two oligoclonal bands or increased CNS synthesis of immunoglobulin G (IgG). In addition to this evidence, evoked potentials, particularly visual or somatosensory evoked potentials, are slowed or absent and may contribute to or support the clinical diagnosis.

Course and Etiology

MS can have a widely variable clinical course. The most common course or type, defining 85% to 90% of MS cases, is relapsing–remitting, where the patient has acute relapses of neurologic/neuropsychiatric symptoms lasting at least 24 hours, but usually several days to weeks, with eventual

Telegram: @medical_k

www.konkur.in

remission and almost complete recovery. A secondary progressive type may evolve from the relapsing–remitting type, leading to incomplete recovery after acute exacerbations of illness. In about 10% of cases, signs and symptoms may persist, worsen, and expand from the outset of the illness, and the disorder then takes on a chronic progressive nature known as the primary progressive type. This form may be rapidly progressive and is rarely seen in patients younger than 40 years of age.

The relationship between these different forms is not clearly understood, and it is uncertain to what extent they represent different types of illness with regard to etiology. The etiology of MS is becoming more fully understood as an autoimmune disorder leading to damage to the myelin with an inflammatory reaction, the resolution of which leads to the formation of plaque in various parts of the brain. Recent research has revealed the presence of peripheral lymphatic ducts in the CNS, which was previously thought to be “immune privileged,” and will likely lead to a new understanding of the pathophysiology of MS and other immune system–related neurologic disorders.

Neuropsychiatric Aspects

Fatigue. Various neuropsychiatric syndromes are overrepresented in MS (Table 2.7–3). Fatigue is one of the most common presenting symptoms of patients with all demyelinating disorders and has been extensively described in MS. Fatigue substantially contributes to the disability and poor quality of life that these patients experience. Fatigue may be profound and usually includes both physical fatigue, which makes the patient feel less able to perform physical activity, as well as mental fatigue, which makes the patient unable to participate in their usual activities, including work. Fatigue is one of the most prominent and enduring symptoms of MS, and it is estimated to occur in almost all patients with MS and to be the predominant and often the presenting symptom at the time of diagnosis in up to 50% of cases. Fatigue in MS can have a reverse diurnal rhythm in that it is worse as the day progresses, so many patients with MS alter their lifestyle to do much of their activities early in the day before the fatigue of the later day and evening becomes disabling.

Table 2.7–3.
Neuropsychiatric Syndromes Associated with MS, Rates, Mechanisms, and Treatment

Syndrome	Rate in MS	Relative Rate	Associated Lesion Locations/Mechanism/ Risk Factor	Treatment Suggestions
Depression	50%	3x	Dominant (usually left) hemisphere inferomedial frontal, anterior temporal lesions	SSRIs, SNRIs, TCAs, lithium augmentation, mirtazapine CBT, mindfulness, exercise ECT*
Anxiety disorders	8–36%	3x	Unknown lesion location association New diagnosis, increased disease activity, depression experience of pain, fatigue, sleep disturbance	SSRIs, buspirone, pregabalin, gabapentin, β-blockers
Bipolar (mania)	0.3–2.5%	2x	Right hemisphere lesions, steroid and ACTH Tx genetic risk overlap	Lithium, valproic acid, carbamazepine, atypical antipsychotics, reduction of causative drugs
Euphoria	25%		Advanced disease, high frontal lesion load, gray matter atrophy	No specific treatment, patient and family education
PLC (PBA)	10%		Basis pontis, internal capsule, and cerebral peduncle	SSRIs, levodopa, TCAs, amantadine, dextromethorphan/quinidine
Psychosis	2–3%	2–3x	Temporolimbic region lesions; younger age of onset	Antipsychotics with low risk for anticholinergic and EPS may be preferred
Cognitive dysfunction	43–65%		Diffuse	Modest effect of acetylcholinesterase inhibitors. Address depression, fatigue, sleep issues, polypharmacy
Fatigue	>80%		Sedating medications	Amantadine, modafinil, armodafinil, methylphenidate, amphetamines
Sexual dysfunction	Up to 90%		Spinal cord lesions, medication effects	Phosphodiesterase inhibitors

*ECT is for treatment resistant cases, may increase risk of MS relapse. ACTH, adrenocorticotropic hormone; CBT, cognitive-behavior therapy; ECT, electroconvulsive therapy; SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor; TCA, tricyclic antidepressant; Tx, treatment; PLC, pathologic laughing and crying; PBA, pseudobulbar affect; Relative rate, rate in MS/rate in general population.

The etiology of fatigue in MS is complex and multidetermined and remains an area of active research. There are no clear etiologic factors identified, but neurologic and endocrine factors may contribute. Other factors may also worsen fatigue, such as comorbid medical disorders, associated depression, sleep difficulties, and the side effects of medications used to treat the symptoms of MS and comorbid conditions (Table 2.7–4). In particular, fatigue may be related to comorbid depression, where fatigue is also a common symptom and treatment of depression may, to a varying extent, alleviate the symptom of fatigue.

Depression and Anxiety. Of the broad range of neuropsychiatric symptoms associated with MS (see Table 2.7–3), depression is the most prominent and common but remains underrecognized and underdiagnosed or misdiagnosed as a separate entity rather than a result of the underlying pathology (demyelination) disrupting mood regulation networks and circuits. Over the course of their illness, approximately half of patients with MS will have at least one episode of signs and symptoms meeting the diagnostic criteria for major depressive disorder. Point prevalence rates may be as high as 20%. Depression can be the presenting feature of MS and is often the dominant complaint of MS

Telegram: @medical_k

www.konkur.in

patients. Neurovegetative symptoms, frustration intolerance, discouragement, and irritability may more likely characterize the depression of MS than depression in the general population.

Table 2.7–4.
Potential of MS Therapeutics Neuropsychiatric Benefits and Adverse Effects

Therapeutic Agent	Potential Benefits	Potential Adverse Effects
Corticosteroids adrenocorticotropic hormone	Reduced flair symptoms	Mania, insomnia, psychosis, depression, hyperglycemia, weight gain, osteoperosis
Immunomodulatory drugs ▶ Interferon β-1a ▶ Interferon β-1b ▶ Glatiramer ▶ Monoclonal antibodies (natalizumab, alemtuzumab, daclizumab, ocrelizumab, rituzimab*)	Improved cognition, information processing, memory, visuospatial ability, and executive function. Reduced relapse rate and lower white matter disease burden	Fatigue, depression, infusion reactions
Chemotherapeutics (mitoxantrone)	Reduced disease activity	Fatigue, infection, nausea
Small-molecule oral agents (Fingolimod, dimethyl fumarate, teriflunomide)	Reduced disease activity	Seizures (rare), infections, progressive multifocal leukoencephalopathy, malignancies
Dalfampridine	Gait improvement	Anxiety, focal seizure
Baclofen, dantrolene, tizanidine	Reduced spasticity	(Hypo)mania

Data from Filley CM. *The Behavioral Neurology of White Matter.* 2nd ed. Oxford University Press. 2012; Reich DS, Lucchinetti CF, Calabresi PA. Multiple sclerosis. *N Engl J Med.* 2018;378(2):169–180; and Tobin WO. Management of multiple sclerosis symptoms and comorbidities. *Continuum.* 2019;25 (3, multiple sclerosis and other CNS inflammatory diseases): 753–772.

As described by G.M. Galeazzi and colleagues in a review, the cause of depression in MS patients may be due to (1) depression as a prodromal feature of MS, (2) depression and MS as coincidental but independent conditions, (3) depression and MS as the same condition with common etiology, (4) depression as a reaction to the chronicity and disability of MS, (5) depression as a side effect of MS treatment, particularly corticosteroids and interferon, or (6) any combination of these.

Table 2.7–5.
Reported MS White Matter Lesion Location and Associated Focal Neurobehavioral Syndrome

Bifrontal	Executive dysfunction
Left frontal	Broca aphasia, transcortical motor aphasia
Left temporal	Amnesia
Left temporoparietal	Alexia with agraphia
Left occipital, splenium of corpus callosum	Pure alexia
Left arcuate fasciculus	Conduction aphasia
Left periventricular	Global aphasia
Bilateral occipitotemporal	Visual agnosia
Right hemispheric	Left hemineglect
Corpus callosum an bihemispheric	Left tactile anomia, agraphia, and apraxia
Diffuse	Neurocognitive disorder (dementia), mixed transcortical aphasia

Adapted with permission from Filley, CM. *The Behavioral Neurology of White Matter*. 2nd ed. Oxford University Press; 2012.

Table 2.7–5 presents the associated lesion location for each major neurobehavioral syndrome associated with MS. Based on multiple

Telegram: @medical_k

www.konkur.in

neuroimaging and other epidemiologic studies, it is generally agreed that dominant hemisphere (usually left), inferior medial frontal, and anterior temporal MS plaque burden is linked with depression in MS. Indeed, lesions in these areas accounted for 42% of depression variance in a regression analysis. Likewise, other demyelinating, vascular, traumatic, infectious, inflammatory, toxic, metabolic, and neoplastic white matter disorders involving these networks frequently cause depression. Smaller hippocampal volumes and associated cortisol hypersecretion, and a possible role for cytokine regulation, have also been related to depression in MS and suggest a more complex neuroendocrine-limbic etiology.

The occurrence of major depressive syndrome in MS patients may substantially add to the disability and the burden of illness associated with MS and dramatically increases the risk for suicide to seven times that of normal populations. Suicide, tragically, is a frequent cause of death for MS patients that can be prevented with recognition and treatment.

The research to date on the antidepressant treatment of depressive syndromes associated with MS is limited, and the efficacy of antidepressants has not been clearly demonstrated. In a Cochrane review, only two studies on pharmacologic treatment of depression in MS met quality inclusion criteria and showed only a trend toward efficacy for desipramine and paroxetine but with the expected adverse effects common with these agents limiting their usefulness. More tolerable agents, including fluoxetine, sertraline, and duloxetine, were shown to be beneficial in open-label studies.

Randomized controlled trials have shown a significant benefit of cognitive-behavior therapy (CBT) for depression in MS. Mindfulness training has also shown benefits. Expert recommendations for treatment of depression in MS are similar to those for the general population and include antidepressants, CBT, mindfulness training, and lifestyle and social interventions, as well as electroconvulsive therapy (ECT) in treatment-refractory cases, though it is cautioned that ECT may exacerbate active disease. Psychoeducation for patients and their families on the prevalence and cause of depression in MS may be especially helpful.

Anxiety in MS remains poorly studied. Anxiety is frequently comorbid with depression in the general population and in MS; clinically significant anxiety is present in about half of MS patients with depression and is correlated to thoughts of self-harm, somatic complaints, and social

Telegram: @medical_k

www.konkur.in

dysfunction. Pathologic anxiety disorders, including generalized anxiety disorder, panic disorder, and obsessive-compulsive disorder, are roughly three times more common in MS patients than in the general population. Social phobia is found in about 8% of MS patients and is thus less common than in the general population (about 13%). Guidelines for treating anxiety disorders in MS are lacking, and thus the clinician must rely on clinical judgment and guidelines for treating anxiety in the general population. SSRIs such as escitalopram, fluoxetine, and sertraline are generally preferred.

Mania and Bipolar Disorder. Mania-like episodes or the full syndrome of bipolar mood disorder can be the presenting and predominant feature of MS. Bipolar disorder has been estimated to be 2 to 10 times more frequent in MS patients than in the general population. Feinstein associated mania with bilateral temporal lesions. In general, neurologic disorders resulting in right hemisphere lesions are associated with mania, and lesions within the right anterior temporal, orbitofrontal, and cingulate regions may be more highly correlated with mania. In bipolar patients with a rapid-cycling course, the possibility of MS as a course-modifying factor for bipolar disorder should be considered. Mania secondary to corticosteroid treatment in MS patients is also a relevant concern affecting approximately 30% of MS patients.

Due to the dearth of research on the treatment of mania in MS, treatment recommendations follow those for the general population. Of course, corticosteroid or adrenocorticotropic hormone treatments may require special consideration for discontinuation in this context.

Euphoria, Disinhibition, and Other Frontal Personality Changes. Euphoria, a persistent state of impaired insight and judgment with apparent unconcern and even elation regarding disability, is a striking syndrome associated predominantly with MS, with a prevalence of about 10% in the disease. The presence of euphoria is generally indicative of more advanced disease with more disseminated plaque burden and atrophy and is associated with more impaired neurologic and cognitive functioning and social disability. The persistent cheerfulness and unconcern of euphoria may overlap somewhat with mania but is distinct from the full mania syndrome and does not represent a “climate shift” in the mood nor fluctuate, and may even co-occur with depression.

Telegram: @medical_k

www.konkur.in

Cortical or subcortical gray or white matter lesions from MS or other causes can result in the other classic frontal lobe syndromes, including dysexecutive, disinhibited, or apathetic if the lesion burden is in the associated dorsolateral–prefrontal, orbitofrontal, or medial frontal/cingulate systems, respectively.

A 41-year-old, right-handed, married male dentist with a family history of bipolar disorder and a past psychiatric history of an isolated episode of depression 3 years prior presented for voluntary inpatient hospitalization at the recommendation of his outpatient psychiatrist for treatment of a first-ever manic episode beginning 4 months prior to presentation and in the context of the onset of use of THC pills. He denied the use of nitrous oxide or other inhalants. On evaluation, he exhibited an elevated and expansive mood with notable euphoria, decreased need for sleep, grandiosity, and pressured speech with flight of ideas, but with notable retained insight regarding the abnormality of his current state. He was empirically started on lithium and Seroquel, and his manic symptoms gradually improved. MRI of the brain (Fig. 2.7–1) was ordered as part of the workup and revealed numerous T2 intense intracranial white matter lesions in the posterior fossa and supratentorial brain, including corpus callosum, and a newer-appearing lesion in the white matter deep to the right cingulate gyrus, all consistent with the diagnosis of demyelinating disease, likely MS. A follow-up MRI of brain and spinal cord with contrast revealed additional T2 hyperintense lesions consistent with demyelination in the cervical cord at the C2 level. No enhancement suggesting active inflammation was seen with contrast administration. A more detailed history was obtained, and the patient recalled when he was in college, he had an acute episode of weakness and paresthesia ascending from his feet and ultimately involving most of his body, which was diagnosed at the time as peripheral neuropathy. This episode resolved spontaneously after a couple of weeks. With this history and the imaging findings, the patient was referred to a neurologist who specialized in MS and was diagnosed with MS based on the history of the prior clinical attack and the objective evidence of corresponding two T2 lesions in the dossal cord at C2–C3 as well as other T2 disseminated in time and space. The right frontal lesion was hypothesized to be potentially causative of his manic symptoms, and the older appearing left hemisphere lesions could have contributed to his prior depressive syndrome, but a definitive causal relationship cannot be asserted. He was started on Copaxone as this was considered the DMA least likely to affect mood, and it was recommended that he avoid cannabinoids and continue treatment with

Telegram: @medical_k

www.konkur.in

lithium. He was referred to an MS clinic at a university hospital for further evaluation.

FIGURE 2.7–1. MRI for case presentation. Axial (**A**) and sagittal (**B**) T2 FLAIR MRI of the brain revealing numerous T2 intense intracranial white matter lesions in the posterior fossa and supratentorial brain consistent with the diagnosis of demyelinating disease, likely multiple sclerosis. Sagittal images (**B**) show the relatively MS-specific "Dawson fingers"—periventricular T2 hyperintensities (indicative of demyelinating plaques) perpendicular to the body of the lateral ventricles (along the axis of medullary veins). **C:** Sagittal T2 MRI spinal cord revealing additional T2 hyperintense lesions consistent with demyelination in the cervical cord at the C2 level.

Affect Disorders. As distinct from the more persistent abnormalities of mood discussed above, MS and other white matter disorders can cause disordered affect (defined as the experienced and expressed transient emotional state; see DSM-5 Glossary of Clinical Terms). This includes emotional lability, pathologic laughing, and crying (PLC; also known as pseudobulbar affect, emotional incontinence, and other descriptors). PLC in MS is associated with a heavier lesion burden, usually in the basis pontis, internal capsule, and cerebral peduncle.

Telegram: @medical_k

www.konkur.in

Psychosis. The syndrome of psychosis in MS is more frequent than in the general population, occurring in up to 5% of cases, and maybe the initial presenting feature of the disease. Psychosis is a more common presenting feature of other white matter disorders, including metachromatic leukodystrophy. In MS patients, psychosis has been associated with earlier onset of disease and plaque burden in bilateral temporolimbic regions, especially the left temporal horn and left trigone. Persecutory delusions are more common than auditory or visual hallucinations, with incidences of about 70%, 20%, and 20%, respectively. In general, treatment with an antipsychotic with a low risk for anticholinergic and extrapyramidal side effects is preferred.

Sleep Disorders. Various disturbances of sleep/wake are associated with MS, including insomnia, sleep-disordered breathing, restless legs syndrome (RLS), rapid eye movement (REM) sleep behavior disorder, and narcolepsy, and can have a significant impact on fatigue and general health-related quality of life, as well as on cognitive impairment, depression, anxiety, and other neuropsychiatric symptoms.

Cognitive Impairment. It has been estimated that up to 50% to 70% of patients with MS show evidence of cognitive impairment on an appropriate battery of neuropsychological tests. However, unlike the typical pattern of amnesia and aphasia seen in Alzheimer disease, for example, impairments in processing speed and attention are more likely in MS and may not be assessed adequately by cognitive screening instruments. Cognitive symptoms contribute substantially to the dysfunction and to poor quality of life that occurs in patients with MS. Cognitive dysfunction in MS may be broad based and involve multiple neurocognitive domains, and in nearly a quarter of patients, the severity of deficit may surpass the threshold for diagnosis of a neurocognitive disorder (dementia).

In general, white matter dementias negatively affect the speed or efficiency of a given neurocognitive domain rather than cause complete loss of that domain. For example, all aspects of memory function, especially memory retrieval, may be slowed, but procedural memory is generally normal, and the patient would not usually have dense amnesia as seen in cortical dementias. Higher-order functions, such as complex attention, information processing, and executive function, may likely be impaired, and these may contribute substantially to impairments at work,

Telegram: @medical_k

www.konkur.in

driving, and in relationships and limit the ability to benefit from physical rehabilitation. However, overall intellectual abilities are spared, as are language abilities (aphasias are uncommon), although some dysfunction in these domains may be determined on broad-based neuropsychological tests.

Most of the studies of cognitive impairment in MS are cross-sectional in nature. There are limited data on the longitudinal course of cognitive difficulty. In general, however, these studies show a gradual decline in all aspects of cognitive function in the patient with MS.

Full neuropsychological testing is the gold standard for cognitive assessment but is time-consuming and may not be available in some settings. The Minimal Assessment of Cognitive Function in MS (MACFIMS) is a relatively brief (90-minute) validated battery assessing domains usually affected in MS and is commonly utilized in research and in MS clinics for clinical monitoring.

Cerebellar Involvement. Cerebellar white matter is commonly involved in MS, 85% of cases in one study, and is associated with various kinds of dysfunction, including problems with motor coordination as well as problems with regulation of emotion, cognition, and behavior, depending on the cerebellar region involved with the cerebellar motor syndrome being associated with anterior lobe lesions and the cerebellar cognitive affective syndrome (CCAS) being associated with posterior lobe lesions. In MS, the disease burden in the middle cerebellar peduncle (MCP) is most highly correlated with cognitive dysfunction.

Differential Diagnosis

MS presents a substantial challenge as far as differential diagnosis is concerned. In those with the common relapsing-remitting course of illness, together with typical clinical, laboratory, and MRI findings, the diagnosis is more easily made. However, in atypical cases, differential diagnosis can be difficult. This applies particularly at the onset of the disease, during the first episode when the conventional clinical criteria are hard to apply. With the first attack of MS, it is difficult to differentiate this illness from other demyelinating disorders.

There are a variety of other conditions to consider in the differential diagnosis of MS. These include the following:

Telegram: @medical_k

www.konkur.in

1. Disseminated encephalomyelitis: Factors that may point to this diagnosis include systemic symptoms, signs of cortical dysfunction, and, perhaps, bilateral optic neuritis. MRI may be quite characteristic of this disorder and helps distinguish it from MS.
2. Cerebral vasculitis: This has numerous causes. They include primary cerebral vasculitis, which is extremely rare, associated with systemic lupus erythematosus, AIDS, lymphoproliferative disorders, and Wegener granulomatosis. Various ancillary laboratory findings may help distinguish these various forms of the disease. Rarer forms of vasculitis may include Behçet disease and also CNS sarcoidosis.
3. Leukodystrophies: These disorders are characterized by the accumulation of unchanged adrenoleukodystrophy, which may have an adult-onset form. These conditions are rare and can usually be identified by the presence of family history.
4. Chronic fatigue syndrome: It has been previously emphasized that fatigue is one of the most predominant symptoms of MS. Chronic fatigue syndrome, also known as fibromyalgia, requires differentiation, especially if no focal neurologic symptoms are found. Failure to elicit specific neurologic symptoms, as well as the presence of other associated features of fibromyalgia, including sleep disturbance, myalgias, and arthralgias, among other relatively nonspecific symptoms, is supportive of this diagnosis.

Treatment

Treatment of the clinical neuropsychiatric syndromes discussed above is generally initiated empirically in a symptom-targeted approach while workup for a potential identifiable cause is conducted. Care should be taken to educate the patient and family on the potential causal relationship between the MS flair and neuropsychiatric symptoms. Clinicians should avoid the erroneous description of “inorganic” or assume that these symptoms are a manifestation of a psychological reaction to the illness.

CONCLUSION AND FUTURE DIRECTIONS

While the demyelinating disorders present etiopathologic and diagnostic challenges, it is clear that they can produce phenomenology across the spectrum of neuropsychiatric disorders. The most common demyelinating disorder, MS, requires differentiation from other disorders because of its distinct clinical presentation and course of illness, as well as specific

Telegram: @medical_k

www.konkur.in

treatments that may reduce relapse rates and degree of dysfunction. MS usually presents with neuropsychiatric symptoms, and depressive syndromes and symptoms are especially common. While the broad range of pharmacologic and nonpharmacologic interventions used in primary psychiatric disorders are often used, with good effect, in MS patients, large-scale, well-designed studies are needed to provide a good evidence base for the treatment of psychiatric symptoms and disorders associated with this condition, which may require specific intervention or psychotropic agents. The association of MS with specific major histocompatibility complex (MHC) class II alleles and the relatively recent discovery of peripheral lymphatic duct in the CNS, previously thought to be immune privileged, may open new avenues for research on these disorders.

ACKNOWLEDGMENT

This chapter represents an update and revision of previous chapters in this series, most recently by Dr Russell T. Joffe from the last edition. I am indebted to Dr Joffe for his work and retain much of his prose in this current edition.

2.8 Neuropsychiatric Aspects of HIV Infection and AIDS

Glenn Jordan Treisman, M.D., Ph.D., Andrew F. Angelino, M.D., Jeffrey Hsu, M.D., Anna Moukouri Kouoh, C.R.N.P., and Nicholas P. Schweizer, Ed.D., L.C.A.D.C., L.C.P.C.

Since the original description of acquired immune deficiency syndrome (AIDS) in 1981, the human immunodeficiency virus (HIV) epidemic has remained a public health concern due to continued infections, comorbid conditions, and specialty treatment. In the mid-1990s, the discovery of combined antiviral therapy (ART) radically changed the course of the illness from an inevitably fatal illness to a chronic treatable condition. This provoked optimism and spurred research in a way that has transformed the field of medicine. The virus has now become a chronic disease for most patients, and effective multidrug therapy (initially referred to as HAART—**h**ighly **a**ctive **a**nti**r**etroviral **t**herapy but now usually just ART for antiviral therapy), inhibits viral replication so that it is undetectable in the blood of most effectively treated patients. Over the years, alterations in treatment options, prophylactic treatment of opportunistic infections, prevention of maternal–fetal transmission and the advent of pre-exposure prophylaxis (PrEP) have all contributed to improving the quality of life and prognosis of persons living with HIV (PLWH), and made it so that this patient population has a life expectancy near that of the general population when diagnosed early and treated effectively.

xs

Psychiatric disorders play several roles in the transmission of HIV and the continued epidemic, in elements of treatment, and in comorbidity. Psychiatric conditions are associated with increased risk behaviors for infection, decreased access to care, decreased adherence to HIV therapies, and increased medical comorbidity. Because of this, some authors have gone as far as saying that HIV is a psychiatric epidemic.

Prevention of HIV transmission became a goal in the mid-1980s when the routes of transmission were defined and testing became available. The massive effort at education resulted in a decrease in the spread of HIV in people able to modify their risky behaviors, but vulnerable people who were either unable or unwilling to modify their behavior or unable to understand the risks continued to spread the infection. While there are still individuals who contract HIV as a result of ignorance and bad luck, the vast majority of new infections arise in individuals who are aware of HIV but continue to engage in high-risk behaviors. As HIV treatment has become accessible and with more effective and better-tolerated antiviral cocktails, some people have become less cautious and there has been a resurgence of risky behaviors in some populations. A major breakthrough in prevention came with the development of PrEP, an antiviral combination that prevents HIV infection if taken before exposure. Again, a very effective intervention but one that vulnerable people may not be able to access or effectively utilize.

PrEP is available as either of two oral formulations or a long-acting injectable formulation, is well tolerated, and has the remarkable potential to decrease the HIV epidemic. Unfortunately, patients at risk for HIV often have limited interactions with health care and PrEP has not yet had the impact that it could. Many patients present to mental health settings, particularly those treating substance abuse, with HIV risk behaviors and the potential to benefit from PrEP, and mental health providers could provide access to PrEP for at-risk patients. Newer forms of PrEP are coming and may be even more effective in helping prevent infections.

www.konkur.in

Since many of the high-risk behaviors that can result in HIV infection are those that are associated with the brain's reward systems, it is understandable that humans would be drawn to these behaviors and that they would be common. Sex and substance use are indeed common behaviors. Individuals with various types of untreated mental illness are vulnerable to engage in such behaviors unsafely at a higher frequency, and thus increase their risk of acquiring HIV. Several major efforts have been successful in curbing the epidemic. The concept of "treatment as prevention," greatly encouraged more aggressive identification and treatment of infected individuals and encouraged clinicians to come up with ways to get patients into treatment. This has resulted in "test and treat" programs to try to accelerate the goal of achieving an undetectable viral load, a condition where patients are minimally infectious to others. Once infected, there is a stepwise hierarchy for accessing care (see Fig. 2.8–1). Based on the description by Eldred and Malitz, it is possible to stratify the degree of engagement in care in various populations. Vulnerable populations (such as those with psychiatric conditions) tend to lag behind in accessing care. Figure 2.8–1 shows the current level of care continuum from the Centers for Disease Control and Prevention (CDC) in 2019.

Once an individual is engaged in care, they must adhere to the antiviral regimen prescribed for them. This has been greatly aided by efforts to simplify treatment, and many regimens have achieved the goal of "one pill once a day." Untreated mental illness has been shown to lead to nonadherence, higher viral loads, more morbidity, and a higher mortality rate. The continued presence of virus in the blood of those with inadequately controlled HIV infection makes it possible to transmit HIV and perpetuates the epidemic. Recognition and treatment of mental illness is crucial to ending the spread of HIV and implies a critical role for psychiatry in integrated care for these patients.

The introductory part of the chapter is a medical overview of HIV disease. The second part considers psychiatric conditions associated with HIV, and the third part considers related neurologic issues that have an impact on psychiatric function and are part of the differential diagnosis of any patient presenting with HIV and psychiatric complaints.

OVERVIEW OF HIV INFECTION AND AIDS

Telegram: @medical_k

www.konkur.in

Epidemiology

HIV was originally recognized through a series of case descriptions involving young homosexual men with *Pneumocystis carinii* (now *Pneumocystis jirovecii*) pneumonia and other rare conditions, including an aggressive form of Kaposi sarcoma, (a usually indolent condition seen prior to that time most often in older Caucasian men of middle eastern extraction), in the early 1980s in Los Angeles (see Fig. 2.8–2 for the first report of the epidemic). These patients suffered from unusual infections associated with immune systems that had been compromised, termed "opportunistic" infections. Subsequently, it became clear that these patients were vulnerable to infections that were usually restricted to immunocompromised individuals.

The World Health Organization (WHO) has case definitions for HIV surveillance and clinical staging based on clinical conditions; patients are sorted into one of four stages with higher stages indicating worse clinical conditions, Stage 1 consists of asymptomatic or with persistent generalized lymphadenopathy of at least two sites for longer than 6 months, and up to stage 4 indicating AIDS-defining illnesses like HIV wasting syndrome, pneumocystis pneumonia (PCP), recurrent severe or radiologic bacterial pneumonia, extrapulmonary tuberculosis, HIV encephalopathy, central nervous system (CNS) toxoplasmosis, chronic (more than 1 month) orolabial herpes simplex infection, esophageal candidiasis, and Kaposi sarcoma. The CDC describes three stages of HIV infection: acute, chronic, and AIDS (see Box 2.8–1). In Stage 1, the acute HIV infection produces large amounts of virus in the blood and flu-like symptoms. During this stage, there are high titers of viral products and patients are most infectious. In Stage 2 called chronic HIV infection, patients are asymptomatic and while the virus is still active it produces lower viral titers and patients are less infectious. In Stage 3, the number of CD4 cells is low and the patient becomes vulnerable to opportunistic infections. This is now defined as having AIDS, similar to the WHO definition.

Epidemiologic Notes and Reports

Pneumocystis **Pneumonia — Los Angeles**

In the period October 1980-May 1981, 5 young men, all active homosexuals, were treated for biopsy-confirmed *Pneumocystis carinii* pneumonia at 3 different hospitals in Los Angeles, California. Two of the patients died. All 5 patients had laboratory-confirmed previous or current cytomegalovirus (CMV) infection and candidal mucosal infection. Case reports of these patients follow.

FIGURE 2.8–2. Image from the front page of the CDC weekly morbidity and mortality report showing the first report of five cases of pneumocystis pneumonia reported as part of what became the HIV epidemic. All five also had CMV and candidiasis. (From Centers for Disease Control and Prevention. (2022). HIV and AIDS timeline. https://npin.cdc.gov/pages/hiv-and-aids-timeline#1980)

The 2019 the joint united nations programme on HIV/AIDS (UNAIDS) report suggests that the overall prevalence of HIV globally appears to have stabilized (at 0.7%) but continues to increase in some countries. In 2019, 36.2 million adults and 1.8 million children (<15 years old) were living with HIV/AIDS, 1.5 million adults and 150,000 children were newly infected with HIV, and 600,000 adults and 95,000 children died of AIDS that year. The 2019 incidence of new HIV infections represented a decline of 50% from 2001 when there were 3.4 million new infections. Nearly 60% of the world's population living with HIV are located in sub-Saharan Africa. Children bear a substantial proportion of the burden of HIV with an estimated 70% of the children and infants living with HIV also being born in sub-Saharan Africa. Although HIV/AIDS has been one of the top 10 causes of death since 2010, there has been a decline in the AIDS-related mortality by 39% in the last decade. Currently, the epidemic is escalating in other parts of the world like Southeast Asia and Eastern Europe.

Telegram: @medical_k

www.konkur.in

In the United States, there were an estimated 1.2 million people living with HIV in 2019, approximately 14% of whom were not aware of their infection. There were an estimated 36,400 new HIV diagnoses and although this is an overall 7% decrease compared with 2014, there is evidence that cases are rising again over the last 2 to 3 years. Despite the decrease in rates, certain populations are disproportionately affected by HIV, including men who have sex with men (MSM), transgender people, African Americans, and Hispanic/Latin Americans. The highest rates of new infections are accounted for in the MSM population and people who inject drugs (PWID). There has been a great decrease in incidence of mother-to-baby transmission.

Early in the epidemic, transfusion-associated infection represented a significant risk, particularly among those who required pooled or high-frequency transfusions. The transfusion-related risk has now been reduced to less than one in 1.5 million. Currently, the populations at highest risk are MSM, PWID, female partners of IV drug users, and those who trade sex for money or drugs. Mother-to-fetus transmission remains a serious problem in developing countries but has been dramatically curtailed in the United States to less than 2% by the use of antiviral treatment during pregnancy and prophylaxis at parturition.

Efforts at promoting safer sex practices, clean needle use, bleaching of drug paraphernalia, and prenatal HIV testing had an impact on behaviors on a great number of individuals, as evidenced by the flattening of the epidemic curve from an exponential shape to a linear shape. Unfortunately, psychiatric disorders continue to play a significant role in thwarting prevention efforts by making vulnerable patients unable to access or benefit from prevention measures. MSM remain the group with the highest risk of new HIV infection, and psychiatric comorbidity, including addictions, remains one of the major drivers of new infections. Internationally, psychiatric disorders have been identified in both the developed and developing countries as an important comorbidity associated to the risk of infection, lower likelihood of successful treatment, and higher morbidity and mortality.

The retrovirus subfamily to which HIV belongs is called lentivirus (lenti: slow). Early in the HIV epidemic, it was thought that HIV was a “slow virus” that integrated into the cell genome and then was latent until activated much later. In the early 1990s, studies demonstrated very high rates of turnover of CD4-expressing T-lymphocyte cells during the course

Telegram: @medical_k

www.konkur.in

of HIV infection, with the production of vast quantities of virus. Without treatment, approximately 10 billion viral particles are made on an average day. Untreated HIV infection can be described as a war of attrition in which the virus gradually depletes the immune system. During this fight, the body mobilizes enormous immune system resources, producing up to 2 billion CD4 cells a day. HIV has a relatively high error rate when it is transcribed, and therefore produces large numbers of mutants, thus giving rise to strains of virus that can be resistant to drugs, target different cell receptors, and evade the body's strategies for defense. More remarkably, the virus has several specific mechanisms of disrupting the immune defenses of the host.

www.konkur.in

FIGURE 2.8–3. Schematic representation of the course of HIV if left untreated. On the y-axis is the decline in CD4 cell counts and the years of infection are on the x-axis. As noted, after an initial precipitous drop in CD4 cells, the cell count stabilizes and then declines by about 100 per year with death occurring in approximately 10 years. Common clinical issues at each CD4 level are notes on the curve. (Courtesy of John G. Bartlett, M.D.)

HIV infects cells expressing the CD4 surface protein (referred to as the CD4 antigen or receptor), mostly T lymphocytes and macrophages. The main disease mediator is the infection and destruction of T4 helper cells or CD4 cells critical in cell-mediated immunity. The average person has approximately 1,000 CD4 lymphocytes per cubic millimeter (or microliter) of blood. Before the development of effective treatment for HIV, the average patient's CD4 cell count dropped approximately 100 CD4 cells per cubic millimeter (or microliter) per year, so over a 10-year average

Telegram: @medical_k

www.konkur.in

course, the infected person would lose effective immune function and develop infections that are usually neutralized by cell-mediated immunity (Fig. 2.8–3). The immune system becomes quite compromised as the CD4 cell count drops below 200. At these levels, “cellular” immunity diminishes and is finally lost. At this point, the patient becomes vulnerable to opportunistic infections. There are also several tumors that occur in immunocompromised patients that are also found in patients with AIDS. The term “AIDS” (acquired immunodeficiency syndrome) is used to describe the syndrome in which patients develop these opportunistic medical conditions.

There were several major breakthroughs that changed the overall understanding of the infection: the ability to measure CD4 cells, the ability to measure and quantitate the “viral load” (the quantity of viral particles in the blood), and the ability to detect HIV mutant virus and predict sensitivity to antiviral medications. Currently, certain tests are routinely run at the time of initiation of therapy to make certain that the chosen regimen will be effective. Regular laboratory studies to assess viral load are used to make certain that the virus remains well controlled and that the presence of viral particles in the blood remains undetectable with the current clinical assay.

The HIV virus itself is thought to have originated in Africa. It is genetically related to a family of retroviruses that all infect immune cells that have been extensively researched and mapped. The generic term HIV usually refers to HIV-1, while a second genetically distinct type of human-specific immune virus called HIV-2 also targets humans but accounts for less than 5% of the infected people and is mostly limited to Africa. HIV is a zoonotic infection that mostly likely spread to humans from chimpanzees and gorillas. Current molecular biologic evidence suggests that simian immunodeficiency virus (SIV) “jumped” to humans from both gorillas and chimpanzees and that the jump happened on several occasions leading to different subtypes of infection. SIV infections in chimpanzees and other large apes produce illness, but many monkeys are endemically infected and the virus is tolerated as a chronic infection by those species which are probably the source of infection in large apes. Based on genetic mapping of the changes in the HIV virus over time, it appears that HIV jumped to humans in the early 20th century. Confirmed cases from the 1960s support the view that HIV was slowly moving toward epidemic spread for many years before it came to our attention. The

Telegram: @medical_k

www.konkur.in

numerous conspiracy theories that persist are often believed to be proven and many people cannot be dissuaded from their viewpoint.

HIV is a lentivirus, a single-stranded, positive-sense, enveloped RNA retrovirus that requires the action of an enzyme (reverse transcriptase, an RNA-dependent DNA polymerase not found in normal cells) to transcribe RNA into DNA in a process counter to normal information flow from nuclear DNA to RNA. The HIV viral particle is an icosahedral particle that is made up of an outer envelope and a viral core. The envelope is mostly derived from the host cell membrane. It is studded with viral proteins including gp120 and the transmembrane gp41 proteins, which perform specific roles in the viral life cycle. The viral envelope is lined with the matrix protein (MA) referred to as p17. The cone-shaped core is made of capsid protein p24 and contains nucleic capsid protein p7 associated with two copies of single-stranded viral RNA and the enzymes reverse transcriptase and integrase.

www.konkur.in

FIGURE 2.8–4. The HIV life cycle and sites of action of ART. **1.** During binding and internalization, the viral gp120 protein binds to CD4 receptor–expressing cells. This is the site of action of the attachment inhibitor fostemsivir. Once bound, the virus binds to a second receptor, either CCR5 (most commonly) or CXCR4, and can then be internalized. The CCR5 antagonist maraviroc works at this stage. During internalization, the outer coating of the viral particle fuses with the cell membrane. This is the site of action of the drug enfuvurtide. Once inside the cell, the virus is uncoated and the contents released. **2.** During reverse transcription the enzyme reverse transcriptase which was carried within the viral particle transcribes the RNA into a double-stranded piece of DNA. This is the site of action of all NRTI's and NNRTI's that comprise the largest group of HIV drugs (see Table 2.8–1 for the list). **3.** During translocation, the transcribed DNA is moved into the nucleus with the help of the enzyme integrase. Once in the nucleus, integrase can insert the viral DNA into the human. This is the target of the integrase strand transfer inhibitors. **4.** After translocation, the viral DNA that has been inserted into the host DNA can direct the cell machinery to produce large quantities of viral messenger RNA. The viral RNA then uses the cells own machinery to produce the proteins required to make viral particles and other viral proteins. The viral DNA can also sit silently within the host DNA as a provirus and get activated when the cell is stimulated to perform immune function and then take over the cell. **5.** After activation, viral RNA and viral proteins are made within the cell in large quantity. Using the machinery of the cell, the proteins are assembled around the viral RNA and the immature virions bud outward from the cells surface onto the outer membrane. **6.** The viral particles "mature" due to the cleavage action of the viral protease and released from the cell surface into the host to infect other immune cells. This is the site of action of the protease inhibitors. (Courtesy of Glenn Treisman, M.D., Ph.D, and Andrew F. Angelino, M.D.)

Telegram: @medical_k

www.konkur.in

HIV selectively infects immune cells, particularly T lymphocytes and macrophages. Infection requires direct contact between a viral particle with immune cells displaying the CD4 receptor. Infection takes place when viral particles are bound to CD4 receptors on immune cells. There are two primary cell types that get infected: T cells that express CD4 receptors (T4 cells or CD4 cells) and macrophage-derived cells. The usual route of initial infection is viral contact with dendritic cells in mucus membranes that then present the viral particles to T cells. The viral particles bind to the CD4 receptors on the T-cell surface and binding is aided by a co-receptor, either the chemokine receptor (CCR5) found on macrophages or the chemokine receptor (CXCR4) found on some T cells. New cells can be infected by virus being released into the blood and binding to the new cell, but probably occurs more often by T-cell to T-cell contact, by macrophage to T-cell contact, or by dendritic cells presenting virus to an uninfected cell.

Viral Life Cycle (Replication) and Treatment of HIV Disease and AIDS

The steps by which the virus infects a cell are summarized in Figure 2.8–4 and can be seen as a series of six different steps: the first step involves entry of the virus into the cell, which includes binding and fusion. The second step is reverse transcription followed by integration and replication where transcription and translation occur. Finally, in the last two steps, there is assembly, budding, and maturation. Figure 2.8–4 outlines the HIV life cycle and these steps. Each of the steps in the process of HIV infection provides a target for antiviral agents. There are now many drug classes available in various combinations which allow treatment to be tailored to a variety of patient-specific issues. See Table 2.8–1 for a list of the various drugs in each class discussed below. The sites of action for each class are shown in the figure.

Binding of the viral particle to the CD4 receptor on the cell surface and binding to the co-receptor are both targets for inhibition. Maraviroc is a drug that inhibits binding to the CCR5 co-receptor and is an effective antiviral drug in patients where the HIV virus has evolved to use the CCR5 receptor. An assay can be used to look for virus that can use the CXCR4 co-receptor which makes maraviroc less effective. The fusion of the viral particle with the cell membrane can be inhibited by enfuvirtide (also called T-20) and although it is rarely used now, it was lifesaving when it was developed. Fostemsavir is an attachment inhibitor that binds directly to the

Telegram: @medical_k

www.konkur.in

HIV-1 gp120 protein and prevents viral attachment and entry of virus into host T cells. It was approved for use in the United states in 2020.

Once the viral RNA enters the cell, it is “reverse transcribed” by an enzyme carried within the viral particle and not normally found in eukaryotic cells. This enzyme was the target for the first effective HIV drugs. The reverse transcriptase step is the most utilized target for HIV therapy. The nucleotide and nucleoside reverse transcriptase inhibitors (collectively known as “nucs” or NRTIs) were the first drugs that were effective antivirals for HIV. This enzyme is also targeted by non-nucleoside reverse transcriptase inhibitors (“non-nucs” or NNRTIs).

The DNA copy made in this step is then integrated into the nucleus and the host genome by an enzyme called integrase, which is targeted by the drug class called integrase strand transfer inhibitors (INSTIs).

The viral DNA is transcribed to viral messenger RNA and is translated into viral proteins, assembled into virions, and finally cleaved from the cell membrane by a protease. This is the target point for the drug class protease inhibitors (PIs) (see Fig. 2.8–4).

Antiviral treatment recommendations change frequently and can be found on numerous websites. Guidelines for treatment are issued by several organizations and the Johns Hopkins POC-IT online guide summarizes most of the current information as does the CDC and the national institutes of health (NIH) guidelines.

The initial clinical use of these agents began in the late 1980s with AZT (originally called azidothymidine, now called zidovudine). When the drugs were given as monotherapy, eventually the virus became resistant to the drugs through mutation. In the mid-1990s, combination therapies (usually two “nucs” and a third agent, either a PI or a “non-nuc”), were shown to be effective in stopping the progress of HIV infection and essentially suppressed the virus. At first called “triple therapy,” then later HAART, it is currently called ART. While treatment suppresses viral replication so effectively that the virus does produce enough copies to develop viral resistance mutations and remains suppressed, extended treatment does not result in a cure. The clinical goal is suppression of viral replication to a level where virus particles are undetectable using the current standard assay. The newest treatments allow most patients to take one pill once a day or twice a day. The newer drugs provide treatment for even those who have been infected for a long time and are resistant to older therapies.

Several key studies have shown that the single most important factor in successful treatment is the ability to accurately and completely take the prescribed medications. Adherence correlates highly with treatment success in terms of viral load reduction. Resources are often scarce in HIV clinics and patients with psychiatric barriers to adherence must be identified and treated to effectively prevent treatment failure, transmission of HIV, and comorbidity. The ability to provide adequate psychiatric care to PLWH is critical for effective treatment of HIV.

Psychiatric disorders compromise the ability to take medications, adhere to treatment, practice safer sexual behaviors, and stop using IV drugs. While they are not the only factors driving the HIV epidemic, they have been largely overlooked in the past as a critical factor in the continued spread of HIV.

Psychiatry is clearly a necessary component of treatment in HIV settings. Psychiatrists can help manage the patients most likely to fail treatment and transmit the infection. An important question is what the psychiatrist's role should be in caring for patients at risk for HIV, or those who may have dropped out of treatment, or those with barriers to care? Should we test patients with unknown status? Should we prescribe PrEP to our patients at risk for infection? Do we go as far as to prescribe HIV medications to patients who have no access otherwise? The amazing simplification of PrEP down to two currently approved combination fixed-dose drugs with more safety than most psychiatric drugs argues that we should be considering it. Testing for HIV and helping patients access treatment seems appropriate in substance abuse treatment programs, when treating patients with chronic mental illness, as well as other patients at high risk for infection, but probably should be part of a standard psychiatric evaluation. If we are going to stop the epidemic spread of HIV,

Telegram: @medical_k

www.konkur.in

there must be psychiatric collaboration and inclusion in the medical care of these patients.

PSYCHIATRIC CONDITIONS IN THE HIV CARE

Delirium

Delirium is a state of global derangement of cerebral function. The term encephalopathy is often used for the same condition. It is often confused with psychosis in clinical settings and distinguishing delirium from psychotic disorders is crucial as delirium has high lethality. It occurs more frequently in medically ill, brain-injured, or metabolically unstable patients. Prevalence of delirium in HIV-infected populations has been reported between 43% and 65%. The clinical presentation and significance of delirium in patients with HIV are the same as in non–HIV-infected individuals, and is characterized by inattention, disorganized thinking or confusion, and fluctuations in level of consciousness. Emotional changes are common and often unpredictable, and hallucinations and delusions are frequently seen. The syndrome has an acute or subacute onset, and remits fairly rapidly once the underlying etiology is treated. If untreated, a marked increased risk of mortality is seen, with estimates of about 20% mortality rate in hospitalized delirious inpatients.

Aside from general risk factors such as older age, multiple medical problems, multiple medications, impaired visual acuity, and previous episodes of delirium, patients with HIV-associated dementia (HAD) are at increased risk to develop delirium. The differential diagnosis of delirium includes HAD, especially with AIDS mania, minor cognitive–motor disorder, major depression, bipolar disorder, panic disorder, and schizophrenia. Delirium can usually be differentiated from the above conditions based on its rapid onset, fluctuating level of consciousness, and link to a medical etiology. Delirium is most commonly seen in patients with advanced HIV disease, complex medical comorbidity with polypharmacy, or patients with limited resilience due to brain pathology.

The cause of delirium should be aggressively sought by intensive medical examination. Vital signs and oxygen saturation, careful history and physical examination, laboratory tests, electrocardiogram (EKG), radiologic examinations, and critical review of all medications are essential to the workup. Possible etiologies include toxic (poisonings, drugs, and new, recently changed or interacting medications, especially

Telegram: @medical_k

www.konkur.in

medications with potent anticholinergic activity), metabolic (electrolyte disturbances), infectious (CNS infections or sepsis), endocrine (especially thyroid and adrenal axes), neoplastic (especially CNS), cardiovascular (myocardial infarction, arrhythmia), neurologic (seizure, stroke), pulmonary (hypoxia, hypercapnia), and traumatic (head injury, burns) causes. In toxic/metabolic causes especially, the electroencephalogram may show diffuse slowing of the background alpha rhythm, which resolves as confusion clears.

Treatment consists of three parts: the first is the identification and removal of the underlying cause. The second is the reorientation of the patient by maintaining a normal diurnal variation of light cycles, getting patients up and moving, providing orienting stimuli, such as calendars, clocks, and a view of the outside world, and active engagement and reorientation by staff members, family, and friends. The third, if necessary, is the management of behavior or psychosis. In this third step, low doses of high-potency antipsychotic agents work well. Newer, atypical antipsychotics are currently being used with some success, but those with more anticholinergic activity may worsen the condition. Benzodiazepines should be used with caution, as they may contribute to delirium in some patients, but are of particular use in delirium caused by alcohol or benzodiazepine withdrawal. Physical restraint may be necessary if the patient becomes violent, but all attempts should be made to use this at a minimum, not only because of the legal issues it poses, but because restriction of movement or access to orienting stimuli worsens delirium and restraints have been known to cause death in some cases when patients are not monitored properly.

Over the last several years, there has been increasing recognition of postdelirium-related psychiatric conditions, particularly post-traumatic stress disorder (PTSD). Other psychiatric conditions such as depression, anxiety, and cognitive dysfunction also appear at increased incidence. This is not specific to HIV, but seems to be a consequence of delirium in general patient populations and appears to be related to severity of the underlying comorbidity.

Delirium in HIV-infected patients has a broadened differential diagnosis and greater number of possible causes. In immunosuppressed or advanced HIV illness, patients may suffer from unsuspected opportunistic causes of delirium. These are described at the end of this chapter.

www.konkur.in

HIV-ASSOCIATED DEMENTIA

Introduction and Neuropathology

Early in the AIDS epidemic, some patients presented with rapidly progressing neurocognitive disturbances leading to an intensive search for etiology. Several CNS opportunistic conditions such as cytomegalovirus (CMV) encephalitis, progressive multifocal leukoencephalopathy (PML), cerebral toxoplasmosis, cryptococcal meningitis, and CNS lymphoma were suspected. However, a subset of patients remained for which no identifiable pathogen causing the neurocognitive disturbances could be found and it was deduced that HIV itself was the causative factor behind the decline. These patients had a subcortical dementia characterized by increasing loss of attention and concentration, marked motor slowing, and variable behavioral components that usually progressed to death in less than a year. Autopsy studies of demented patients with AIDS revealed characteristic white matter changes and demyelination, microglial nodules, multinucleated giant cells, and perivascular infiltrates, but a marked absence of HIV within neurons. This has led to the current theories of neuronal loss due to inflammation through action of macrophages and microglial cells and/or through activation of cytokines and chemokines that trigger abnormal neuronal pruning. It appears that basal ganglia and nigrostriatal structures are affected early in the dementia process, with diffuse neuronal losses following. Typical late findings show an approximate 40% reduction in frontal and temporal neurons with atrophy appreciable on imaging studies.

With the development of ART, there has been a dramatic reduction in HIV-induced dementia of the type seen earlier in the epidemic. It is now uncommon in developed countries and less common even in underdeveloped settings. There is, however, still a high prevalence of cognitive impairment in HIV-infected patients, often subtler and with an unpredictable course, and with some marked clinical differences.

Epidemiology, Risk Factors, Clinical Course, and Treatment

With the development of ART, there was a hope that HIV dementia would become a thing of the past. Before ART, HIV dementia presented as a rapidly progressive subcortical dementia that usually ended in death. In the era of effective antivirals, HIV-associated cognitive impairment is

Telegram: @medical_k

www.konkur.in

harder to assess, and there is considerable debate about the prevalence, causes, and methods of assessment. There is also no effective treatment if the patient is well controlled on ART. Although there is even debate about the terminology, to assist with diagnosis and classification of patients for research and clinical purposes, most authors divide patients with HIV-associated neurocognitive disorder (HAND) by severity into three groups, applied when the patient's presentation cannot be explained by other conditions. Asymptomatic neurocognitive impairment (ANI), mild neurocognitive disorder (MND), and HAD are the three groups in order of increasing severity. One of the problems with assessment of these conditions is that accurate control groups are not well studied and much of the current prevalent data come from cohort studies. The currently used nosology was published in 2007 and was directed toward research but has been widely adopted clinically and has been the basis of significant discussion. The changing nosology has led to changes in the measure of prevalence of HIV-associated cognitive disorders. Although up to 50% of HIV-infected individuals can be shown to have cognitive impairment on careful testing, most patients are clinically asymptomatic. More importantly, unlike the steady downhill course that characterized HIV dementia prior to ART, cognitive impairment may get better with retesting and patients are often unaware of the changes. There has also been a significant increase in cortical dysfunction rather than the subcortical deficits that characterized HIV-induced cognitive impairment in the past.

Although the prevalence of HAD has declined, studies show overall rates of HAND are still remarkably high, especially milder forms. For example, reported data from 15,380 patients with HIV followed in the CASCADE cohort (Concerted Action on Seroconversion to AIDS and Death in Europe) showed a decrease in the incidence of HAD from 6.49 per 1,000 person-years before ART was available declining to 0.66 per 1,000 person-years by 2003 to 2006. A clinically diverse cross-sectional study of 1,555 patients at six academic centers showed the overall rate of cognitive impairment at 52% with 33% ANI, 12% MND, and only 2% HAD.

Various reasons for this continued prevalence of milder cognitive impairments have been hypothesized, with some being: possible subclinical brain injury that developed before treatment with ART was initiated, other comorbidities especially those that are vascular in nature, substance use, untreated psychiatric comorbidities, and effects of aging that may advance faster in PLWH. Higher medical comorbidity may result

Telegram: @medical_k

www.konkur.in

in increased HAND. Severity of disease, measured by current CD4 cell count and historical CD4 nadir as well as opportunistic infections, contribute to risk. Serum viral load and detectable virus in the CNS, all appear to contribute to the risk as well.

The persistent development of HIV cognitive impairment in treated patients could be caused by many factors, including persistent damage from the presence of latent HIV virus, damage from the immune system after the virus is controlled (immune reconstitution), toxicity from antiviral drugs, or persistent viral replication in the CNS because of poor entry of antiviral drugs. Initially, identification of variable drug penetration into the CNS appeared to be an exciting and remediable cause of continued viral injury. The expected finding that better penetrating antivirals would be associated with less HAND has not materialized, perhaps because of the confounds of poor correlation between CSF concentrations and those in the brain, direct mitochondrial toxicity of the drugs, degree of immune reactivation in patients with previous immunosuppression from HIV, and subtle ongoing viral replication in the CNS. There has also been the suggestion that the chronic immune activation associated with continued HIV infection, even with complete viral suppression, causes more rapid “aging” and therefore cognitive impairments that are usually associated with older age groups. In fact, the aging of the entire population of patients with HIV is a confound.

HAND in the current era involves both cortical and subcortical dysfunction. Prior to ART, patients had predominantly subcortical loss of function with greater impairments in motor skills, cognitive speed, and verbal fluency (as well as apathy and personality coarsening), whereas current patients tend to show more impairment in memory (learning) and executive function including deficits is prospective memory (the ability to “remember to remember”) that has been shown to produce problems with medication adherence. Patients now have characteristics in common with cortical dementias such as Alzheimer disease. The course of HIV dementia prior to ART was almost always clinical progressive worsening of dysfunction, while in the current longitudinal studies, some patients decline while others actually improve.

The best treatment for patients with any HAND is aggressive ART in patients who are untreated or inadequately treated. Typical responses after initiation of ART may produce dramatic improvement, although patients with long-term deficits may have slower recovery. Patients with

Telegram: @medical_k

www.konkur.in

prominent subcortical features may respond to stimulants, particularly if there is a lot of apathy. There is at least some support for switching patients to a better CNS-penetrating regimen of antiviral medications. Safety assessments should be done when indicated and patients requiring intensive monitoring should be referred to appropriate facilities. To date, despite numerous trials, no clear effective treatment for HAND has emerged. There are patients who individually respond to interventions, sometimes dramatically, but clinical trials have not yet shown reliable results in populations, probably because of the heterogeneity of the underlying causes.

MAJOR DEPRESSION IN PATIENTS WITH HIV DISEASE

Epidemiologic Considerations

Depressive symptoms are the most common complication of chronic medical illness. Depression has a negative impact on adherence with medical treatments, quality of life, and treatment outcome. Despite education and efforts to improve treatment, depression remains underrecognized, underdiagnosed, and undertreated in medical clinics. Depression is a significant problem in HIV/AIDS. There are several long-standing issues for patients with comorbid medical conditions and depression. Major depression as a disease state is different from the depressive symptoms in patients who are demoralized (psychologically distressed due to their circumstances). Most research uses checklists and mood questionnaires to measure depression, making it difficult to clearly assess prevalence of and associations with major depression. To add to the complexity, severe psychological stress may trigger episodes of major depression in vulnerable individuals, and the body of research suggests a role for both the stress axis and the immune axis in major depression.

Despite these complexities, early studies showed that patients with depression had an increased likelihood of getting infected with HIV. Several risk factors for HIV infection associated with depression may explain this, including increased high-risk sexual behavior, increased substance use, and increased high-risk injecting practices. In addition, epidemiologic studies showed that advanced HIV disease correlated with the development of depression. Interpreting these studies is complicated

Telegram: @medical_k

www.konkur.in

by ascertainment methods using different depressive symptom rating scales, clinical records, and actual prospective clinical evaluation. Despite this, the data show that HIV is associated with a three- to fourfold increase in the prevalence of depression compared to the general population, and that depression has a negative influence on medical care and medical outcome. Depression is associated with poorer adherence to antiviral drugs, poorer engagement with health care, and higher risk of behaviors associated with transmission. Meta-analyses of data on the increased risk of depression in patients with HIV and the negative impact of depression on HIV outcome have been published over the course of the epidemic, with studies showing increased mortality associated with depression and several studies demonstrating the effectiveness of treatment of depression in terms of outcome. Although increased rates of depression have been found in MSM and patients with substance use disorders, a recent meta-analysis of 10 studies comparing HIV-positive and at-risk HIV-negative patients demonstrated a twofold increase in the prevalence of major depression in patients infected with HIV.

Major depression is a risk factor for HIV infection by virtue of its impact on behavior, intensification of substance abuse, exacerbation of self-destructive behaviors, and promotion of poor partner choice in relationships. In this way, depression can be seen as a vector of HIV transmission thus fueling the epidemic. Depression has been clearly shown to hinder effective treatment of infected individuals. Patients with major depression are at increased risk of disease progression and mortality. HIV increases the risk of developing major depression through a variety of mechanisms, including direct injury to subcortical areas of the brain, chronic neuroinflammation, chronic stress, worsening social isolation, and intense demoralization. While direct evidence for a relationship between worsening HIV disease and the development of major depression is limited, there are several studies that support this link, particularly the study based in the Multicenter AIDS Cohort Study (MACS) showing that there is a two-and-a-half-fold increase in rates of depression as the CD4 count falls below 200 just before patients develop AIDS.

Taken together, these lines of evidence suggest that HIV is a causal factor in depression, and that depression is a causal factor in HIV transmission and its morbidity, making the patients with these disorders a treatable vector for the HIV epidemic, and suggesting an important role of mental health care in HIV treatment and prevention.

Telegram: @medical_k

www.konkur.in

Suicidal ideas, suicidal behavior, and successfully completed suicide have been shown to be increased in HIV-infected patients. The increased risk appears similar to other chronic diseases. Several of the risk factors for suicide (substance abuse, major depression, personality vulnerabilities, nongender conforming and homosexual orientation, and other factors) have been associated with both HIV infection and suicide risk. It appears that HIV-infected patients have an elevated risk for suicide beyond the contribution of these risk factors when comparing those at risk with those who are infected. The development and use of ART has been associated with a decrease in suicide risk but not to the level of background populations.

Differential Diagnosis of Major Depression

The differential diagnosis of depression includes nonpathologic states of grief and mourning (sometimes made quite severe by the vulnerabilities of the person) and a variety of disorders related to both psychological and physiologic disturbances. Patients with complaints of depressive syndromes can have dysthymia, dementia, delirium, demoralization, intoxication, withdrawal, CNS injury or infection, acute medical illness, and a variety of other conditions. AIDS dementia and other HIV-related CNS conditions can produce a flat, apathetic state that is often misdiagnosed as depression. Cocaine withdrawal produces a depressive syndrome, and delirium can mimic many psychiatric conditions including depression. CNS syphilis, a condition that had become quite rare has been reappearing in medical centers with HIV specialty services and remains “the great imitator” as it was called when it was originally described and can present with depression.

The diagnosis of major depression in the HIV clinic is complicated by the high frequency of depressive symptoms that are associated with chronic illness, significant losses and isolation, and complex medical treatments. The diagnosis may be further complicated by the presence of comorbid neurologic illness, comorbid substance use, and the use of many medications that can alter mental function. Despite this, studies of patients with major depression have shown that the response to treatment is similar to that expected in other populations.

Mood is the feature of affective life that describes the prevailing emotional tone a patient experiences. Patients express depression as feeling blue, low, sad, or sometimes flat, devoid of emotion, or empty.

Telegram: @medical_k

www.konkur.in

Some say that they are miserable, in agony, anxious, worried, angry, upset, and irritable. Although some are apathetic, most find the state extremely uncomfortable. Moods may vary with the time of day, usually worse in the morning and better in the afternoon, but sometimes in other patterns. Pleasure (or a sense of reward) is associated with many behaviors, including those driven by appetite like sleeping, eating, and sex, and those associated with function, such as work, hobbies, dress, social activity, and artistic expression. Hedonic responsiveness refers to the enjoyment or positive reinforcement related to activities and experiences of life. Anhedonia describes the state in which hedonic responsiveness is blunted or absent, and is a principle feature of depression. Vital sense is the subjective sense of well-being. Depressed patients say they are sick, have a heavy pressure in their chest, have low energy, and even feel themselves dying. Self-attitude is the feeling directed at self. Depressed patients feel guilty, think that they are bad or evil, that they are undeserving of things they have, or that they have failed those they love.

Neurovegetative symptoms are commonly associated with this cardinal syndrome. These include difficulties with sleep, appetite, concentration, and memory. Sleep disturbances can include insomnia or hypersomnia, but most characteristically, patients describe waking early in the morning with difficulty falling back asleep. Appetite may be decreased or increased significantly, and patients often complain that food has lost its flavor. Appetite changes result in corresponding weight changes if untreated for long periods of time. Patients report slowed thought processes, with impairments in concentration and short-term memory, and, occasionally, generalized confusion.

Patients with HIV suffering from major depression frequently present to internists and family medicine doctors with multiple somatic symptoms. These include, but are not limited to, headache, gastrointestinal (GI) disturbances, inexplicable musculoskeletal or visceral pain, cardiac symptoms, dizziness, tinnitus, weakness, and anesthesia. Given the burdens of HIV, the medical problems associated with it, and the side effects of medications, depression may be very low on the list of considered causes of the patient's complaint. Even patients complaining of depressive symptoms may have depression overlooked or discounted due to a plethora of other diagnoses. Nonspecific somatic symptoms may

Telegram: @medical_k

www.konkur.in

be the result of depression rather than HIV infection in patients who do not have concurrent medical illness.

As an example, fatigue has been found to be associated with depression and not HIV disease progression. Worsening of fatigue and insomnia at 6-month follow-up was highly correlated with worsening depression but not CD4 count, change in CD4 count, or disease progression by CDC category. These findings support the notion that somatic symptoms generally suggestive of depression should trigger a full psychiatric evaluation.

In the later stage of HIV infection, a variety of illnesses are common, often moving depression down on the differential diagnosis list. Somatic symptoms should always be evaluated carefully, and considered in context, that is, either with other indicators of progression of HIV disease or with other indicators of depression. Certain HIV-related medical conditions and medications can cause depressive symptoms. These include CNS disorders such as toxoplasmosis, cryptococcal meningitis, lymphoma, syphilis, and others. Some investigators have found significant rates of depressive symptoms among male patients with HIV with low testosterone levels and male patients with hypogonadism and major depression often have treatment-refractory depressive episodes until the testosterone is repleted. Of the antiretroviral agents, efavirenz is most often associated with depressive symptoms, which may remit spontaneously in a number of patients but persist in a few. More recently, rilpivirine and efavirenz (both NNRTI) and dolutagravir (INSTI) have been implicated in depression as well. Efavirenz (NNRTI) has been reported to cause frank psychosis in some patients, necessitating its withdrawal in these cases. Patients receiving interferon are at risk of depression from this agent, as are patients receiving chronic steroids (both anabolic and corticosteroids) for comorbid medical problems. Because of high coinfection rates, hepatitis C treatment with interferon-containing regimens often complicates HIV-related depression. The development of hepatitis C–directed antiviral agents, has allowed interferon use for hepatitis C to become a largely historical problem. A number of other agents, including metoclopramide, clonidine, propranolol, sulfonamides, muscle relaxants, and many others have all been reported to produce major depression or similar syndromes.

While these depressive syndromes often respond to withdrawal of the offending drug, when they do not, they should be treated as major

Telegram: @medical_k

www.konkur.in

depression with appropriate antidepressant medication. HIV-infected patients with major depression respond to antidepressant medication similarly to other patients with major depression. Routine screening for psychiatric disease in HIV treatment settings can effectively preempt urgent referrals for rapidly progressing disorders. Several screening tools for depression in medical settings have been studied and in one study specifically, looking at HIV-infected patients, the combination of two brief self-administered questionnaires, the Beck Depression Inventory (BDI) and the General Health Questionnaire (GHQ), prospectively predicted a psychiatric disorder (other than substance abuse) with a sensitivity of 81%, specificity of 61%, and a positive predictive value of 71%.

Treatment of Major Depression

Pharmacotherapy is the mainstay of treatment for major depression. Several studies have demonstrated efficacy of various antidepressant agents in patients with HIV, but no single antidepressant has been found superior in treating HIV-infected patients as a group. In a recent study examining the overall efficacy of antidepressants in patients with major depression and HIV, technical variations among studies were found to account for the largest portion of the variance of results, but overall, the use of antidepressants was supported.

Aside from how well the pharmacology of the antidepressant matches a patient's disease, the engine that drives effectiveness is patient adherence. Patients who reliably take adequate doses of antidepressants have the best chance of improvement. A general rule is to start at low doses of any medication, titrating slowly up to a "full" dose or therapeutic serum level (when meaningful), so as to minimize early side effects that may act as obstacles to adherence.

Although some papers have suggested that selective serotonin reuptake inhibitors (SSRIs) antidepressants are the "first-line treatment," the data do not show any advantage of one antidepressant over another, and most recommend using a medication that best fits the other elements of the case. Tables 2.8–2 and 2.8–3 list antidepressants often used in HIV disease, their dosages, and common side effects. In many patients, side-effect profiles of certain agents may be used to an advantage, and these "good match" agents should be tried first. Second choices are medications that do not have side effects that might worsen the patient's symptoms (e.g., a medication that is not associated with insomnia for a patient

Telegram: @medical_k

www.konkur.in

having difficulty falling asleep). Later choices include medications that have side-effect profiles that would likely exacerbate a patient's symptoms (e.g., a medication associated with increased GI motility for a patient with chronic diarrhea).

The first week of treatment with a medication usually determines whether a patient will be able to tolerate the medication. Following this brief period, the dosage of any antidepressant should be increased slowly to either a typical full dose or a therapeutic serum level. Once at this level, patients should be encouraged to wait as long as possible for the therapeutic effect, which may take longer than 6 weeks to achieve in some patients. Side effects should be assessed at every visit, and attempts should be made to treat any side effects the patient finds bothersome. For example, insomnia caused by SSRIs may respond well to low doses of trazodone (25 to 150 mg at bedtime). Constipation from a tricyclic antidepressant (TCA) is often relieved by increased water and fiber intake and polyethylene glycol. Sexual side effects from SSRIs are common; erectile difficulty may be treated with nitric oxide synthase inhibitors (NOS inhibitors include sildenafil, tadalafil, and vardenafil) in select patients, while decreased libido and delayed orgasm may be alleviated with a drug holiday or by the addition of bupropion.

Patients who show only partial response to antidepressant medication should be offered an augmentation strategy or an alternative treatment. There are several other agents that have been used for antidepressant augmentation. The best studied is lithium, but its side-effect profile may limit its use in the HIV setting. Thyroid preparations, especially triiodothyronine, have also been shown to be of benefit, and may be of particular advantage in patients complaining of fatigue. Atypical neuroleptics have also been shown to be effective augmenting agents. Many other strategies have also been used with less support from the literature, including a second antidepressant, other mood stabilizers, trazodone, other antipsychotic medications, methylphenidate, benzodiazepines, sleep deprivation, and bright light therapy.

Tranylcypromine	Slight	Slight	Low	Low	None	Slight	Slight	High

Scale: None/slight/low/moderate/high/no data (inadequate data).
Notes: Sertraline is associated with higher rates of diarrhea/trazodone is rarely associated with priapism/levomilnacipran can cause dose-dependent urinary hesitancy.

If no benefit is gained from the primary antidepressant, even after augmentation, or if it must be abandoned due to intolerable side effects, a new primary agent should be chosen, titrated slowly, and augmented as necessary. Although medications in the same class may produce similar side effects and therefore may not be tolerated, there is evidence to suggest that a response may be seen from one drug where none was seen from another in the same class.

Finally, clinicians often wonder about the interaction of antidepressant medications and ART medications. Some of these interactions may

Telegram: @medical_k

www.konkur.in

increase or decrease serum concentrations of either the antidepressant or the antiretroviral drug, which in turn, may make the side effects worse or decrease the effectiveness of either drug. First, since depression is associated with reductions in adherence to ART, untreated depression may be equally or more detrimental to disease progression than any medication interaction. Second, our experience in working with comorbid HIV and depression has not yet shown most predicted drug–drug interactions to be clinically significant, and it is unclear if dose adjustments for either antidepressants or ART are needed for successful outcomes to occur. Drugs with narrow therapeutic windows benefit from blood level assessment any time therapy is changed. If patients are better on their current treatment and there is a needed change in ART or antidepressant, it may be useful to assess blood levels prior to changing therapy so that subsequently if therapeutic response is altered, levels can be checked and adjusted to see if this will provide therapeutic benefit.

Psychotherapeutic Treatment. Psychotherapy is an important and integral part of the treatment of major depression. Treatment with medication plus psychotherapy has been shown to be more effective for patients than either modality alone. The type of psychotherapy most appropriate to provide remains a major open question. Among the individual psychotherapies, interpersonal psychotherapy and cognitive behavioral psychotherapy are quite popular for the treatment of depression and have the best evidence to support their efficacy. The literature on the use of psychotherapy for the treatment of depression in patients with HIV is extensive but clinical trials data are sparse. There are multiple meta-analyses favoring the combination of psychotherapy with pharmacotherapy and less discontinuation of treatment in randomized controlled trials.

Improvements have been demonstrated as well for patients with HIV treated with group cognitive behavioral therapy either as a single treatment modality or combined with medication. Supportive psychotherapy helps patients with major depression who interpret their suffering to be a reaction to the diagnosis or morbidity of HIV infection. These patients often believe they can pull themselves out of depression and get frustrated when they continue to expend effort with little result. Education about the disease nature of their depression, encouragement to

Telegram: @medical_k

www.konkur.in

keep going, and therapeutic optimism that the treatments will work can help to decrease frustration.

In addition, psychotherapy applied judiciously and in combination with effective antidepressant medication provides patients with a framework for the provider–patient relationship that is crucial to success. The medical providers who keep the concept of psychotherapy in mind will structure their interactions with patients to slowly empower and enable the patients to take control of their lives, thus relying on the providers less and less.

BIPOLAR (MANIC-DEPRESSIVE) ILLNESSES IN PATIENTS WITH HIV DISEASE

Clinical Course of Bipolar Illness

Bipolar disorder is a condition in which patients experience episodic alterations in mood that cause disorder. Manic episodes are associated with increased rates of substance abuse and impulsive behavior, and there has been speculation that bipolar disorder may be a risk factor for HIV infection. To date, there has been no unequivocal evidence to show that bipolar illness directly increases the risk of HIV infection, but the technical difficulties in demonstrating this link are considerable.

In the classic presentation, patients alternate between extended episodes of depression similar to major depression and briefer episodes of increased mood, energy, and confidence and well-being, often with grandiose ideas about themselves and their circumstances. The synonymous appellation “manic-depressive insanity” is a reminder that many patients suffer from auditory hallucinations and frank delusions when they are ill. Most often, patients cycle from one type of mood state to the other, at times interspersed with periods of normal mood, but occasionally show features of both depressive and elevated mood states simultaneously (mixed states) or in very rapid succession (rapid cycling). Milder forms of mania are seen in a condition termed bipolar illness type II. The spectrum of bipolar illness is broad, ranging from a severely crippling and chronic mental illness to a mildly disordering alternating experience of prevailing mood. This has made it difficult to accurately measure prevalence and incidence and to explore the relationship of bipolar illness with HIV disease. In addition, it is often difficult to distinguish severe bipolar illness from schizophrenia even in studies that

Telegram: @medical_k

www.konkur.in

utilize rigorous research approaches. Thus, investigators looking at the relationships between HIV and mental illness often will use the term “chronically mentally ill” for patients with severe disability from either schizophrenia or bipolar disease.

The elevated mood states form a continuum from increased energy, euphoria, irritability, and decreased sleep called hypomania to a more extreme condition complicated by hallucinations, delusions, disordered thinking, disorganization, and, sometimes, violently agitated behavior called mania. Hypomania is characterized by euphoria, an improved self-attitude, and an elevated vital sense. Patients feel elated, energized, and as if they are functioning better than usual. Thoughts speed up and horizons expand such that the patient feels many brilliant things are coming to them in rapid succession. Often, there is a noticeable increase in the amount and speed of speech. It may be necessary (although difficult) to interrupt these patients. Since energy is so high, patients feel a decreased need for sleep and occasionally do not sleep at all. When these symptoms impair judgment and function is lost, the patient may develop frank mania. Manic patients not only have pressured speech, they often demonstrate a thought disorder in which ideas come so quickly that it is impossible to see the connections between them, the so-called flight of ideas. The expansive self-attitude may take on proportions outside the realm of reality, known as grandiose delusions. Paranoid delusional thoughts may be seen, and hallucinatory experiences occur in some patients.

AIDS Mania

In the early days of the HIV epidemic, some patients developed a type of mania that was specifically associated with late-stage HIV infection and cognitive impairment. This syndrome was termed AIDS mania and often occurred in patients with a lack of previous manic episodes or family history of bipolar disorder. This form of mania is now rarely seen as ART has had a significant impact on both the frequency of AIDS dementia and mania. Mania can occur anytime in the course of HIV infection for individuals with pre-existing bipolar disorder, but AIDS mania is usually confined to late HIV infection, thus appearing to be a consequence of HIV brain involvement. In general, manic syndromes in patients with HIV occur with higher frequencies after the onset of AIDS. Furthermore, patients with AIDS develop mania at rates substantially greater than the general

Telegram: @medical_k

www.konkur.in

population: in one series, mania occurred in 8% of all patients with AIDS seen at the HIV clinic over 17 months (more than 10 times the 6-month general population prevalence). The study grouped mania patients into those whose first manic episode came late in their HIV course with CD4 count <200 and those whose episode came early with CD4 count >200. The late-onset patients were less likely to have a personal or a family history of mania or any mood disorder, which presumably means they were less likely to have bipolar disorder or a genetic predisposition to mania. They were also more likely to have dementia or other cognitive impairment indicating brain damage.

AIDS mania has several features that distinguish the condition from the usual appearance of bipolar-associated mania. The history will usually reveal progressive cognitive decline prior to the onset of mania and patients will usually progress to the subcortical dementia associated with AIDS. Although most cases of cognitive impairment in current practice have mixed features of cortical and subcortical dementia, the dementia seen in very advanced HIV disease is still predominantly subcortical and progressive unless aggressive intervention with ART occurs. In AIDS mania, irritable mood is more characteristic than euphoria. Sometimes, prominent psychomotor slowing accompanying the cognitive slowing of AIDS dementia will replace the expected hyperactivity of mania, which complicates the differential diagnosis. Clinical experience has suggested that AIDS mania is usually quite severe in its presentation and malignant in its course. In one series, late-onset patients had a greater total number of manic symptoms than early-onset patients. They were also more commonly irritable and less commonly hypertalkative. AIDS mania seems to be more characteristically chronic than episodic, has infrequent spontaneous remissions, and usually relapses with cessation of psychiatric treatment. Because of their cognitive deficits, patients have little functional reserve to begin with. Also, they are less able to pursue treatment independently or consistently. One common clinically described manifestation is the delusional belief that one has discovered a cure for HIV or has been cured of HIV. While this may serve to cheer otherwise demoralized and depressed patients, it may also result in the resumption of high-risk behavior and lead to the spread of HIV and exposure to other infectious entities. When euphoria is a prominent symptom in otherwise debilitated late-stage patients, caregivers may wistfully question the humaneness of robbing patients of the illusion of happiness. It is the

Telegram: @medical_k

www.konkur.in

clearly impairing, often devastating effects of the other symptoms of mania that tips the balance of the risk/benefit equation toward treatment.

Treatment of Bipolar (Manic-Depressive) Illnesses

The treatment of mania in early-stage HIV infection is not substantially different than the standard treatment of bipolar disorder. It relies on the use of mood-stabilizing medications, particularly lithium salts and the anticonvulsants like valproic acid, lamotrigine and carbamazepine, and antipsychotic agents, now more commonly atypical antipsychotics. These medications decrease manic symptoms and may prevent recurrence.

AIDS mania in advanced HIV disease with low CD4 counts, more medical illnesses, more CNS involvement, and greater overall physiologic vulnerability may require different treatment strategies. While treatment with traditional mood stabilizers may be preferred, it can be very difficult in patients with advanced disease. There has been considerable experience with traditional mood-stabilizing agents in selected AIDS mania patients, but with relatively sparse documentation. Lithium use has been problematic for several reasons including high rates of associated delirium and cognitive difficulty, GI symptoms including nausea and diarrhea, and polyuria resulting in dehydration. Lithium is also associated with the development of diabetes insipidus in rare patients and may be difficult to use in combination with tenofovir, an NRTI with known renal side effects. The major problem with lithium in patients with AIDS has been rapid fluctuations in blood level, occurring even in the hospital on previously stable doses, causing lithium intoxication. Valproic acid has been used with success, titrating to the usual therapeutic serum levels of 50 to 100 ng/dL. Enteric-coated Depakote is better tolerated in most patients. This is sometimes limited by side effects, especially hepatotoxicity in the setting of chronic viral hepatitis. Monitoring of liver function tests is essential, but hepatic toxicity is not often a problem. In cases of severe hepatic *Mycobacterium avium* complex (MAC) infiltration, for example, with portal hypertension, valproic acid should likely be avoided, but this and related considerations have not been formally studied. Carbamazepine may also be effective but more poorly tolerated because of sedation, and because of the presumed potential for synergistic bone marrow suppression in combination with antiviral medications and HIV itself. Depakote and carbamazepine can also affect hematopoietic function, so white blood cell and platelet counts must be monitored. Lamotrigine is often used to

Telegram: @medical_k

www.konkur.in

successfully treat bipolar disorder and may have special promise in treating patients with prominent depressive episodes. There are no studies showing an increased incidence of rash or Stevens–Johnson syndrome in patients with HIV receiving lamotrigine, but prescribers should monitor for these adverse events closely, as with any patient. Other agents such as gabapentin, oxcarbazepine, and topiramate have been tried, but the reports of success remain anecdotal.

AIDS mania patients respond to treatment with relatively low doses of antipsychotic agents and these became the mainstay of treatment. Second-generation antipsychotics were reported to be better tolerated. In general, late-stage patients are far more sensitive to the therapeutic effects, but even more so to the toxic side effects of antipsychotic agents. AIDS mania patients are very sensitive to the side effects of antipsychotic medications, even those in the second generation, and extrapyramidal symptoms treated with even modest doses of anticholinergic agents can result in delirium. Because AIDS mania is seldom seen now in developed countries, the treatment has had little study in the last two decades. AIDS mania is seen in developing countries with high prevalence of HIV and can confound the use of ART and make patients difficult to treat.

SCHIZOPHRENIA IN PATIENTS WITH HIV DISEASE

The literature on patients with severe and chronic mental illnesses, accounted for primarily by schizophrenia and bipolar I disorder, reports prevalence rates of between 4% and 19% in both inpatient and outpatient samples. There is no evidence that HIV infection causes schizophrenia, but there are data to show that schizophrenia contributes to behaviors that may lead to HIV infection. Although injection drug use accounts for the majority of infections in many studies, there has also been a wealth of information published regarding the sexual risk factors for patients with schizophrenia. In particular, data reveal high rates of unprotected sex, multiple sex partners, trading sex for money or other goods, and sex while intoxicated. Further, there is evidence that patients with more positive symptoms and impulse control problems are at increased risk of high-risk sexual behavior despite demonstration of adequate knowledge of HIV risk factors. Practitioners that see patients with schizophrenia should be sensitive to the risk of acquiring HIV and should screen patients carefully

Telegram: @medical_k

www.konkur.in

for high-risk behaviors in addition to inquiring about patients' knowledge of HIV transmission routes.

The principles of treatment for HIV-infected patients with schizophrenia follow the same basic principles as any other patient with schizophrenia, namely control of symptoms with medications and psychosocial support and rehabilitation. In these cases, however, close ties with HIV providers are strongly suggested, so that HIV treatment can be coordinated and monitored. In a recent survey, HIV care providers were just as likely to recommend antiretroviral therapy for patients with schizophrenia who met criteria as those without schizophrenia, but to recommend avoiding efavirenz-based regimens due to higher risk of neuropsychiatric side effects. Further, these practitioners were more likely to seek collaboration with a mental health care provider to coordinate treatment for patients with schizophrenia, suggesting that this population is recognized as outside the scope of practice for solo management by an HIV primary care provider.

ISSUES OF SUBSTANCE USE DISORDERS AND ADDICTION IN HIV DISEASE

The term "addiction" has been criticized and changed in the literature but remains the most widely used term for the ongoing and disordered use of psychoactive substances. The DSM-5 recognizes that substance use disorders exist on a continuum from mild to severe consisting of escalating substance use, physiologic and psychological dependence, and increasing impairment of function. For example, it is often difficult to define precisely when the transition from heavy drinker to alcoholic occurs. Some patients use heavily but never actually become disordered by their use. Others are disordered by surprisingly modest use of a substance. The key feature of addiction is the habitual, compulsive use of substances where drug procurement and use become the main focus and goal of the person's life and continues despite negative physical, psychological, and social consequences. Physiologic dependence defined by tolerance and/or withdrawal may be present but should not be confused with addiction or a substance use disorder as defined by DSM-5.

A multifactorial matrix of influences initiates, drives, and sustains substance use and addiction. Many of these are due to the intrinsic

Telegram: @medical_k

www.konkur.in

rewarding effect of the substances themselves, but others are characteristic of the host or the environment. Behavioral approaches to understanding addiction have been particularly fruitful, as seen in the work of Joseph Brady and his colleagues. Their approach developed animal models of self-administration and measured the reinforcing properties of different drugs, many of which are profoundly predictive of human behavior. However, environmental influences and the understanding of the individual and cultural and social forces that impact substance use are essential to the translation of those models into human settings.

Psychiatric and psychological comorbidity can also increase vulnerability to substance use disorders. For example, patients with major depressive disorder may find the ordinary experiences of life to be less rewarding and are more sensitized to the positive reinforcement of drugs. Patients with cluster B personality traits may engage in more risk-taking behavior, have a greater likelihood to experiment with novel sensations, and experience an increased sensitivity to the rewarding effects of drugs and alcohol, leading to a greater likelihood of developing a substance use disorder. Other personality types are consequence and risk avoidant, and are relatively protected from addiction. However, these risk avoidant types may become addicted because of an underlying affective or anxiety disorder and turn to the rewarding properties of drugs and alcohol to “self-medicate” dysphoria and anhedonia. Life experiences that expose people to drugs such as social acceptance of drug use within peer groups or family members, particularly during adolescence, can also increase the risk of addiction.

Individual biology is involved in several ways. In the case of alcohol, genetic factors may affect the degree to which alcohol is rewarding, so that some patients report that their first drink was so gratifying that they began a lifetime of heavy drinking immediately. Others will say they never really liked drinking all that much, and therefore are surprised as they gradually become more dependent on alcohol to control the emotional discomforts of their lives. Genetic predisposition may play a lesser role in stimulant and opioid use. These substances are intrinsically more rewarding and patients exposed to these substances have a higher use-to-addiction ratio. Finally, co-occurring medical problems common in HIV such as chronic pain, opportunistic infections, and surgical procedures may result in exposure to opioids and/or sedatives, which can lead to addiction in a vulnerable individual. Substance use disorder is a primary

Telegram: @medical_k

www.konkur.in

vector for the spread of HIV through engagement in a number of high-risk behaviors during states of intoxication or engaging in actions necessary to use or obtain drugs. Such behaviors include the following:

- Sharing of contaminated needles
- Prostitution
- Risky sexual behavior (e.g., not using condoms)
- Sexual contact within a high-risk population of injection drug users

At the end of 2018, injection drug use accounted for approximately 15% of all HIV diagnoses in the United States. Heroin (80%) was reported to be the most commonly injected drug, followed by heroin and cocaine combined (61%), cocaine (48%), methamphetamine (32%), and prescription opioids (15%). Although new diagnoses of HIV in injection drug users have decreased by 48% from 2008 to 2014, the rate of new infections has remained steady over recent years at approximately 10%. There has been a rise in reported outbreaks of injection-related HIV infection in certain rural communities due to increased use of heroin, illicit fentanyl, and oxymorphone driven by the opioid epidemic, and decreased prescribing of opioid pain medications by providers. Strategies to decrease HIV transmission in injection drug users include needle exchange programs, HIV PrEP, medication-assisted treatment (MAT) for opioid use disorder, and linkage to HIV care. Patients with opioid use disorder should also be prescribed naloxone to reduce risk of death from opioid overdose.

In alcohol and noninjecting drug users, substance use also plays a major, although subtler, role in HIV transmission. Addiction and high-risk sexual behavior have been linked across a wide range of settings. For example, female crack cocaine abusers are more likely to engage in prostitution to obtain money for drugs. MSM who use crack cocaine or methamphetamine are more likely to engage in anal sex without condoms and have multiple sexual partners. Alcohol use, which is very prevalent in the HIV population, can lead to risky sexual behaviors during intoxication by way of cognitive impairment and disinhibition.

Ongoing substance use can not only facilitate HIV transmission, but can also negatively affect outcomes in HIV treatment. Once infected by HIV, patients are often demoralized, become hopeless, and are more likely to continue using drugs and engage in high-risk behaviors. Patients with substance use disorders may not seek health care or may be excluded

Telegram: @medical_k

www.konkur.in

from health care because of stigmatization. In addition, intoxication and the behaviors necessary to obtain drugs interfere with adherence to medication regimens and medical appointments.

Substance Use Disorders and Their Interaction with HIV Disease and Treatment

Ongoing substance use has grave medical implications for HIV-infected individuals. Screening for alcohol and drug use disorders is essential during the initial clinical evaluation and a number of quick and easy screening tools are available to clinicians, such as the CAGE, AUDIT-C, and DAST-10. Substance use may be difficult to detect because physical symptoms of HIV infection overlap with those of substance intoxication and/or withdrawal, including malaise, fatigue, weight loss, fevers, and night sweats. In addition, the accumulation of medical sequelae from chronic substance abuse can accelerate the process of immunocompromise and amplify the progressive burdens of HIV infection itself. Injection drug users, for example, are at higher risk of developing bacterial infections such as pneumonia, sepsis, soft tissue infections, and endocarditis. Tuberculosis, sexually transmitted disease (STDs), viral hepatitis infection, and coinfection with human CD4 cell lymphotropic virus occur more commonly in injection drug users who are infected with HIV. Certain malignancies, lymphomas in particular, occur more frequently in HIV-infected drug users. Alcohol users may experience faster progression of HIV disease and poorer response to antiretroviral therapy secondary to the immunosuppressive effects of alcohol. In addition to the direct physical effects caused by drugs, active substance use is highly associated with both nonadherence and reduced access to antiretroviral medication.

Neurologic symptoms can overlap between HIV infection and substance abuse. For instance, both AIDS dementia and drug intoxication can present with apathy, disorientation, aggression, and an altered level of consciousness. Drug withdrawal can present with seizures and neurovegetative symptoms, as can opportunistic infections of the CNS. HIV-infected injection drug users tend to be at higher risk of developing fungal or bacterial infections of the brain and spinal cord. HIV-infected patients who drink alcohol, particularly those older than 50, may be more vulnerable to cognitive decline and structural brain changes on neuroimaging than patients who are nondrinkers.

Telegram: @medical_k

www.konkur.in

The duration of survival in HIV-infected PWIDs has improved substantially since 1997 with the introduction of effective antiretroviral therapy, reaching rates similar to those in HIV-seronegative PWIDs. However, because the HIV-infected patient is likely to be on a variety of antiretroviral agents and prophylactic agents for opportunistic infections, the clinician must be especially mindful of interactions between these medications and the abused substances. For example, the so-called “D drugs,” didanosine (ddI) and stavudine (d4T), which are seldom used today but which many older patients have been exposed to, can cause peripheral neuropathies as a side effect which may be worsened by the neurotoxic effects of alcohol and malnutrition related to chronic substance abuse. Opioid users on methadone maintenance treatment are at particular risk of medication interactions. Rifampin, for example, increases the elimination of methadone from the body and may result in the rapid onset of withdrawal symptoms. Decreased plasma levels of methadone also occur with concurrent administration of abacavir, amprenavir, ritonavir, nelfinavir, loprinavir/ritonavir, elvitegravir/ritonavir, rilpivirine, efavirenz, fosamprenavir, and nevirapine; necessitating adjustments in methadone dosage should withdrawal symptoms occur. This has important implications for treatment adherence in that the patient on methadone maintenance may be less likely to take a medication because of the fear of going into opioid withdrawal. Patients may be more likely to relapse if opioid withdrawal symptoms do occur when they are started on antiretrovirals without proper communication with their methadone provider. Sublingual buprenorphine may be alternatively used for treatment of opioid use disorder. Studies examining drug interactions between buprenorphine and antiretrovirals have shown no clinically significant interactions with the exception of atazanavir which may cause increased buprenorphine concentrations and sedation.

Substance Use Disorders, HIV, and Co-Occurring Psychiatric Disorders

Co-occurring psychiatric disorders are common in the drug-using HIV population. In the past, the term “dual diagnosis” referred to a patient diagnosed with both a drug use disorder and another psychiatric disorder and “triple diagnoses referred to a dual-diagnosis patient who also has HIV infection. Such patients are overrepresented in treatment settings because of their symptom severity and chronicity. For instance, in inner

Telegram: @medical_k

www.konkur.in

city Baltimore, as many as 44% of new entrants to the HIV medical clinic at Johns Hopkins Hospital had an active substance use disorder. Twenty-four percent of these patients had both a current substance use disorder and a co-occurring nonsubstance-related Axis I diagnosis.

Affective disorders, especially major depression, are the most common co-occurring psychiatric disorder in this population with studies estimating a prevalence of 15% to 30%. Diagnosing affective disorders (and other psychiatric disorders) in drug users can be difficult. It may be necessary to observe the patient over a period of abstinence before the presence of an independent mood disorder can be established. Family psychiatric history, temporal relationship of symptoms to periods of drug use and abstinence as well as a longitudinal history of the patient's symptoms obtained from family members, friends, and other psychiatric providers can help clarify the presence of a separate affective disorder. Given the prevalence of overlapping substance use and affective disorders in clinical settings, as well as the poor prognosis associated with both disorders if left untreated, a treatment approach should necessarily emphasize simultaneous and equal treatment of both entities.

The importance of identifying affective disorders lies not only in their own well-known sequelae, including suicide, but also in their complex interactions with addiction and HIV disease. Depression is associated with higher severity of addiction, resistance to treatment, nonadherence to antiretrovirals, higher viral loads, and lower CD4 counts. The anhedonia of depression can be a sustaining factor in addiction. Addicts with major depressive disorder find it difficult to respond to and enjoy life's other rewards that pale in comparison to the intense, though, ephemeral rewarding effect of intoxicating drugs. Depressed patients are also more difficult to engage, invest in, and sustain treatment, given their anergy and negativism. It is essential, therefore, for the clinician to recognize and treat depression early to maximize a successful outcome and improve patient adherence and retention in treatment.

Difficulties in the realm of personality (Axis II) are also commonly seen in this population. Although personality disorder diagnoses are currently described in a categorical fashion in the DSM-5, it is probably more useful to view personality as being dimensional in nature. Using this model, personality traits exist along a continuum, which predicts habitual maladaptive approaches to life's difficulties.

Telegram: @medical_k

www.konkur.in

Many HIV-positive substance abusers would be classified as “unstable extraverts,” (see below) with personality traits of risk taking, reward seeking, emotionally driven, and present-time oriented. These traits are commonly present in the cluster B personality disorders in the DSM-5 (antisocial, borderline, narcissistic, and histrionic) and can be found in as many as 49% of all substance abusers. Not only do these traits result in a vulnerability to addiction and other risky behaviors that predispose one to become infected with HIV, but they also pose significant barriers to both HIV and addiction treatment. These patients tend to act on strong, impulsive feelings rather than on carefully considered treatment instructions. Their behavior tends to be driven by the transient, immediate rewards of drugs rather than by their lasting future consequences. Such patients tend to get bored easily and treatment is often unexciting. They tend to “want what they want when they want it” rather than when it may be good for them. It is critical to identify these personality vulnerabilities because they can have a profound effect on treatment engagement and prognosis.

Treatment of Substance Use Disorders in Patients Infected with HIV

Although oversimplified, the steps for the treatment of substance use can be outlined in this simple way. These steps often occur simultaneously as treatment begins, but will be described as a sequence.

1. Role induction and motivation to change
2. Detoxification
3. Treatment of co-occurring conditions
4. Rehabilitation
5. Relapse prevention

Role Induction and Motivation to Change. The initial and often most daunting task of treating the addict are engagement and induction of the patient role. The general rule is that addicts and treatment providers begin with differing agendas—addicts tend to come to treatment settings seeking comfort and crisis relief, whereas physicians and other health care providers look at long-term goals of improvement in the patient’s health and overall function. One of the critical initial tasks of the health care provider is to engender the gradual evolution of the patient’s attitudes to coincide with those of the treatment team.

Telegram: @medical_k

www.konkur.in

Prochaska and DiClemente have described a “transtheoretical stages of change” model to explain the addiction and recovery process. The patient is viewed as progressing through several different stages of change: (1) precontemplation—the patient has no intention to change their addictive behavior; (2) contemplation—the patient is considering change because of the negative consequences of drug use but is ambivalent about it; (3) preparation—the patient shows intention to change and takes initial steps to seek treatment; (4) action—the patient decides to modify behavior, environment, and circumstances in order to relinquish the addictive lifestyle; (5) maintenance—the patient works to prevent relapse and consolidate his changed behavior and lifestyle. The clinician’s job is to assist the patient in moving from one stage to the next in order to facilitate the recovery process. A technique known as “motivational interviewing” developed by Miller and Rollnick can be used to heighten the patient’s readiness to change by using empathy and gentle confrontation to amplify the discrepancy between the substance abuser’s current lifestyle and long-term life-enhancing goals.

Detoxification. In order for intoxicated patients to understand and process the cognitive steps needed for recovery, detoxification is the first step. Many HIV-positive substance abusers benefit from a brief hospital stay to stabilize their psychiatric and medical comorbidities. Slowly tapering either the drug of dependence or using a cross-dependent drug that has a similar pharmacologic mechanism of action best accomplishes detoxification.

Detoxification is often unpleasant, and there has been no evidence to support the idea that noxious withdrawal during detoxification improves outcome. In fact, some behavioral studies suggest that patients suffering through severe withdrawal during detoxification may actually develop conditioned withdrawal, such that exposure to environments similar to the one experienced during “cold turkey withdrawal” can bring about subacute withdrawal symptoms months later leading to relapse. It should be noted that benzodiazepine, barbiturate, and alcohol withdrawal can be life-threatening and clinicians should have a low threshold for admitting these patients for inpatient detoxification. Active tapers using a slow downward titration of medication from the class to which the patient is addicted is recommended for opiates and sedative-hypnotics. Some authors have used antidepressants to help patients detoxify from psychomotor stimulant

Telegram: @medical_k

www.konkur.in

classes of drugs (amphetamines and cocaine) but data to support this practice is controversial. This approach may work best for patients with clear evidence of major depression.

Sedative-hypnotics or alcohol are best detoxified through the use of a long-acting benzodiazepine such as diazepam or chlordiazepoxide. Lorazepam or oxazepam should be used in patients with liver disease to prevent the accumulation of active metabolites. Detoxification of opiates is accomplished by starting patients on a taper of sublingual buprenorphine or oral methadone. Clonidine, methocarbamol, dicyclomine, loperamide, and ibuprofen can be used adjunctively to provide symptomatic relief.

Treatment of Co-Occurring Psychiatric Conditions. Many patients with HIV and addictions have co-occurring psychiatric conditions, which need to be treated in order to maximize treatment adherence and abstinence. Conditions such as major depression, bipolar disorder, and schizophrenia are best managed with pharmacologic treatment. Because these patients tend to have multiple medical complications, it is important to remember to start medications at low dosages and to titrate slowly to minimize the risk of developing adverse side effects and delirium.

Disorders of personality, in particular, unstable extraversion, are managed with cognitive behavioral forms of psychotherapy. The ways that unstable extraverts may sabotage treatment include staff splitting, doctor shopping, general nonadherence, and manipulative behavior. Therapy addressing these personality issues should include firm limit setting and consistency on the part of all health care providers involved. To this end, a documented treatment plan with clear goals agreed upon by all the treatment staff is essential. The treatment plan should be reviewed with the patient at the initiation of treatment and regularly during treatment so that he understands clearly what is expected of him and what he can expect from his treatment providers if he is adherent to these goals. Frequent and consistent communication among all treatment providers during the course of treatment can minimize splitting and address issues of nonadherence as they arise.

Maintenance Treatment and Relapse Prevention. Long-term treatment is necessary for patients to begin the process of lifestyle change and recovery since addiction is a chronic disorder. Because this patient population is complicated and especially vulnerable to relapse, the most useful model of treatment is integrated care. To this end, an HIV clinic with

Telegram: @medical_k

www.konkur.in

comprehensive care is especially useful to engage and maintain patients in treatment. Ideally, a clinic treating HIV-positive addicts should include medical providers, psychiatrists, social workers, housing counselors, peer support workers, and substance abuse counselors. Integrated settings can help the patient access needed services, adhere to the overall treatment plan, and improve provider communication. Specific strategies integrating substance abuse treatment with HIV care include the on-site provision of sublingual buprenorphine for opioid maintenance treatment at HIV clinics (see Buprenorphine-HIV Evaluation and Support [BHIVES] Collaborative model below) and providing directly observed antiretroviral therapy and HIV care at opioid treatment centers.

It is important to remember that addiction treatment is active rather than passive and involves transforming previously held beliefs, attitudes, and personal identity into a new way of life. To this end, group therapy should be included as part of all substance abuse treatment. Various group modalities are available, including 12-step meetings (Alcoholics or Narcotics Anonymous), network therapy, rational recovery, therapeutic community, or SMART recovery. Group principles are similar in that more experienced members of the group provide both confrontation and support for the newly initiated member. Group support also provides the newly recovering addict with a hopeful view of the benefits to be achieved with recovery, exemplified by the lifestyle and achievements of group members with longer periods of abstinence. A commitment to a community of recovery assists the patient in severing ties from the drug-using community and provides the patient with new bonds that help maintain a sense of purposefulness and hopefulness. Specific HIV-positive recovery groups are widely available and may be helpful for addicts who are uncomfortable with their HIV status in a regular group setting.

Patient-individualized therapy should focus on identifying triggers to substance use, on minimizing or decreasing exposure to substances, and on defining a clear plan of action if relapse occurs. It is important to realize that relapse is often the rule and not the exception, and plans should be in place for early intervention. Objective measures such as urine and serum toxicologies and Breathalyzer tests should be used to monitor drug use and can help guide treatment. Contingency management using a variety of positive and negative reinforcers tied to urine toxicology results has also been shown to be effective in maintaining sobriety.

Telegram: @medical_k

www.konkur.in

Individual and family therapies can enhance the effectiveness of treatment but should not take the place of group therapy. In individual treatment, it is important that the treatment provider remain flexible in the treatment approach. While regular psychotherapy may work for some patients, others may need a more “hands-on” approach and benefit from being referred to vocational rehabilitation, occupational therapy, and social skills training. Treatment failures often result when the therapist has a “one-size-fits-all” mentality and adheres too rigidly to one model of therapy.

Pharmacologic treatments are available for alcohol, opioid, and nicotine use disorders, can be used as adjuncts to the overall treatment plan and are particularly helpful for patients with opioid use disorder. Pharmacologic treatment can be divided into the following categories:

1. Aversive conditioning
    1. Disulfiram (alcohol)
2. Blockade of positive or negative reinforcement
    1. Naltrexone (opioids, alcohol)
    2. Acamprosate (alcohol)
3. Drive suppression
    1. Bupropion (tobacco)
    2. Buprenorphine (opioids)
    3. Methadone (opioids)
    4. Naltrexone (opioids)
    5. Varenicline (tobacco)
    6. Nicotine replacement therapies (tobacco)

Relapse to alcohol use can occur during a single impulsive moment, and some patients find pharmacologic therapy helpful as a type of “insurance policy” against cravings. Disulfiram, an inhibitor of acetaldehyde dehydrogenase, is taken once daily at dosages from 250 to 500 mg and causes an unpleasant reaction when alcohol is ingested due to the buildup of acetaldehyde in the body. Symptoms include nausea, flushing, headaches, and hypotension. Liver enzymes should be monitored because of the risk of hepatotoxicity. Naltrexone orally once a day has been shown to reduce alcohol cravings in a number of studies, probably by reducing the pleasurable effects of alcohol in alcoholics. Naltrexone is also available in an extended-release injectable formulation

Telegram: @medical_k

www.konkur.in

(Vivitrol) given once a month, which may help patients who have problems with medication adherence. As with disulfiram, liver function tests are monitored in patients on naltrexone because of the risk of hepatotoxicity. Acamprosate reduces alcohol relapse by inhibiting excitatory glutamatergic transmissions that can cause subacute withdrawal symptoms in newly abstinent individuals. This medication is excreted renally so it can be particularly useful in patients with liver disease or impairment; however, it is dosed three times a day which makes medication adherence more problematic.

For patients with opioid use disorder, pharmacotherapy or MAT with opioid agonists has been shown to be highly effective in preventing relapse to opioid use as well as reduction in HIV injecting risk. Treatment with methadone, a mu-opioid receptor agonist, is considered the “gold standard” for opioid use disorder use and has been extensively studied for MAT. The typical therapeutic dose ranges from 60 to 120 mg daily and can only be dispensed in a federally regulated opioid treatment program (OTP). Patients on methadone maintenance treatment show better levels of antiretroviral adherence and reduced HIV risk behaviors and transmission. Several agents used to treat HIV and related infections induce methadone metabolism so providers should be aware of drug–drug interactions and monitor patients closely for signs of withdrawal once therapy has been initiated. Buprenorphine, a partial mu-opioid receptor agonist has been shown to be as effective as methadone in opioid maintenance treatment and has the advantage of being more accessible because it can be prescribed in an outpatient clinic setting by a qualified provider with a Drug Enforcement Agency waiver. Buprenorphine is available in several transmucosal formulations combined with naloxone to reduce the risk of diversion and misuse. Buprenorphine/naloxone (bup/nx) is well tolerated by HIV patients and has minimal drug–drug interactions with antiretroviral medications. The patient should show signs of mild to moderate opioid withdrawal before initiating bup/nx to avoid precipitated withdrawal. A long-acting injectable formulation of buprenorphine (Sublocade) is also available and is a subcutaneous abdominal injection given monthly after a patient has been on a stable dosage of transmucosal bup/nx for 7 days. Naltrexone is an opioid antagonist that has a high affinity for blocking mu-opioid receptors. Patients with opioid use disorder maintained on naltrexone experience little or no euphoria when opiates are used. In particular, the extended-release injectable form

Telegram: @medical_k

www.konkur.in

of naltrexone (Vivitrol) is effective in reducing opioid cravings and has shown comparable effectiveness to bup/nx in decreasing opioid use and preventing relapse. The medication should only be started in patients when they are opioid free for 7 to 10 days to avoid precipitated withdrawal.

Integrating pharmacologic treatment into HIV care can result in improved treatment outcomes and patient satisfaction with care. The BHIVES Collaborative was a multisite demonstration and evaluation project funded by the U.S. Department of Health Resources and Services Administration from 2005 to 2007 that examined the integration of sublingual bup/nx treatment into HIV primary care clinics. Patients participating in integrated treatment were 52% less likely than nontreated patients to use illicit opioids during each treatment quarter and reported overall decreased illicit stimulant use. Patients not on antiretroviral therapy at baseline were found more likely to be started on treatment after initiating bup/nx and to achieve nondetectable viral loads over time. Improvements were also noted in their health-related quality of life. Patients receiving integrated treatment subjectively reported being highly satisfied with the effects of bup/nx and with their treatment outcomes. One study site found clear advantages to integrated treatment compared to referral for treatment to an OTP offsite: patients prescribed bup/nx in the HIV clinic were more likely to start on opioid agonist therapy, less frequently found to have positive opioid and cocaine test results, and attended significantly more HIV primary care visits.

ISSUES OF PERSONALITY IN PATIENTS INFECTED WITH HIV

A disturbing trend in the HIV epidemic has been the persistence of high-risk behaviors among individuals who are infected with HIV. Such individuals, who report high rates of sex and/or drug risk behaviors include HIV-infected drug users, patients presenting at HIV primary care clinics for medical treatment, and HIV-infected men who have sex with other men. Apparently, knowledge of HIV and its transmission is insufficient to deter these individuals from engaging in HIV risk behaviors, suggesting that certain personality characteristics may enhance their vulnerability to practice such behaviors.

Telegram: @medical_k

www.konkur.in

Traditional approaches in risk reduction counseling emphasize the avoidance of negative consequences in the future, such as using a condom during sexual intercourse to prevent sexually transmitted infections (STIs). Such educational approaches have proved ineffective for individuals with certain personality characteristics. Most theoretical models of HIV risk behavior have not considered the role of personality factors and few studies have examined mechanisms accounting for dispositional influences on sexual risk taking. Effective prevention and treatment programs for HIV-infected individuals must consider specific personality factors that render them vulnerable to practicing risky behaviors that further endanger their health as well as the health of others. This section will:

1. Discuss extraversion/introversion and stability/instability, measurable traits of temperament that drive personality and behavior
2. Outline the role of personality characteristics and personality disorder in HIV risk behavior
3. Highlight specific interventions to reduce HIV risk behaviors that are formulated for individuals whose personality characteristics place them at increased risk

Dimensional Traits and Personality

Personality is defined by the emotional and behavioral characteristics or traits that constitute stable and predictable ways that an individual relates to, perceives, and thinks about the environment and the self. Personality emerges as the underlying disposition or temperament of an organism and is shaped and affected by development and environment. Traits that may appear to be positive or negative are in fact adaptive in one setting and maladaptive in another. Individuals vary in the degree to which they possess a given trait and in the way it influences their behavior. When traits found in certain individuals exceed the levels found in most of society and are sufficiently rigid and maladaptive to cause subjective distress or functional impairment, a personality disorder is usually diagnosed.

Most personality models depict individuals along affective temperamental dimensions of extraversion–introversion and stability–instability or variations on this theme. The dimension of extraversion–introversion refers to the individual's basic tendency to respond to stimuli

Telegram: @medical_k

www.konkur.in

with either excitation or inhibition. Individuals who are extraverted are present oriented, feeling directed, and reward seeking. Their chief focus is their immediate and emotional experience. Feelings dominate thoughts and the primary motivation is immediate gratification or relief from discomfort. Extraverts are sociable, crave excitement, take risks, and act impulsively. They tend to be carefree, inconsistent, and optimistic. By contrast, introverted individuals are future and past oriented, cognition directed, and consequence avoidant. Logic and function predominate over feelings. Introverts are motivated by appraisal of past experience and avoidance of future adverse consequences. They are unlikely to engage in a pleasurable activity if it might pose a threat in the future. Introverted individuals are quiet, dislike excitement, and distrust the impulse of the moment. They tend to be orderly, reliable, and rather pessimistic.

The second personality dimension, stability–instability, defines the degree of emotionality or lability. The emotions of stable individuals are aroused slowly and minimally and return quickly to baseline. By contrast, unstable individuals have intense, mercurial emotions that are easily aroused and return slowly to baseline. If these two personality dimensions are juxtaposed, four personality types emerge as described from the time of the ancient Greeks: phlegmatic (stable introverts), sanguine (stable extraverts), melancholic (unstable introverts), and choleric (unstable extraverts).

Traditional Personality Models, Their Instruments and Findings Related to HIV Risk Behaviors

After the higher-order traits of extraversion and neuroticism, personality models have elaborated other trait domains and developed personality inventories to empirically assess these traits. The major models and their inventories are as follows:

1. The three-factor model (Eysenck & Eysenck) Extraversion, Neuroticism, and Psychoticism, measured by the Eysenck Personality Questionnaire (EPQ).
2. The five-factor model (Costa & McCrae) Neuroticism, Extraversion, Openness, Agreeableness, Conscientiousness, measured by the NEO Personality Inventory (NEO).
3. The alternative five factor model (Zuckerman) Neuroticism–Anxiety, Sociability, Impulsive Sensation Seeking, Aggression–Hostility, Activity,

Telegram: @medical_k

www.konkur.in

measured by the Zuckerman Kuhlman Personality Questionnaire (ZKPQ).

4. The seven-dimensional model (Cloninger) Novelty Seeking, Harm Avoidance, Reward Dependence, Persistence, Self-Directedness, Cooperativeness, and Self-Transcendence, measured by the Tridimensional Personality Questionnaire (TPQ).

Personality traits appear to influence a variety of sexual risk behaviors, yet there is relatively little research on sexual risk taking from the major personality models. On the EPQ, extraversion is associated with sexual promiscuity, desire for sexual novelty, and multiple sex partners. Neuroticism is related to unprotected anal sex. Psychoticism is associated with number of sexual partners and unprotected sex in several studies. On the NEO, neuroticism is associated with unprotected sex and to a lesser extent, sex with multiple partners. Low conscientiousness is also associated with unprotected sex. Low openness to experience is associated with the denial of risk of HIV infection. The TPQ has minimal research on sexual risk taking, but one study shows that novelty seeking is associated with unprotected sex. The impulsive sensation seeking scale of the ZTPQ has received the most research attention and predicts number of sex partners, unprotected sex, and high-risk sex encounters, such as sex with a stranger, across a variety of populations.

Research on personality traits links extraversion and neuroticism to drug and alcohol addiction. On the EPQ, psychoticism and to a lesser extent, neuroticism has been linked prospectively to alcohol dependence in a 6-year study. On the ZTPQ, impulsive sensation seeking is consistently associated with addiction severity as well as amount and variety of illegal drug use. While there is no specific “alcoholic” or “drug-using” personality, there appears to be a modest link between substance abuse and either impulsivity/high novelty seeking or high on neuroticism/negative emotionality. Individuals with both these traits may be at the greatest risk of addiction.

Sensation Seeking. A significant empirical contribution to the understanding of the role of personality factors and HIV risk is the conceptual model connecting sexual sensation seeking, alcohol expectancies, and drinking before sex as key predictors of risk.

In a series of studies, Kalichman et al. adapted Zuckerman sensation seeking scale that measures preference for exciting, optimal, and novel

Telegram: @medical_k

www.konkur.in

levels of stimulation or arousal. Sensation seeking functions as the “third variable” connecting alcohol use to sexual risk behaviors. Using path analysis in a series of experiments, Kalichman et al. tested a model that predicts the association among sensation seeking, alcohol use expectancies, alcohol use, and sexual risk behavior in both men at risk of HIV and HIV-positive men. Sensation seeking is associated with alcohol outcome expectancies (or the beliefs that the individual has about the effects of alcohol on experience or behaviors). Having positive expectancies about the effect of alcohol on sexual pleasure or sexual behavior increases the likelihood that alcohol will be used in sexual situations. In turn, having sex when under the influence of alcohol is associated with an increased likelihood of having unprotected sex. The importance of this model is identifying a marker, sensation seeking, for multiple risk practices as well as identifying alcohol expectancies that can be a point of intervention for prevention and treatment. Recently, this model has been corroborated in heterosexual women and men. With the use of a cross-lagged panel design to explore the relationship between perceived susceptibility to AIDS and HIV risk behavior preincarceration and post release, it was found that HIV/AIDS patients that rate high in sensation seeking, per Zuckerman scale, have a high association with having unprotected sex. Interestingly there was not found to be a high association between patients who rated high in terms of impulsivity and unprotected sex, unless there was the addition of methamphetamines. A systematic review in 2014 looked at personality as a predictor of unprotected sexual behavior and found similar results to the study where the cross-lagged panel design was used. The results of these studies showed that personality constructs that were more compatible with sexual risk taking and a focus on the immediate intense sexual pleasure reward, such as sexual compulsivity and sex-related subcomponents of sensation seeking, had relatively direct associations with unprotected sex.

Implications for HIV Risk Behavior: Clinical Observations

There has been relatively little empirical investigation of the influence of personality characteristics on HIV risk behavior; however, the authors’ clinical observation suggests that of the four temperaments, unstable extraverts are the most prone to engage in HIV risk behavior. The authors estimate that in Psychiatry Service of the Johns Hopkins AIDS Service, about 60% of the authors’ patients present with this blend of extraversion

Telegram: @medical_k

www.konkur.in

and emotional instability (unpublished observation). These individuals are preoccupied by and act upon their feelings, which are evanescent and changeable. Thus, their actions tend to be unpredictable and inconsistent. They tend to be sensitive to emotional stimuli; easily becoming emotionally labile and subsequently have a slow return to baseline. Most striking is the inconsistency found between thought and action.

Regardless of intellectual ability or knowledge of HIV, unstable extraverts can engage in extreme behaviors that put them at increased risk of acquiring HIV. Past experience and future consequences have little salience in decision making for the individual who is ruled by feeling; the present is paramount. They live their lives through the lens of their emotions and believe their feelings to be factual and thus their feelings are their reality. Their overarching goal is to achieve immediate pleasure or removal of pain, regardless of circumstances. Furthermore, as part of their emotional instability, they experience intense fluctuations in their mood. It is difficult for them to tolerate anything considered painful like boredom, sadness, or unresolved drive; they want to escape or avoid these feelings as quickly and easily as possible. Thus, they are motivated to pursue pleasurable experiences however risky and eliminate low moods.

Unstable extraverts are less likely to plan ahead and carry condoms and more likely to have unprotected vaginal or anal sex. They are more fixated on the reward of sex and remarkably inattentive to the STI they may contract without use of protection. These patients may consistently test positive for syphilis due to the choice of partners and lack of condom use, but refuse to change their behavior. Unstable extraverts are also less likely to accept the diminution of pleasure associated with the use of condoms or once aroused, to interrupt the “heat of the moment” to use condoms. Similarly, unstable extraverts are more vulnerable to alcohol and drug abuse. They are drawn to alcohol and drugs as a quick route to pleasure and reward. They are more likely to experiment with different kinds of drugs and to use greater quantities. Unstable extraverts are also more likely to become injection drug users because the experience is more intense. They are also less likely to defer this intensity in the interest of safety.

The second most common personality type that the authors have observed, which may represent about 25% of Johns Hopkins AIDS Service patients referred to psychiatry is the stable extravert. Stable

Telegram: @medical_k

www.konkur.in

extraverts are also present oriented and pleasure seeking; however, their emotions are not as intense, as easily provoked, or mercurial. Hence, they are not as strongly driven to achieve pleasure. Their emotional imperturbability (described by many as sanguine) may generate a kind of indifference to HIV risk more than a drive to seek pleasure at any cost. Stable extraverts may be at risk because they are too optimistic or sanguine to believe that they will become HIV infected.

Introverted personalities appear to be less common among the authors' psychiatric patients. Their focus on the future, avoidance of negative consequences, and preference for cognition over feeling render them more likely to engage in protective and preventive behaviors. HIV risk of introverts is determined by the dimension of emotional instability–stability. About 14% of the authors' patients present with a blend of introversion and instability. Unstable introverts are anxious, moody, and pessimistic. Typically, these patients seek drugs and/or sex not for pleasure, but for relief or distraction from pain. They are concerned about the future and adverse outcomes, but believe that they have little control over their fates. Stable introverts comprise of the remaining 1% of patients. These patients with their controlled, even-tempered personalities are less likely to engage in risky or hedonistic behaviors.

Personality Disorders in HIV

Personality disorders represent extremes of normal personality characteristics and are disabling conditions. Prevalence rates of personality disorders among HIV-infected (19% to 36%) and HIV at-risk (15% to 20%) individuals are high and significantly exceed rates found in the general population (10%). Antisocial personality disorder (ASPD) is the most common and is a risk factor for HIV infection. Individuals with personality disorders, particularly ASPD, have high rates of substance use disorder and are more likely to inject drugs and share needles compared to those without a personality disorder diagnosis. Approximately half of drug abusers meet criteria for a diagnosis of ASPD. Individuals with ASPD are also more likely to have higher numbers of lifetime sexual partners, engage in unprotected anal sex, and contract STIs compared to individuals without ASPD.

Clinically, it has been useful to characterize patients along the dimensions of extraversion/introversion and emotional stability/instability rather than in the discrete categories such as narcissistic, histrionic, and

Telegram: @medical_k

www.konkur.in

antisocial. This approach is useful for several reasons. First, it is easier and quicker for all staff to determine where a patient falls along two dimensions than to evaluate, for example, each of the criteria to make a personality disorder diagnosis. Second, a diagnosis of antisocial or borderline personality disorder can be stigmatizing, particularly in a general medical clinic where health care providers may have less experience managing such patients. Also, it is not clinically good practice to diagnose a personality disorder in a patient that has other mental health disorders that have not been fully treated. In some case studies written for the Journal of the National Medical Association, it was noted that the clinical team performing the case studies found it extremely valuable to understand a PLWH's personality type in order to most effectively treat them medically. The authors have found a dimensional model of personality as described to be more clinically useful and a better predictor of risk behavior than models that categorically define personality disorders.

Implications for Medication Adherence

Average medication adherence across a variety of diseases and patient populations has been consistently estimated at 50%. Adherence is especially challenging in HIV disease, which is associated with all of the components of low adherence like long duration of treatment, preventative rather than curative treatment, asymptomatic periods, and frequent and complex medication dosing. Average rates of nonadherence to antiretroviral therapy range from 50% to 70% with adherence rates of <80% associated with detectable viremia in a majority of patients.

Personality factors have received little investigation in relation to adherence and antiretroviral therapy. Personality traits such as neuroticism were significantly associated with poorer quality of life whereas conscientiousness and extraversion were associated with better quality of life. In contrast, personality traits were not directly related to ART adherence. However, the authors' clinical experience suggests that nonadherence is more common among their extraverted or unstable patients. The same personality characteristics that place them at risk of HIV also reduce their ability to adhere to demanding drug regimens. Specifically, their present-time orientation, combined with reward seeking, makes it more difficult for these patients to tolerate uncomfortable side effects from PI drugs whose treatment effects may not be immediately

Telegram: @medical_k

www.konkur.in

apparent. It is also difficult for feeling-driven individuals to maintain consistent, well-ordered routines. Hence, following frequent, rigid dosing schedules can also be problematic. The authors' unstable, extraverted patients are usually intent upon following the schedule, but their chaotic and mercurial emotions are more likely to interfere and disrupt daily routines. For example, a patient may report that he felt very upset and nihilistic after a fight with a family member and miss several doses of his ART medicines. Missed doses of ART can increase the chance of HIV resistance developing. Identifying factors that influence adherence in HIV disease is important in improving overall health outcomes.

Treatment Implications

Psychiatric and medical treatment of patients with extraverted and/or emotionally unstable personalities is challenging. Such patients are often baffling or frustrating for physicians and other medical care providers because they engage in high-risk sex and drug behaviors in spite of knowing the risks, or fail to adhere to treatment regimens for HIV infection in spite of knowing the consequences. A patient may stop his antidepressant medicine because of a headache while being perfectly willing to inject heroin into multiple sites on his body. After 6 months of missed medical appointments, a patient may impulsively leave the clinic if the primary care provider is 15 minutes late for the appointment. Such personality traits reflect relatively stable, lifelong modes of responding; thus, direct efforts to change these traits are unlikely to be successful. It is possible, however, to modify the behavior that is an expression of the trait. By recognizing individual differences in risk-related personality characteristics, interventions can be better targeted and their impact maximized.

The authors have found that a cognitive behavioral approach is most effective in treating patients who present with extraverted and/or emotionally unstable personalities. Following are the five principles that guide the authors' standard care:

1. Focus on thoughts, not feelings. Individuals with unstable, extraverted personalities benefit from learning how they are predisposed to act in certain ways. Often, they do not recognize the extent to which their actions are driven by the impulse or feeling of the moment. These patients can fail to understand why they intend to stay clean but later

Telegram: @medical_k

www.konkur.in

find themselves “shooting dope.” Treatment helps to identify the role that strong feelings play, so that these patients can begin the process of understanding their own chaotic, often irrational behavior.

Simultaneously, treatment encourages the patient’s cognitive, logical side. This process begins by identifying what the patient thinks in a given situation, as opposed to what they think about the situation: “I deserve some cocaine because I have had a difficult day.” The influence of the patient’s assumption upon feelings, behavior, and ultimately the consequences of behavior are examined. Through the treatment dialogue, patients understand that the notion of a “cocaine reward” creates a feeling of urgency and entitlement to getting high. As a consequence of using cocaine, the development of other more constructive reward systems or coping methods is preempted, a relapse into cocaine dependence can occur, and/or family or employers may be alienated. Through treatment, patients learn to identify maladaptive assumptions that drive feeling and behaviors so that they can either lessen the force of these assumptions or substitute more constructive assumptions to guide their life experience.

2. Use a behavioral contract. A behavioral contract is developed with all patients. The contract outlines goals for treatment, often only a day or a week at a time. While patients and mental health professionals may develop the contract, the focus of treatment is not on what patients want or are willing to do to get off of drugs, but rather on established methods, such as drug treatment and Narcotics or Alcoholics Anonymous. The importance of the behavioral contract lies in the creation of a stable plan that supersedes the emotional meanderings of these patients. Unstable extraverts present an ever-changing array of concerns and priorities. The task of the treatment is to order the priorities with patients and help them follow through on these, regardless of changing emotions. In short, behavioral contacts provide consistent, cognitive focus to patients’ bewildering emotional experience of life.
3. Emphasize constructive rewards. In developing the behavioral contract and in treatment, the purpose is cast in terms of the rewards that will follow from their behavioral change. Positive outcomes, not adverse consequences, are salient to extraverts. Most of the patients have already experienced negative consequences from their behavior, HIV, drug addiction, homelessness, and such. Exhortations to use condoms to avoid STDs are unpersuasive. More success has been achieved

Telegram: @medical_k

www.konkur.in

with extraverts by eroticizing the use of condoms or by the addition of novel sexual techniques (erotic massage, use of sex toys) into sexual repertoires. Similarly, the rewards of abstaining from drugs or alcohol are emphasized, such as having money to buy clothing, having a stable home, or maintaining positive relationships with children.

In building adherence to antiretroviral therapies, the focus is on the rewards of an increased CD4 count and reduced viral load, rather than avoiding illness. Using the viral load as a strategy to build adherence can increase acceptance in all patients but is especially effective in reward-driven extraverts.

4. Use relapse prevention techniques. The relapse prevention model, originally developed for treatment of substance abuse behavior, is an effective method for changing any habitual way of behaving. This intervention trains individuals to recognize and interrupt the sequence of behaviors that link to the final high-risk behavior. Behavioral therapy methods are also used to teach individuals how to recognize and avoid situations that trigger high-risk behaviors.
5. Coordinate with medical care providers. Medical care providers are often frustrated or discouraged when treating unstable, extraverted patients. It is useful to provide education about a patient's personality and how it influences behavior. Particularly effective is the development of a coordinated treatment plan, where medical care provider and mental health professional work in tandem to develop behavioral contracts to reduce HIV risk behaviors and build medication adherence.

Conclusion

Personality characteristics and personality disorders reflect relatively stable, lifelong propensities that are difficult to change. This does not mean, however, that HIV risk reduction efforts are necessarily futile. Rather, by understanding personality characteristics and their role in HIV risk behavior and medication adherence, the mental health professional can develop more effective, specific treatment strategies. Similarly, the HIV-infected patient who can identify aspects of their personality that might interfere with intentions to practice safer behavior, and who knows strategies for dealing with these situations, is less likely to practice high-risk behaviors. Finally, the mental health professional can provide valuable assistance to medical care providers to improve health outcomes for these patients.

PSYCHOLOGICAL PROBLEMS IN PATIENTS INFECTED WITH HIV

In the context of the psychological realm of living with HIV, it is difficult to distinguish which came first, the variety of psychiatric disorders the patient has, the HIV risk behaviors, the losses and psychological traumas, or the impact of having HIV itself. In fact, it is a common sentiment from patients to echo one of the patients at the authors' clinic who said "HIV is not even one of my biggest problems." Each of these factors seems to be both a consequence and an antecedent to all the other factors. The DSM-5 provides psychiatrists with the opportunity to choose between "adjustment disorder" and "PTSD" for patients living with violence, despair, and loss of unthinkable proportion. Unfortunately, the psychological difficulties of living with HIV are infinitely more complex than this.

Patients with HIV report more trauma and more severe trauma than the general population and at-risk controls. They have high rates of PTSD and anxiety, economic and social disenfranchisement, and high rates of interpersonal instability. Cognizance of the psychological issues in the care of patients with HIV is essential. The treatment of these problems is well within the scope of most clinicians in our field. The psychotherapy for patients infected with HIV can be broadly divided into three categories:

1. Psychotherapy for the problems of life encountered by patients infected with HIV
2. Psychiatric treatment for specific psychiatric conditions associated with HIV infections
3. Specific psychoeducational and psychotherapeutic interventions associated with specific types of interactions with HIV-infected patients

For numbers 1 and 2 above, the psychotherapeutic issues are largely similar to those seen in patients who are not infected with HIV. While specific papers have been written regarding coping skills, social isolation, grief, PTSD, intimate relationships, family problems, and many other issues, these recommendations are largely similar to those found in patients coping with other chronic medical conditions, or chronic impoverishment elsewhere in this text. The psychotherapy issues of conditions commonly seen in HIV clinics have been reiterated where appropriate, but are also similar to those issues for patients with the same conditions but without HIV infection. This chapter includes a section on

Telegram: @medical_k

www.konkur.in

PTSD because of the high prevalence and special issues for patients with HIV.

Post-Traumatic Stress Disorder

Traumatic events such as those associated with actual or threatened death, serious injury, or sexual violence often provoke terror, anxiety, and stress and some individuals develop chronic psychiatrically disabling symptoms now called PTSD. Characteristics of the condition include (1) vivid recollection and re-experiencing the trauma (often in the form of nightmares or vivid flashbacks); (2) persistent avoidance of thoughts, places, people, or feelings associated with the trauma; (3) persistent negative emotional changes often with distortions of the event and its significance; and (4) persistent hyperarousal often including insomnia, irritability, and hypervigilance. PTSD has a prevalence of less than 1% in the general population and a lifetime prevalence of 1% to 9% with a female-to-male lifetime prevalence ratio of 2:1. In civilian populations, rape is the event most likely to produce PTSD, particularly if it occurs before or during adolescence.

PTSD increases the likelihood of engaging in destructive behaviors such as alcohol and other drug abuse, sexual promiscuity, or prostitution. PTSD is of particular concern in HIV treatment and research because it may engender or exacerbate HIV risk behaviors and worsen health outcomes. Cross-sectional research has shown that symptoms of PTSD have been associated with HIV risk behaviors and markers of HIV progression. Symptoms of PTSD in adolescence have been associated with prostitution, injection drug use, and choice of a high-risk sex partner in young adults. HIV-infected adults who have a history of childhood sexual or physical abuse have reported engaging in more HIV risk behaviors such as drug abuse and sexual compulsivity than persons with no history of trauma. A high prevalence (42%) of HIV-infected women attending county medical clinics had PTSD symptoms sufficiently severe to meet a diagnosis of PTSD. In patients infected with HIV, traumatic stressors and PTSD symptoms have also been associated with lower CD4-to-CD-8 T cell ratio at follow-up visits.

Veterans with a diagnosis of PTSD are at greatly increased risk of HIV infection, particularly if they are also diagnosed with a substance abuse disorder. Women prisoners with a lifetime history of PTSD are more likely to have engaged in prostitution and receptive anal intercourse prior to

Telegram: @medical_k

www.konkur.in

incarceration compared to women prisoners without PTSD. These studies of PTSD symptoms and HIV risk behaviors have been cross-sectional; thus, a causal relationship cannot be inferred. It may be that HIV risk behaviors, such as prostitution or drug abuse, increase exposure to trauma, and thus the likelihood of developing PTSD. Alternatively, PTSD that stems from early trauma may predispose an individual to engage in sex or drug behaviors that can increase the risk of HIV infection.

The presence of PTSD in an at-risk or HIV-infected positive individual is of particular concern because of high rates of comorbidity (up to 80%) with other psychiatric disorders. Specifically, PTSD is most often comorbid with depression and cocaine/opioid abuse—both risk factors for HIV. Prior depressive episodes may be either a risk factor for the development of PTSD following a traumatic event or a co-occurring response with PTSD to a traumatic event. Substance abuse may be either an attempt to “self-medicate” suffering after a traumatic experience or a lifestyle that increases exposure to traumatic events, such as robbery or assault.

PTSD and substance use disorders that occur together can also adversely affect treatment. Comorbid conditions have been associated with poorer treatment adherence and motivation, quicker relapse, more inpatient hospitalizations and medical problems, and lower global functioning than either disorder alone. Thus, treatment of PTSD that does not address coexisting depression or substance abuse may be insufficient or even worsen psychiatric status. PTSD treatment that typically involves behavioral exposure and flooding has been reported to exacerbate emotional arousal and precipitate relapse, although this had not yet been shown in experimentally controlled investigations. Likewise, the AA philosophy of surrender and sharing one’s story may be counterproductive to substance-abusing HIV-infected individuals with PTSD.

HIV at-risk or HIV-infected individuals should be routinely screened for PTSD. Instruments such as the Trauma History Questionnaire and the PTSD checklist have increased detection rates of the disorder. Similarly, any individuals presenting with symptoms of PTSD should routinely be screened for depression and substance abuse. For HIV-infected individuals with PTSD and another concurrent psychiatric disorder, treatment that simultaneously addresses both disorders is likely to be more effective and practical.

HIV-Specific Psychotherapeutic Issues

Telegram: @medical_k

www.konkur.in

There are a number of specific circumstances regarding HIV-infected patients that should be discussed here. They include the following:

1. Pretest, test, and posttest counseling issues
2. Risk behavior reduction in patients at risk or infected with HIV
3. Issues of partner notification in patients infected with HIV
4. Impaired patients with issues of capacity and competence
5. ART adherence issues

Pretest/Test Counseling and Education

Patients at risk of HIV infection are often reticent to get testing. Surveys suggest they fear the results of the test or are too overwhelmed by the issues of their current life and behavior to present for testing. Prior to 1993, patients who received a positive HIV test result saw their diagnosis as essentially fatal. In addition, many patients thought it would be burdensome to know that they were placing others at risk of infection. In more recent years with the advent of ART, HIV has become a chronic treatable illness. In this setting, it seems more reasonable for patients to get tested and engage in treatment. Nonetheless, survey data show that a large number of patients that are at significant risk are not getting tested. Psychoeducational psychotherapy directed at encouraging patients to get tested has been offered to a variety of at-risk populations of patients. Intervention studies using psychoeducational psychotherapy suggest that patients receiving therapy are more likely to get tested, more likely to receive a diagnosis, and more likely to begin treatment, particularly in settings where rapid-testng and same-day medication-start are offered.

Pretest counseling has been described in a number of papers. When HIV testing became available in the 1980s, a positive test was associated with an almost certain fatal outcome and HIV testing was regulated and required extensive pretest counseling and usually required a separate informed consent process. Now, most clinicians see HIV testing as a routine test with implications no worse than many other tests in medicine. Different forms of HIV testing are used and therefore patients should be informed about the particular elements of the test they are getting. The most rapid tests and the home testing kits test for antibodies to HIV, while more sophisticated tests also look for viral elements in blood. Depending on which test is used, results remain negative for a time after infection and therefore after a recent exposure, a patient may have a negative test but

Telegram: @medical_k

www.konkur.in

be in fact infected. Patients may also present immediately after an exposure and may benefit from postexposure prophylaxis treatment with ART. It is therefore important to ask patients about recent potential exposures if they come for testing.

Pretest counseling should also include information on safe sex, safe needle exchange, and other risk-reduction interventions as well as preventative PrEP. This is because a significant percentage of patients who obtain testing do not return for their results for extended periods of time and sometimes not at all. The development of rapid testing using cheek cell swabs has provided a much faster turn-around time, thus enabling a quicker result for the patient, but confirmation with a blood test is usually recommended. So, a combination of pre- and posttest counseling and then another pretest counseling session may be required in short order.

For patients with HIV infection, a number of monitoring tests are necessary, including CD4 counts and HIV RNA loads, and sometimes resistance testing. In similar fashion to the counseling required before HIV antibody testing, patients should be counseled before each of these types of tests, explaining what the test is for, what the possible results will be, and what the test results could mean as to the overall treatment and prognosis. Time should be allowed for questions, and many clinics have developed take-home pamphlets on these tests. The most important initiatives are to integrate mental health professionals in clinics for these types of visits in order to have wraparound type of services.

Posttest Counseling

A number of articles have described posttest counseling psychotherapy issues and interventions. These include both psychoeducational interventions regarding the meaning of test results, recommendations for treatment, and importantly, risk reduction interventions to stem the spread of HIV infection. These posttest interventions should occur in both HIV-negative and HIV-positive patients.

At the time of test results being given to patients, it is not uncommon for patients to have a variety of intense psychological reactions including suicidal feelings, anger, homicidal thoughts directed at potentially infecting partners, overwhelming grief, and complete psychological breakdown. Patients with poor coping skills, poor impulse control, history of suicidal feelings and behaviors, substance abuse disorders, and lack of social

Telegram: @medical_k

www.konkur.in

supports are at increased risk of impulsive behaviors and self-destructive behaviors. Because of these circumstances, availability of psychological interventions at the time of HIV testing and result provision is critical.

For established HIV-positive patients, bad news regarding progression of HIV disease or detection of resistance can provoke similar responses and should be considered in a similar way. Transition from the asymptomatic phase to the development of an opportunistic infection or to a formal diagnosis of AIDS because of a decline in CD4 cells may provoke denial, anger, depressive feelings, anxiety, hopelessness, or a myriad of other emotions. Again, the presence of psychological evaluation and intervention is extremely critical in this setting. Patients may be overwhelmed by the news that they need to start antiretroviral drugs, and therefore need emergent attention at this time. In particular, discussions around detection of viral resistance may evoke a number of defensive responses from the patient, as there may be a perception of failed adherence and guilt.

Psychotherapy to Prevent HIV Transmission in Selected Populations of Patients

Men who have sexual contacts with other men may either be exclusively homosexual, bisexual, or heterosexual men. Men with sexual contacts with other men were the largest subgroup in terms of new AIDS diagnoses in the United States in the year 2000. In states where HIV is reported, it continues to be the largest subgroup of newly reported HIV infections. In intervention studies looking at men who have sex with other men, many interventions have shown a decrease in either risk behaviors or infection. Studied psychotherapeutic interventions focus on education, behavioral change, management of emotions, and assertiveness including some tailored to specific high-risk populations or environments. Although there are fewer data, similar studies have been done targeting heterosexually transmitted HIV, substance-related risk behaviors, women, and IV drug users. It is unclear from the data what the best intervention is and how to stratify the interventions. The use of PrEP in this at-risk patient population has been a big risk reduction intervention now especially when taken correctly.

Studies of rates of psychiatric disorders in at-risk population show impressively high rates of affective disorders, substance use disorders, personality disorders, and psychological distress. As of now, no

Telegram: @medical_k

www.konkur.in

systematic study on treatment and targeted intervention methods based on psychiatric diagnosis has been reported. It is clear from the data on risk and epidemiology that this is the direction that needs to be taken to try to improve prevention.

Partner Notification

The landmark legal decision in the Tarasoff case in California has resulted in the increased scope of responsibility for health care providers. A variety of legislation differing from state to state has afforded practitioners an increased number of options with regard to confidential situations. In some states, Tarasoff statutes (those statutes providing a duty to warn vulnerable individuals of imminent danger from a patient overriding issues of confidentiality) have completely changed the way in which mental health professionals handle confidential issues.

Numerous articles have been written about the issues of ethics, confidentiality, duty to warn, and medical/legal aspects of this element of practice. Although no clear consensus has been reached, recommendations are that patients who are sexually active and infected with HIV be counseled about potential risk to their sexual partners. In addition, known partners should be notified of exposure risk and potential infection as well. Partner notification has been an extremely hotly debated topic. However, many states have developed legislation requiring or allowing either physicians or health department officials to notify partners of HIV-infected patients of their risk. The current standard, despite the controversy, appears to be an obligation on the part of health care professionals (in some areas, health departments) to ensure notification to anyone who could be construed as clearly at risk and who may be unaware of their risk.

A particularly difficult situation is that of sex workers, known to be HIV infected and known to be working actively as prostitutes. There are public health issues that pose a risk both for these patients and depending on the politics of the circumstances for their potential partners, clients, customers, victims, or victimizers. The responses to this problem have ranged from a sense that sex care workers and their clients can make their own decisions and should be responsible for their own behavior all the way to the sentiment that HIV-infected sex workers should be arrested and jailed for attempted murder. It has additionally been noted that some sex workers are impaired by a variety of psychiatric conditions including

Telegram: @medical_k

www.konkur.in

cognitive impairment, major mental illness, personality disorder, and substance use disorders. These may further contribute to the sense that some sex workers may be less than fully responsible for their behavior. Recommendations have been made for voluntary and involuntary interventions regarding these patients. Specific psychiatric interventions regarding competency, ability to consent, capacity, and most importantly treatment for the conditions that impair such people are critical to the mental health needs of patients with HIV.

Capacity to Consent/Competence

Patients with psychiatric disorders in HIV clinics often have a variety of difficulties with medical care provision. In some of these settings, the patient's capacity or competence to make medical decisions regarding their health care can be in doubt. Provision of mental health care evaluations to determine this is an often-unmet need in HIV clinics. The issues of competence and capacity in these patients are often no different than those described elsewhere in this textbook; however, the consequences of inadequate assessment of patients' competency and capacity can have grave consequences in this clinical setting. HIV dementia and delirium can be overlooked in this population, as can intoxication with substances, creating problems in obtaining meaningful consent.

The question of capacity and consent involves several issues, but most important is the specific question that the patient is being asked. In many cases, medical care providers want a judgment about competence as a general rule, a judgment impossible to make. To have capacity to give a particular informed consent, a patient must understand that there is a decision before them regarding some aspect of care, and must understand the consequences not only of each option but also of refusal to make a choice. The patient should be able to repeat the benefits and risks of each possible option and must be able to clearly communicate the decision and have the ability to maintain the choice made over time. Finally, in the process of making the decision, the patient must be able to manipulate the information in a rational way. Thus, patients who are delirious or intoxicated may not maintain choices over time as concentration and memory are often impaired. Demented patients may have difficulty maintaining choices due to impaired memory as well. Psychotic patients may not base decisions in reality, occasionally arriving

Telegram: @medical_k

www.konkur.in

at choices that derive from delusional constructs. While physicians from many disciplines may be able to determine capacity in many situations, it is in these patients with psychotic illness that psychiatrists are often especially helpful.

In many cases, the danger to the person, patterns of prior behavior, severity of illness, poor judgment, and psychiatric vulnerabilities complicate these decisions and play an important role in tempering the way in which patients are managed. The ethics of a particular case may get very complex when a patient understands the issues cognitively, but their judgment is colored by their affective state, temperament, drug cravings, social situation, or simply difficulty with tolerating discomfort. These cases often divide medical teams and require consultation and a group conference to resolve. It is critical to get all providers to discuss the most difficult cases, clarify the issues, and come to a decision based on the patients' best interests, not the most expedient management.

Adherence Counseling

The single most important factor regarding outcome of HIV treatment is the patient's ability to adhere to prescribed regiment. While this has been debated in the literature, a study by Margaret Fischel looking at HIV-infected prisoners revealed that 100% of patients who received directly observed therapy in a prison setting developed undetectable viral loads. This strongly supports adherence as the major feature of treatment. There are compelling studies suggesting that major depression, substance abuse, personality disorder, and psychosocial disruption all affect adherence. Interventions to address these conditions are presented above. More subtle factors affecting adherence include psychosocial support networks, individual coping skills, life structure, access to resources, and behavioral control. Interventions such as cognitive behavioral psychotherapy, structured psychoeducational psychotherapy, supportive psychotherapy, and group interventions have all been used to improve patient adherence to office visits and medication regimens.

In the current literature on HIV, medication adherence focuses on technical interventions such as pill box and timer reminders, less complex pharmacologic interventions, decreased pill burden, and increased access to care. A growing literature examines psychosocial interventions, relationships with health care providers, case management, and psychiatric disorders as barriers to adherence. It is in this arena that

Telegram: @medical_k

www.konkur.in

mental health care can have an enormous impact on outcome. Psychotherapy has been shown to improve clinic visit adherence, the best indirect predictor of medication adherence.

NEUROLOGIC COMPLICATIONS OF HIV AND AIDS

Opportunistic Infections

Toxoplasmosis. *Toxoplasma gondii is* a protozoan acquired most commonly from cat feces or uncooked meat. Approximately a third of people are latently infected with toxoplasmosis, but in the United States, it is approximately 11%. In immunocompetent hosts, the organism is encysted and infection is usually clinically silent unless the person becomes infected during pregnancy, where there can be catastrophic results. Recent studies have shown substantial influences on personality and behavior in aggregate populations suggesting infection may be less silent than previously thought. Active infection in patients with HIV generally occurs in patients who are immunocompromised with less than 200 CD4 cells/mL. In patients with AIDS, toxoplasmosis is the most common reason for intracranial masses, affecting between 2% and 4% of the AIDS population, with the most common findings being pulmonary and ocular involvement. Other manifestations are possible, including chorioretinitis and pneumonitis. Lymphadenopathy may be present in cutaneous cases. Symptoms of CNS infection are fever, change in level of alertness, headache, focal neurologic signs (approximately 80% of cases), and focal or generalized seizures (approximately 30% of cases). CT and MRI scans usually show multiple, ring-enhancing lesions in the basal ganglia or at the gray–white matter junction. CSF studies are normal in 20% to 30% of cases, but more often show a mild monocytosis. Serum *T. gondii* IgG is generally helpful in the diagnosis, but has a false-negative rate of 5% to 10%. Brain biopsy provides the definitive diagnosis, but since this invasive procedure carries some risks, empiric treatment is often offered if the clinical and radiographic pictures suggest infection.

The preferred treatment consists of sulfadiazine and pyrimethamine because with this combination, patients do **not** require additional trimethoprim-sulfamethoxazole (TMP-SMX) for prophylaxis against *P. jirovecii* infections. In the care of a sulfadiazine allergy, clindamycin in addition to pyrimethamine **plus** leucovorin is an alternate treatment

Telegram: @medical_k

www.konkur.in

option. There are other alternate regimens such as use of dapsone plus pyrimethamine and leucovorin in case of intolerance. Clinical and radiologic improvement is seen in 75% to 80% of patients. Since these medications are effective only against the tachyzoite form of the protozoan, maintenance therapy using a combination of sulfadiazine and pyrimethamine should be continued, but at lower doses than those used for initial treatment as the goal is to prevent recrudescence. The use of trimethoprim-sulfamethoxazole as prophylaxis has reduced the incidence of *T. gondii* infection. Patients with hypersensitivity to sulfa drugs may use pyrimethamine plus dapsone for maintenance.

Cytomegalovirus. CMV infection is an uncommon complication of AIDS and prior to ART, presented in about 2% of HIV patients before the advent of ART. The development of clinically evident CMV encephalitis is fairly rare and most usually occurs only in patients with CD4 counts less than 50 cells/μL with close to 80% reduction in cases since the development of ART. Symptoms of CMV neurologic disease are dependent on the anatomic location involved. There have been several cases of immune reconstitution inflammatory syndromes (IRIS) reported after start of ART. These patients often have presentations consistent with encephalitis and CNS involvement of infection. The most common symptoms in CMV encephalitis include delirium, confusion, apathy and focal neurologic deficits. Other manifestations involve myelitis, polyradiculopathy, and peripheral neuropathy.

Investigation of CMV encephalitis begins with examination for signs of CMV infection of the retinae, electrolyte studies to look for adrenal insufficiency, and viral blood cultures. CT scan may show ventriculomegaly or decreased attenuation diffusely throughout the parenchyma. MRI may show increased signal intensity around the ventricles. CSF studies may be normal or show high protein, low glucose, and pleocytosis. CSF CMV cultures are usually negative but PCR may reveal the presence of the virus. Brain biopsy may be needed for a definitive diagnosis.

Treatment consists of getting patients on optimal ART but otherwise depends on neurologic involvement and severity of disease. Ganciclovir and foscarnet have been the primary treatment for CNS CMV, but are not necessarily beneficial. Cidofovir is an alternative therapy especially if patients cannot tolerate any of the other above options.

Telegram: @medical_k

www.konkur.in

Cryptococcal Meningitis. While meningitis caused by *Cryptococcus neoformans* is rare in immunocompetent persons, it was one of the leading opportunistic infections in patients with untreated HIV. The incidence is now around five cases per 1,000 PLWH and it is usually seen in untreated patients with advanced HIV. Patients generally present with fever and delirium. Meningeal signs (headache, stiff neck, photophobia, and nausea) are not universally seen. Seizures and focal neurologic deficits occur in about 10% of patients. CT scans are normal, but gadolinium-enhanced MRI may show meningeal inflammation. Intracranial pressure is elevated in 50% of patients. CSF studies are normal in about 20%, but otherwise show mild-to-moderate monocytosis, elevated protein, decreased glucose, and positive fungal cultures. The fungus can be seen on India ink stain of CSF about 60% to 80% of the time. There is also a test for *C. neoformans* antigen, which is usually positive in both serum and CSF.

Treatment of cryptococcal meningitis requires amphotericin B and flucytosine. Patients who survive must receive prophylaxis against recurrence, since this is very common. Some authors suggest that patients who receive ART for 6 months with a rise in CD4 count to >100 cells/mL may terminate secondary prophylaxis. Prophylaxis can be prescribed as oral fluconazole or intermittent IV amphotericin B. Primary prophylaxis for *C. neoformans* is not recommended.

Progressive Multifocal Leukoencephalopathy. PML is a demyelinating disease of white matter in immunocompromised patients. First described in cancer patients, the causative agent is a polyomavirus, named JC virus after a patient (not to be confused with Creutzfeldt–Jakob disease, caused by a prion). Its transmission route is unclear but may be respiratory and the virus is commonly present in an asymptomatic form in immunocompetent people. The prevalence of PML prior to ART in AIDS patients was between 1% and 10%. Typically, PML affects patients with AIDS with fewer than 100 CD4 cells/μL. Although rare, it has been reported in patients after initiation of ART with increasing T-4 cell counts.

The pathology of PML consists of demyelination and death of astrocytes and oligodendroglia, with a multifocal presentation. The clinical syndrome consists of multiple focal neurologic deficits, such as mono- or hemiparetic limb weakness, dysarthria, gait disturbances or sensory deficits, and progressive dementia, with eventual coma and death.

Telegram: @medical_k

www.konkur.in

Occasionally, there may be seizures or visual losses. There is usually no fever or headache.

MRI is more useful than CT in diagnosis, displaying multiple areas of attenuated signal on T2 images primarily in the white matter of that brain, although gray matter, brain stem, cerebellar, and spinal cord lesions are possible. CSF studies are generally unhelpful, except for PCR evaluation for the presence of JC virus, which is sensitive and specific. Brain biopsy provides the definitive diagnosis, but is rarely used. There is no specific ART for JC virus. Treatment of PML includes support for the patient and ART. There are no data suggesting that higher CNS-penetrating antiretrovirals are of any particular benefit, and this logical conclusion is often followed by providers. The prognosis is poor for patients with PML but the course is more variable in the small group of patients who develop PML after starting ART.

CNS Neoplasms

There has been much data showing that cancer is diagnosed in over 40% of HIV patients with over 28% of HIV-related deaths being caused by some sort of malignancy. Lymphoma, specifically non-Hodgkin lymphoma (NHL), is the most common neoplasm seen in patients with AIDS, affecting up to 10% of patients. AIDS is the most common condition associated with NHL and systemic NHL accounts for most of the HIV-related lymphoma cases. The patient is generally afebrile and may develop a single lesion with focal neurologic signs or small, multifocal lesions most commonly presenting with a mental status change. Seizures are present in about 15% of patients. CNS lymphoma is at times misdiagnosed as toxoplasmosis, HIV dementia, or other encephalopathy. CT scan of the brain may be normal or show multiple hypodense or patchy, nodular enhancing lesions. MRI generally shows enhanced lesions that may be difficult to differentiate from CNS toxoplasmosis, but thallium SPECT scanning may help differentiate the two disorders and is 90% sensitive and specific for lymphoma. CSF studies may be normal or show a moderate monocytosis; cytology studies reveal lymphoma cells in less than 5% of patients. Brain biopsy is required for the confirmation of the diagnosis of CNS lymphoma. As this procedure carries some morbidity, clinicians should weigh the clinical presentation carefully, suspecting lymphoma in afebrile patients with a negative toxoplasma IgG screening test, patients with a single lesion, and patients who fail to

Telegram: @medical_k

www.konkur.in

respond to empiric therapy for toxoplasmosis as demonstrated by clinical examination and repeat MRI at 2 weeks. The differential diagnosis of CNS neoplasm also includes metastatic Kaposi sarcoma and primary glial tumors. Lymphoma may respond in part to radiation therapy and steroids, thus alleviating high intracranial pressure and its associated symptoms. Chemotherapy is generally adjunctive for lymphoma. While CNS lymphoma had a grim prognosis with an average survival of 3 to 5 months prior to the advent of ART, the prognosis is now dependent on the ART response, with considerable improvement possible in patients who respond to ART.

Direct CNS Manifestations of HIV

1. Guillain–Barré syndrome. A small percentage of patients, usually young men, will present with Guillain–Barré, a syndrome associated with early HIV infection. Guillain–Barré syndrome is an inflammatory demyelinating polyneuropathy causing symmetrical paralysis and few, if any, sensory symptoms, usually beginning in the lower extremities and progressing upward. The condition becomes especially serious if abdominal musculature is involved, as it may impair respiration. The disorder is thought to be autoimmune in etiology and is generally self-limited. IV immunoglobulin and plasmapheresis have been used to shorten the course, but neither treatment has been studied well in HIV-infected individuals.
2. Vacuolar myelopathy. Vacuolar myelopathy is highly prevalent among patients with AIDS, being found in approximately 50% of patients at autopsy. Clinical manifestation of this disease is much less common, affecting 20% to 30% of end-stage patients with AIDS. The presence of vacuolar myelopathy has been associated with history of *P. carinii* and *Mycobacterium avium-intracellulare* infections, suggesting that the development of vacuolar myelopathy is related to more severe immunosuppression. The mechanism of the disease is unclear, but appears similar to the myelopathy of combined systems disease associated with vitamin B_{12} deficiency. Multinucleated giant cells are seen on histologic examination, and theories about mechanism focus on immunologic activation damage, direct toxicity of HIV products, and metabolic dysfunction of transmethylation processes.

Telegram: @medical_k

www.konkur.in

The clinical manifestations of vacuolar myelopathy appear when the disease progresses to affect the lateral and posterior columns, and thus includes spastic paraparesis, loss of proprioception and vibration sense, bowel and bladder urgency or incontinence, and impotence. There are now reports of improvement with the initiation of ART.

Peripheral Nervous System Disorders in HIV

Peripheral Neuropathy. Patients with HIV infection may develop peripheral neuropathy, most often in the feet but occasionally in the hands. The neuropathy may range from paresthesia to burning pain, and patients will have a vibratory-sense gradient with decreased sensation in the distal extremity compared to more proximal points. The incidence of peripheral neuropathy increases as HIV disease progresses, but cases are found in patients with well-preserved immune function. Treatment of peripheral neuropathy may include TCAs, pregabalin, gabapentin, or other antiepileptic drugs used to treat neuropathic pain. Opiate analgesics should be used sparingly, and longer-acting agents are preferable, since long-term use of opiates presents the risk of eventual tolerance and dependence. Benzodiazepines are of no use.

Special Issues in HIV

Fatigue. Fatigue is a common symptom in HIV-infected patients, which is often overlooked, improperly assessed, or inadequately investigated. Several authors have commented on the high prevalence of fatigue as a symptom of HIV infection, especially in later stages. Fatigue may be mild and annoying, or it may be severe enough to impair function. Several scales have been published to assess fatigue symptoms and severity. Fatigue is a nonspecific symptom and may have a single or multifactorial etiology. Medical causes include pneumonia, bronchitis, hypothyroidism, hepatitis, heart failure, renal failure, many cancers, and myopathy among others. In a sample of ambulatory patients with AIDS, fatigue is significantly correlated with anemia and pain. In addition to disease causes, patients may present with fatigue as a side effect of medications such as antihypertensives, anticonvulsants, benzodiazepines, antidepressants, narcotic analgesics, antipsychotics, antiemetics, antihistamines, and most importantly for patients with HIV, ARTs. In fact,

Telegram: @medical_k

www.konkur.in

fatigue has been found to be one of the most common side effects of PIs and may be a reason for nonadherence.

Fatigue may also be the result of a psychiatric disorder. Alcohol and substance use disorders may lead to fatigue either related to the use or withdrawal of the substance or as a symptom of demoralization in addicts. Most importantly, fatigue is caused by major depression. Patients with HIV and major depression are much more likely to complain of fatigue than patients without depression. Many depression screening tools, such as the BDI and Hamilton Depression Rating Scale have not been very useful in distinguishing fatigue from major depression usually because fatigue symptoms are present on the screening tools.

In general, the evaluation of a patient complaining of fatigue should include a careful history of its temporal characteristics, severity, and associated symptoms. It should also include careful review of current and recent medications, physical examination, and a mental status examination. The latter should carefully examine for anhedonia, diminished sense of self-worth, guilty feelings, sleep disturbance—especially early morning awakening with inability to return to sleep, appetite changes—a recent, more than 5% change in body weight, thoughts of death or suicide, and impairments in concentration or memory. Certain laboratory studies should also be obtained, including complete blood count, electrolytes, liver function tests, oxygen saturation, and thyroid function tests.

If fatigue is thought to be related to a medical or medication cause, all attempts should be made to treat the illness or modify the medication so as to alleviate the fatigue. In this context, testosterone is a successful treatment of fatigue in HIV-infected men even when depressive symptoms are present. Of course, a clinical major depression should be treated with standard therapies as discussed above. More activating antidepressants such as fluoxetine, escitalopram, venlafaxine XR, or bupropion SR or XL may be better tolerated by fatigued depressed patients. Some authors have reported that dextroamphetamine may be useful in treating fatigue and depression in HIV. Care must be exercised in using stimulants as long-term use may lead to dependence or worsening depression on some cases.

HIV/HCV Coinfection

Telegram: @medical_k

www.konkur.in

Hepatitis C virus (HCV) is a blood-borne pathogen that is currently most commonly transmitted by injection drug use, but may be transmitted sexually, although far less commonly than HIV. Some studies have reported that up to 30% of HIV-infected patients are also infected with HCV in the United States and Western Europe. The natural history of HCV infection in HIV-negative individuals is that 15% of patients clear the infection after the acute phase, while 85% progress to a chronic infection. Hepatic fibrosis develops, often requiring about 10 years to reach significant levels, with cirrhosis following about 20 years from time of infection. Chronic HCV infection is the most common etiology of hepatocellular carcinoma (HCC), which usually develops about 30 years after infection in HIV-negative patients. Unfortunately, HIV infection is likely to make individuals more susceptible to contract HCV if exposed, likely due to immunosuppression and also to cause more rapid progression of liver disease, cutting the above approximate timetable in half (i.e., fibrosis in 5 years, cirrhosis in 10, HCC in 15). The leading causes of mortality in HIV-infected patients are hepatic diseases, most often related to HCV infection.

Chronic hepatitis C is associated with increased rates of depression. In addition, treatment with interferon—ribavirin combinations (previously used) increases risk of major depression and can produce mania. In particular, it appears that interferon-alpha has been associated with depressive syndromes, suicide, and, on rare occasions, mania. Patients with pre-existing depression or bipolar disorder are more likely to develop affective symptoms while receiving the drug, but may not be more likely to stop treatment than patients developing these symptoms de novo. Further, depressive symptoms associated with interferon-alpha have been successfully treated with both SSRIs and TCAs. Because of the development of direct-acting antivirals that target and cure hepatitis C in greater than 90% of patients without the use of interferon, the current preferred antiviral treatment option for most patients includes interferon-free regimens like ledipasvir-sofosbuvir (Harvoni), a combination of an NS5A inhibitor and NS5B inhibitor typically taken for an average of 12 to 24 weeks, depending on severity of disease.

Coinfected HIV/HCV patients should be screened for the presence of psychiatric disturbance like any other patient with HIV, but special monitoring should be performed especially if the patient is being treated with interferon-containing drugs for the purpose of early recognition and

Telegram: @medical_k

www.konkur.in

treatment of affective symptoms. Alcohol hastens the progression of HCV disease and should be strongly discouraged in any amount. Drug use, in general, exacerbates neuropsychiatric symptoms and patients should be stabilized prior, during, and after antiviral treatment.

CONCLUSIONS

HIV and AIDS are conditions intimately linked to psychiatry. In a sense, psychiatric disorders can be seen as vectors of HIV transmission and additionally complicate the treatment of HIV. Also, HIV produces a number of psychiatric conditions and exacerbates many others. The authors have attempted to show the significant comorbidity and links between various types of psychiatric conditions: the way depression exacerbates addiction, the way personality disorder exacerbates addiction, and the way in which addiction exacerbates both personality vulnerabilities and depression. HIV disease is driven by behaviors that are intimately connected with all these conditions.

The authors see the integration of psychiatry into HIV care as a model that psychiatry may apply when interacting with general medicine and the health care system in general. There is abundant data showing the need for presence of psychiatry in every phase of HIV care, and yet, sadly, there is mostly inadequate funding that limits the availability of psychiatric care in HIV clinics.

The authors' experience in caring for patients with HIV is that by developing a comprehensive diagnostic formulation on which to base treatment, especially in an interdisciplinary setting, they have significant success with even challenging clinical scenarios. The authors' formulation includes disease syndromes such as major depression and schizophrenia, personality vulnerabilities such as unstable extraversion, substance use disorders/addiction, and problems with life experience such as trauma and trust issues. Each problem has the potential to sabotage treatment for all the remaining conditions. The treatment plan must be comprehensive in scope in order to address the whole person.

ACKNOWLEDGMENTS

The authors would like to gratefully acknowledge the contribution by Dr Joyce E King whose suggestions and edits were essential to this chapter.

2.9 Neuropsychiatric Aspects of Other Infectious Diseases (Non-HIV)

JESSICA HARDER, M.D., RISHAB GUPTA, M.B.B.S., M.D., RUTH MCCANN, M.D., AND IRENE GONSALVEZ, M.D.

Infectious disease represents a critical and yet often overlooked contributor to nervous system malfunction and neuropsychiatric symptoms. All major classes of infectious agents, including viruses, fungi, bacteria, protozoa, and helminths can have neuropsychiatric manifestations, whether via direct neurotropism, associated immune or vascular processes, or some combination (Table 2.9–1). This chapter will address some of the infectious conditions with the most prominent central nervous system (CNS) effects (with the exception of HIV/AIDS and prion disease which are addressed separately).

VIRUSES

COVID-19

Epidemiology. COVID-19, or coronavirus disease 2019, is a viral illness caused by severe acute respiratory syndrome coronavirus 2, or SARS-CoV-2. SARS-CoV-2 is a positive-sense, single-stranded RNA virus, belonging to the family *Coronaviridae* (see Table 2.9–1). The first case of this disease was reported from Wuhan, China in December 2019, and it was declared a global pandemic by March 2020. At the time of this writing, it had infected 380 million people worldwide, killing 5.6 million of them. The United States has been one of the worst affected countries by this virus, with more than 75 million people being infected and more than 885,000 deaths.

Pathophysiology. Despite vigorous research efforts, the pathology of COVID-19 is still not fully understood. SARS-CoV-2 is known to enter various cells of the body, mainly in the upper and lower respiratory tract

Telegram: @medical_k

www.konkur.in

epithelium and endothelium via angiotensin-converting enzyme 2 (ACE-2) receptors, which have moderate to high expression in a wide variety of tissues throughout the body. Despite being a vital entry point for SARS-CoV-2, ACE-2 expression does not account for the significant interindividual variability in the clinical presentation and outcomes seen in the patients. SARS-COV-2 quickly replicates in the infected cells, causing cellular damage directly, and indirectly via generalized inflammation, and through alterations in blood supply via endothelial dysfunction. In some patients, it also leads to a cytokine storm, an aggressive, systemic inflammatory response, sometimes leading to multiorgan dysfunction. SARS-CoV-2 is known to affect nearly every major organ in the body, including the lungs, heart, brain, kidneys, GI system, and skin. ACE-2 receptors are expressed at low levels in neurons, but they are highly expressed in the pericytes, which are derived from neural crest stem cells, physically connect endothelial cells and astrocytes, and help to maintain the blood–brain barrier. SARS-CoV-2 RNA has been found in human brain tissues and the viral proteins have been detected in the endothelial cells within the olfactory bulb among the patients who died due to COVID-19. Converging evidence for the direct neuroinvasion is slowly emerging from the human brain organoid (self-organizing, 3D cell cultures that histologically resemble the human brain) models, mouse models, and human autopsy studies. Direct neuroinvasion may lead to local hypoxia and vessel dysfunction, which, in turn, may lead to ischemic infarcts and enhance the susceptibility of local regions to viral invasion. A recent study using human brain organoid demonstrated that pericytes may act as “trojan horses,” carrying the virus to the neurons and glia. Various other mechanisms through which the virus may enter the brain are through a leaky blood–brain barrier, direct penetration through olfactory neurons, and axonal retrograde transport of the viral particles through nerve fibers. Cytokine increase and microglia activation lead to increased kynurenine, quinolinic acid, and glutamate, and reduction of monoamines and neurotrophins. These are some biochemical underpinnings of how COVID-19 may lead to occurrence of new-onset neuropsychiatric symptoms or exacerbate preexisting neuropsychiatric disorders.

Clinical Presentation. Clinical severity of COVID-19 is quite variable, ranging from asymptomatic infection to acute respiratory distress syndrome (ARDS). In more than 90% of the patients, COVID-19 presents

Telegram: @medical_k

www.konkur.in

with a mild upper respiratory or a flu-like illness, with fever, cough, malaise, nasal congestion, sore throat, myalgias, arthralgias, fatigue, anosmia, ageusia, and headaches, with shortness of breath seen in moderate to severe cases (around 15–20% of cases). Some patients present with GI symptoms, like nausea, vomiting, abdominal pain, and diarrhea. A large number (up to 40%) of patients may develop rashes. It has protean clinical manifestations due to its ability to affect practically any organ system. Among patients hospitalized due to COVID-19, relatively common extrapulmonary complications include delirium (55%), hepatic dysfunction (characterized by transaminitis, hyperbilirubinemia, seen in 14% to 53%), venous thromboembolism (31% to 40%), heart failure (23%), myocarditis (8% to 28%), arrhythmias (16%), acute renal failure (1% to 46%). Some of the infrequently reported extrapulmonary presentations associated with COVID-19 are myocardial infarction (0.33%), ischemic stroke (0.86% to 1.3%), encephalitis, seizures, neuropathy, myopathy, Guillain–Barré syndrome, coagulopathy, and precipitation or worsening of diabetes mellitus or thyroid dysfunction. In around 5% of patients, initial respiratory symptoms complicate into a severe disease, requiring oxygenation, ICU admission, mechanical ventilation, and sometimes, intubation. Between 0.1% and 10% of people infected with COVID-19 die, with the variability explained by patients' age, sex, comorbidities, ethnicity, and quality of and access to healthcare.

There seems to be a strong relationship between COVID-19 and psychiatric disorders. Available literature demonstrates a bidirectional relationship between the two, such that COVID-19 increases the risk of various psychiatric illnesses and the latter increases the risk of COVID-19 infection and associated mortality. In a study utilizing a nationwide database of electronic health records of 61 million adult patients across all 50 states in the United States, patients recently diagnosed with a mental disorder had an elevated risk for COVID-19 infection. This effect was strongest for those diagnosed with depression and schizophrenia. Female sex and African American ancestry were important covariates in this relationship. COVID-19 infection among those with a recent psychiatric illness diagnosis was associated with higher death rate and hospitalization rate compared to those with no psychiatric disorder. Similarly, patients with dementia are more vulnerable to SARS-CoV-2 infection and are more likely to develop severe disease compared to other individuals.

Table 2.9–1. Infectious Diseases with Neuropsychiatric Manifestations

Disease	Infectious Agent	Mode of Infection	Incidence	Typical Neuropsychiatric Symptoms	Diagnosis
VIRUSES					
COVID-19	RNA Virus, *Coronaviridae* family (SARS-CoV-2)	Inhalation; droplet and airborne spread	Variable; 380 million people worldwide affected so far	Delirium, depressive symptoms, anxiety symptoms, PTSD symptoms, insomnia, fatigue, cognitive symptoms; rarely, psychosis, catatonia, mania	RT-qPCT assay from nasal swab
Chikungunya	RNA Virus, *Togaviridae* family (Chikungunya virus)	*Aedes* mosquito bite	Wide variability across countries; >200,000 cases in 2021 (mostly from Brazil and India)	Encephalitis, encephalopathy in adults Meningoencephalitis, developmental delay in affected neonates	Clinical syndrome, ± RT-PCR (week 1), ELISA for IgM antibodies later
Western equine encephalitis (WEE)	RNA virus, *Togaviridae* family (WEE virus)	*Culex* mosquito bite	1–2 cases per year in the United States, rarely occurs in the rest of countries in the Americas	Encephalitis (worse in infants)	Detection of serum IgM antibodies
Eastern equine encephalitis (EEE)	RNA virus, *Togaviridae* family (EEE virus)	*Aedes, Coquillettidia, Culex* mosquito bite	About 11 cases per year in the United States	Encephalitis, seizures	Detection of CSF or serum IgM antibodies
Dengue fever	RNA virus, *Flaviviridae* family (Dengue virus)	*Aedes* mosquito bite	100–400 million cases estimated per year, worldwide	Postinfection persistent fatigue, intracerebral hemorrhage, ischemic stroke, encephalitis, Guillain–Barré syndrome, cranial neuropathy. Rarely, psychosis and mania have been associated	Detection of serum antidengue-virus IgM antibodies, serum NS-1 antigen assay
Powassan virus disease	RNA virus, *Flaviviridae* family (Powassan virus)	Hard ticks, *Ixodes scapularis* and *Ixodes cookie* bite	Rising over time, 100 cases reported between 2003–2018 in the United States	Encephalitis	ELISA to exclude negative samples and followed by more specific, Plaque Reduction Neutralization Test, to confirm the exposure
West Nile virus (WNV) disease	RNA virus, *Flaviviridae* family (WNV)	*Culex* mosquito bite	1,000–2,000 cases per year in the United States	Meningitis, encephalitis	Detection of WNV-specific IgM antibodies in CSF or serum
Rabies	RNA virus, *Rhabdoviridae* family (Rabies virus)	Dog bite in endemic regions; in the United States, exposure to aerosols from racoons and bats	Around 60,000 deaths per year, worldwide	Encephalitis, acute anxiety and psychosis-like symptoms, hydrophobia, Guillain–Barré-like symptoms, cranial neuropathy, seizures, abnormal movements	Detecting viral RNA by hemi-nested RT-PCR from saliva, CSF, urine, or hair follicles
Herpes simplex virus encephalitis (HSVE)	DNA virus, *Herpesviridae* family (primarily herpes simplex virus-1)	Exposure is endemic; viral DNA becomes integrated into host cell and remains latent; encephalitis may occur with latent or reactivated infection	Estimated 2.2 cases per million population per year	Protean manifestations acutely, including mood lability, irritability, agitation, mania, psychosis, amnesia, apathy, and catatonia. Long-term sequelae include depression, anxiety, memory impairment, and other cognitive deficits	CSF PCR
Mononucleosis	DNA virus, *Herpesviridae* family (Epstein–Barr virus [EBV], or human herpesvirus 4 [HHV-4])	Human saliva, transfusion/ transplant, possibly also breastfeeding and sexual transmission. Can reactivate	Highest incidence in late adolescence/ early 20s. ~90–95% of adults worldwide have EBV antibodies	Fatigue, depressed mood (~28%), uncommonly meningitis/encephalitis	Heterophile antibody test (first-line) or EBV-specific antibody test

Telegram: @medical_k

www.konkur.in

Cytomegalovirus (CMV) infection	DNA virus, *Herpesviridae* family (CMV or human herpesvirus 5 [HHV-5])	Close contact with children, transfusion/ transplant, sexual transmission, perinatal transmission. Can reactivate	About 1.6 cases per 100 U.S. adults (ages 12–49) per year. Between 30–40,000 U.S. infants per year affected by congenital CMV.	Congenital CMV: Developmental delay, seizures, inattention, hyperactivity. CMV in immunocompromised adults: Encephalitis, meningitis	PCR (serum, CSF). In congenital CMV: Urine/ saliva PCR, prenatal ultrasound
HHV-6 infection/ Roseola infantum	DNA virus, *Herpesviridae* family (Human herpesvirus 6 [HHV-6])	Saliva, transplant (rarely), prenatal transmission. Can reactivate	Common in early childhood; over 70% of adults in developed countries have antibodies	In immunocompromised patients: Encephalitis, delirium, inattention	In adults: PCR (plasma, CSF). In children: clinical diagnosis
Measles (Rubeola)	RNA virus, *Paramyxoviridae* family (measles morbillivirus)	Airborne and droplet transmission, person-to-person contact, vertical transmission	49 cases in the United States in 2021, more in developing countries	In ADEM: confusion, seizures, psychosis. In SSPE: behavior change, seizures, dementia	Measles antibodies, CSF (lymphocytic pleocytosis/ elevated protein, measles IgM)
Rubella (German measles)	RNA virus, *Matonaviridae* family (rubella virus)	Airborne and droplet transmission, vertical transmission	Less than 10 cases in the United States per year, more in developing countries	Autism, aggression, impulsivity, self-injury (later childhood manifestations of congenital Rubella)	Rubella IgM
Influenza viruses	RNA viruses, *Orthomyxoviridae* family	Droplet transmission, contact with contaminated surfaces	About 35 million cases in the United States in 2019–2020 season	Encephalitis, aseptic meningitis, ADEM (in children)	RT-PCR or rapid antigen tests on respiratory specimens
Zika	RNA virus, *Flaviviridae* family (Zika virus)	Mosquito bites, vertical transmission, sexual contact	57 cases in the United States territories in 2020	Adults: Meningoencephalitis Congenital: Microcephaly, developmental delay, seizures	RT-PCR (serum, urine)
BACTERIA					
Listeriosis	Aerobic Gram-positive rod (facultatively anaerobic) (*Listeria monocytogenes*)	Ingestion of contaminated soil or food (unwashed produce, soft cheese), vertical transmission	~0.29 per 100,000 people per year in the United States, higher among pregnant and older adult individuals	Meningoencephalitis. Sequelae of neonatal infection: Cognitive impairment, behavioral problems, depression, anxiety	Blood cultures and stool studies (in pregnant women), CSF culture (if concern for meningitis/ encephalitis)
Syphilis	Spirochete bacteria (*Treponema pallidum*)	Sexual contact, vertical transmission	~7 million people with new syphilis infection in 2020 worldwide; variable surveillance for neurosyphilis worldwide leads to unclear incidence, however, estimated annual prevalence in United States between 0.8–2.5%	Early neurosyphilis: syphilitic meningitis/ meningovascular meningitis, personality change, emotional lability, insomnia, and poor memory. Late neurosyphilis: tabes dorsalis, general paresis, syphilitic gummas, cognitive deficits, speech disorder, headache/ dizziness, facial/ tongue tremor, epileptic seizures, dementia	Serologic and CSF tests: VDRL, RPR
Lyme disease	Spirochete bacteria (*Borrelia burgdorferi sensu lato*, *B. afzelii*/*B. garinii* [Europe, Asia]; *B. burgdorferi sensu stricto* [United States])	Transmitted by *Ixodes* species ticks bite	~476,000 cases are diagnosed and treated per year in the United States and >200,000 cases per year in Western Europe	Early neurologic symptoms: facial nerve palsy, headache, lymphocytic meningitis, motor/ sensory radiculoneuritis, encephalitis Neuropsychiatric symptoms: Depression, irritability, insomnia, cognitive problems, psychosis, mania, or dementia	Two-tiered serology/ CSF protocol: 1. ELISA 2. Western Blot

Telegram: @medical_k

www.konkur.in

Leptospirosis (Weil Disease)	Spirochete bacteria (*Leptospira*)	Direct or indirect contact with the urine, blood, and tissues of infected animals; Can occur via mucosal surfaces or damaged skin exposed to contaminated soil or water	0.5–1 million infections annually worldwide	Aseptic meningitis (most common); Also, encephalitis, myelitis, encephalomyelitis Intracranial bleeds, cerebellitis, movement disorders, flaccid paraplegias, mononeuritis, neuralgias, autonomic lability, polymyositis	Confirmed exposure+ Clinical findings– Lab testing: MAT-gold standard ELISA PCR Dark-field microscopy Blood culture
Sydenham chorea	Anaerobic gram-positive bacteria (*Streptococcus pyogenes* [Group A beta-hemolytic streptococcus])	Upper respiratory tract (streptococcal pharyngitis) leading to autoantibody production	Up to 40% of patients with rheumatic fever (RF); RF incidence is 8 to 51 per 100,000 people worldwide	Choreoathetoid movements (St. Vitus dance), hypotonia, behavioral problems, and OCD symptoms	Clinical diagnosis
PANDAS	Anaerobic gram-positive bacteria (*Streptococcus pyogenes* [Group A beta-hemolytic streptococcus])	Autoimmune response to streptococcal infection	Prevalence unknown; estimated by one group to be 1:200 children in the United States	Obsessive-compulsive symptoms, tics (remitting- relapsing pattern). Cognitive decline and behavioral changes (irritability, aggression), behavioral regression.	Clinical diagnosis; five clinical criteria required for diagnosis (history of streptococcal infection required)
MULTIPLE ETIOLOGIC ORGANISMS					
PANS	Multiple infectious agents, including *Mycoplasma*, influenza, varicella, and *Borrelia*	Autoimmune response associated with multiple infectious agents	Prevalence unknown; estimated by one group to be 1:200 children in the United States	Obsessive-compulsive symptoms, restrictive eating, tics, cognitive decline, behavioral changes/regression.	Clinical diagnosis; history of infection does not have to be proven to diagnose PANS
PROTOZOA					
Malaria	Protozoa (*Plasmodium*, including *P. vivax*, *P. ovale*, *P. malariae*, *P. knowlesi*, *P. falciparum*)	Bite of the *Anopheles* mosquito	Estimated 240 million cases per year worldwide; increased risk for cerebral malaria in the immunocompromised	Cerebral malaria, marked by encephalopathy, seizures, alterations in consciousness, retinal hemorrhages; survivors may have persistent cognitive deficits, behavioral problems, seizures, deafness, blindness; postrecovery autoimmune encephalitis may occur	Blood smear microscopy
Human African Trypanosomiasis	Protozoa (*Trypansoma brucei*)	Bite of the tsetse fly; vertical mother-to-child transmission; sexual transmission	Declining; <1,000 reported cases in 2019	Prominent sleep disturbance with daytime somnolence, seizures, cognitive decline, personality change, sensory disturbance, psychosis	Trypanosome identification in blood or CSF on microscopy
Toxoplasmosis	Protozoa (*Toxoplasma gondii*)	Accidental ingestion of food and water contaminated with the protozoa oocysts, transplacental	Around one-third of the world's population is infected	Symptomatic in immunocompromised, encephalitis, seizures, abnormal movements, psychosis, cognitive deficits; congenital infection causes hydrocephalus, intellectual disability	Serum or CSF PCR, CT head or MRI brain for cerebral toxoplasmosis
Primary amoebic meningoence-phalitis (PAM)	Amoeba (*Naegleria fowleri*)	Freshwater recreation, inhaled water	Rare (~2.6 cases per million exposures)	Altered mental status, behavioral changes	Trophozoites observed in CSF

Telegram: @medical_k

www.konkur.in

Granulomatous amoebic encephalitis	Amoeba (*Acanthamoeba* in immunocompromised, *B. mandrillaris* in immunocompetent)	Soil or freshwater exposure	Rare	Visual disturbances, behavioral changes, focal neurology deficits	Trophozoites and cysts on brain biopsy
HELMINTHS					
Neurocysticercosis	Pork Tapeworm (*Taenia solium*) larvae	Fecal-oral route via close contact with a *T. solium* carrier excreting *T. solium* eggs in their feces	Serum antibodies in >10% of the developing world	Seizures, encephalitis, hydrocephalus, cognitive deficits	CT head/MRI brain; serology to confirm diagnostically challenging cases
FUNGI					
Mucormycosis	Fungus (*Mucorales*)	Opportunistic infection among immunocompromised, through airborne fungal spores	Wide variability across countries, from 0.02 per 100,000 in the Philippines to 14 per 100,000 in India	Stroke, intracranial hemorrhage, brain abscess	Demonstration of fungal hyphae in scrapings or biopsy of affected tissue

COVID-19 has increasingly been shown to have various neuropsychiatric complications, including new-onset depression, anxiety, psychosis, PTSD symptoms, chronic fatigue, and dysexecutive syndrome. A recent, large sample (N = 62,354) study among COVID-19-positive patients assessed the incidence and risk for psychiatric disorders during the first 14 to 90 days after COVID-19 diagnosis. The recovering patients had a significantly higher rate of psychiatric disorders, with a 5.8% probability of being newly diagnosed with a psychiatric illness within 90 days post-COVID-19 diagnosis. The most frequently acquired psychiatric diagnoses were anxiety disorders and trauma-related disorders, with a probability of occurrence of 4.7% within 90 days. Adjustment disorder, generalized anxiety disorder (GAD), PTSD, and panic disorder were the most frequent. Occurrence of a new mood disorder diagnosis (mostly depressive disorder) within 14 to 90 days after COVID-19 was 2%. The risk of new-onset psychiatric illness was higher among those with more severe COVID-19 disease, but it remained significantly elevated even after controlling for the disease severity.

A cross-sectional study of 402 adult COVID-19 survivors of varying time out from illness found the prevalence of PTSD symptoms, anxiety, and obsessive-compulsive symptoms to be 28%, 42%, and 20%, respectively, using self-rated questionnaires. A major limitation of most studies assessing neuropsychiatric disorders among COVID-19 survivors has been their reliance on standardized questionnaires (mostly self-report) to assess psychiatric disorders instead of using clinical interviews. There are a few reports of new-onset psychosis and mania emerging in the context of COVID-19 infection, but so far, the evidence for increased risk of psychosis or mania due to COVID-19 is very limited. Some studies have

Telegram: @medical_k

www.konkur.in

found increased risk of suicidality and suicidal behavior among patients with COVID-19, but the evidence is still inconclusive.

It is yet to be determined whether some of the aforementioned psychiatric syndromes are due to the neurobiologic effect of the virus or occur as a psychological reaction to the life-threatening complications of COVID-19. Most studies assessing cognitive deficits after COVID-19 infection have employed small sizes and have not undertaken comprehensive cognitive assessment. Some studies have not controlled for the recent severe medical complications due to COVID-19, including ARDS, which may be independently associated with cognitive deficits. Nonetheless, many of them have highlighted deficits in sustained attention.

As COVID-19 is being researched more thoroughly, both clinicians and researchers are taking note of persistent neuropsychiatric sequelae in the form of a loosely described syndrome termed “long-haul COVID,” “long COVID” or more formally, post-acute sequelae of COVID (PASC). Some of the symptoms attributed to PASC include fatigue, dyspnea, brain fog, subjective cognitive symptoms like poor concentration and memory, fever, GI symptoms, headache, sleep impairment, anxiety, and depression. These symptoms may last for months, and vary in their severity, from mild to debilitating. A smartphone app-based prospective, observational multinational study of over 4,000 patients found that 13% had symptoms lasting ≥28 days, 5% for ≥8 weeks, and 2% for ≥12 weeks. Long COVID was characterized by fatigue, headache, shortness of breath, and anosmia. Its risk factors were increasing age, high BMI, and female sex. Having >5 symptoms during the first week of illness was also associated with long COVID.

A 1-year prospective cohort study was conducted at a single center in Wuhan, China among COVID-19 survivors (laboratory-confirmed diagnosis) who had required hospitalization and age, sex, and comorbidity-matched controls. Most survivors recovered functional status; 88% of previously employed participants returned to work. However, sequelae including fatigue, sleep difficulty, hair loss, anosmia, palpitations, arthralgia, low appetite, dysgeusia, dizziness, diarrhea, vomiting, chest pain, sore throat, rash, myalgia, headache, and lung diffusion impairment persisted for 12 months in some patients, especially in those who were critically ill. Anxiety or depression symptoms were more frequently seen at 12-month (26%) than 6-month (23%) follow-up. This increase in

Telegram: @medical_k

www.konkur.in

psychiatric symptoms may be multifactorial in etiology, with contributions from persistent dysimmune response as well as psychosocial complications of severe COVID-19 disease like social isolation, loss of employment, and poor physical health.

Diagnosis. The most commonly performed diagnostic test for COVID-19 infection is the detection and quantification of viral RNA using reverse transcriptase-polymerase chain reaction (RT-qPCR) assay. It is highly sensitive and specific, and detects early infection as well. Antibody testing using ELISA and antigen detection may be employed to get rapid results. CT chest may indicate the presence of lung involvement. More recently, CRISPR-based nucleic acid detection has been used by some laboratories. To diagnose the neuropsychiatric complications of COVID-19, clinical assessment is the gold-standard. Comprehensive assessment, including routine blood counts and chemistries, thyroid hormone assay, EEG, and CT head or MRI brain should be done to rule out the presence of any other underlying causes. A lumbar puncture for CSF studies may be warranted depending on the clinical presentation.

Management. Disease prevention methods using vaccines, social distancing measures, and the use of surgical masks and N95 respirators have been found to be very effective in reducing the spread of infection at both the individual level and in the community setting. Of the variety available, including mRNA vaccines, DNA vaccines, viral vector vaccines, and inactivated virus vaccines, mRNA vaccines have been shown to be the most effective.

Most patients either remain asymptomatic or develop mild disease which subsides spontaneously or with symptomatic treatment, including antipyretics, anti-inflammatory drugs, antitussives, and bronchodilators. Those with moderate to severe disease may require inhalational and/or systemic steroids, oxygen therapy, ICU care, and mechanical ventilation. The US FDA has approved remdesivir for the treatment of COVID-19 requiring hospitalization for those 12 years and above and weighing at least 40 kg. In addition, the IL-6 receptor antagonist tocilizumab and the JAK (Janus kinase) inhibitor baricitinib have been approved for certain hospitalized adults with COVID-19. An antiviral combination of nirmatrelvir and ritonavir, called Paxlovid, is US FDA-approved to treat mild-moderate COVID-19 in adults at high risk for progression to severe COVID-19, including hospitalization or death. High-dose steroids used to treat

Telegram: @medical_k

www.konkur.in

COVID-19 can be lifesaving but may increase the risk of neuropsychiatric disorders including delirium, psychosis, mania, and depression as well as increasing susceptibility to infections.

There are no specific treatments available for the neuropsychiatric complications of COVID-19. Depressive and anxiety syndromes have been treated by a combination of antidepressants and psychotherapy. For psychotic or manic symptoms, one may use antipsychotics or a mood-stabilizing drug. So far, no treatment trials have been performed to address the cognitive symptoms associated with COVID-19. It is conceivable that they will respond to cognitive rehabilitation and regular physical activity, based on the efficacy of these approaches in other conditions (e.g., the benefit of cognitive rehabilitation in HIV/AIDS). It will be extremely important to conduct systematic studies on the neuropsychiatric complications, particularly suicidality, associated with COVID-19 to understand its true psychological burden on the survivors. In a similar vein, it is critical to investigate PASC, considering that it may become the next “pandemic” once the COVID-19 pandemic subsides.

There is burgeoning literature on the higher risk of severe COVID-19 disease and resultant mortality among patients with Alzheimer disease (AD), and other dementias. On the other hand, it is unknown whether having COVID-19 increases the risk of neurodegeneration and occurrence of dementia. Based on the neurobiologic changes seen in COVID-19 (for example, elevated IL-6 levels) that are known to be associated with hippocampal atrophy, microglial activation, and vascular damage, and a few cases of new-onset parkinsonism occurring in the context of COVID-19 infection, several experts have speculated that COVID-19 infection may trigger neurodegenerative diseases such as Alzheimer and Parkinson in some vulnerable patients.

Mucormycosis: An Opportunistic Fungal Infection in the Setting of COVID-19. Mucormycosis is an opportunistic and potentially fatal fungal infection caused by fungi of the order Mucorales (see Table 2.9–1). These ubiquitous pathogens are saprobes, found in soil and decaying matter, and spread through spores that become airborne. Blood vessel invasion causes thrombosis due to endothelial injury, leading to infarction and necrosis of different tissues. Infection mainly affects immunocompromised patients, especially those with diabetes mellitus, prolonged corticosteroid use, organ transplant recipients, neutropenia, and hematologic cancers.

Telegram: @medical_k

www.konkur.in

Severe manifestations like rhino-orbital mucormycosis have a very poor prognosis, with a mortality rate of 50% despite appropriate treatment.

Affected individuals often develop fever, nasal congestion, purulent nasal discharge, and headache initially. If not treated early, contiguous spread to adjacent structures like the orbit may occur. Intracranial spread can occur through the cribriform plate, supraorbital fissure, and perineural routes. Cavernous sinus or sagittal sinus thrombosis, carotid occlusion, cerebral infarction, intracranial aneurysm, intracranial hemorrhage, and cerebral abscesses are potential complications.

Prevalence varies across countries, from 0.02 per 100,000 in the Philippines to 14 per 100,000 in India. Various countries have reported mucormycosis associated with COVID-19, including the United States, but in India it has reached epidemic proportions, affecting 1.8% of patients with COVID-19 admitted to tertiary care centers. SARS-CoV-2 impairs cell-mediated immunity via decreases in $CD4^+$ and CD8+ cell counts, thereby increasing the risk of fungal infections. In one study of mucormycosis after COVID-19, the mortality rate was over 23%. Comorbid medical conditions including diabetes mellitus, diabetic ketoacidosis, and ARDS, and the use of corticosteroids and broad-spectrum antibiotics are additional risk factors. Of those affected, almost 90% had developed moderate-to-severe pneumonia, and over 40% had required invasive ventilation in one study; all were given steroids and broad-spectrum antibiotics. On average, 12 days elapse between COVID-19 diagnosis and the onset of symptoms (most common symptom being nasal congestion with or without discharge) suggestive of mucormycosis. Men seem to have a higher risk than women. The average age of affected patients is 55 years.

The infection is diagnosed by demonstrating the presence of fungal hyphae (nonseptate, broad-based hyphal structures with 90-degree branching), by direct examination in scrapings and biopsy of the affected tissue. Imaging modalities like CT and/or MRI of the orbit, brain, and/or paranasal sinuses can be used in suspected cases of rhino-orbital disease. It is treated using systemic antifungals such as amphotericin B, posaconazole, and isavuconazole and surgical debridement of the necrotic tissue.

Alphaviridae

Telegram: @medical_k

www.konkur.in

The *Alphaviridae* genus of the *Togaviridae* family includes several viruses known to be pathologic and neurotropic in humans, including Chikungunya virus, Eastern equine encephalitis (EEE) virus, Western equine encephalitis (WEE) virus, and Venezuelan equine encephalitis virus. Several of these are addressed below.

Chikungunya. Chikungunya is an enveloped, positive-sense, single-stranded RNA arbovirus, spread by the *Aedes* mosquito (see Table 2.9–1). Since being first described in 1952 in Tanzania, this virus has spread across the world and into other mosquito vectors. It is predominant in Africa, Asia, including the Indian subcontinent, and in recent years, Europe and the Americas (especially Caribbean countries, Brazil, and Colombia) have also been affected.

The virus appears to enter the CNS via the choroid plexus, but the extent to which it affects neurons and astrocytes is unknown.

Most (72% to 95%) patients develop symptoms, mainly fever and arthralgias, along with headache, fatigue, myalgias, joint swelling, rash, and GI symptoms. Some patients develop chronic disease leading to arthralgias lasting for several weeks to months, mimicking rheumatoid arthritis. Neurologic complications occur in the acute phase in approximately 0.1% of the cases, mostly encephalitis and encephalopathy. Apart from that, it may also lead to myelopathy, acute flaccid paralysis, meningoencephalitis, Guillain–Barré syndrome, uveitis, retinitis, and optic neuritis.

Vertical transmission from a mother to child does occur at a rate of about 50% for both vaginal and cesarean deliveries; antepartum fetal infections do not occur as the virus does not cross the placenta. Symptomatic newborns develop severe typical symptoms of the disease, including fever and arthralgia, rashes, and can have shock and hemorrhage, as well as occasionally meningoencephalitis and long-term neurodevelopmental delays. One study of apparently asymptomatic infected children of mothers who had Chikungunya infection during pregnancy demonstrated significantly worse neurocognitive functioning compared to uninfected children, and survivors of symptomatic neonatal infections have high rates of neurodevelopmental delay (51% in one study). Diagnosis is typically made based on clinical suspicion in endemic regions. RT-PCR is highly specific but sensitive mainly in the first week of infection. After that, paired ELISA may be used to detect a four-fold rise in

Telegram: @medical_k

www.konkur.in

anti-CHIKV IgM antibodies to make a diagnosis. Treatment is supportive. Survivors of Chikungunya encephalitis have 17% to 43% rates of persistent neurologic sequelae (cognitive deficits, epilepsy, language impairment).

Western Equine Encephalitis. WEE is caused by WEE virus, a positive-sense, single-stranded RNA virus, which is transmitted by *Culex* mosquitoes (see Table 2.9–1). Up till the mid-20th century, it led to huge outbreaks of encephalitis in the United States. Fortunately, and mysteriously, its incidence has reduced drastically over the years, ascribed to reduction in the rural population. Its annual incidence in the last two decades has been one to two cases. Humans and horses are its dead-end hosts. Its incubation period is 1 to 2 weeks. It mostly causes a subclinical infection. In its severe form, WEE manifests with fever, vomiting, headache, neck stiffness, and altered sensorium; some patients may develop tremors. Some develop coma, that can last for up to 4 days, and coma duration predicts the severity of neurologic sequelae. Acute illness lasts up to 2 weeks. Infants are hit the hardest as the infection leaves them with cognitive, behavioral, motor deficits, and seizures. Overall, disease mortality is below 5%. CSF shows the typical profile of viral infection with lymphocytic pleocytosis after the first two days, normal or elevated protein, and normal glucose. EEG findings are usually nonspecific. Diagnosis is confirmed using serology. Management of acute cases is supportive since there are no effective antiviral agents known. A vaccine is available for persons at occupational risk of acquiring the infection (i.e., laboratory workers studying the virus).

Eastern Equine Encephalitis. About 11 cases of EEE are reported annually in the United States, with cases mostly in Atlantic and Gulf Coast regions. It is caused by EEE virus and is transmitted by *Aedes, Coquillettidia, and Culex* mosquitoes (see Table 2.9–1). Infection has a 30% mortality rate, making it the deadliest arboviral infection in the United States. EEE virus causes more severe disease in older adults and children, and asymptomatic cases are uncommon. It mainly affects basal ganglia, thalami, substantia nigra, cerebral cortex, and the hippocampus, and may also involve adjacent white matter. Incubation period is 3 to 10 days, with a prodromal phase characterized by fever, headache, and abdominal distress. Some patients experience rapid deterioration with high-grade fever, delirium, vomiting, focal neurologic signs, and seizures.

Telegram: @medical_k

www.konkur.in

A vast majority (~70%) of the patients develop coma within two days of hospitalization; as above, approximately one-third of patients die, and another one-third become severely disabled. On exam, patients manifest fever, leukocytosis with neutrophilia, and hyponatremia. CSF also shows neutrophilia. MRI shows basal ganglia and thalamic involvement in most patients. Some patients have the "parenthesis sign," linear hyperintensities on T2/FLAIR in the external and internal capsules with sparing of the lentiform nuclei. Detecting IgM antibodies in the serum or CSF is used to make a confirmatory diagnosis. CSF PCR is another method employed. Treatment is supportive, as no specific treatments are available against this infection.

Dengue

Dengue fever is caused by the dengue virus, a single-stranded, positive-sense RNA virus belonging to the *Flaviviridae* family, transmitted by *Aedes* mosquitoes (see Table 2.9–1). It has four serotypes. It is endemic in >100 countries in the tropical/subtropical climate range. In the United States, Florida, Texas, and Hawaii have witnessed recent outbreaks, and it regularly occurs in the U.S. territories of Puerto Rico, Virgin Islands, and Samoa. Its global incidence has increased by 30 times in the last five decades. An estimated 100 to 400 million cases of dengue infection occur annually worldwide. The incubation period is 4 to 8 days. Most infections are asymptomatic or subclinical, and symptomatic disease often manifests with self-limiting flu-like symptoms. Dengue is also associated with the cytokine storm phenomenon. Only a small proportion of the patients develop a severe disease, usually after being infected for the second time. Severe disease manifests with plasma leakage, and hypovolemic shock may set in, leading to multiorgan dysfunction, disseminated intravascular coagulopathy, and severe bleeding. It may also be complicated by hepatitis, neurologic involvement, and myocarditis. Untreated severe disease can lead to mortality in up to 20% of the cases. Various neurologic presentations associated with dengue include intracranial bleeding, ischemic stroke, encephalitis, Guillain–Barré syndrome, and isolated cranial nerve damage. Case reports and case series have described neuropsychiatric complications like mania and acute psychosis following dengue infection. More than 50% of patients (two-third women and one-third men) may experience persistent symptoms (arthralgia, fatigue, etc.) for up to 2 years after the resolution of acute infection.

Telegram: @medical_k

www.konkur.in

Infection with one serotype provides lifelong immunity against that strain but renders partial and temporary crossimmunity to other serotypes. Subsequent infections by other serotypes increase the risk of severe disease.

Presence of serum antidengue-virus IgM antibodies indicates active infection. Alternatively, serum NS-1 antigen assay may be used as a rapid diagnostic test. RT-PCR can detect the virus within the first week of illness.

There are no specific treatments or prophylactic agents available. Symptomatic patients are managed conservatively. At present, the key strategy remains mosquito control. A vaccine exists for children with previous infection living in endemic areas.

Powassan Virus Disease

Powassan virus disease is caused by the Powassan virus, a positive-sense, single-stranded flavivirus, mainly transmitted by hard ticks, *Ixodes scapularis* and *Ixodes cookie* (see Table 2.9–1). It is mostly reported from North America and Eastern Russia. It has seen a dramatic rise over the last two decades in the United States (with over 100 cases reported between 2003 and 2018), attributed to proliferation of *I. scapularis* ticks and its reproductive host, the white-tailed deer, in the northeastern and midwestern United States. It has been increasingly affecting middle-aged and older adults. The incubation period ranges from 1 to 5 weeks. Severe cases develop encephalitis, which may be complicated by seizures, paralysis, and coma. Significant neurologic disability occurs in around half of the severe cases, with mortality risk of around 10%. It's unclear what proportion of the infections comprises severe disease, since nonsevere cases may go undetected. CSF may show pleocytosis and elevated protein. MRI findings are nonspecific, showing T2/FLAIR hyperintensities in the brainstem, basal ganglia, and thalami. Diagnosis involves ELISA to exclude negative samples and then using a more specific assay, Plaque Reduction Neutralization Test, to confirm the exposure. Treatment of infected cases is mainly supportive.

West Nile Encephalitis

West Nile Encephalitis is caused by West Nile Virus (WNV) which is an enveloped positive-stranded RNA virus of the family *Flaviviridae* (see Table 2.9–1). It was first isolated from a febrile patient in the West Nile

Telegram: @medical_k

www.konkur.in

district of Uganda in 1937. The virus has a wide geographical distribution, including southern Europe, Africa, central and south Asia, and Oceania. WNV has become endemic in all 48 contiguous states in the United States, and Canada since its discovery in North America in New York City in 1999. The annual number of reported WNV disease cases can fluctuate widely due to periodic epidemics, with most cases reported in the summer-fall season (July through September).

Although the virus infects a wide variety of animals, including horses, cattle, and humans, the major vertebrate hosts are wild birds, and migratory birds are important in the spread of the disease owing to long-term high-titer viremia. The principal vectors are mosquitoes of the *Culex* genus.

Most (~80%) infections are asymptomatic. Clinical manifestations include West Nile fever in 25% of those infected with symptoms consisting of headache, generalized weakness, morbilliform or maculopapular rash (often at time of defervescence), fever (often low grade), and myalgia; and neuroinvasive disease in less than 1% of those infected. Neuroinvasive disease can manifest with three different clinical presentations: (1) meningitis characterized by clinical signs of meningeal inflammation, including nuchal rigidity, Kernig or Brudzinski sign, or photophobia or phonophobia; (2) encephalitis characterized by depressed or altered level of consciousness, lethargy or personality change lasting more than 24 hours; and (3) acute flaccid paralysis characterized by abrupt onset limb weakness with marked progression over 48 hours, typically asymmetric, areflexic or hyporeflexic, and without sensory abnormalities. All neurologic presentations may be accompanied by other symptoms and signs: nausea and vomiting, myalgia, chills, rash (less common than in West Nile fever), arthralgia, ataxia, visual disturbance, tremors, myoclonus, and bulbar dysfunction (dysarthria, dysphagia).

Diagnosis is most readily made by detection of WNV–specific IgM antibody in cerebrospinal fluid (CSF) or serum. CSF generally shows normal glucose, elevated protein, and pleocytosis (>5 leukocytes/μL). Treatment is supportive for both WNV fever and neuroinvasive disease. Illness duration is days to weeks with complete recovery in case of WNV fever (prolonged fatigue may continue for weeks to months) and weeks to months in neuroinvasive disease. Long-term functional and cognitive difficulties are common in patients with encephalitis and paralysis.

www.konkur.in

Rabies

Rabies virus, a neurotropic RNA virus, belongs to the *Lyssavirus* genus in the family *Rhabdoviridae* (see Table 2.9–1). Stray dogs are the major cause of rabies globally, while raccoons and bats are common reservoirs in the United States. Around 60,000 deaths occur annually due to rabies worldwide, mostly due to lack of postexposure prophylaxis. The risk of infection from a bite is much higher than from a scratch. Aerosol spread is also possible through exposure to infected bats. The incubation period lasts anywhere from 1 to 2 months up to 8 years. The most common virus variant–that found in dogs–multiplies inside myocytes after binding to the alpha subunit of the nicotinic receptor, hence deep bites into muscle are high risk. CNS entry occurs through retrograde axonal transport. Soon, it spreads through motor and sensory axons leading to extraneural organ involvement, including the heart and autonomic plexuses, skin, and salivary glands. When symptoms develop, the virus has already disseminated throughout the CNS.

There are two main clinical presentations—classical and nonclassical. The classical furious and paralytic (resembling Guillain–Barré syndrome) forms occur mostly due to the dog rabies variant. Nonclassical type occurs in patients exposed to bats. In furious rabies, the initial presentation resembles intense anxiety or acute psychosis, worsened by thirst, fear, bright light, or loud noise. Fever is common, starting after the prodromal phase. Soon, the patients develop fluctuating consciousness (alternating periods of severe agitation and normalcy or depression), phobic and inspiratory spasms, and autonomic dysfunction. Aggressive behavior is common. Coma ensues as the disease progresses. Paralytic rabies does not involve aggression or impaired consciousness. Most people die within a week due to furious rabies and within 2 weeks due to paralytic rabies. In the classical type, encephalopathy, hydrophobia, and aerophobia are more common.

Nonclassical type leads to choreiform movements of the bitten extremity during the prodromal phase. The patients may have focal brainstem signs and myoclonus, convulsive and nonconvulsive seizures, and hallucinations. Cranial, motor and sensory deficits, tremor, myoclonus, and exposure-site symptoms (burning, itching, piloerection) are more common in the nonclassical type.

CSF is typically normal. Most cases, both furious, and paralytic, have MRI abnormalities in the brainstem and hippocampus. Late-stage blood–

Telegram: @medical_k

www.konkur.in

brain barrier breakdown shows up as midline gadolinium contrast-enhanced lesions. The diagnosis is confirmed by detecting viral RNA by heminested RT-PCR from saliva, CSF, urine, or hair follicles (viremia does not occur).

There is no effective treatment once the clinical signs develop. The best way to manage rabies is by using pre-exposure vaccination for people at high risk of exposure or postexposure prophylaxis which includes aggressive wound cleaning followed by administering an approved rabies vaccine. Transdermal wound also needs local infiltration with rabies immunoglobulin.

Human Herpesviruses

There are over 100 known herpesviruses, of which eight (the human herpesviruses or HHV) are known to cause infection in humans. These include herpes simplex virus (HSV) 1 and 2, varicella-zoster virus (VZV or HHV-3), Epstein–Barr virus (EBV or HHV-4), cytomegalovirus (CMV or HHV-5), HHV-6 and -7 (both of which can cause roseola), and HHV-8, which is the cause of Kaposi sarcoma. The human herpesviruses are made up of a linear, double-stranded DNA genome enclosed in an icosahedral capsid beneath a lipid envelope. The viral DNA becomes integrated into the host cell genome. Following primary infection, human herpesviruses establish latency and can later be reactivated, especially in the setting of immunologic compromise. Almost all human herpesviruses can result in CNS infection in adults and children, including HSV-1 (most commonly), and CMV (in the setting of AIDS).

Herpes Virus Encephalitis

EPIDEMIOLOGY. HSV type 1 (HSV-1) and HSV type 2 (HSV-2) can both cause severe neuropsychiatric disease, with HSV-2 representing a common cause of viral meningitis. HSV-1 however can spontaneously develop into herpes simplex virus encephalitis (HSVE) in the immunocompetent patient, making it an important viral cause of neuropsychiatric symptoms (see Table 2.9–1). Viral encephalitis overall affects about 20,000 people per year in the United States, and HSV-1 is the most commonly identified cause of sporadic acute viral encephalitis, representing 8% of encephalitis and meningitis cases in a large-scale study of over 26,000 patients, but up to 25% to 50% of cases in other

Telegram: @medical_k

www.konkur.in

studies. HSVE affects all age groups, with mortality rates up to 70% in the untreated and 25% to 50% for those receiving treatment.

Neuropsychiatric symptoms are common in HSVE, varying from depression and anxiety to irritability, agitation, mood lability, mania, and psychosis, to amnesia, apathy, and more. Overall behavioral changes appear to be the presenting symptom of HSVE in about a quarter of cases. Long-term, there are significant neuropsychiatric sequelae of HSVE, including depression (18%), anxiety (45%), panic attacks (27%), irritability (64%), and apathy (1%) when measured about 6 months after acute illness in one study. Other work has identified long-term sequelae that include memory impairment in 69%, behavioral problems in 45%, OCD-like symptoms in 7%, and aggression and hyperphagia each in 3%. Kluver–Bucy syndrome can be a consequence but is less common when acute HSVE is treated with acyclovir. Persistent functional impairment is usually secondary to emotional or behavioral sequelae rather than memory problems.

PATHOPHYSIOLOGY. HSVE appears to plausibly arise from both primary (30%) and latent or reactivated (70%) infection. Entry into the parenchyma may occur via the olfactory nerve or trigeminal nerve; entry via the olfactory nerve may explain the virus's predilection for the adjacent temporal lobes, or alternatively, this may reflect a viral affinity for this region. In addition to the temporal lobes (including hippocampus) and insula, HSVE may also affect the cingulate gyrus and orbitofrontal cortex. Damage to frontal and amygdalar regions may be responsible for persistent behavioral problems in survivors, whereas hippocampal and amygdalar damage likely underwrite persistent memory problems. The virus may impair major histocompatibility complex antigen expression on infected neurons and inhibit autophagy in order to evade host immune response. This leads to tissue edema evolving into hemorrhagic necrosis. Individuals with Toll-like receptor mutations may have increased vulnerability to developing HSVE.

CLINICAL PRESENTATION. A prodrome of fever and headache may precede the abrupt onset of changes in personality and behavior, alterations in consciousness, seizures, and motor abnormalities. Neuropsychiatric symptoms may fit broadly into four categories: psychosis, catatonia, depression with psychotic features, and mania, but with considerable

Telegram: @medical_k

www.konkur.in

overlap between categories rather than strictly fitting into conventional diagnostic specifications. With regards to psychotic symptoms, delusional thinking can occur, as well as auditory, visual, olfactory, and gustatory hallucinations. Irritability, aggression, and violence, restlessness or hyperactivity, anxiety, disinhibition, perseveration, and confusion can also occur. Memory disorders are prominent, with anterograde memory markedly more affected than retrograde. Disturbances in executive functioning, visuospatial abilities, and language may also develop. Some research on post-HSVE neuropsychological function suggests universal impairment in memory encoding, naming, and semantic memory, with the majority (~75%) affected by executive function, working memory, and autobiographical memory dysfunction, and about half showing visuospatial dysfunction.

DIAGNOSIS. A clinical history of fever together with focal neurologic signs, seizures, confusion, or decreased consciousness, should raise clinical suspicion for HSVE. Lumbar puncture will show elevated opening pressure, xanthrochromic CSF, elevated protein, normal glucose, and a lymphocyte-predominant elevated leukocyte count. PCR more often shows HSV-1, and is positive 24 hours after symptoms begin and until 7 days after antivirals are started. It is also important to rule out other viruses, bacteria, fungi, and autoimmune causes of encephalitis. EEG findings are variable, ranging from nonspecific slowing, asymmetric spikes, slow waves, to intermittent periodic lateralizing epileptiform discharges (PLEDs). Early on, brain imaging may not show abnormalities, but later temporal lobe signal abnormalities, edema, and sometimes hemorrhage can be observed on MRI. However, treatment should not wait for confirmation of the diagnosis given that delaying can adversely impact morbidity and mortality.

After resolution of the acute illness, it may be helpful to obtain neuropsychological testing to characterize deficits and guide rehabilitation efforts, as well as to monitor for seizures as postencephalitic epilepsy can develop.

MANAGEMENT. Suspected or confirmed HSVE should be treated with intravenous acyclovir for up to 21 days. There is very limited data to guide treatment of neuropsychiatric symptoms. Case reports have suggested that atypical antipsychotics and mood stabilizers may help with specific

Telegram: @medical_k

www.konkur.in

symptom domains, although these patients may be at increased risk for neuroleptic malignant syndrome so antipsychotics should be dosed cautiously. Ropinirole may be helpful for postencephalitic apathy and depression. Bupropion should be avoided given its effect on the seizure threshold and high rates of epilepsy in post-HSVE patients. Antiseizure medications can sometimes address both seizures and behavioral problems. There may be a role for empiric trials of other classes as well, such as antidepressants, benzodiazepines, cholinesterase inhibitors, and stimulants. ECT can help with catatonia.

If cognition is not too severely impaired after HSVE then psychotherapy may provide some benefit. For those with more severe residual memory deficits, undesirable behaviors may respond to behavioral tokens and reinforcers. Management of sources of anxiety and agitation (such as disorientation to time) may also benefit the severely impaired patient. For encoding new material, these individuals may respond to repeated learning trials, cuing, and visually presented material.

Overall, early acyclovir treatment and rehabilitation in multiple domains may help to prevent and treat neuropsychiatric sequelae of HSVE.

Epstein–Barr Virus

Epstein–Barr virus (EBV, or HHV-4) is typically transmitted through saliva, though EBV can also be acquired through blood transfusion, organ transplantation, and possibly also sexual contact. EBV is tropic for B- and T lymphocytes, NK cells, myocytes, and epithelial cells (see Table 2.9–1). Approximately 90% to 95% of adults worldwide have antibodies to EBV, with rates being higher in developing countries than in the United States.

Acute EBV infection is typically subclinical but can also manifest as infectious mononucleosis, which presents with 1 to 3 weeks of fever, tonsillitis/pharyngitis, cervical lymphadenopathy, and fatigue (which can last months). Additional complications can include mild hepatitis (~90%), splenomegaly (up to 50%), and depression (28%). Following acute infection, EBV becomes a chronic, latent infection. A so-called transforming virus, EBV is associated with a higher prevalence of malignancies, including B- and T-cell lymphomas, Hodgkin lymphoma, and nasopharyngeal and gastric carcinomas. This is particularly true in immunocompromised individuals (e.g., patients who have HIV or are immunosuppressed post-transplant).

Telegram: @medical_k

www.konkur.in

In 0.5% to 7.5% of cases, acute EBV can have neurologic manifestations, most commonly aseptic or viral meningitis. Other neurologic complications can include encephalitis, myelitis, cranial and peripheral neuropathies, Guillain–Barré syndrome, and primary CNS lymphoma in patients with AIDS. There is some evidence to suggest a relationship between EBV exposure and the development of autoimmune diseases, including multiple sclerosis, possibly through interactions between viral proteins and human genes related to inflammation. Based on limited data, prior EBV infection has also been posited as a risk factor for psychosis, depression, fibromyalgia, and chronic fatigue syndrome.

Serum positivity for heterophile antibodies or EBV-specific antibodies confirms the diagnosis of infectious mononucleosis. Treatment is typically supportive. In acute CNS involvement, CSF can show lymphocytic pleocytosis and EBV positivity on PCR, and patients are typically treated with corticosteroids.

Cytomegalovirus

Like other human herpesviruses, CMV can establish latency and reactivate later in life, particularly in the setting of immunologic compromise (see Table 2.9–1). Worldwide, the prevalence of CMV IgG antibodies is between 40% (in industrialized countries) and 100% (in some developing countries). Approximately 0.6% of infants worldwide are born with congenital CMV. Symptomatic congenital CMV typically results from primary CMV infection, usually in the first trimester. CMV infection can occur through contact with young children, sexual contact, contact with blood, and vertical transmission.

In immunocompetent hosts, primary CMV infection can be asymptomatic or can resemble infectious mononucleosis. Among individuals with immunologic compromise (due to post-transplant immunosuppression, AIDS, etc.), CMV can result in tissue-invasive disease, including enteritis, colitis, and retinitis. Usually in the setting of immunologic compromise, CMV can have CNS manifestations, including encephalitis, meningitis, and Guillain–Barré syndrome. Congenital CMV can present with petechiae, hepatosplenomegaly, microcephaly, chorioretinitis, and sensorineural hearing loss. Symptoms of congenital CMV can also present later in development, and can include developmental delay, abnormal tone, seizures, and inattention/hyperactivity.

Telegram: @medical_k

www.konkur.in

A growing body of evidence suggests links between CMV and neuropsychiatric symptoms. A leading hypothesis is that CMV adversely affects CNS function through chronic neuroinflammation, potentially mediated by interferon-gamma. CMV IgG positivity has been associated with higher rates of psychiatric illness (including somatoform symptoms and bipolar disorder with later-life onset) and suicide attempts. Associations have also been found between CMV IgG levels and the presence of Alzheimer neuropathology in postmortem brain tissue.

Primary CMV is diagnosed via serum PCR. Acute CNS CMV is diagnosed through CSF PCR. In congenital CMV, prenatal ultrasound may show periventricular calcifications, ventriculomegaly, and evidence of abnormal brain migration, for example, pachygyria. Treatment in acute infection involves use of an antiviral (e.g., ganciclovir, valganciclovir, or foscarnet).

HHV-6

Like most herpesviruses, HHV-6 can establish latency before reactivating in later life (see Table 2.9–1). Acute infection with HHV-6 can cause roseola infantum in children but typically does not cause symptoms in immunocompetent adults. Immunocompromised patients—particularly, hematopoietic cell transplantation (HCT) recipients—are vulnerable to HHV-6 reactivation, which may precipitate hepatitis, pneumonitis, and encephalitis. HHV-6 has known neurotropism, and HCT patients with HHV-6 reactivation are acutely at higher risk of delirium and impaired attention. HHV-6 has also been proposed as a causative factor in medial temporal lobe epilepsy (given increased prevalence of HHV-6 in brain tissue from affected patients). Connections between HHV-6 and ME-CFS and psychosis have been proposed but have not been borne out.

Measles (Rubeola)

A single-stranded, negative-sense RNA virus, measles (rubeola) is an extremely contagious disease that spreads through airborne transmission or interpersonal contact (see Table 2.9–1). After infecting the host through the respiratory mucosa or conjunctivae, measles can travel through the lymphatic system and bloodstream to various organs, including the lungs and brain. Although the introduction of the measles vaccine in the 1960s dramatically decreased the number of cases worldwide, outbreaks continue to occur in areas with lower rates of immunization (including,

Telegram: @medical_k

www.konkur.in

recently, Nigeria and Pakistan). Measles was declared eliminated in the United States in 2000, but regions of the United States with lower vaccination rates continue to be vulnerable; the year 2019 saw the highest number of U.S. measles cases since 1992.

Primary measles infection typically involves a prodrome of fever, anorexia, and malaise, followed by cough. Other symptoms can include rhinitis, conjunctivitis, Koplik spots, and a maculopapular exanthem. Complications such as pneumonia, keratitis, and (rarely) encephalitis can also occur. In resource-limited settings, acute measles can be fatal in up to 10% of cases. Infection during pregnancy can result in fetal or maternal death, spontaneous abortion, premature birth, and low–birth-weight.

In approximately 1 in 1,000 cases, measles can cause acute disseminated encephalomyelitis (ADEM), a demyelinating syndrome thought to be an autoimmune response to an infectious trigger. ADEM typically presents within 2 weeks of the measles rash and confers a 10% to 20% mortality rate. Symptoms can include fever, headache, meningismus, confusion, coma, and seizures. Rarely, psychosis can be a presenting symptom.

Up to 7 to 10 years after measles infection, patients can develop subacute sclerosing panencephalitis (SSPE), a progressive, fatal complication thought to result from persistent CNS infection. SSPE can present with behavioral changes (lasting weeks to years), seizures, and lethargy, followed by myoclonus, motor and sensory symptoms, and dementia.

Vaccination with the MMR (measles, mumps, and rubella) vaccine is a valuable preventative measure. While there has been some public concern that the MMR vaccine can lead to autism, evidence does not support this association. Diagnostic testing involves serum assay for IgM antibodies, or isolation of virus in nasal or oropharyngeal culture. In the case of neurologic symptoms, CSF studies can show a lymphocytic pleocytosis, elevated protein, and positive IgM antibodies. Vitamin A supplementation is recommended in children with acute measles, but treatment is otherwise supportive.

Rubella

Also known as “German measles,” rubella is caused by a togavirus that spreads through both airborne and droplet transmission (see Table 2.9–1). Following a 2-week incubation period, patients can develop

Telegram: @medical_k

www.konkur.in

maculopapular rash, mild fever, and lymphadenopathy. Potential complications include arthritis and, rarely, postinfectious encephalitis. However, many people with acute rubella are asymptomatic or have a subclinical presentation.

While not a particularly threatening illness in children and adults, rubella poses great risks to fetuses infected through vertical transmission, especially during the first trimester. Acute rubella in pregnancy can result in spontaneous abortion, intrauterine growth restriction, and preterm delivery. Symptoms of the congenital rubella syndrome include cataracts, retinopathy, hearing loss, hydrocephalus, cardiac defects, petechiae, endocrine abnormalities, meningoencephalitis, and seizures. Later manifestations can include intellectual disability (in about one-third of patients), autism, aggression, impulsivity, self-injury, and motor delay, even in infants who are asymptomatic at birth. Rarely, patients with the congenital rubella syndrome can develop a progressive panencephalitis resembling SSPE. Use of the live attenuated rubella virus vaccine (part of the MMR) is key in preventing congenital rubella.

Other Prenatal Infections (Influenza, Zika, and Listeria)

Maternal infection during pregnancy with various pathogens (including several discussed elsewhere in this chapter) is known or suspected to cause neuropsychiatric symptoms in some affected children. Influenza virus, Zika virus, and *Listeria* bacteria fall into this category and will be discussed briefly here.

Connections between prenatal maternal infection and schizophrenia were first hypothesized in the 1980s by researchers drawing on data from flu epidemics. Although most influenza viruses are not neurotropic, it is thought that influenza (an orthomyxovirus) results in a maternal inflammatory cascade that can adversely impact the developing fetal brain. Birth in the winter or spring months is a risk factor for schizophrenia, and influenza has been proposed as a potential mediator of this association. Limited data suggest that maternal influenza confers an increased risk of bipolar disorder with (but not without) psychotic features. While initial data also suggested a link between maternal influenza and schizophrenia, a more recent study did not replicate those findings, and the relationship between influenza and psychosis remains unclear.

Although adults with acute influenza typically present with symptoms such as fever, malaise, and dry cough, influenza can also cause CNS

Telegram: @medical_k

www.konkur.in

manifestations, such as encephalitis, aseptic meningitis, and Guillain–Barré syndrome. Children with influenza can develop febrile seizures or ADEM (see Table 2.9–1).

The 2015 to 2016 outbreak of the Zika virus raised the global profile of this flavivirus (a relative of dengue and West Nile). Zika is typically transmitted by mosquitoes but can also be spread vertically and through sexual contact. About 20% to 25% of infected adults experience clinical symptoms, which are typically mild and include fever, pruritic rash, and arthralgias. Zika is neurotropic and can also have CNS manifestations, such as meningoencephalitis and Guillain–Barré syndrome (see Table 2.9–1).

The congenital Zika syndrome can affect up to 40% of children whose mothers contracted Zika during pregnancy. The risk is greatest with 1st- and 2nd-trimester infection. Congenital Zika syndrome is thought to be the result of Zika's known toxicity to neural progenitor cells. Affected infants can present with microcephaly, intracranial calcifications, hypertonia, hearing loss, ocular abnormalities, developmental delay, and seizures. The effects of in-utero Zika exposure are still being characterized, but early data suggests that exposed children who were asymptomatic at birth may nonetheless exhibit deficits in motor and cognitive functioning starting in early childhood.

A Gram-positive rod, *Listeria monocytogenes* is transmitted through ingestion of contaminated food (e.g., unwashed produce, soft cheeses). Adults exposed to *Listeria* can develop febrile gastroenteritis, and bacteremia may lead to complications (e.g., meningoencephalitis, cerebritis). Listeriosis has a 10-fold higher incidence in pregnancy. Maternal infection can result in fetal or neonatal infection (via bacteremia) with adverse outcomes including fetal death, preterm labor, neonatal sepsis, and meningitis. Prognosis is most favorable for infection occurring in the 3rd trimester. Long-term sequelae of early-life meningitis (due to *Listeria* or other causes) can include cognitive and motor impairment, hydrocephalus, hearing loss, and higher incidence of behavioral problems, depression, and anxiety.

BACTERIA

Spirochetes

Telegram: @medical_k

www.konkur.in

The family Spirochaetaceae includes *Treponema*, *Borrelia,* and *Leptospira*. Spirochetes have a wavelike body and flagella enclosed between the outer and inner membranes.

Syphilis

EPIDEMIOLOGY. *Treponema pallidum*, the causative agent of syphilis, is a bacterial spirochete that was first identified in 1905. Infection occurs through sexual contact with infected individuals, though may also be transmitted vertically from the infected mother to the fetus in utero or in neonates during passage through the infected birth canal during delivery (see Table 2.9–1). On rare occasions, syphilis may be acquired by transfusion of infected human blood or via epithelial lesions.

During the second half of the 20th century syphilis rates declined due to use of penicillin. However, since reaching a historic low in 2000 to 2001, rates have been steadily climbing almost every year, with unprotected sex largely driving the increase (rates increased 11.2% during 2018 to 2019). In 2019, over 129,000 cases of all stages of syphilis were reported in the United States. Currently, men who have sex with men (MSM) account for approximately 80% of cases in the United States. Sex workers, transgender women, and incarcerated individuals have also been identified as at elevated risk for contracting syphilis. Individuals with HIV infection who are untreated, have low $CD4^+$ counts, or detectable HIV RNA levels are also at high risk due to both increased susceptibility and overlapping risk factors such as unprotected anal intercourse (in 2002 risk was reported to be 77 times greater in HIV-infected individuals than in the general population by the CDC).

Although syphilis is a reportable condition, rates of neurosyphilis in the United States are not known partially due to difficulties with data requirements to meet surveillance definitions. Similarly, although infectious syphilis is reportable in many countries, the rates of neurosyphilis are unknown as this stage of infection is often not reportable at the national level or insufficient data may be available to classify this stage of infection. Globally, there were an estimated 7 million new syphilis infections in 2020, with particularly high incidence in Africa. Rates of progression to neurosyphilis have been described to be up to 10% of patients with untreated syphilis, being more likely in HIV-infected individuals than those without HIV due to level of immunosuppression

Telegram: @medical_k

www.konkur.in

(patients with a CD4 count of ≤350 cells/μL have a threefold increase in neurologic involvement). The risk of neurosyphilis is two to three times greater in white than in black populations and is two times more common in men than in women.

PATHOPHYSIOLOGY. *Treponema pallidum* gains access to the body through mucosal membranes as well as epithelial breaks in the skin. This is the early stage of syphilis, *primary syphilis*, when rough induration occurs at the entry point of the pathogen approximately 10 days to 3 months after infection. This results in a painless ulcer, known as "chancre," with regional lymphadenopathy. In 60% to 70% of all patients, the primary ulcer remains the only manifestation of syphilis.

Mucopolysaccharidase helps *T. pallidum* attach to host cells, leading to obliterative endarteritis and necrotic changes in the terminal arterioles. Such an inflammation of the intima, the inner lining of the artery, can actually occlude the lumen of the vessel, leading to focal ischemia and a wide variety of focal neurologic deficits. On the other hand, some of the late neurologic complications of syphilis (i.e., general paresis and tabes dorsalis) are attributed to parenchymal damage from syphilis infection. This phase of hematogenic and lymphogenic spread (systemic infection) which happens within a few months of infection, is known as *secondary syphilis*. Approximately one-quarter of those with untreated infection develop the systemic illness which presents with constitutional symptoms (fever, fatigue, headache, joint pain, and/or muscle pain), adenopathy, *Condylomata lata* (hypertrophic papules most commonly found on the mucous membranes), and a characteristic rash, classically maculopapular that affects the palms and the soles. All organs can be affected, including the CNS. Approximately 25% to 40% of patients have "neuroinvasion" at some point, typically during the primary or secondary stage of infection, with up to 10% of syphilis cases developing symptomatic neurosyphilis. In most cases, the infection from the CSF is spontaneously cleared without requiring treatment for neurosyphilis and potentially without having any symptoms (*asymptomatic neurosyphilis),* while others may present with aseptic meningitis including lymphocytic pleocytosis in the CSF.

In the late phase, after a latent period (many years after infection), disease is known as *tertiary syphilis.* Presents with tuberous skin changes, ulcerating granulomatous lesions in different organs (gummas), and cardiovascular changes (mesaortitis, aneurysms), along with

Telegram: @medical_k

www.konkur.in

neuropsychiatric symptoms including mood disturbance (both depressed mood and euphoria), anxiety, hallucinations, delusional thought, personality change, apathy, dementia, disinhibition, and irritability.

CLINICAL PRESENTATION OF NEUROSYPHILIS. Early neurosyphilis can include *syphilitic meningitis*, characterized by headache, meningism, nausea/vomiting, and cranial nerve lesions (affecting one or more of the third, seventh, and eighth nerves), along with potential optic nerve involvement, polyradicular symptoms, and vascular brainstem syndromes; *meningovascular neurosyphilis* resulting from the ischemic changes caused by proliferative endarteritis, causing permanent CNS damage, and presenting most commonly as a stroke syndrome. The latter can also occur many years after infection and is therefore often included as a manifestation of late neurosyphilis as well. During the early stage of neurosyphilis, there may be mild neuropsychiatric symptoms, including personality change, emotional lability, insomnia, and decreased memory.

Late neurosyphilis, which generally starts 10 to 20 years after infection can include *tabes dorsalis:* chronically progressive dorsal radiculoganglionitis with loss of reflexes in the lower extremities, pallanesthesia, pupil disorders, hyperextensibility of the knee and hip joints, micturition disorders, and optic damage; *paralytic neurosyphilis/general paresis:* peaking in incidence 20 to 30 years after infection, a chronic progressive frontotemporal meningoencephalitis with ongoing loss of global cortical function; *syphilitic gummas:* circumscribed granulomas that develop from the meninges of the cerebral convexity–described as a brain mass with irregular enhancement, dura-contact, and surrounding edema (if intracranial pressure is increased, brain edema, or aggravated neurologic dysfunction may need surgical intervention); and/or <u>neuropsychiatric symptoms:</u> typical symptoms are increasing cognitive deficits, weakness of discrimination and judgment, psychotic episodes, speech disorders, headache and dizziness, abnormal pupillary reaction, tremor of the tongue, facial tremor, epileptic seizures, reflex anomalies, and finally severe dementia, urinary and fecal incontinence, and marasmus. The disease can mimic any psychiatric disorder, making it impossible to distinguish between primary psychiatric illness and psychiatric presentations of neurosyphilis based on clinical phenomenology alone. As per data on neurocognitive testing, patients with neurosyphilis (more specifically those with paralytic

Telegram: @medical_k

www.konkur.in

neurosyphilis/general paresis) indicated worse scores than the normal control group in memory, language, attention, executive function, and spatial ability. This result suggested that there is an overall decline in cognitive function. Moreover, when compared to a group of AD patients (matched for age, education, and MMSE scores), the group with neurosyphilis presented a similar pattern of cognitive impairment to those with AD. More advanced cognitive symptoms associated with neurosyphilis are associated with increased risk for neuropsychiatric symptoms such as mood disturbance and psychosis.

Atypical neurosyphilis: The more recent literature includes cases of temporal lobe encephalitis that resembled herpes simplex virus 1 (HSV-1) infection or limbic encephalitis, in which the main clinical manifestations are cognitive deficits and epileptic seizures.

DIAGNOSIS. There is no gold standard for the diagnosis of neurosyphilis, which relies on a combination of clinical findings, serologic tests for syphilis, CSF analysis, and, on occasion, neuroimaging. Serologic tests for syphilis include the nontreponemal venereal disease research laboratory (VDRL) test or rapid plasma reagin (RPR) test and, to confirm positive results, the fluorescent treponemal antibody absorption (FTA-ABS) test. More recently, real-time PCR techniques have been developed, which allow for the detection of *T. pallidum* with estimates of sensitivity of 80% and specificity of 98%. CSF studies are essential for diagnosis of neurosyphilis and can also serve to detect asymptomatic involvement so that treatment can be started and efficacy followed. In most cases, a normal CSF excludes neurosyphilis. The different CSF tests are as follows: CSF VDRL—highly specific and is generally accepted as the diagnostic test of neurosyphilis. A positive test and appropriate clinical history establishes the diagnosis of neurosyphilis. CSF RPR—lower sensitivity than VDRL. A positive result and appropriate clinical history also establish the diagnosis of neurosyphilis. CSF treponemal tests (FTA-ABS)—highly sensitive; however, it is nonspecific and thus more useful to rule out neurosyphilis when the pretest probability is moderate to low. CSF pleocytosis: the diagnosis of neurosyphilis usually needs a CSF white blood cell (WBC) count of 20 cells/μL or more. Sensitive but nonspecific (increased cell count occurs in both infectious and noninfectious causes). Patients with comorbid HIV may have pleocytosis regardless of the presence of neurosyphilis, particularly if they are not on antiretroviral

Telegram: @medical_k

www.konkur.in

therapy (ART). CSF protein: elevated levels support the diagnosis, but are neither sensitive nor specific.

FIGURE 2.9–1. Neuroimaging (MRI) of neurosyphilis patients illustrating a variety of manifestations. Images **A–D** demonstrate abnormal signal in left temporal lobe and hippocampus (**A, B**) progressing to left temporal lobe atrophy and hippocampal sclerosis (**C, D**) 2 years later despite treatment for syphilis. Images **E–F** and **G–H** show two separate patients with left frontal lobe nodular enhanced lesion with surrounding edema. Images **I–L** exhibit an example of a cortical nodular lesion at the base of the frontal lobe. (Reprinted with permission from Shang XJ, He CF, Tang B. et al. Neuroimaging features, follow-up analyses, and comparisons between asymptomatic and symptomatic neurosyphilis. *Dermatol Ther (Heidelb).* 2020;10:273–283. doi: 10.1007/s13555-020-00361-3.)

Neuroimaging studies can be helpful in the diagnosis and management, but findings are generally nonspecific and can be diverse. The most common findings are frontal and temporoparietal atrophy. Patients with

Telegram: @medical_k

www.konkur.in

general paresis reveal frontocortical atrophy and nonspecific white matter lesions in a frontal distribution. Figure 2.9–1 shows examples of some neuroimaging findings in neurosyphilis, including temporal atrophy and frontal lesions. SPECT imaging in general paresis reveals a marked reduction in cerebral perfusion, particularly in the bilateral frontal and temporal cortices. Changes consistent with infarction are usually encountered in patients with meningovascular disease.

Novel biomarkers are being studied such as beta-2 microglobulin. Its presence in CSF may help in the diagnosis of CNS involvement and may aid in monitoring the response to therapy.

MANAGEMENT. CDC guidelines recommend parenteral penicillin G for all stages of syphilis and for neurosyphilis. Standard courses of antibiotics for 10 to 14 days consist of IV aqueous penicillin G (divided doses every 4 hours), or alternatively intramuscular injections of benzathine penicillin (once weekly) or procaine penicillin (four times a day).

The goal in clinical neurosyphilis is to reverse the manifestations or arrest the disease progression, although, in some patients, antibiotic therapy may not be able to achieve these goals. Certain conditions, such as comorbid HIV infection, may place patients at greater risk for persistence of treponemal infection after antibiotic treatment. A large review found that in HIV-positive patients treatment with antibiotics is associated with serologic failure (defined as a less than fourfold decline in RPR/VDRL titer) in 0% to 33% of cases. ART reduces this risk by roughly 60%.

In terms of psychiatric symptoms, there are no definitive guidelines for proceeding with the utilization of psychotropic medication in combination with appropriate antibiotic therapy, although in published case reports it has been suggested to have been effective in reducing symptoms. Haloperidol, as well as the atypical agents risperidone and quetiapine at or below recommended doses for schizophrenia, appear to have clinical benefits for psychosis in this population. Furthermore, the addition of divalproex sodium appeared to exert some benefit in mood stabilization and agitation. As in AD, no clear standard exists for the management of noncognitive neuropsychiatric symptoms of syphilis.

After commencing treatment, tests of cure via VDRL/RPR are recommended in all patients. Unlike other infectious diseases, the definition of cure cannot include documentation of complete eradication of

Telegram: @medical_k

www.konkur.in

the infecting organism because *T. pallidum* cannot be cultured in vitro. A fourfold drop in titer is considered an appropriate reduction at 12 months after treatment of primary, secondary, or early latent syphilis (early syphilis) and at 24 months for late latent syphilis and syphilis of unknown duration (late syphilis) if the initial titer was high. Serum monitoring should be performed monthly for three months, and at 6 and 12 months for early syphilis. For patients with late syphilis, this should take place every 6 months until negative. Due to the strong association with HIV, patients that are HIV-positive should have repeat testing yearly. Regarding neurosyphilis, CSF studies should be tested every 6 months until negative.

The likelihood of marked improvement for patients with general paresis is less than that for patients with syphilitic meningitis or meningovascular syphilis, reflecting the pathologic process, which in the former is irreversible neuron damage and in the latter CNS inflammation.

Lyme Disease

Epidemiology. Lyme disease is a multisystem infection caused by *Borrelia burgdorferi* (see Table 2.9–1). Lyme disease was first described in the United States in the late 1970s during an investigation of an unusual epidemic of what appeared to be juvenile rheumatoid arthritis in Lyme, Connecticut. However, retrospective serologic data suggest that Lyme disease was endemic in the United States as early as 1962, and the clinical manifestations of this infection have been known in Europe since the early 1900s. The causative agent was isolated from *Ixodes* ticks in 1982, allowing the start of a better understanding of this disease. Lyme disease is the most common tick-borne disease in both the United States and Europe; an estimated 476,000 cases are diagnosed and treated per year in the United States and >200,000 cases per year in western Europe. The risk for acquiring Lyme disease in the United States varies with the distribution, density, and prevalence of infection in vector ticks. Most cases of Lyme disease occur in the northeastern and north-central states. The incidence of Lyme disease in Europe is highest in the Scandinavian and Baltic states in northern Europe and in Austria, the Czech Republic, Germany, and Slovenia in central Europe. Lyme disease also occurs in Russia, Japan, and China.

Lyme disease is a reportable disease in the United States; for surveillance purposes, confirmed infection is defined as either (1)

Telegram: @medical_k

www.konkur.in

physician-diagnosed erythema migrans greater than 5 cm in diameter in a person exposed to ticks in a Lyme-endemic region or laboratory evidence of infection or (2) one or more objective late manifestations of (arthritis, neurologic signs, or cardiac conduction defects) with laboratory evidence of infection with *B. burgdorferi*.

Pathophysiology. *B. burgdorferi* is transmitted to man by *Ixodes* ticks that become infected while feeding on infected animals. Laboratory studies indicate that transmission of *B. burgdorferi* by the ticks requires a minimum of 36 to 48 hours of attachment. The natural hosts for *B. burgdorferi* are wild and domesticated animals, including mice and other rodents, deer, sheep, cattle, horses, and dogs. Infection in these animals may not be apparent, although clinical infection has been observed in cattle, horses, and dogs. In areas endemic for Lyme disease, 2% to 50% of ticks may carry *B. burgdorferi*. Most Lyme disease cases result from bites by infected nymphs, as their small size (about the size of a poppy seed) allows them to easily go unnoticed. Infections are most common during the months of May through August (northern hemisphere), when both the nymph ticks' activity and human outdoor activity are at their peak.

Of note, congenital infection may occur with serious, potentially fatal, consequences for the fetus.

Clinical Presentation. Clinical manifestations may differ in the United States and Europe, mostly due to significant differences in the bacterial strains causing infection in the two continents. As a result, *B. burgdorferi* is divided into three different genospecies distributed in two antigenic distinct groups.

- *B. afzeli* and *B. garinii* are responsible for most Lyme disease in Europe and Asia and are associated with chronic skin and neurologic symptoms, respectively.
- *B. burgdorferi sensu stricto* is the sole cause of Lyme disease in the United States where Lyme arthritis is a common complication of infection.

Clinically, Lyme disease is divided into early and late disease. Lyme disease usually begins with the characteristic skin lesion: a spreading annular rash (sometimes appearing as a bull's eye) known as erythema chronicum migrans (ECM), at the site of the tick bite between 3 and 22

Telegram: @medical_k

www.konkur.in

days after infection (ECM may be absent in about 10% of patients with early Lyme disease). In the United States, secondary skin lesions similar to those of ECM are common as *B. burgdorferi* rapidly disseminates by the blood stream throughout the body. The rash and secondary lesions fade within 3 to 4 weeks. The most common early neurologic manifestations are cranial neuropathy, particularly facial nerve palsy (cranial nerve VII palsy, which may be bilateral), headache, lymphocytic meningitis, and motor or sensory radiculoneuritis, in addition to encephalitis characterized by mood lability and disturbances of memory or sleep. *B. burgdorferi* has been found in the CNS as soon as 2 weeks after initial skin infection. Between 15% and 40% of patients may have neurologic signs as their presenting feature.

Cardiac involvement occurs in 4% to 8% of untreated patients, the most common feature being a fluctuating atrioventricular block. Constitutional symptoms, arthralgias, myalgias, and severe fatigue are common, and regional lymphadenopathy also may occur. Asymmetric oligoarticular arthritis, especially involving the knees, occurs in about 60% of untreated patients at a mean of 6 months from the onset of the disease.

Patients may also have asymptomatic infection or only nonspecific symptoms.

In Europe, *B. afzelii* and *B. garinii* infection cause a firm, painless, bluish-red nodular lesion usually localized on the earlobe or nipple, known as Borrelia lymphocytoma.

B. burgdorferi may remain latent, causing illness months to years later (late disease). Partly because of this latency in disease expression, patients may be unable to recall the initial tick bite or rash.

Late neurologic Lyme disease may present as a subacute mild encephalopathy affecting memory and concentration; chronic mild axonal polyneuropathy manifested as distal paresthesias and/or, less commonly, as radicular pain.

Lyme disease has been reported to cause a vast array of neuropsychiatric disorders, ranging from depression/irritability and cognitive problems (short-term memory loss, impairment in processing speech, and/or verbal fluency problems) to, less commonly, psychosis, mania, or dementia. Although the full spectrum of psychiatric disorders has been associated with *B. burgdorferi* infection, by far the most frequent are disturbances of mood, characterized by irritability, dysthymia, and sleep loss, which are usually seen during the disseminated phase of the

Telegram: @medical_k

www.konkur.in

infection. Studies have looked at both the presence of Lyme in identified psychiatric patients and the emergence of neuropsychiatric symptoms in identified Lyme patients after becoming infected. In identified psychiatric patients, one study of 517 hospitalized psychiatric patients in a highly endemic area failed to find sufficient immune diagnostic reactivity to *B. burgdorferi* meeting CDC surveillance criteria in a single patient, while another study of 1,810 demonstrated a higher prevalence of antibodies to *B. burgdorferi* in hospitalized psychiatric patients when compared to matched pairs of healthy subjects (33% vs. 19%). Given these somewhat discordant findings, additional research would be beneficial.

In a recent study, United States and Danish researchers report that patients with diagnosis of Lyme disease had a 28% higher rate of mental disorders and were twice as likely to have attempted suicide postinfection, compared to individuals without the diagnosis. In addition, patients with diagnosed Lyme also had a 42% higher rate of affective disorders, such as depression and bipolar disorder, and a 75% higher rate of death by suicide than those without the diagnosis.

POST-TREATMENT LYME SYNDROME VERSUS CHRONIC LYME DISEASE. Two distinct terms refer to the problem of persistent symptoms after antibiotic treatment: *Post-treatment Lyme syndrome* refers to those patients who experience persistent nonspecific symptoms including fatigue, sleep disorders, headache, memory and concentration difficulties, myalgias, and arthralgias after antibiotic treatment of well-defined prior Lyme disease. *Chronic Lyme disease* can include a vastly heterogeneous patient population, including patients with late Lyme disease, those with post-Lyme disease syndrome, and those who have no objective evidence of prior Lyme disease (patients exhibiting non-specific illness who do not test positive on FDA-approved serologic tests). While the exact cause of persistent symptoms after treatment is unclear and most likely multidetermined, it is possible that some symptoms represent ongoing postinfectious secondary immune effects.

Diagnosis. Currently in the United States, a two-tiered serology protocol is the only validated diagnostic approach for LD diagnosis recommended by the CDC. This is typically an enzyme-linked immunoassay (ELISA) to detect IgM or IgG antibodies to *B. burgdorferi* in serum and if the sample is positive or equivocal on the screening assay,

Telegram: @medical_k

www.konkur.in

then a Western Blot is used to detect serum IgM (during first 30 days of infection) or IgG antibodies (after 30 days of infection) to *B. burgdorferi*. Use of IgM testing is recommended during the first 30 days of infection, after which only IgG tests should be used.

False positive results may occur due to cross-reactivity with other microorganisms; a problem particularly among patients with syphilis infection, but also found in multiple other infections (leptospirosis, periodontitis, relapsing fever, tularemia, Southern tick-associated rash illness (STARI), and Epstein–Barr virus infection) and with some autoimmune disorders (rheumatoid arthritis, systemic lupus erythematosus, multiple sclerosis). Thus, if the clinical syndrome does not fit, clinician judgment should be used, and other more specific tests should be performed (i.e., indirect hemagglutination antibody (IHA) test using *B. burgdorferi* strains).

False-negative results may occur if the patient is tested before the opportunity for an appropriate antibody response (too soon after infection). Therefore, if clinical suspicion is strong and symptom onset is recent, repeat testing is indicated.

Other laboratory studies include: polymerase chain reaction (PCR) for borrelial DNA, which is highly specific for *B. burgdorferi* DNA but rarely positive beyond the stage of the rash (the organism is tissue-tropic and does not reside for prolonged periods in the bloodstream) and antigen detection assays. CSF analysis (all prior laboratory studies can be performed in CSF) has a critical role ruling out other possible causes of CNS disease and establishing diagnosis of Lyme meningitis or encephalitis. Lymphocytic pleocytosis, mildly increased protein, and an elevated *Borrelia*-specific IgG index are observed. ELISA of CSF should be drawn at the same time as the serum ELISA so that a Lyme index can be calculated. In rare cases, Lyme-specific antibodies at diagnostically high levels may be found in the CSF but not in the serum. It has been reported that in as high as 20% of cases of late-stage neurologic Lyme disease, the CSF may appear normal. MRI may show punctate white matter lesions on T2-weighted images, EEG is usually normal, but diffuse slowing or epileptiform discharges have been described, and SPECT/PET can demonstrate a non-specific pattern of diffuse heterogeneous hypoperfusion in the late-stage CNS Lyme disease.

Telegram: @medical_k

www.konkur.in

Management. Antibiotic therapy including penicillins, macrolides, cephalosporins, and tetracyclines have all been used successfully. However, it appears that tetracyclines (e.g., doxycycline) may produce fewer late complications than penicillin therapy. For early Lyme disease without CNS involvement, a 2- to 3-week course of oral antibiotics is recommended, while for Lyme disease with CNS involvement, the recommendation is IV antibiotic treatment for 3 to 4 weeks. Patients with Lyme encephalopathy have gradual improvement in their symptoms, usually starting a few months after completion of therapy, and continue to improve slowly for up to 1 to 2 years. While early treatment with antibiotics at the time of the skin rash (erythema migrans) often results in rapid resolution of the illness, delayed treatment may result in a more entrenched set of symptoms and a longer course of illness. Postexposure antimicrobial prophylaxis with a single 200-mg dose of doxycycline has been shown to reduce the risk for Lyme disease after an *I. scapularis* tick bite and is recommended for consideration in the United States.

Leptospirosis (Weil Disease)

Leptospira is the agent of Weil disease, which can have CNS manifestations (see Table 2.9–1). Leptospirosis is a zoonotic disease caused by pathogenic spirochetes of the genus Leptospira, and carriers include wild and domesticated animals such as rodents, cattle, dogs, and pigs. It is transmitted by direct or indirect contact with the urine, blood, and tissues of infected animals (most commonly found in rodents, cattle, dogs, and pigs; though any mammal can be a carrier). In addition, infection can occur via mucosal surfaces or damaged skin exposed to contaminated environments such as moist soil or contaminated water. Spirochetes colonize the proximal renal tubules of infected reservoir hosts and are excreted in the urine. Between half to one million infections occur annually worldwide with approximately 60,000 deaths a year. Leptospirosis is more prevalent in tropical countries primarily due to occupational exposure than in developed countries where it is associated with water-related recreational activities. The disease is expected to become more prevalent in developing countries where slum settlements, climate change, and rapid urbanization lead to increased transmission.

The disease spectrum ranges from mild anicteric leptospirosis, characterized by fever, headache, myalgia, sore throat, and cough to a more serious Weil syndrome manifested as jaundice, renal dysfunction,

Telegram: @medical_k

www.konkur.in

and bleeding diathesis including pulmonary hemorrhage. Neurologic manifestations of leptospirosis include encephalitis (altered sensorium, psychosis, seizures, hemiplegia), intracranial bleeds, cerebellitis, movement disorders, myelitis, flaccid paraplegias (including Guillain–Barré syndrome-like presentation), mononeuritis, neuralgias, autonomic lability, polymyositis, and ADEM. However, the most common manifestation of neuroleptospirosis is aseptic meningitis and could account for 5% to 13% of all aseptic meningitis cases (presence of clinical and laboratory evidence of meningeal inflammation in the absence of positive routine bacterial cultures in CSF).

Diagnosis relies on medical history of possible occupational or recreational exposure and appropriate clinical findings, confirmed by laboratory testing. The microscopic agglutination test (MAT), which can indicate the likely infecting serogroup or serovar, is generally accepted as the "gold standard." ELISA (detecting IgM in early infection) and PCR are also used. The detection of leptospires with dark-field microscopy offers the earliest confirmation of infection (in blood within the first week of illness and, less reliably, in urine during the second week). Blood culture may be useful in severe, fulminant disease.

Antibiotics are preferably started within 24 to 48 hours of illness onset. In severe illness, intravenous benzylpenicillin is the drug of choice. For milder infections a 7- to 10-day course of oral amoxicillin is appropriate. Patients allergic to penicillins can be treated with erythromycin. The value of antibiotic treatment has limited support from clinical trials, however, supportive management to maintain tissue and organ function, such as the temporary maintenance of renal function by dialysis, may be life-saving.

Group A β-Hemolytic Streptococcus

Group A beta-hemolytic streptococcus (GAS) can cause several postinfectious, immune-mediated diseases including acute rheumatic fever (with Sydenham chorea as only neurologic manifestation), poststreptococcal reactive arthritis, pediatric autoimmune neuropsychiatric disorders associated with streptococcus infection (PANDAS), and poststreptococcal glomerulonephritis. This chapter will focus on Sydenham chorea and PANDAS, both of which share an array of neuropsychiatric symptoms (see Table 2.9–1). However, distinguishing

Telegram: @medical_k

www.konkur.in

one from the other, especially at onset of symptoms, can prove challenging.

Epidemiology. Since GAS infections are found worldwide in humans, they are considered a global health problem. However, the distribution among different populations and the incidence of infection vary by time and geographic region, which presumably reflects a population's susceptibility to particular strains, but also the natural variation in the predominant types. Although GAS infections may be observed in persons of any age, the prevalence of infection is higher in children, presumably because of the combination of multiple exposures (in schools or nurseries, for example) and host immunity. The age of onset in both neuropsychiatric manifestations of GAS is typically prepubertal. Sydenham chorea usually occurs between the ages of 5 and 15 years and PANDAS symptoms are most often found in patients between 3 years of age and onset of puberty (with mean age of 6). Regarding gender differences, a female predominance (2:1) is found in Sydenham chorea studies whereas in PANDAS, boys outnumber girls by a ratio of 2.6:1. Sydenham chorea is the only recognized neurologic manifestation of rheumatic fever, occurring in about 20% of patients, most often weeks to months after group A streptococcal infection. It is important to note that diagnosis for these pathologies is often delayed by an average of 8 years from disease onset, highlighting the need to increase clinicians' awareness of this condition. Indeed, the majority of patients receive the diagnosis after consulting with multiple specialists.

Pathophysiology. Streptococcus pyogenes (group A beta-hemolytic streptococcus [GABHS]) is an anaerobic gram-positive coccus whose only reservoir is humans. The pathophysiology of both PANDAS and Sydenham chorea is thought to be autoimmune. Antibodies produced against GABHS in the context of acute infection are proposed to cross-react with basal ganglia epitopes, disrupting cortical-basal ganglia–thalamo–cortical (CBGTC) circuits, leading to motor, behavioral, and cognitive symptoms. Genetic vulnerability seems to play an important role in disease expression. The rate of tic disorders and OCD in first-degree relatives of pediatric probands with PANDAS is higher than those reported in the general population. The majority of children exposed to GABHS infections remain unaffected which suggests genetic or other vulnerability or susceptibility in some individuals. Inquiring about a family history of tics

Telegram: @medical_k

www.konkur.in

and OCD in first-degree relatives would therefore be deemed important in both conditions.

Clinical Presentation. PANDAS encompasses a complex of obsessive-compulsive disorders (OCD) and/or tics, both characterized by a pattern of remitting and relapsing symptoms, with the initial episode occurring abruptly or even overnight. Caregivers may describe their child as ‘‘completely new and unrecognizable.’’ Within a short time, children with PANDAS may also develop cognitive decline and behavioral regression, including attention difficulty, severe anxiety, deterioration in handwriting or other fine-motor skills, decline in school performance, night terror, and occasionally even psychosis. Urinary urgency or frequency may be observed as an initial manifestation, frequently misdiagnosed as urinary tract infection in the absence of other typical neurologic symptoms.

Sydenham Chorea is characterized by the abrupt onset of choreoathetoid movements. Although chorea is the most important neurologic symptom, hypotonia may be prominent—and both combined can lead to severe problems with feeding, dressing, and walking—and tics can occur as well. In severe cases, speech may become dysarthric with a slurred and explosive character. Psychiatric symptoms can also be prominent (present in up to 70% of patients with Sydenham chorea) and include emotional lability, anxiety, depression, obsessive–compulsive symptoms, as well as ADHD features, and even psychosis. OCD has been extensively described in relation with Sydenham chorea, with different time courses of onset (before, concomitantly, and after the characteristic choreatic movements had begun). Prevalence of patients with OCD has been reported up to 40% in patients with Sydenham chorea, with the higher percentages observed in those with persistent chorea (more than 2 years since onset).

Diagnosis. To date, there is no single clinical manifestation, laboratory test, or imaging technique that is pathognomonic for either PANDAS or Sydenham chorea. Clinically, five criteria have been proposed for diagnosis of PANDAS: (1) presence of obsessive-compulsive or tic disorder; (2) prepubertal symptom onset; (3) abrupt onset (24 to 48 hours) and episodic course (relapse–remission cycle); (4) neurologic abnormalities, such as choreiform movements during symptom exacerbations; and (5) a temporal relationship between GABHS infection and symptom onset (typically 7 to 14 days). In addition, careful

Telegram: @medical_k

www.konkur.in

observation of the electrophysiologic nature of the abnormal movements may prove informative. The choreiform movements associated with Sydenham can be described as irregular, semipurposeful, avolitional, adventitious in nature, and almost always result in functional impairment. In contrast, the choreiform movements in PANDAS cause no functional impairment.

In terms of laboratory testing, serum autoantibody profile with elevated Antistreptolysin O and Anti-DNase B antibody titers have been described in both PANDAS and SC (elevated in up to 80% of PANDAS confirmed cases). Also, the presence of some other markers may suggest or support the diagnosis. Antibasal ganglial antibody (ABGA) are found in PANDAS in 100% of acute disease and 69% of persistent forms as well as at an undefined frequency in SC. Specific monoclonal antibodies (D8/17) have been observed in 85% of PANDAS cases and 89% of SC cases versus 17% of healthy controls. In addition, structural neuroimaging has shown volumetric increases in basal ganglia structures (caudate, putamen, globus pallidus) in both PANDAS and Sydenham chorea cases.

Management. As there are multiple neurologic, behavioral, and emotional symptoms involvement in both conditions (PANDAS and Sydenham chorea), a multimodal treatment approach is recommended, including cognitive behavior therapy, selective serotonin reuptake inhibitors, steroids, intravenous immunoglobulins, and plasmapheresis.

Pharmacologically, antibiotics penicillin, cephalosporin, and amoxicillin are all considered appropriate treatments for GAS infections. There has been some evidence that antibiotic treatment for GAS infections both prevents neurologic manifestations (e.g., tics) and improves OCD symptoms in PANDAS, but the data available are inconclusive and cannot determine the full efficacy of antibiotics in prophylaxing against tics and OCD. Children with Sydenham chorea require long-term benzathine penicillin prophylaxis to reduce the risk of rheumatic heart disease. Immunomodulatory treatments (IV immunoglobulin IVIG) and plasmapheresis have been shown to reduce neuropsychiatric symptom severity in children with PANDAS, and more specifically OCD symptoms and tics. Tonsillectomy may also represent an effective treatment option in children severely affected by PANDAS.

Pediatric Acute Onset Neuropsychiatric Symptoms

Telegram: @medical_k

www.konkur.in

More recently a new broader diagnostic category was established, known as pediatric acute-onset neuropsychiatric symptoms (PANS) to include similar clinical presentations to PANDAS but that are more etiologically diverse and can involve infectious agents that are not exclusively due to Group A Streptococcal infections (see Table 2.9–1). Unlike PANDAS that requires a temporal relationship with GAS infection specifically, PANS do not require a specific infectious agent as a precursor to symptom onset, as other infections (e.g., mycoplasma pneumonia, viral infections, *B. burgdorferi*) have also been linked to new-onset OCD.

Criteria include (1) abrupt and dramatic onset of OCD or severely restricted food intake; (2) concurrent presentation of 2 out of 7 other neuropsychiatric symptoms: anxiety, emotional lability and/or depression, irritability, aggression, and/or severe oppositional behaviors, behavioral (developmental) regression, deterioration in school performance, sensory or motor abnormalities including heightened sensitivity to sensory stimuli, and somatic signs or symptoms such as sleep disturbance or enuresis; and (3) symptoms not better described by an otherwise known neurologic or medical condition such as Tourette disorder, Sydenham chorea, or systemic lupus erythematosus. No laboratory or imagining studies have been shown to help establish diagnosis.

As in patients with PANDAS, long-term antibiotic prophylaxis with benzathine benzylpenicillin has been shown to result in a substantial benefit to patients' outcome, along with potentially preventing relapses of neurological manifestations over time.

PROTOZOA

Malaria

Plasmodium is the genus of parasitic protozoans that cause malaria, and disease-causing species include *Plasmodium vivax* (the most common), *P. ovale*, *P. malariae*, *P. knowlesi*, and *P. falciparum* (see Table 2.9–1). Infection is acquired via the bite of the Anopheles mosquito. Malaria as a whole affects an estimated 240 million people annually, killing over 500,000. One study found neurologic involvement in 48% of children with malaria; those living in endemic areas of sub-Saharan Africa are at highest risk. Older adults, pregnant women, HIV-infected individuals, and patients with a history of splenectomy are also at increased risk for cerebral involvement. Parasitized red blood cells sequestered in cerebral

Telegram: @medical_k

www.konkur.in

capillaries, cytokine production/immune cell accumulation, and BBB endothelial lesions leading to edema and vascular injury all contribute to the mechanism of neurologic disease. Presentations of malaria involve cyclic spikes of high fever and chills, with frequency varying by species, as well as diaphoresis, fatigue, headache, myalgia, jaundice, and spleno- or hepato-megaly. *P. falciparum* carries the special risk of being associated with prominent neuropsychiatric symptoms, or cerebral malaria.

Cerebral malaria presents as encephalopathy that occurs as impaired consciousness, delirium, or seizures. Retinal hemorrhages occur in 30% to 40% of cases. Untreated, cerebral malaria is generally fatal; with treatment mortality drops to 15% to 20%. Survivors of pediatric cerebral malaria may have neuropsychiatric sequelae including cognitive and language deficits and behavioral problems, as well as seizures, deafness, blindness, and other neurologic problems. Autoimmune encephalitis may rarely develop after resolution of cerebral malaria. Diagnosis is made by blood smear microscopy. Low CSF glucose also suggests cerebral malaria over viral encephalitis. Intravenous artesunate is the treatment of choice. Management of cerebral edema and seizures are other neuropsychiatrically relevant considerations, but no agents have been demonstrated to be unequivocally beneficial in clinical trials.

Human African Trypanosomiasis

Trypanosomes are protozoan parasites found in Africa; *Trypanosoma brucei rhodesiense* causes a more acute and *T. brucei gambiense,* a more chronic form of trypanosomiasis (see Table 2.9–1). *T. b. gambiense* is the more common cause of illness in humans. Exposure to the tsetse fly, which transmits the infection, is greater in rural and poor communities. Initially, trypanosomes penetrate the skin and circulate via the blood and lymphatic system; subsequently they infect the CNS. Presentation may involve fever, weight loss, lymphadenopathy, and neurologic manifestations; CNS involvement may not occur for 2 years. Sleep disturbance with daytime somnolence may be striking, earning trypanosomiasis the designation “sleeping sickness.” Seizures, cognitive decline, psychosis, personality change, and sensory disturbance can also occur. Identification of trypanosomes in blood or CSF by microscopy is diagnostic. Treatment is with antitrypanosomal agents such as fexinidazole, pentamidine, nifurtimox, or eflornithine.

Telegram: @medical_k

www.konkur.in

Toxoplasmosis

Toxoplasmosis is caused by *Toxoplasma gondii*, an obligate intracellular, neurotropic protozoan parasite (see Table 2.9–1). Cats are its definitive host, producing oocysts, which are found in their feces. Oocysts are most often transmitted to humans through accidental ingestion of contaminated food or water, for example with insufficient hand hygiene after handling cat litter or consumption of raw or undercooked contaminated meat. Infection can also occur transplacentally. Around one-third of the world's population is infected by *T. gondii*, making it one of the most successful human parasites. Infection leads to cyst formation, predominantly inside neurons and glial cells, and may be unifocal or multifocal. Symptomatic infection is most common in immunosuppressed hosts. Clinical presentation depends on the location and number of lesions. Usual symptoms include headache, fever, focal neurologic deficits, seizures, delirium, ataxia, lethargy, and visual alterations. Some patients may present with psychotic symptoms, cognitive dysfunction, and involuntary movements.

Immunocompetent individuals are usually asymptomatic. However, latent infection may predispose people to neuropsychiatric symptoms. This concept is gradually evolving based on converging evidence from studies among humans and rodents. Rodents infected with *T. gondii* have elevated dopamine levels, lose their natural aversion to the odor of cat urine, and may develop an attraction to cat's pheromones. Some human studies have found that *T. gondii* seropositivity is associated with higher likelihood of risk-taking, both financial (entrepreneurship) and physical (increased rate of motor vehicle accidents), as well as reduced memory performance. However, studies are inconsistent on whether *Toxoplasma* infection is associated with risk-taking. A recent meta-analysis did find a significant association between IgM antibodies against *T. gondii* and acute psychosis compared to controls. One strain of *T. gondii* (Type I) has been associated with an increased risk of psychosis in the offspring of infected mothers and demonstrates a greater effect on neuroepithelial host cell expression of genes involved in brain development and synaptic plasticity compared to other strains. Differences in strain may explain why, despite high seroprevalence of *Toxoplasma*, only a small proportion of the population has psychotic illness.

Congenital toxoplasmosis occurs in 1/1,000 to 1/10,000 live births. Maternal-fetal transmission risk is <20 % during the first trimester but increases to around 80% in the third trimester. Infection acquired earlier in

Telegram: @medical_k

www.konkur.in

gestation typically leads to more severe fetal outcomes, including spontaneous abortion, hydrocephaly, and intellectual disability, while infection occurring later in gestation leads to mild disease, with most cases being asymptomatic or presenting with recurrent chorioretinitis. Toxoplasmosis is diagnosed using a combination of clinical, serologic, and radiologic evidence. A presumptive diagnosis is often confirmed with a positive response to antiprotozoal drugs, with a favorable clinical response expected within 2 weeks. Serum or CSF PCR is also a useful method to diagnose *T. gondii* infection. CT head or MRI brain is critical for the diagnosis of cerebral toxoplasmosis. Single or multifocal lesions may be seen, with a typical pattern of a hypodense lesion with ring-enhancing and perilesional edema. Those with latent infection maintain IgG antibodies in their serum. Active infection is treated with pyrimethamine and sulfadiazine, pyrimethamine and clindamycin or atovaquone, or trimethoprim/sulfamethoxazole for at least 6 weeks. If immunosuppression is present, secondary prophylaxis with trimethoprim/sulfamethoxazole or pyrimethamine/sulfadiazine is continued indefinitely.

Amoebiasis

Amoebas are free-living environmental protozoa that do not require a host for survival, nor a vector for transmission. Four genera cause human disease, and all four can cause CNS infections: *Naegleria, Acanthamoeba, Balamuthia,* and *Sappinia.* CNS syndromes associated with amoebic infection are primary amoebic meningoencephalitis (PAM) and granulomatous amoebic encephalitis (GAE) (see Table 2.9–1).

Naegleria fowleri is found in freshwater and soil worldwide, and recreational water activities are a risk factor for infection, particularly if water is inhaled. Prevalence is low, with approximately 2.6 cases per million exposures. Presentation is typically PAM, an acute hemorrhagic meningoencephalitis with a mortality rate that approaches 100%. Symptoms include fever, headache, nausea/vomiting, photophobia, seizures, and altered mental status/behavioral changes. Uncal herniation can occur, and death typically occurs 10 days after exposure. Serum shows a neutrophilic leukocytosis, CSF shows frank hemorrhage and a markedly elevated white count, with elevated pressure; imaging is nonspecific. The exclusion of bacterial and viral encephalitis should raise suspicion for PAM, and the diagnosis is confirmed by observation of trophozoites in CSF. Optimal treatment regimen is unclear, but should

Telegram: @medical_k

www.konkur.in

include amoebicidal drugs that can cross the blood–brain barrier and steroids to control edema.

Acanthamoeba, Balamuthia mandrillaris, and *Sappinia pedata* can cause GAE, a subacute/chronic CNS infection. *Acanthamoeba* largely affects the immunocompromised, and is often transmitted via inhalation or via skin contact leading to hematogenous spread. Headache, low-grade fever, visual disturbances, behavioral abnormalities, and focal neurologic deficits can progressively worsen over weeks to months, eventually leading to seizures, elevated ICP, coma, and death. Brain biopsy is required for diagnosis, and will show trophozoites and cysts. Treatment relies on multiple drugs with anti-amoebic activity. *B. mandrillaris* can cause disease in the immunocompetent, and soil or water exposure may be related. An initial skin lesion is followed by development of neurologic manifestations and progresses to death within 3 months. *S. pedata* has been the identified cause of a single case of GAE.

HELMINTHS

Neurocysticercosis

Neurocysticercosis is caused by CNS penetration of *Taenia solium* larvae and is endemic to most of the developing world, including Central and South America, sub-Saharan Africa, the Indian subcontinent, most of Southeast Asia, and parts of China (see Table 2.9–1). It has a major public health impact since 30% of the epilepsy cases in these regions can be attributed to this disease. Epidemiologic studies have shown that specific serum antibodies may be seen in >10% and intraparenchymal brain calcifications on CT may be present in 10% to 20% of the general population in the endemic zones, suggesting high prevalence rates, though most cases are asymptomatic.

Humans acquire neurocysticercosis through fecal-oral route via close contact with a *T. solium* carrier excreting *T. solium* eggs in their feces. The larval cysts can form in most tissues, including the brain, and develop to their usual size in 2 to 3 months. CNS lesions can vary from a few millimeters to 1 to 2 centimeters in size and are found at the gray/white matter junction in the cerebral hemispheres or in the deep gray matter. Clinical symptoms appear years after the infection. The clinical symptoms, management, and prognosis depend on the CNS parasite burden, parasite size, location of the lesions, and host inflammatory response.

Telegram: @medical_k

www.konkur.in

Patients with exclusively intraparenchymal brain lesions typically present with seizures only, which tend to subside over the years. Neurocysticercosis may sometimes present with “cysticercotic encephalitis” where hundreds of small cysts are seen with severe diffuse inflammation, seizures, and raised intracranial pressure. This presentation occurs more commonly in children and young women, reflecting an intense host immune response. Antiparasitic treatment alone in these cases may worsen the symptoms and lead to mortality.

Lesions in the ventricular and basal subarachnoid space cause hydrocephalus and/or intracranial hypertension, leading to significant morbidity and mortality. Mass effect may lead to focal neurologic deficits, endocrinologic, and ophthalmologic abnormalities. Fourth ventricle cysts may cause Bruns syndrome, presenting with episodic severe headache, vomiting, vertigo, and sudden loss of consciousness related to head movement due to ball valve mechanism. Cognitive deficits are common, ranging from mildly impaired cognitive performance to severe dementia. Psychotic episodes can occur, likely as a complication of epilepsy.

The diagnosis is made using neuroimaging, with CT head used for screening and MRI brain, where available, used for better lesion characterization, while serology is employed to confirm diagnostically challenging cases.

In most patients, seizures respond well to monotherapy with first-line antiseizure medications. The optimal duration of antiseizure medication use is not very clear. More than 50% of patients develop recurrent seizures after discontinuing antiseizure medications. Multiple lesions, a history of recurrent seizures, and the presence of brain calcification(s) all predict a higher likelihood of seizure relapse. The underlying parasitic infection, including CNS lesions, is treated with anthelmintics like praziquantel and albendazole. Corticosteroids are used to reduce inflammation in case of encephalitis, angiitis, and arachnoiditis, and to control the host immune response when anthelmintic treatment leads to exposed parasitic antigens causing local inflammation.

2.10 Neuropsychiatric Aspects of Prion Disease

Brian Giunta, M.D., Ph.D., Alireza Minagar, M.D., M.B.A., Paul Shapshak, Ph.D., Nadejda Alekseeva, M.D., and Francisco Fernandez, M.D.

Transmissible spongiform encephalopathies (TSEs), also known as prion diseases, are an unusual and uncommon group of neurodegenerative disorders that are caused by conformational changes, misprocessing, and malfunction of the cellular prion protein (PrP^{C}). In 1982, Stanley B. Prusiner proposed the term prions to distinguish the spongiform group of nervous system disorders (TSEs) from other conventional infectious disorders caused by infective agents such as viruses. Prusiner pointed out that prions cause TSEs and are *pro*teinaceous *in*fectious particles that resist inactivation by most procedures that denature proteins and nucleic acids.

Prions (a member of a group of pathologies known as "proteinopathies") self-aggregate and are capable of generation of abnormal molecular aggregates with toxic intracellular signaling. The scrapie isoform of the PrP^{C} (PrP^{Sc}) is the infectious agent behind diseases such as Creutzfeldt–Jakob disease (CJD) in humans. After transmission to a naive host, prions initiate misfolding of the PrP^{C} in an autocatalytic manner, resulting in an

Telegram: @medical_k

www.konkur.in

exponential increase in PrP^{Sc} in the brain and spinal cord, culminating in neuronal death. The primary amino acid sequence of PrP^{Sc} is governed by host PrP^{C}. PrP^{C} is encoded by the prion gene, *PRNP*, which is located on the short arm of chromosome 20 (20pter-p12). In humans, neurodegenerative disorders caused by prions can present as hereditary/genetic (about 14% of cases), sporadic (85%), or acquired infectious disorders of the central nervous system (CNS; 1%).

The human prion diseases are sporadic Creutzfeldt–Jakob disease (sCJD), the variant Creutzfeldt–Jakob disease (vCJD), iatrogenic Creutzfeldt–Jakob disease (iCJD), familial CJD (fCJD), fatal familial insomnia (FFI), Gerstmann–Sträussler–Scheinker (GSS) disease, and Kuru. sCJD is rare and 100% fatal; it typically presents in persons with no known risk factors or inherited genetic mutations. vCJD is believed to be acquired through the consumption of beef products made from cattle infected with bovine spongiform encephalopathy (BSE), an animal prion disease commonly referred to as “mad cow” disease. iCJD is known to have been caused by corneal and meningeal grafts contaminated with prions, human growth hormone (hGH), prion-contaminated surgical instruments, and blood transfusions. Familial forms of CJD are transmitted as autosomal dominant traits with *PRNP* mutations, although other genetic loci have been implicated in the pathogenesis of human prion diseases. FFI is characterized by progressive insomnia and has been diagnosed in only about 25 to 40 families worldwide. Almost always inherited, GSS disease is an extremely rare and fatal prion disease observed in only a few families worldwide. Kuru is found among the Fore people of New Guinea. It was transmitted among members of the Fore tribe through ritualistic cannibalism when the Fore people prepared and consumed infected brain tissue of deceased family members. Today Kuru has nearly disappeared as a result of governmental discouragement of the practice of cannibalism.

The prion diseases of animals include scrapie, BSE or “mad cow disease,” chronic wasting disease (CWD), and transmissible mink encephalopathy (TME). In both humans and animals, these diseases are variations on a theme. That is, PrP^{C} conformational changes result in several phenotypes but have common end points: rapidly progressive dementia and death.

In humans, prion diseases are an uncommon cause of dementia and present with rapidly progressive cognitive and behavioral changes

Telegram: @medical_k

www.konkur.in

associated with visual and cerebellar impairments, extrapyramidal and pyramidal signs and symptoms, and akinetic mutism. In addition, as a group, these disorders share a spongiform degeneration of the brain and variable amyloid plaque formation. During the last two decades of the 20th century, worldwide concerns increased regarding BSE outbreaks in various regions of the world, particularly the United Kingdom, and its concomitant transmission of vCJD to humans. Thus, vCJD is a major concern for physicians and scientists, although its incidence has declined significantly since the 20th century. Clinically, sCJD differs from vCJD: in the latter, patients present with early psychiatric symptoms including anxiety, depression, apathy, and social withdrawal, with dementia being a late complication. In contrast, clinical features of sCJD include rapidly progressive dementia, ataxia, and myoclonic involuntary movements (Table 2.10–1). The emergence of multifocal neurologic deficits over days to weeks differentiates typical cases of sCJD from more common forms of dementia. Early diagnosis is not typical as cases may present initially with isolated syndromes, including cerebellar ataxia, acute stroke-like deficits, and cortical visual impairment (for review, see Will and Ironside, 2017). It should be noted that the causative agents of vCJD in humans and BSE in cattle share a common origin and differ from the causative agent of sCJD. This discovery stimulated interest in TSEs in general and in the possibility of their transmission from animals to humans.

NONFAMILIAL PRION DISEASES

Sporadic (Nonfamilial) CJD

sCJD has been found around the globe. The distribution of cases within countries or regions appears random, with no good evidence of clustering to suggest an environmental, infectious source. This is consistent with case-control studies of risk factors for sCJD development, which have been negative for the most part. Positive findings have been suggested to result from methodologic biases as opposed to authentic biologic risk factors. However, this is not the case for individuals with a history of prior surgery where an increased frequency of sCJD is observed. However, this is not consistent across all studies. For example, there is a lack of evidence of an increased risk from working in medical or paramedical occupations. Moreover, there is strong evidence that sCJD is not transmitted through blood transfusion. Indeed, the epidemiologic evidence

Telegram: @medical_k

www.konkur.in

points to sCJD developing because of a random conversion of PrP^{C} to PrP^{Sc} rather than from an external infectious source.

FAMILIAL GENETIC PRION DISEASES

Genetic prion diseases are categorized by their clinical symptoms and neuropathology. They include fCJD, FFI, and GSS disease. *PRNP* mutations are autosomal dominant, highly penetrant, and are composed of missense mutations, insertions, and deletions. Disease onset typically starts in the fifth or sixth decade of life.

Familial CJD

fCJD is defined as a form of CJD that results from mutation(s) in the gene that encodes PrP^{C} and exhibits autosomal dominant inheritance. Approximately half of the individuals carrying the mutated form of the *PrP^{C}* gene develop CJD. Although clinically, the presentation of fCJD varies with the mutation site within the *PrP* gene, it most closely resembles sCJD in its manifestations.

Fatal Familial Insomnia

FFI is a hereditary prion disease that is identified by disrupted sleep, motor abnormalities, and hyperactivation of the autonomic nervous system. As with fCJD, it is inherited by autosomal dominance with an atypical presentation and exclusive bilateral degeneration of the thalamus without the neuropathologic changes of spongiform degeneration or amyloid deposits. FFI is a midlife disease that affects both genders equally. The age of onset of FFI ranges from 36 to 62 years, and the disease is uniformly fatal and causes death in 8 to 72 months with an average of 18 months.

Table 2.10–1. Characteristics of CJD Subtypes

Acquired	Kuru	Progressive cerebellar ataxia	▶ Chromosome location: 20pter-p12 ▶ OMIM#: 245300	▶ Atrophy of the cerebellar vermis and flocculonodular lobe, ▶ Microscopically, loss of granule and Purkinje cells, fusiform swelling of the proximal portion of Purkinje cells' axons, and severe radial gliosis of Bergmann astrocytes
	Iatrogenic CJD	Ataxia	Dependent on the mutations of the prion protein gene of the original contaminant	Dependent on the mutations of the prion protein gene of the original contaminant
	Variant	▶ Psychiatric and behavioral symptoms, dysesthesias ▶ Median age of onset: 26 years (range 12–74) ▶ Median duration: 13 months (range 6–39) ▶ Cerebellar signs in 100% of patients	▶ Chromosome location: 20pter-p12 ▶ OMIM #: 176640, 123400 ▶ val129 provides resistance to vCJD prion	▶ Abundant PAS-reactive, PrP amyloid plaques in the cerebrum and cerebellum ▶ Diffuse PrP plaques ▶ Cerebral plaques may be surrounded by a halo of spongiform vacuoles and form florid plaques. ▶ Other PrP plaques and amorphous pericellular and perivascular PrP deposits in the cerebellar molecular layer. ▶ Caudate nucleus and putamen with spongiform alterations ▶ Thalamus with severe neuronal loss and intense gliosis; most prominent thalamic nuclei ▶ No periodic EEG complexes ▶ CSF 14–3–3 protein in 33% of patients ▶ Readily detected in lymphoid tissue ▶ Frequently absent hyperintense signal in the caudate and putamen on diffusion-weighted and FLAIR sequences of MRI ▶ Pulvinar sign on brain MRI are frequently present ▶ Marked increased ratio of protease-resistant glycoform of prion protein on immunoblot analysis
Inherited	Familial CJD	Psychiatric and behavioral abnormalities, dementia, ataxia, and myoclonus	▶ Mutation(s) in the gene that encodes PrP. ▶ Autosomal dominant pattern of inheritance. ▶ Chromosome location: 20pter-p12 ▶ OMIM #: 176640, 123400 ▶ Mutation: met129	▶ Presentation of fCJD varies with site of mutation within the PrP gene ▶ Resembles sCJD in its manifestations.
	Fatal familial insomnia	Sleep disturbance, autonomic instability	▶ Mutation(s) in the gene that encodes PrP. ▶ Autosomal dominant pattern of inheritance. ▶ Chromosome location: 20pter-p12 ▶ OMIM#: 600072 ▶ Mutation: asp178-to-asn (D178N)	▶ Exclusive bilateral degeneration of the thalamus without the typical neuropathologic changes of spongiform degeneration or amyloid deposits
	Gerstmann–Sträussler–Scheinker (GSS) disease	Cerebellar abnormalities, hyporeflexia, dysesthesias	▶ Mutation(s) in the gene that encodes PrP. ▶ Conglomerate of at least six dominantly inherited syndromes, each of which is linked to a different mutation and GSS (Q217R) ▶ Chromosome location: 20pter-p12 ▶ OMIM#: 137440	▶ multicentric amyloid (PrP) plaques in the molecular layer of the cerebellar cortex, cerebral cortex, and basal ganglia. ▶ Plaques with a central larger mass surrounded by smaller satellite amyloid deposits. ▶ Each mutation coupled with different subtypes of PrP plaques ▶ Some mutations cause considerable neurofibrillary tangle neuronal degeneration and generation of neuritic plaques ▶ Amyloid plaques consist of highly truncated PrP

Telegram: @medical_k

www.konkur.in

Sporadic	Sporadic CJD	▶ Progressive dementia, ataxia, myoclonus, 40% of patients with cerebellar signs ▶ Median age of onset: 65 years (range 15–94) Median duration 4 months (range 1–74)	▶ Chromosome location: 20pter-p12 ▶ OMIM #: 176640, 123400 ▶ Mutation: met129 and met/val129	▶ Macroscopically, spongiform encephalopathy in cerebral and/or cerebellar cortex and/or subcortical gray matter, and/or encephalopathy with rare PrP plaque immunoreactivity ▶ Microscopically, spongiform degeneration of neurons, neuronal loss, severe astrocytosis, formation of amyloid plaques ▶ >90% of patients with periodic EEG complexes ▶ CSF 14–3–3 protein in 99% of patients ▶ Not readily detected in lymphoid tissue ▶ Frequent presence of hyperintense signal in the caudate and putamen on diffusion-weighted and FLAIR sequences of MRI

In terms of neuropathology, FFI is ambiguous but has been observed to manifest as a focal neuronal loss in the thalamus, inferior olivary nucleus, cerebellum, and varying degrees of spongiform changes in the cerebral cortex. FFI is described to mainly affect the thalamus with a propensity for anterior ventral and mediodorsal thalamic nuclei. Other parts of the brain, including the inferior olives of the medulla oblongata and the cerebral cortex, have also been shown to be involved. The PrP^{Sc} deposition pattern favors the brainstem and thalamus earlier in the disease, but the thalamus is understood to be more vulnerable to subsequent degenerative changes. The reason for this involvement pattern is poorly understood but can explain the variety of symptoms seen in the disease.

Gerstmann–Sträussler–Scheinker Disease

GSS disease is another human prion disease that typically occurs in the fourth or fifth decade and mainly manifests with cerebellar ataxia and motor deficits. It has a familial autosomal dominant pattern of inheritance. GSS disease, like CJD, is not one single entity. There are at least six dominantly inherited syndromes with dissimilar clinical features, underlying neuropathology, and linkage to different mutations of the *PRNP* gene. GSS disease is an extremely rare neurodegenerative disorder with an incidence of 2 to 5 cases per 100 million.

Acquired Prion Diseases

Kuru is a prion disease that was discovered among geographically and ethnically isolated tribes in the Fore highlands of New Guinea. In the Fore language, Kuru means “trembling with fear.” Carlton Gajdusek and colleagues discovered that endocannibalistic funeral practices, by which deceased tribal members were ritualistically cooked and consumed by other family members, had a causal relationship to disease contraction.

Telegram: @medical_k

www.konkur.in

During this ceremony, female relatives and children typically consumed the deceased's brain. It was demonstrated that women and children had an increased incidence of Kuru compared to others.

The development of CJD in small groups of individuals exposed to human tissues during medical procedures lends substantial support to the hypothesis of iatrogenic transmission of CJD. Indeed, iCJD has occurred in more than 200 patients treated with human pituitary hormones and in an almost equal number of patients receiving human dura mater grafts. A small number of cases of iCJD have been traced to corneal grafts, depth electrodes, as well as contaminated neurosurgical instruments. Cases linked to hGH and human dura mater grafts continue to be observed, indicating extended incubation periods of up to 42 and 30 years, respectively. The presentation of iCJD also varies in that it typically presents with motor findings (ataxia and gait abnormalities) associated with only mild dementing signs and symptoms toward the later phase of the disease. It is assumed that tissues from sCJD cases entered the production process and that pooling of pituitary glands or dura mater grafts led to the dissemination of infection. The incidence of hGH CJD varies by country, likely in relation to the level of contamination entering the production process. On the other hand, the rates for dura mater CJD likely reflect the frequency of use of this material in neurosurgery. For the most part, recombinant pituitary hormones and synthetic or autologous grafts are now used rather than human-derived treatments. As such, new iatrogenic exposures are unlikely to develop.

Nonhuman Mammalian Spongiform Encephalopathies

Scrapie is a fatal disease of sheep and goats that is characterized by chronic itching, loss of coordination, and progressive degeneration of the CNS. Studies during the 1940s and 1950s by Björn Sigurdsson, an Icelandic veterinarian, defined the new concept of slow infections, utilizing the Koch postulates via experimental verification.

TMEs are defined as infectious neurodegenerative diseases that affect human and animal hosts. It has been identified in the United States, Canada, Russia, Finland, and Germany and is believed to be a result of dietary exposure to a prion-infected animal. Nevertheless, the origin of the disease remains uncertain, and no cases have been reported for over 30 years.

Telegram: @medical_k

www.konkur.in

CWD is a TSE that affects deer, elk, and moose. CWD is another slowly developing prion disease with a prolonged incubation period. Experimental inoculation of mule deer resulted in the discovery of a 2- to 4-year incubation time. Symptoms include physical and behavioral changes. Detection can be difficult, and these symptoms can be subtle early in the disease course or even fall within the normal range of behavior or seasonal body mass fluctuations. As such, diagnosis based on clinical signs is unreliable. Pathologic or biochemical analyses of the brain or lymphatic tissues are required. These would demonstrate neuronal vacuolation and spongiform changes, astrocytosis, and PrP^{Sc} accumulation in the brain or PrP^{Sc} deposits in lymphoid tissues. In most prion diseases, PrP^{Sc} and infectivity are primarily within the brain. However, in CWD, PrP^{Sc} can be identified in an array of extraneural tissues, body fluids, and excreta. This, in turn, promotes horizontal transmission.

Prions have caused multispecies epidemics and have spread as a zoonosis. BSE was first described in 1986, and within 10 years of its discovery, over 180,000 cases were diagnosed in cattle, zoo bovids, felids, and primates in the United Kingdom. It is currently classified as a potentially lethal zoonotic disease acquired *via* contaminated food. Indeed, the utilization of ruminant-derived meat and bone meal (MBM) as a food source for animals is the most well-accepted hypothesis for its spread in bovine populations. MBM contains CNS tissues and other tissues that contain the protease-resistant, disease-associated isoform of the PrP^{Sc}. BSE spread from the United Kingdom to at least 28 other countries, the majority of which are in Europe, with sporadic cases confirmed in Asia, the Middle East, and North America. BSE has an incubation period of approximately 2.5 to 8 years, with clinical manifestations usually observable in adult cattle at a peak age onset of 4 to 5 years. BSE is characterized by altered behavior, abnormal posture, incoordination and difficulty in rising, reductions in milk production, and weight loss. Histopathologic analysis reveals neuronal and neuropil vacuolation, glial reaction, and an absence of inflammatory lesions.

It should be mentioned that prion-like proteins also occur in fungi such as yeast. This demonstrates the importance of prion-like proteins in normal cell function as such proteins are present in fungi. For example, two yeast proteins, including ure2p and sup35p, are partially protease resistant and promote amyloid-like filament aggregation. Moreover, yeast

Telegram: @medical_k

www.konkur.in

"prion" proteins serve as paradigms for animal and human prion diseases. They also undergo conformational changes in their function, propagation, and strain variation. Yeast prions are infectious when propagated in the bacterial cytoplasm. Such findings are supportive of a wider significance than previously hypothesized for prions in biology.

HISTORY OF PRION DISEASES

The history of prion diseases commenced in the year 1920 when Hans Gerhard Creutzfeldt reported a 22-year-old woman with a mysterious and progressive focal syndrome of the CNS that was clinically identified by psychomotor abnormalities and cortical symptoms. Autopsy of this patient revealed prominent gliosis with noninflammatory focal lesions of the cerebral cortex. In 1921, Alfons Maria Jakob observed three additional cases of chronic neurologic disease, which he considered a new entity. In these patients, Jakob reported a spastic pseudosclerosis and encephalomyelitis with the spread of focal degeneration. A few years later, Walter Spielmeyer reviewed these cases and, based on their similarities, coined the name CJD. Subsequently, GSS disease was described in 1936 and FFI in 1986. In 1957, in the Kuru tribal region of New Guinea, Carlton Gajdusek and Walter Zigas characterized the clinical and neuropathologic features of Kuru and reported that the disease may be associated with cannibalism. In 1959, Hadlow distinguished certain similarities between Kuru and the spongiform encephalopathy of scrapie in sheep. This astute observation led to a series of experiments to transmit Kuru to nonhuman primates, accomplished by Gajdusek and Gibbs, and further discovery of salient similarities between Kuru and the spongiform encephalopathy of sheep scrapie. sCJD and sheep scrapie were found similarly related as well. Further research into the nature and pathogenesis of prion diseases was kindled after the discovery that BSE in the United Kingdom was causally related to vCJD. It is to Gajdusek's credit that he was able to reduce the incidence of Kuru among the Fore people by convincing them to halt ritual cannibalism.

The precise nature of the transmissible infective agent in TSEs has been investigated for several decades. Initially, it was hypothesized that slow viruses cause TSEs. However, a lack of normative immune responses against TSE agents and the unusual resistance to certain treatment procedures that normally denature and inactivate nucleic acids

Telegram: @medical_k

www.konkur.in

led scientists to propose that “an agent devoid of nucleic acids” or a protein may be the causative agent of TSEs. In 1982, Bolton isolated a protease-resistant sialoglycoprotein, designated as PrP, from brain homogenates. Contemporaneously, Stanley Prusiner coined the term prion (from proteinaceous infectious particle) and characterized prions in molecular and biologic detail. It should be noted that since then, immune responses against prions have been accomplished.

EPIDEMIOLOGY OF PRION DISEASES

Ritual cannibalism, which was practiced by Fore tribes in New Guinea, transmitted Kuru to females as well as children (of both genders) who consumed the brain tissue of deceased individuals. Brain tissue possesses elevated quantities of transmissible infective agents, and its ingestion transmitted disease to these two groups more than to other groups who did not consume brain tissue. Although Kuru is transmitted horizontally, after the cessation of cannibalism in New Guinea, Kuru has no longer been observed.

The epidemiologic assessment of CJD only exists in certain countries where surveillance centers document every new case. As noted previously, CJD can be sporadic, acquired, genetic, or iatrogenic. Patients with CJD die rapidly, and annual statistics for incidence, prevalence, and mortality rates are problematic and not easily obtained. However, generally, the worldwide annual incidence of CJD is estimated at 1 million individuals per year. Human prion diseases affect most populations around the globe with a frequency of 1 to 1.5 cases per million, with some variation internationally. The United States averages approximately 300 diagnosed cases of prion diseases annually.

PRION MOLECULAR BIOLOGY AND PATHOGENESIS

Prion Introduction

Analysis of the biologic, biochemical, and molecular activity and properties of prion proteins PrP^{C} (cellular) and PrP^{Sc} (scrapie) enables one to better understand the pathogenesis of prion diseases. Research since the discovery and identification of prions supports the concept that prion diseases result from the conversion of the normal host-encoded cell-surface glycoprotein, PrP^{C}, into abnormally and conformationally altered

Telegram: @medical_k

www.konkur.in

isoforms PrP^{Sc}. These studies also analyze mechanisms of how the structure and function of prions of form PrP^{C} are altered to prions of form PrP^{Sc} and how these processes lead to the development of inexorable terminal, progressive neurodegenerative disease. A fundamental finding that sets prions apart from any other known life forms and also is contradictory to the original Watson–Crick "fundamental dogma" of molecular biology is that PrP^{Sc} proteins are infectious and can propagate in the absence of nucleic acids.

Molecular Pathogenesis

During prion disease, characteristic destructive CNS damage occurs in the form of spongiform vacuolation, widespread neuronal loss, microglial activation, the proliferation of astrocytes, and PrP^{Sc} production. Great strides are being made in scientists' understanding of prion diseases, tropism, and molecular pathogenesis. There is extensive data pertaining to the mechanisms by which PrP^{Sc} prions gain access to the CNS after infection. Prions are generally transmissible by inoculation into, for example, subhuman primates, hamsters, and rodents. Intracerebral inoculation of brain homogenate is the most rapid method for inducing spongiform encephalopathy. In addition, TSE can be induced through peripheral routes, including intravenous (IV) and intraperitoneal injections, feeding, and via various aspects of introduction into the eye. Iatrogenic needle sticks, scalpel cuts, blood transfusions, and tissue grafts also result in human disease transmission of CJD and, as mentioned above, cannibalism-transmitted Kuru.

Cerebral accumulation of misfolded PrP^{Sc} is central to the pathophysiology of prion diseases. Several mechanisms are thought to underlie the toxicity of prion proteins. Dysregulated neuronal proteostasis takes place in prion disease at various levels. PrP^{Sc} disrupts the ubiquitin/proteasome system early in the disease progression, thus enhancing the buildup of PrP^{Sc} through impaired protein degradation. In turn, the accumulation of PrP^{Sc} disrupts the autophagy/lysosome pathway, which normally degrades aggregated proteins. Moreover, exhaustion of unfolded protein response (protection of the endoplasmic reticulum's function in protein synthesis and sorting pathways) occurs early in the disease process. This initiates a feed-forward cycle wherein disrupted PrP^{C} trafficking, impaired PrP^{C} function, and translational cessation

Telegram: @medical_k

www.konkur.in

deteriorates the neurons, triggering synaptic loss and, eventually, inducing cell death pathways.

Studies have revealed the close interaction between PrP^{Sc} deposits and the neuronal plasma membrane. There are two major mechanisms through which toxicity may occur from this interaction. First, PrP^{Sc} aggregates cause a significant membrane disruption, conceivably by disturbing the functionality of neuronal receptors and thereby changing plasma membrane permeability. Glycosylphosphatidylinositol (GPI)-anchored PrP^{C} can proficiently transduce neurotoxicity, and prion disease is accelerated in mice in which PrP^{C} shedding is disrupted. In the second mechanism, membrane-bound PrP^{C} is thought to function as a receptor of prion toxicity. A direct interaction between PrP^{Sc} and PrP^{C} induces neurotoxicity analogous to the mechanism first described in Alzheimer disease (AD), wherein oligomeric amyloid β-peptides bind membrane PrP^{C} complexed to the metabotropic glutamate receptor mGluR5. This, in turn, sets off an intracellular signaling cascade where Fyn kinase is activated and culminates in synaptotoxicity. PrP^{C} has also been implicated in neurotoxicity. Antibody binding to the C-terminal globular domain results in neurotoxic signal generation through the N-terminus, inducing calpain activation and overproduction of reactive oxygen species (ROS). Likewise, PrP^{Sc} has also been demonstrated to cause similar toxic signaling transduction with calpain activation and ROS generation. It should be noted that the sequence of events leading to receptor-mediated neurotoxicity has yet to be fully elucidated, and GPI-anchored PrP^{C} would require a coreceptor to make intraneuronal signal transduction possible.

After contacting the intestinal epithelium, prions are able to spread via M cells. Once they have penetrated the subepithelial area, neurotropic prions, are believed to further transmit through retrograde axonal transport into the brain stem through the autonomic peripheral nervous system. Lymphotropic prions, including sheep scrapie, deer CWD, and possibly vCJD, spread within hours to Peyer patches and draining lymph nodes. In the lymphatic tissue, PrP^{Sc} builds up in the germinal centers of lymphoid follicles, where it persists. Follicular dendritic cells (FDCs) capture antigens on the plasma membrane for presentation to B cells. FDCs have also been shown to be productive replicators of prions, resulting in sustained lymphoid prion infections for months to years. On the surface of FDCs, CD21/35 receptors are likely to bind a PrP^{Sc} complement complex.

Telegram: @medical_k

www.konkur.in

Subsequently, the hematogenous spread is promoted by eosinophils, neutrophils, monocytes, and mast cells. Ultimately, these cells cross the blood–brain barrier via multiple Trojan horse mechanisms. Nonetheless, it should be noted additionally, that cell-free blood and lymph spread occur as well. The timeframe and detailed mechanisms are under continued investigation.

Once prions have penetrated the brain and spinal cord, their numbers are further increased by neurons and astrocytes. Astrocytes are highly prone to in vitro prion infection and transfer prions to neurons. On the other hand, microglia are not a major factor in replication but rather are key for the clearance of prions. Oligodendrocytes do not possess any known substantial contribution to prion replication or CNS spread.

PrP^{c} concentration is highest in CNS (brain and spinal cord) neurons at both early stages of embryogenesis and in the adult, specifically in association with synaptic membranes as well as nicotinic acid/acetyl choline and NMDA receptors. Tissues infected by PrP^{Sc} prions extend beyond the CNS, including the spleen and muscle tissue of patients with sCJD. In addition, chronic inflammation can broaden the tropism of prion infectivity to other tissues, including the liver, pancreas, kidney, muscle, and mammary glands, although these tissues were originally considered to be prion free.

Cell Function Properties

It has been proposed that PrP^{C} is a multifunctional protein. PrP^{C} functions include its role in neural development, cell adhesion, axon guidance, synapse formation, neuroprotection, regulation of circadian rhythm, maintenance of myelin, maintenance of ion homeostasis, and signaling. Some of the most well-characterized functions are not directly due to PrP^{C} in its membrane-bound, GPI-anchored form but instead arise from soluble PrP^{C} fragments. For example, this has been reported for soluble PrP in regulating myelin homeostasis or in promoting neurite outgrowth. In the case of myelin maintenance, binding of N-terminal soluble PrP agonizes a Schwann cell G-protein–coupled receptor, Adgrg6 (Gpr126), whereas the molecular mechanisms subserving neurite outgrowth–promotion are unclear. It has been suggested that membrane-bound PrP^{C} functions as a receptor via homophilic interactions. In both cases, regulated proteolysis could serve as a form of functional regulation for transmitting the

Telegram: @medical_k

www.konkur.in

information. Indeed, such is the case for proteolytic cleavage fragments from the amyloid precursor protein (APP).

PrP^C may exert antiapoptotic protective activity in mammalian cells, mice, and yeast, which is due to internal or environmental stress factors that initiate apoptosis. For example, PrP^C is able to protect human fetal neurons in culture against Bax pathway apoptosis.

Oxidative stress affects several interconnected cellular pathways and can potentially cause mitochondrial dysfunction, damage to the ubiquitin protease system, aggregation of proteins, altered iron metabolism, and excitotoxicity. In contrast to the potential neurotoxicity discussed previously, several observations support a potential cytoprotective role for PrP^C against oxidative stress. PrP^C may protect cells from oxidative stress that is associated with superoxide dismutase (SOD) activity. It has been hypothesized that chronic oxidative stress of neurons is a major promoter of neurodegenerative disorders; this is exemplified in neuro-AIDS and drug abuse, in which there is an increase in neuronal nitric oxide synthase expression. It has been demonstrated that neurons (cerebellar granular and neocortical) cultured from *Prn-p*$^{0/0}$ mice are more susceptible than neurons from wild-type mice to treatments with oxidative agents such as hydrogen peroxide xanthine oxidase and copper irons. PrP^C appears to have both antiapoptotic and SOD activities that are obviously crucial neuron protective functions. However, it should be noted that work by other investigators finds no SOD activity associated with PrP^C. The still puzzling observation is that PrP^C has SOD activity but also contains copper ions within its normal structure. A discussion of the copper association with *PrP*^{C} follows.

Table 2.10–2.
Normal and Abnormal Forms of Prion Proteins

Features	Normal	Pathologic/Disease
Name	*PRNP, PrP*^{C}	*PrP*^{Sc}, CJD, GSS, FFI, etc.
Molecular weight	Monomer, 22–36 Kd	Stacked aggregates, >400 Kd
Cellular location	External, GPI linked at cell surface, synaptic clefts	Internal, Golgi, vesicles
Sensitivity to protease K	Yes	No
Biochemical structure	40% α-helices	40% β-pleated sheets
	3% β-sheets	30% α-helices
Cellular location	GPI linked at cell surface, synaptic clefts	Internal Golgi, vesicles, extracellular
Detergent miscibility	Miscible	Fibrils and rods form
Human tissue distribution	Brain, lymphocytes, heart, lung	Brain, lymphoid tissue
Concentration in normal brain	Variable, 1–5 μg/g tissues	Absent
Sensitivity to typical autoclave	—	No
Sensitivity to 4N NaOH hydrolysis	—	Yes
Apoptosis	Protective	Not protective
Superoxide dismutase	Yes	No
Binds Cu^{+2} cations	Yes	No
Coupled to tyrosine kinase Fyn	Yes	No

CJD, Creutzfeldt–Jakob disease; FFI, familial fatal insomnia; GPI, glycosyl phosphatidyl inositol; GSS, Gerstmann–Sträussler–Scheinker disease; *PrP*^{C}, prion protein cell; *PrP*^{Sc}, prion protein scrapie.

Data from Irani DN, Johnson RT. Diagnosis and prevention of bovine spongiform encephalopathy and variant Creutzfeldt-Jakob disease. *Annu Rev Med*. 2003;54:305; Johnson RT. *Viral Infections of the Nervous System*. 2nd ed. Lippincott-Raven; 1998; Roucou X, Gains M, LeBlanc AC. Neuroprotective functions of prion protein. *J Neurosci Res*. 2004;75(2):153; Van Rheede T, Smolenaars MMW, Madsen O, de Jong WW. Molecular evolution of the mammalian prion protein. *Mol Biol Evol*. 2003;20:111.

PrP^{C} may be a copper-binding protein. The histidine-containing octapeptide repeats (OR) bind up to four Cu^{+2} ions in a pH-dependent and negatively cooperative style. This binding interaction between *PrP*^{C} and Cu^{+2} ions changes the biologic and biochemical functions of the PrP^{C} (Table 2.10–2). Endocytosis of PrP^{C} via clathrin-coated pits is stimulated by micromolar concentrations of Cu^{+2} ions.

Structure

The physiologic form of the prion protein is GPI anchored and possesses two N-linked glycosylation sites. Mature PrP^{C} is composed of approximately 210 amino acids in a disordered N-terminal domain and a globular C-terminal domain of three α-helices and an antiparallel β-pleated sheet. PrP^{C} is largely present as a diglycosylated protein at the outer leaflet of the plasma membrane in lipid-enriched microdomains in its mature form. After internalization, PrP^{C} is recycled to the plasma membrane or the Golgi apparatus. Alternatively, it can be transported to late endosomes and then to intraluminal vesicles within multivesicular bodies (MVBs) for release as exosomes or for lysosomal degradation. PrP^{C} is a protease-sensitive sialoglycoprotein that possesses two N-linked complex oligosaccharide chains, like other GPI-anchored proteins; most of *PrP*^{C} is found in cholesterol-rich lipid membrane rafts.

Importantly, PrP^{C} is subject to α-cleavage and shedding of the protein. α-Cleavage results in an unstructured N-terminal protein fragment and a C-terminal globular fragment embedded in the cell membrane. These events occur during vesicular trafficking of PrP^{C} within the secretory pathway. The precise nature of the responsible protease remains uncertain. Cleavage occurring at the distal C-terminus of PrP^{C} and releasing almost full-length PrP is known as PrP shedding. This occurs only on the plasma membrane, and ADAM10 (a disintegrin and

Telegram: @medical_k

www.konkur.in

metalloproteinase-10) is the only relevant PrP sheddase, with diglycosylated PrP^C being the major substrate.

There are 23 enzymes involved in the biosynthesis of human GPI-linked proteins that are on 11 chromosomes, including two on chromosome 2. There are at least six GPI-linked proteins on neurons. A search for GPI-anchored human proteins at NCBI indicates that there are several hundred. Thus, compared to the entire proteome, there are few GPI-linked proteins. The function of this linkage is under investigation. The PrP^C molecule contains 253 amino acids and possesses two consensus sequences for N-linked glycosylation with molecular variants that have different degrees of glycosylation: unglycosylated, monoglycosylated, and diglycosylated. Some PrP^C is transferred to clathrin-coated pits where it undergoes endocytosis and recycling. PrP^C from humans, mice, Syrian hamsters, and cattle share common properties, including a flexible amino-terminal tail (residues 23 to 128), three α-helices, and a two-stranded antiparallel β-sheet that flanks the α-helix. A large flexible loop connects the second β-sheet and the third α-helix. The N-terminal portion of the *PrP^C* contains two conserved regions: a region of five repeats of octameric amino acid sequence, identified as the OR region (OR, octa-repeat region), and a second region with a high hydrophobicity (hydrophobic core), which is preceded by a hydrophilic domain known as charge cluster.

The OR region of PrP^C is significant for several reasons. This region contains the histidine residues that are capable of binding copper with copper-binding locations within the OR region. Copper complexing is associated with endocytosis of PrP^C and, through this, plays a role in the metabolism of this surface glycoprotein. The other reason for the significance of the OR region is that the expansion of the OR domain of up to 13 total repeats is also associated with genetic CJD and GSS disease (Table 2.10–3).

www.konkur.in

PrP^{C} and PrP^{Sc} have the same primary amino acid sequence, and their different secondary structures impart dissimilar physiologic and physicochemical properties. A study of their secondary structures demonstrated that PrP^{C} contains a high α-helical content (roughly 42%) and small β-sheet content (3%). The tertiary structure of PrP^{C} shows that the normal molecule possesses three α-helical domains and two β-strands. It is believed that PrP^{Sc} resistance to degradation by protease is related to the alteration of its structure from a molecule with the α-helical structure into a different conformation molecule with a large β-sheet content (Ross et al., 2005). Accumulation of this protease-resistant isoform within neurons disrupts their normal function and results in vacuolization and widespread cell death. PrP^{Sc}, through a self-promoting or -catalyzing mechanism, converts normal PrP^{C} into PrP^{Sc} (Tables 2.10–2 and 2.10–3).

Strains

Different strains of prions are associated with different prion diseases and their separate neuropathologies and the clinical signs and symptoms as described in this section. In animal model studies, biochemical traits were preserved through several passages in prion disease rodent models. Work by I. H. Pattison and G. C. Millson in 1961 provided the first evidence for the presence and production of various prion strains. Goats infected by the same preparation of infectious scrapie agent developed two different clinical syndromes: scratching and drowsy. Prion strains are infectious isolates that show distinct prion-disease phenotypes, including incubation periods, neuropathology, and specific neuronal targets in several regions of the brain, in the same hosts, and with serial transmission. Several mechanisms have been proposed, including that prion strain-specific phenotypic traits may be encoded by an ancillary genome due to specific PrP^{Sc} genetics and conformations in donor inocula, selected postinfection, or by host genetics.

Host Protein Interactions

PrP^{C} interacts with other cellular proteins, and some of these interactions may relate to the pathogenesis of prion diseases. Many of these potential interaction molecules are primarily or entirely cytoplasmic proteins, and their interactions with PrP^{C} are under study. As mentioned, PrP^{C} is a GPI-anchored protein, and its entire polypeptide chain is external to the

Telegram: @medical_k

www.konkur.in

cytoplasmic membrane. Direct PrP^C interactions are probable with other receptors, secreted or transmembrane proteins. However, PrP^C contains a conserved hydrophobic sequence that can span the lipid bilayer in both directions. This results in two transmembrane variants, ^{Ntm}PrP (N-transmembrane) and ^{Ctm}PrP (C-transmembrane). In general, without predisposing mutations in *PRNP,* these variants are present in very small quantities.

Genetics

There are three prion-related genes, *PRNP, PRND,* and *SPRN,* and the detailed study of these genes commenced after the cloning and sequencing of the human, hamster, and mouse prion proteins, first accomplished in 1986.

PRNP. The *PRNP* gene in humans is located on chromosome 20, and its product is PrP^C (see the Online Mendelian Inheritance in Man [OMIM 1 www.omim.org]). Polymorphisms of *PRNP* have been extensively studied, and the polymorphisms in codon 129 may play a critical role in host susceptibility to prion diseases. For example, the presence of the V129 allele is not associated with vCJD, which raises the possibility that the presence of this allele is protective against vCJD superinfection. Some mutations in *PRNP,* including D178N, are associated with fCJD or FFI (depending on the residue *cis* at codon 129), and E200K is associated with fCJD. Moreover, P102L has been linked to GSS disease.

Prion Gene Complex, Downstream. *PRND* (prion gene complex, downstream) encodes the Doppel protein and is another gene related to prion diseases. This is a paradigm known for the human genome that is due to gene tandem duplications. The following are terms used for the Doppel PrP: DPL, prion-like protein Doppel precursor; MGC41841, prion gene complex, downstream; PrPLP, PrP2 (doublet); and dJ1068H6.4, prion-like protein Doppel. The observation that $Prnp^{0/0}$ knockout mice exhibited late-onset ataxia led to the discovery of the *PRNP* Doppel. These mutants had underlying neuropathology of cerebellar Purkinje cell loss. *PRNP* Doppel is located 16 kb downstream of the mouse *PRNP.* The significance of Doppel protein and prion pathogenesis is under further investigation.

Telegram: @medical_k

www.konkur.in

Shadoo. The third prion-related gene encodes a short protein, known as Shadoo (*SPRN*), with similarities to the alanine-valine–rich central hydrophobic domain of PrP^C. The following are terms used for Shadoo (shadow precursor): FLJ41197, shadow of PrP homolog; and SHO, shadow of PrP. *SPRN* gene is not part of the PrP genomic complex and resides on the human chromosome 10. The significance of this protein and prion pathogenesis is under investigation.

Neuropathology

Neuropathologic studies of patients with Kuru have revealed that except for atrophy of the cerebellar vermis and flocculonodular lobe, the brain macroscopically may appear normal. Microscopically, prominent neuropathologic features manifest in the cerebellum with loss of granule and Purkinje cells, fusiform swelling of the proximal portion of Purkinje cells' axons, and severe radial gliosis of Bergmann astrocytes.

Macroscopically, the brains of patients with CJD may offer no specific diagnostic clues, or alternatively, one may observe various levels of cerebral cortical, striatal, and cerebellar atrophy. The WHO proposed neuropathologic criteria for CJD, including the presence of spongiform encephalopathy in cerebral and/or cerebellar cortex and/or subcortical gray matter and/or encephalopathy with PrP immunoreactivity (plaque and/or diffuse synaptic and/or patchy/perivacuolar types). Microscopically, the prominent neuropathologic features of CJD consist of spongiform degeneration of neurons and neuronal processes, significant neuronal loss, presence of severe astrocytosis, and formation of amyloid plaques. Spongiform degeneration that occurs in the context of CJD consists of the development of abundant rounded vacuoles within the neuritic processes and synapses and can be observed in the cerebral cortex (invariably in all cases regardless of the clinical manifestations), the subiculum of the hippocampus, caudate nucleus, thalamus, putamen, and the molecular layer of the cerebellum. Interestingly, the degree of spongiform degeneration and vacuolation in the same cortical section may vary from one area to another. The reactive astrocytosis that occurs during CJD involves the widespread presence of enlarged astrocytes in the cerebral cortex. In 10% of CJD cases, amyloid plaques that are positively immunoreactive with PrP antibodies and not immunoreactive with β-amyloid antibodies are present.

Telegram: @medical_k

www.konkur.in

The neuropathology of vCJD demonstrates morphologic and immunocytochemical features that set it apart from other prion diseases. The most prominent neuropathologic feature of vCJD is the abundant presence of PrP^{Res} in the form of PAS-reactive, *PrP* amyloid plaques in the cerebrum and cerebellum. Many of the cerebral plaques are surrounded by a halo of spongiform vacuoles and form florid plaques. Other PrP plaques and amorphous pericellular and perivascular PrP deposits are prominent in the cerebellar molecular layer. The caudate nucleus and putamen are the focus of spongiform alterations, while the thalamus demonstrates severe neuronal loss and intense gliosis. These abnormalities are more pronounced in the posterior thalamic nuclei.

GSS disease is a TSE that is neuropathologically characterized by the presence of multicentric amyloid (PrP) plaques that are present in the molecular layer of the cerebellar cortex, cerebral cortex, and basal ganglia. The GSS disease–amyloid plaque characteristically contains a central larger mass surrounded by smaller satellite amyloid deposits. Like CJD, GSS disease is a conglomerate of at least six dominantly inherited syndromes, each of which is linked to a different mutation of the *PRNP* gene. These include GSS (P102L), GSS (P105L), GSS (A117V), GSS (Y145Stop), GSS (F198S), and GSS (Q217R), and these dissimilar syndromes possess four general properties on neuropathologic and molecular genetic grounds: (1) the clinical manifestations resulting from each mutation differs with the others; (2) each mutation is coupled with different subtypes of PrP plaques; (3) certain mutations are linked with considerable neurofibrillary tangle neuronal degeneration and generation of neuritic plaques; and (4) amyloid plaques present in the neuropathology of GSS syndromes consist of highly truncated PrP peptides.

The main neuropathologic feature of FFI is thalamic atrophy. The affected thalamic nuclei include anterior ventral, dorsal medial, pulvinar, and centromedian. Although atrophy of the cerebellar cortex is minimal, the inferior olives demonstrate atrophic changes. Some neuroscientists have argued that neuronal loss observed in the neuropathology of FFI may be caused by apoptosis.

DIAGNOSIS AND CLINICAL FEATURES

Prion diseases, as a unique group of spongiform encephalopathies that affect human and animal hosts, have become the subject of intense

Telegram: @medical_k

www.konkur.in

media and popular interest. The significance of this group of invariably fatal disorders is further demonstrated by two Nobel prizes won by D. Carleton Gajdusek and Stanley B. Prusiner in 1976 and 1997, respectively. Prion diseases are a rare but fatal group of neurologic disorders with unique pathophysiology. As a rule, in any patient with rapidly progressive dementia or other neurologic deficits and in the absence of another reasonable diagnosis, the presence of prion diseases should be investigated.

Neurologic Manifestations

A healthy 38-year-old right-handed female complained of weakness of the lower extremities, imbalance, and memory loss. Within a few weeks, this neurologic syndrome was followed by increasing ataxia, startle myoclonus, and moderate dysarthria. Three months later, she was admitted to the neurology service with profound lethargy, dementia, lip-smacking, spasticity of the lower extremities, seizures, and hallucinations. Her electroencephalogram (EEG) demonstrated the presence of periodic sharp wave complexes (PSWC) (Fig. 2.10–1), while her brain magnetic resonance imaging (MRI) was normal. She died within 6 months from the initiation of her neurologic disease, and an autopsy confirmed the diagnosis of CJD.

A 63-year-old previously healthy woman was admitted with visual agnosia, visual hallucinations, and cognitive decline followed by ataxia and depression. CT scan of the brain revealed mild brain atrophy, and her EEG was interpreted as slow and disorganized. Within 2 months, she developed tonic–clonic seizures, and her dementia rapidly deteriorated so that she developed akinetic mutism. MRI of the brain, axial T_2-weighted images revealed the presence of hyperintense signals in the caudate nuclei and putamen (Fig. 2.10–2), and upon examination of her cerebrospinal fluid (CSF), 14–3–3 proteins were detected. Four months after the onset of her neurologic symptoms, she died. Postmortem examination of her brain confirmed sCJD.

Sporadic CJD. sCJD is still the most common and most prominent human prion disease, which usually manifests insidiously and affects both genders equally. sCJD is a disease of late middle age that causes an invariably fatal disease. Usually, sCJD develops insidiously with nonspecific behavioral abnormalities, including anxiety, asthenia, depression, loss of appetite, alteration of the sleep pattern, weight loss, fatigue, dizziness, and social regression. Neurologically, many of these patients develop worsening forgetfulness and progressive decline of higher cortical functions such as reasoning, abstract thinking, calculation, and judgment. Almost one-third of these patients initially present with purely neurologic deficits, mainly cerebellar gait ataxia. A minority of patients present with a combination of cognitive impairment and focal neurologic deficits. With further progression of the disease process,

Telegram: @medical_k

www.konkur.in

patients rapidly become demented, aphasic, or apraxic, and demonstrate choreiform–athetoid movements, myoclonic jerks, and pyramidal and extrapyramidal signs. Initially, most patients do not manifest myoclonus; however, with disease progression, most patients develop myoclonus. Startle myoclonus is a prominent feature of CJD, which is precipitated by certain stimuli such as loud noises or touch. Other symptoms that appear with disease progression include paratonic rigidity, primitive reflexes, cortical blindness, and oculomotor disturbances. Other visual symptoms include diplopia, blurred vision, and visual agnosia. Terminal patients develop akinetic mutism, collapse into a coma, and die of infections or thromboembolic complications. Certain clinical features such as epileptic seizures (only in 10% of patients), sensory deficits, and lower motor neuron features are uncommon among these patients. In addition, the presence of certain signs or symptoms, such as early-onset seizures during the clinical course, acute onset motor deficits, cranial nerves palsy (except for visual loss or diplopia), and significant ataxia without concomitant cognitive decline, raise serious questions about the accuracy of the diagnosis of CJD.

The two rare clinical variants of CJD include Heidenhain and Brownell–Oppenheimer. In the Heidenhain variant of CJD, the neuropathologic changes mainly affect the occipital cortex and result in cortical blindness, optic hallucinations, and agnosia. Brownell–Oppenheimer variant manifests with a pure cerebellar syndrome secondary to widespread neuropathologic changes of the cerebellum (WHO diagnostic criteria for CJD: https://www.who.int/zoonoses/diseases/Creutzfeldt.pdf).

Variant CJD. In 1995, the vCJD form of human CJD emerged from the United Kingdom. vCJD, as a distinct variation, differs substantially from the more typical sCJD because of the following characteristics: Disease clinical picture, development in younger individuals as compared to CJD, initial dominance of psychiatric manifestations, underlying neuropathology, the absence of any mutations in the *PRNP* gene and almost exclusive occurrence in those with methionine homozygosity at codon 129, and its linkage to BSE. The exact mechanism of transmission to humans remains unknown; however, it is hypothesized that consumption of meat or meat products that were contaminated with BSE infectious agent in the late 1980s caused BSE migration of BSE prion from other species to humans, generating the vCJD epidemic. The potential causal link between vCJD

Telegram: @medical_k

www.konkur.in

and BSE has attracted public interest. In addition, to date, it remains unknown why the clinical and neuropathologic abnormalities of vCJD tend to affect younger adults.

In contrast to sCJD, vCJD can be transmitted through blood transfusion and presents with a relatively slow clinical course. The average age of onset of vCJD is 29 years as compared to the sCJD average age at onset of 65 years. Psychiatric symptoms such as depression, anxiety, agitation, delusions, and hallucinations are typically the initial manifestations, and within 6 months, they are followed by more characteristic neurologic features of CJD such as gait ataxia, dementia, dystonia, chorea, myoclonus, upward gaze paresis, and sensory abnormalities. In patients with vCJD, a nerve conduction study is usually normal; however, somatosensory-evoked responses may demonstrate minor abnormalities, indicating central involvement of pain pathways or thalamic origin for the pain. Like what is observed in sCJD, the end-stage patients with vCJD develop profound dementia along with akinetic mutism. Patients die after a median duration of 13 months (WHO diagnostic criteria for vCJD: https://www.who.int/zoonoses/diseases/Creutzfeldt.pdf).

Iatrogenic CJD. As noted previously, the accidental transmission of CJD to humans has been reported and well documented with corneal transplantation, implantation of contaminated EEG electrodes, implantation of dura matter grafts, and following use of contaminated HGH preparations derived from human pituitaries. In addition, one case of CJD following repair of an eardrum perforation with a pericardium graft has been reported. The disease can also be transmitted to humans by using inadequately sterilized neurosurgical instruments. Interestingly, in cases of central transmission (use of inadequately sterilized neurosurgical instruments or implanted EEG electrodes), patients mainly manifest with cognitive decline, while in peripheral cases such as the transmission of CJD via injection of contaminated HGH or gonadotropins, progressive ataxia followed by dementia predominate the clinical picture. Many of these patients develop myoclonic jerks.

Kuru. The word *Kuru* originates from the Fore word for shiver and refers to a progressive cerebellar syndrome that occurs among the highlanders of Papua New Guinea. Kuru affects individuals between the ages 5 and 60 years, with an equal ratio among male and female children but prominent excess in female adults. Kuru is transmitted by ritual

Telegram: @medical_k

www.konkur.in

cannibalism. Women and children, most of the victims of Kuru, participate in the cannibalistic feasts and consume the brain and intestines of the dead relative due to a social order within the tribe (Fig. 2.10–3). It is unclear when the first case of Kuru occurred in this population; however, it is believed that the first case began as sCJD, and then consumption of this infected deceased individual by other tribe members eventually led to the recycling of the prions within this isolated population and occurrence of Kuru at an epidemic proportion. By the late 1950s, cannibalism ceased, and the frequency of Kuru dropped significantly. If Kuru has continued with an even low incidence, then it is not purely due to cannibalism but may have a genetic component as well. In fact, that could be an alternative situation. That is a mutant develops in this highly homogeneous and isolated set of tribes in New Guinea. Their degree of isolation from each other is supported by the very large number of unrelated languages spoken there until they were discovered. Once the mutant prion gene was transmitted, then cannibalism that may have existed prior to that or occurred as a result then propagated the disease and its further spread. In that case, one would expect a continued low level of Kuru to linger after cannibalism ceased. However, secret cannibalism may still be practiced and could contribute to a very low incidence of Kuru. Interestingly, prior to the cessation of cannibalism, each potential patient was exposed to prions many times, which in turn made it difficult to precisely determine the incubation period of Kuru. The Kuru disease process commences with a vague prodrome characterized by malaise, arthralgia, and headache. Neurologically, Kuru usually manifests with gait instability followed by balance problems and frequent falls until the individual can no longer walk independently or sit without support. Gait ataxia is accompanied by dysmetria, dysarthria, incoordination of the upper extremities, various movement disorders such as clonus, chorea, and athetosis, emotional incontinence with inappropriate laughter, and convergent strabismus. Interestingly, weakness and rigidity are absent. Kuru patients' cognition is initially intact, and usually, in the advanced stages of the disease, dementia manifests. As the disease advances, dementia usually occurs, and patients become apathetic and withdrawn. In the end, patients become completely incapacitated and dependent on one another for daily life activities. Usually, within 1 year of disease onset, patients die of aspiration pneumonia, sepsis from decubitus ulcers, or inanition.

Telegram: @medical_k

Gerstmann–Sträussler–Scheinker Disease. GSS disease was initially described by Josef Gerstmann and colleagues in 1928 and 1936 in the members of a large Austrian family with multiple affected generations and autosomal dominant inheritance. However, GSS disease was categorized as a TSE in 1981 when its transmissibility was discovered. Affected patients present with clinical manifestations of cerebellar involvement such as ataxia and dysarthria, and later dementia manifests. In some of the reported families, parkinsonism predominates, while others demonstrate cortical blindness, deafness, and gaze palsies. A codon 102 mutation of *PRNP,* which results in a substitution of a proline for leucine in the *PrP* molecule, has been linked to the ataxic form of GSS disease. Recently, Jones et al. reported a case of GSS disease associated with strongly seropositive VGKC-complex antibodies, which emphasizes the point that these antibodies should be searched for in patients with GSS disease.

Fatal Familial Insomnia. FFI is a rare disease that was initially reported by Medori and colleagues in 1992. FFI is the third most common genetic prion disease with a worldwide occurrence and with analogous clinical manifestations also in different genetic settings. This dominantly

Telegram: @medical_k

www.konkur.in

inherited prion disease manifests with sleep–wake cycle disturbances and insomnia followed by hallucinations, and eventually, patients plunge into a coma. Initially, most patients complain of disturbances of vigilance, such as being unable to go to sleep, attention, visuomotor function, or having uninvigorating sleep and demonstrate personality changes such as apathy. Insomnia is an early manifestation of FFI, which in certain patients may progress to almost complete inability to sleep. The insomnia of FFI is associated with major and lasting disorganization of sleep cycles. Loss of ability to sleep is more obvious and more progressive in the early disease course in subjects who are methionine homozygous at codon 129 than in those who are methionine and valine heterozygous. Some patients also develop visual fatigue with diplopia and sympathetic activation. Other autonomic disturbances, including pyrexia, hyperhidrosis, tachycardia, hypertension, and cardiac arrhythmia, develop. Major motor abnormalities consist of ataxia, spontaneous and evoked myoclonus, and pyramidal signs. In contrast to sCJD, where dementia rapidly develops, in patients with FFI, dementia may or may not develop. Other abnormalities include loss of circadian rhythm for secretion of melatonin, prolactin, and growth hormone, as well as a decrease in the secretion of adrenocorticotropin and an increase in the secretion of cortisol.

FFI rarely affects the thalamus without the involvement of other regions of the forebrain, and the underlying neuropathology extends throughout much of the thalamus and cerebral cortex. Neuropsychological assessment of the original FFI families demonstrated increasing disturbances of attention and vigilance and impairment of working memory and temporal ordering of events. Patients' intelligence was preserved at least until vigilance levels permitted meaningful neuropsychology testing; however, frontal lobe functions were impaired.

Telegram: @medical_k

www.konkur.in

A 67-year-old right-handed man developed depression, visual agnosia, and visual hallucinations. In 3 months, his neurologic syndrome deteriorated, and he developed progressive dementia, myoclonus, and ataxia. CT scan of the brain showed only brain atrophy, and EEG did not reveal any significant abnormalities. Within the next 2 months, his dementia progressed, and he became bedbound and eventually became unresponsive. Examination of CSF demonstrated the presence of protein 14–3–3, and within 7 months from the onset of his first neurologic symptoms, he passed away. Neuropathologic examination of the brain during autopsy confirmed sCJD.

A previously healthy 29-year-old right-handed female developed brief episodes of forgetfulness and lapse of attention. She was initially diagnosed with major depression and was treated with antidepressants. Her neurologic condition deteriorated with progressive further loss of communication and social skills. Within the next 4 months, she became severely ataxic and globally demented. The rapidly progressive dementia led to akinetic mute condition followed by coma and death. EEG revealed rhythmic triphasic sharp wave activity more obvious on the right frontal and temporal areas on a slow background. MRI of the brain on axial T_2-weighted images revealed bilateral hyperintense signal in caudate nuclei and putamen (Fig. 2.10–4). During postmortem examination, typical neuropathologic findings of sCJD were detected.

Psychiatric Manifestations

Psychiatric disorders commonly occur in patients with sCJD and generally manifest during the early phase of this progressive neurodegenerative disorder. In a retrospective review of 126 patients with sCJD who were assessed at the Mayo Clinic, 80% of patients suffered from psychiatric symptoms within the first 100 days of their illness, with 26% having them at presentation. The most frequently reported psychiatric symptoms were sleep disturbances, psychotic symptoms, and depression. The

Telegram: @medical_k

www.konkur.in

investigators concluded that psychiatric symptoms are common in sCJD and occur early prior to formal diagnosis.

FIGURE 2.10–4. T_2-weighted magnetic resonance image of a patient with sporadic Creutzfeldt–Jakob disease. There is a hyperintense signal in the caudate nuclei and putamen. (Courtesy of Donald Collie.)

vCJD, which is less common than sCJD, affects younger individuals and has distinct clinical and neuropathologic features, with more neuropsychiatric manifestations compared to sCJD (Table 2.10–1).

In one series, all vCJD patients had psychiatric symptoms during the early phase of their disease process, and the majority were diagnosed with depression or depression secondary to organic disease. Two patients had symptoms suggestive of psychosis, while the majority manifested transient delusions and auditory or visual hallucinations. Thus, psychiatric symptoms, as consistent early components of vCJD, occur in a majority of these patients. However, they do not manifest any characteristic features that can differentiate them from other common psychiatric disorders. Only the occurrence of associated persistent sensory symptoms may raise the

Telegram: @medical_k

www.konkur.in

possibility of vCJD. Nonetheless, the evaluation of any patient with subtle neurobehavioral signs and symptoms should include the systematic approach described below.

NEUROPSYCHIATRIC WORKUP: THE STRUCTURED PSYCHOLOGICAL AND NEUROPSYCHOLOGICAL HISTORY

A comprehensive cognitive history is essential for initiating the assessment and directing which tests should be used in the evaluation battery. In combination with the clinical pattern of evolving dementia, the history can be key in the differential diagnosis of the etiologies of behavioral and cognitive dysfunction in patients with CJD with psychiatric complaints. Sometimes, the interview identifies the basis of the problem when neuropsychological testing is not possible or available. Table 2.10–4 lists the essentials of the interview for formulating this history. Answers to these questions can help associate patient complaints with cognitive disorders and dementia.

The Mental Status Examination

This introductory cognitive history taking should include an appropriate mental status examination. A standard examination, such as the Mini-Mental State Examination (MMSE), is frequently done because it is well known, and many practitioners have developed a sense of what its score means in terms of overall cognitive functioning. This test was developed to help identify the cortical type of dementia associated with AD. It has a concentration of items associated with language and orientation and has a visuospatial task. As such, it may miss the types of memory, speed of information processing, and attention/concentration problems often associated with early manifestations of CJD. Another screening task, the High Sensitivity Cognitive Screen (HSCS), may be useful in screening for the simple presence or absence of cognitive dysfunction. The creators of this measure report high correlations between this test and the overall result of neuropsychological testing. They note that the HSCS is also correlated with EEG results in medical psychiatric inpatients and with functional status. Results of this measure may then establish the eligibility of the patient for a more in-depth neuropsychological assessment.

Hearing any unusual sounds; see unusual things; have any strange feelings

Any changes in any other senses

Decreased hearing, ringing, or buzzing sounds

Change in smell or taste

Any numbness, “pins or needles,” loss of feeling, tingling, or burning feelings

Any severe pain

Memory

Any areas of memory that are better or worse

Memory for recent information

Information from way back in life

Any difference in memory for *situations* vs. rote facts and figures

Kinds of things most easily forgotten: names, addresses, directions, reading

How long can things be remembered, more notes written than used to

Any lapses noted

Any getting lost or forgetting where one is

Any new difficulties with thinking through problems or solving them, decisions making, staying organized—on job, at home

How is sleep: any trouble getting to sleep; night vs. daytime; any awakenings from which one cannot immediately return to sleep

Any inability to move any parts of the body

Muscle weakness, twitching, spasms, trouble walking, coordination problems, tremors or shakiness, problems with dropping things, feeling like moving more slowly, difficulty using tools or household utensils, getting dressed, telling right from left

Headaches or dizziness, instances thought to be seizures (staring off into space for a long time, uncontrollable movements, periods where one seemed “lose” time, incontinence)

Changes in mood, feelings, ideas

Mood swings, loss of patience or change in temper, increase in irritability, change in amount of worry, sense of panic

Neuropsychological Assessment

Telegram: @medical_k

www.konkur.in

The most prevalent component of cognitive impairment related to CJD includes general cognitive decline. Early problems with abstraction, attention, concentration, learning and memory, and psychomotor speed progress to more serious difficulties with these functions, as well as impaired executive functions, nonverbal problem solving, and visuospatial integration and construction.

As with the language-heavy MMSE, neuropsychological tests for the assessment of other forms of dementia include tasks that gauge such cortical functions as complex language-associated functions (such as aphasia and apraxia), higher-level cognitive functions of verbal and nonverbal abstract reasoning, and problem solving and perceptual functioning. These tasks are still necessary when one suspects or has information that the patient is experiencing dysfunction related to focal disturbances in the CNS. These can be caused by varying conditions such as infection, tumor, stroke, vasculitis, multiple sclerosis (MS), HIV, and other etiologies. Other tasks often used in comprehensive batteries for the evaluation of memory, attention, concentration, and psychomotor speed are more useful for detecting the often-subtle impairments of the early stages of cognitive impairment as may occur in vCJD. Neuropsychologists have often tried to summarize or digest multiple scores into indices that correspond to diagnostic levels (e.g., the Halstead–Reitan Impairment Index). Regarding one of the most generally used instruments, the Rey 15-Item Test, several investigators have shown that genuine conditions may yield false-positive results, and clinical judgment must ultimately determine the validity of this task's performance. Another method, the forced two-choice selection task, in which correct selections below the 50% level (actually, from the research, a much higher cutoff score; 69) may imply an attempt to deceptively manipulate the task, appears to be less problematic. These tasks have not been validated in the CJD population, and unless the patient is obviously severely demented or delirious, there can be high confidence that results reflect the patient's actual effort.

Psychological Functioning

Psychiatric conditions have received much attention as they often arise in vCJD neurobehavioral disorders. The initial manifestations of emotional lability, anxiety, depression, aggression, and psychosis, along with the emotional distress caused by a change in one's behavior and all the

Telegram: @medical_k

www.konkur.in

influences it has on a person, and possible pre-existing psychiatric disorders and/or neurologic syndromes caused by other medical circumstances may necessitate a psychiatric consultation. Several screenings and more comprehensive measures have been used but are not validated in CJD.

Although not formally researched in CJD, screening instruments such as the Beck Depression Inventory and the Symptom Checklist-90 (or its brief form, the Brief Symptom Inventory; Derogatis, 1993) have appeared frequently in the literature with medically ill patients and are simple to administer and score. These instruments and the more comprehensive Minnesota Multiphasic Personality Inventory 2 (MMPI-2) have been used to assess psychological difficulties in medically ill patients. Common problems and points of debate are the overlap of somatic or vegetative symptoms (e.g., fatigue) of depression and the systemic effects of any disease and/or its treatments. A newer, multifactor screening instrument, the Hospital Anxiety Depression Scale (HADS), attempts to avoid this problem by focusing on the psychological distress elements. For psychological evaluations beyond the screening level, a structured interview, as well as administration of the MMPI-2 as a secondary measure, would provide the information required for a full psychological diagnosis.

Clinical Assessment

Psychiatrists will best diagnose CJD by recognizing its characteristic symptoms. The approach described above will assist only in excluding a few other illnesses that mimic or overlap with CJD. Clinically, one would likely make the diagnosis of a mild neurocognitive disorder or fully developed dementia.

Unfortunately, there are several issues with the category for mild neurocognitive disorder in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). For example, the basis for the diagnosis is mostly focused on the presence of neuropsychological impairment instead of clinical findings. Also, there is no listing of motor signs or symptoms and thus is not very specific for prion, progressive supranuclear palsy, Parkinson's disease (PD), HIV, or other etiologies.

Although early diagnosis may be made by clinical psychiatrists, it is the progressive nature of the neurologic dysfunction that leads to neurologic consultation and a definitive assessment and diagnosis made. In one

Telegram: @medical_k

www.konkur.in

survey in the United Kingdom, only 30% of psychiatrists were aware of the diagnostic criteria and the surveillance project for CJD. Although in all the cases of vCJD, psychiatric symptomatology is the rule, it is nearly impossible to make the diagnosis in this early phase of the illness as there is no specific psychiatric phenotype to warn clinicians. Thus, the development and progression of neurologic aspects of the disease and either molecular or neuropathologic examination are necessary to properly identify all CJD cases.

Neurodiagnostic Workup

Laboratory diagnosis of CJD rests on abnormalities found in one or more of these tests: examination of CSF, EEG, or brain MRI. Table 2.10–5 provides a summary of the initial diagnostic workup for CJD.

Routine examination of the CSF is usually within normal limits, although occasionally, slightly elevated protein levels or minimal pleocytosis (less than 10 cells/mL) may be detected. However, the CSF protein level is generally less than 100 mg/dL. A class of 14–3–3 proteinase inhibitor proteins is currently being measured within CSF as surrogate markers for neuronal injury that occurs during CJD. Even though elevated CSF proteins 14–3–3 lend support to a diagnosis of CJD, the elevated levels may occur in other pathologic conditions such as recent stroke, subarachnoid hemorrhage, hypoxic brain damage, glioblastoma, postictal, inflammation, corticobasal degeneration, or paraneoplastic syndromes. However, where CJD is suspected, the detection of protein 14–4–3 improves the accuracy and confidence of diagnosis. Another method for PrP^{Sc} assay in the CSF has been developed, which is known as “protein misfolding cyclic amplification” (PMCA) and is being utilized as a diagnostic test. In certain aspects, PMCA is like a polymerase chain reaction and works as an amplification procedure to multiply misfolded prions. It is presently used for the diagnosis of prion diseases. A modified version of this technique has been developed as real-time quaking-induced conversion (RT-QuIC), which is capable of separating patients with sCJD from AD with 80% sensitivity and no false-positive cases. CSF from patients with sporadic as well as inherited CJD, GSS disease, and FFI have been examined utilizing RT-QuIC, and the results demonstrate that RT-QuIC is as sensitive as a measurement of protein 14–3–3 but more specific than the latter assay.

Telegram: @medical_k

www.konkur.in

EEG of patients with CJD characteristically demonstrates the presence of bi- and triphasic PSWC in the context of slow background. These classic EEG abnormalities are present in up to 70% of patients with sCJD but may take up to 3 months to appear. Other diseases that may imitate EEG abnormalities observed in CJD include AD, HIV-associated neurocognitive disorders, Lewy body disease, MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes), anoxic/ischemic encephalopathy, hypoglycemia, hypo- and hypernatremia, hepatic encephalopathy, hyperammonemia, and lithium toxicity.

CT scan of the brain remains normal in most patients; however, in some, it may reveal cerebral atrophy with enlargement of ventricles and cisterns or cerebellar atrophy. Brain MRI usually demonstrates distinguishing hyperintense signals in the caudate and putamen with less involvement of the cortex or thalamus. These abnormal hyperintense signals can be observed on T_2-weighted proton density and FLAIR sequences.

Compared to sCJD, studies of CSF and EEG are less useful in the diagnosis of vCJD. CSF 14–3–3 proteins are less sensitive in vCJD and are positive in only half of the patients, and EEG traces do not demonstrate the typical PSWC that is seen in sCJD.

MRI of the brain in patients with sCJD demonstrates the presence of hyperintense signals in the caudate and lenticular nuclei or at least two cortical areas (temporal, parietal, or occipital in diffusion-weighted and/or FLAIR images) (Fig. 2.10–5). These abnormal areas on brain MRI correlated with the areas with the most spongiform vacuolation and neuronal loss than gliosis. MRI of the brain in patients with vCJD shows bilateral hyperintense signals in the pulvinar of the thalamus (the pulvinar sign) on T_2-weighted and proton-density images (Fig. 2.10–5). Pulvinar hyperintense signals correlate with gliosis. In patients with FFI routing, neuroimaging does not yield any characteristic features. Brain imaging with fluorodeoxyglucose positron emission tomography ([^{18}F]-FDG PET) demonstrates remarkable thalamic hypometabolism, which is sometimes associated with diffuse hypometabolism of the basal ganglia, cerebral cortex, particularly the frontotemporal cingulate regions, and the cerebellum. Bilateral thalamic with less pronounced cingulate cortex hypometabolism is a typical aspect of FFI. Polysomnographic studies of these patients have shown the absence of sleep spindles and δ-sleep,

Telegram: @medical_k

www.konkur.in

along with prominent autonomic and motor hyperactivity (also known as agrypnia excitata). In FFI patients, stage 1 nonrapid eye movement (NREM) sleep is substantially preserved. In patients with FFI, an increase in 5-hydroxytryptamine synthesizing neurons within the median raphe system has been reported, and examination of CSF of patients with FFI has revealed a four- to fivefold increase in the 5-hydroxyindoleacetic acid (5-HIAA) catabolites compared to normal controls.

Table 2.10–5.
Initial Diagnostic Tests for Creutzfeldt–Jakob Disease

Blood tests: Complete blood count, comprehensive metabolic panel, serum ammonia, RPR, sedimentation rate, C reactive protein, serum vitamin B_{12}, HIV test, Lyme test, PT/INR

Urine tests: Urine analysis, urine drug screen

Cerebrospinal fluid analysis: Cell count and cytology examination for malignant cells, presence of oligoclonal bands, IgG index, protein and glucose level, VDRL

Neuroimaging: MRI of brain with and without contrast including

FLAIR and DWI images

EEG

CT scan of body with and without contrast searching for malignancy

Brain biopsy

CT, computed tomography; DWI, diffusion-weighted imaging; EEG, electroencephalogram; FLAIR, fluid-attenuated inversion recovery; HIV, human immunodeficiency virus; IgG, immunoglobulin G; MRI, magnetic resonance imaging; PT/INR, prothrombin time/international normalized ratio; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory test.

Differential Diagnosis

Kuru does not pose a diagnostic challenge for clinicians since there are not too many other disorders that can cause relentlessly progressive cerebellar disease in Fore tribe members of New Guinea. Similarly, FFI is not a major diagnostic dilemma once it occurs in a member of an FFI pedigree. However, in certain cases, positive family history is absent, or insomnia develops only with disease worsening. In these cases, other prion-disease imitators such as familial AD should be ruled out. However,

Telegram: @medical_k

www.konkur.in

this may not be the case for other prion diseases, and in certain cases, comprehensive diagnostic procedures should be performed.

FIGURE 2.10–5. T_2-weighted magnetic resonance image from a patient with variant Creutzfeldt–Jakob disease. 	Thalamic or corpus callosum infarcts

HIV, human immunodeficiency virus; CNS, central nervous system.

Differential diagnosis of sCJD includes subacute encephalopathies secondary to intoxication with certain drug toxins such as lithium, mercury, or bismuth, and other diseases including CNS vasculitis, Hashimoto thyroiditis, paraneoplastic syndromes, infectious and granulomatous disorders such as neurosyphilis, sarcoidosis, HIV-1–associated neurocognitive disorders, CNS fungal infections, other neurodegenerative disorders such as AD, Lewy body dementia, PD with dementia, corticobasal degeneration, amyotrophic lateral sclerosis, and frontotemporal dementia. An extensive list of differential diagnoses of CJD is presented in Table 2.10–6.

COURSE AND PROGNOSIS

Despite dissimilar ages of onset, clinical manifestations, and durations of survival, CJD is a relentlessly progressive disease with an almost daily compromise of neurologic and psychiatric function that culminates into death. The mean duration of CJD is approximately 7 months, and a disease duration of more than 2 years is rare. Similar to other prion diseases, vCJD is invariably fatal. Patients with FFI may experience worsening of their dysautonomia syndrome and eventually succumb to their fatal illness. To date, no information exists on the effect(s) of pregnancy on prion diseases.

TREATMENT

To date, there is no known treatment for prion diseases, although investigational pharmacotherapies are emerging. Palliative therapy is the cornerstone of treatment for these patients. Despite the differences in

Telegram: @medical_k

www.konkur.in

their age of onset, clinical manifestations, and disease course and duration, prion diseases remain invariably fatal. Symptomatic therapy includes the use of opioids and antiepileptic agents for pain management, selective serotonin reuptake inhibitors (SSRIs) for management of depression and agitation, atypical antipsychotics for the treatment of agitation and psychosis, and clonazepam to manage myoclonus and agitation. Referring patients and families to the CJD Foundation for caregiving planning and end-of-life care should be a priority from the onset of prion disease symptoms.

The basis of experimental therapeutics is the assumption that disease processes arise from the transformation of PrP^{C} to PrP^{Sc} and its subsequent accumulation. Direct inhibition of this conversion is an important therapeutic strategy. Targeting PrP^{C} may make it possible to knockdown or totally remove substrates for prion propagation. In theory, this strategy could be applied to all forms of prion diseases. On the other hand, targeting PrP^{Sc} itself could have no impact on disease progression or may even enhance or prolong disease. Thus, current investigational therapeutic strategies that may assist scientists in developing effective treatments of human prion disease target the conversion of PrP^{C} to PrP^{Sc} and include disruption of PrP^{C} plasma membrane trafficking, stabilization of PrP^{C} structure with chemical chaperones, manipulation of PrP^{C}-related signaling pathways, and disruption of the PrP^{C}–PrP^{Sc} physical interaction.

At present, families of identified patients with CJD may inquire or request genetic testing, especially in the context of familial prion disease. Since there is no available treatment for CJD, it is debatable whether such testing is warranted. Although there are no specific treatment guidelines for genetic counseling in such situations, one can adapt recommendations that exist (see https://cjdfoundation.org/genetic-counseling). If you wish to consider genetic counseling, one can find an expert genetic counselor and consult privately in person or via telehealth through the National Society of Genetic Counselors (see https://findageneticcounselor.nsgc.org/?reload = timezone).

As with any other type of genetic testing and counseling, the risk–benefit ratio of testing should be carefully reviewed with the family and the medical team. If one proceeds with such testing, it should be done under the strictest confidentiality and privacy rules unless otherwise stipulated, as with the U.S. Food and Drug Administration (FDA) ruling on blood donations and genetic analysis (https://www.fda.gov/regulatory-

Telegram: @medical_k

www.konkur.in

information/search-fda-guidance-documents/recommendations-reduce-possible-risk-transmission-creutzfeldt-jakob-disease-and-variant-creutzfeldt). Consistent with these developments, the following recommendations are provided for the clinician:

1. Testing conditions should be voluntary and follow local statutes where available. Pre- and posttest counseling should not be combined in the same session.
2. Either genetic counselors or psychiatrists should be competent in counseling patients about seeking genetic testing and should be well informed about the need for pre- and posttest counseling, provide information about the limits of confidentiality, should be aware of CJD surveillance procedures in their local jurisdictions, and should be aware of resources available to patients and their families.
3. A complete behavioral health assessment should be considered in all cases in order to fully address the individual's reaction to the results. This should include an assessment that the patient is indeed ready to be tested. Patients with high risks of untoward psychological reactions or destructive behaviors should be a special concern to anyone screening for CJD, and a referral to psychiatry should be initiated.
4. Genetic counseling involving pre- and posttest counseling of patients should include an assessment of capacity and discussion of the risks and benefits of testing, previous experience with genetic testing, the implications of a positive or negative result, the limits of confidentiality, strategies for reducing anxiety and depression, and help with the availability of and referral to appropriate resources for further counseling and assistance.
5. Genetic testing should not be performed solely for the purpose of medical team and staff awareness.
6. All CJD testing must be done with appropriate informed consent. It is not sufficient simply to have a consent form signed; it must also be documented that the person is informed and understands the consequences of both a positive and negative result.
7. The confidentiality of information regarding genetic testing for CJD should be protected.
8. Sharing of CJD status should be compliant with applicable state and federal statutes.
9. Patients should be made aware of program policies regarding documentation of CJD status in the medical record before initiating

Telegram: @medical_k

www.konkur.in

genetic testing.

10. Patients should be aware that when third parties pay for genetic testing, both positive and negative test results may be available to the Medical Information Bureau and can subsequently affect eligibility for future insurance.

Living in the era of molecular medicine forces all health professionals to confront difficult legal and ethical issues. Problem solving around issues of genetic testing requires an educated balancing of diverse interests and a thoughtful approach that rationally weighs the benefits and disadvantages of standard as well as new solutions. This field is rapidly changing, and as such, there are no easy answers in terms of whether asymptomatic family members should be tested for an untreatable disease.

PREVENTIVE MEASURES

Since prion diseases remain incurable, universal precautionary measures need to be applied during the care and management of affected patients. Even though the infectious proteins causing CJD can be found in many organs, it appears less frequently in certain body fluids such as tears, saliva, sweat, urine, or feces. However, this infective prion can be detected in CSF and rarely in blood. In terms of infectivity, human tissues are divided into three groups: high-infectivity tissues: CNS tissues that attain a high titer of infectivity in the later stages of all TSEs, and certain tissues that are anatomically associated with the CNS; lower-infectivity tissues: peripheral tissues that have been tested positive for infectivity and or PrP^{TSE} in at least one form of TSE; and tissues with no detectable infectivity: tissues that have been examined for infectivity and/or PrP^{TSE} with negative results.

Health workers should wear gloves while handling these patients' biologic specimens and should avoid any penetrating injuries from contaminated sources that can potentially transmit the infected material. Any accidental exposure of intact skin to these infective proteins must be irrigated with fresh undiluted bleach or 1 N sodium hydroxide, followed by washing and cleansing with copious amounts of water and soap. For medical and surgical procedures, disposable materials and instruments should preferably be used, and once they have been used, they must be destroyed by incineration. In case certain instruments or devices cannot

Telegram: @medical_k

www.konkur.in

be discarded or destroyed, they should be sterilized based on proposed WHO decontamination guidelines. Autopsies and cremation of patients affected with prion diseases must be carried out based on the guidelines published by the Centers for Disease Control (CDC) (https://www.cdc.gov/prions/cjd/funeral-directors.html).

Universal Precautions Regarding CJD Risk

It should also be noted that frequently the patient is unaware of having CJD or other infectious diseases when coming to the doctor's office or emergency room. Under these circumstances, universal precautions should be used. The psychiatry staff inpatient unit, trainees, and attending physicians are responsible for laboratory procedures that are part of the medical workup of the patients admitted to the unit, including the psychiatry emergency room. Moreover, this includes nursing personnel who must provide parenteral injections to patients without knowing their CJD, HIV, or hepatitis C status. Under these conditions, universal precautions must be followed according to the CDC (https://www.cdc.gov/prions/cjd/infection-control.html) as well as the *American Psychiatric Association Compendium of Practice Guidelines* (www.psych.org/AIDS/), the U.S. FDA (http://www.fda.gov/cber/gdlns/cjdvcjd.htm), and the WHO Infection Control Guidelines for TSE (www.who.inf.csr/resources).

Biohazards: Prion Transmissibility and Infectiousness

Overall, the exercise of universal precautions related to biohazards is essential for handling and processing all specimens of human tissues and fluids. The examination of this topic in PubMed indicates that this is discussed in the literature due to ubiquitous biohazard risks. The dangers, risks, remedies, and countermeasures in the laboratory and clinical settings have been well developed through the use and institution of (biosafety level) BSL-3 and BSL-4 laboratories. This has become most apparent during the past Ebola virus outbreaks.

There are several corrective laboratory measures regarding human prion diseases. Thirty-five years ago, it was already recognized that prions derived from spongiform encephalopathies including Kuru, CJD, TME, and scrapie posed biohazard risks for humans. Based upon that, laboratory design proceeded.

Telegram: @medical_k

www.konkur.in

Tissues and fluids infected or even potentially infected (and that includes all human specimens) are treated and handled with care and universal precautions. These precautions are well known for tissues and fluids at risk of HIV and HCV infection. Universal precautions emphasize the risk of infectivity due to unanticipated biologic agents. However, risks of infection by prions are an additional risk that is associated with any human specimens—derived from symptomatic or asymptomatic individuals. Similarly, animal specimens are treated with similar care. The goal is a reduction in the potential exposure risk. In the United States, several accrediting agencies deal with such risks and including the NIH, CDC, and Occupational Safety and Health Administration (OSHA) (see https://www.cdc.gov/prions/cjd/infection-control.html).

The central concept in the infectiousness of PrPs is that they are in misfolded conformations that are self-replicative and can infect, seed, and propagate their strain characteristics in dissimilar host species as well as homologous host species. The seeding infecting PrP converts much of the host's PrP^C into infectious PrP proteinase K–resistant particles. This process is also termed PMCA.

Current investigations also implicate a process of "seeding" misfolded α-synuclein protein involvement in some aspects of PD. This possibility is related to the prion disease CJD. In fact, it has further been proposed that there is a component of prison-related pathogenesis (gain of toxic function) in AD as well as in PD. It has been suggested that these diseases should be included with TSEs or prion diseases with the well-known prion diseases, including CJD and its variant, Kuru, as well as with FFI and GSS disease. In addition, amyotrophic leukospongiosis pathogenesis may involve 18 to 20 kD prion-like globular structures.

As a postscript, it may be noted that the scientific attitude to potential infection by microbial life forms or nonviable particles, for that matter, has wide-reaching implications. For example, there was, apparently, an absence of any sensible biocontainment protocols during the many years of the Apollo Space Program missions. There was also an absence of a functional particle containment protocol even though the lunar surface was composed of dust. There were findings of extensive human and mechanical contamination by lunar dust that have been well documented. Thus, it is not always obvious to the nonbiologically oriented scientist what types of exposure there may be, biologic or mechanical. This is of relevance because of the unanticipated situations, including prion

Telegram: @medical_k

www.konkur.in

diseases in which higher levels of biocontainment or mechanical containment are necessary, though originally not perceived.

2.11 Neuropsychiatric Aspects of Headache

KATHLEEN RIES MERIKANGAS, PH.D., TARANNUM LATEEF, M.D., M.P.H., AND JAMES R. MERIKANGAS, M.D.

During the past decade, there has been growing attention to the enormous public health impact of migraine. Headache disorders in 2019 ranked 14th among global disability-adjusted life years (DALYs) and were the third greatest source of years lost to disability (YLDs), particularly among young females. However, many of those troubled by headaches do not receive effective care. For example, in the United States of America and the United Kingdom, only half of those identified with migraine had seen a doctor for headache-related reasons in the previous 12 months, and only two-thirds had been correctly diagnosed. Most were solely reliant on over-the-counter self-treatment.

There have been multiple developments in the diagnosis and treatment of headaches. First, there has been a revision of the standardized diagnostic criteria for some of the primary headache subtypes in adults and youth. Second, there is growing awareness of the differential manifestations of migraine across the life span, with increasing effort to target both preventive efforts and treatment to different strata of the population. Third, there have been remarkable developments in pharmacologic treatments of headache, with the introduction of a new class of drugs that has rapidly come into widespread use. Fourth, there is a growing effort to track symptoms of headache in real time using electronic diaries in order to identify targets for prevention and intervention, Finally, there has been a burgeoning effort to consider the pervasive comorbidity of headache with both mental and physical disorders in the evaluation and treatment of migraine. Spurred by establishment of large international collaborative studies, there has also been progress in identifying the influence of genetic factors on migraine and other headaches. The goals of this chapter are to (1) provide an overview of the diagnostic nomenclature for headache syndromes; (2) describe the magnitude, risk factors, and

Telegram: @medical_k

www.konkur.in

patterns of comorbidity of migraine and other headache subtypes; (3) summarize the clinical and laboratory examination necessary for making a diagnosis of headache and the neuropsychiatric manifestations of migraine and other headache syndromes; and (4) review current acute and prophylactic treatment strategies for the major headache syndromes.

DEFINITIONS

The International Headache Society (IHS) recently released the third edition of the *International Classification of Headache Disorders* (ICHD-3) (https://ichd-3.org/) that has revised criteria for the following categories: (1) the primary headache syndromes (i.e., migraine without aura, migraine with aura, tension-type headache, and cluster headache), (2) secondary headache syndromes include eight types of headaches secondary to other acute and chronic conditions, and (3) cranial neuralgias and other causes of facial pain. The eight types of secondary causes of headache are shown in Table 2.11–1. These primarily involve brain injuries or conditions that lead to headache among other pathophysiologic manifestations. Below, we consider the three primary headache disorders that include migraine, tension-type and cluster headaches, and a brief discussion of post-traumatic headache.

Migraine

Migraine is a disorder characterized by recurrent attacks or episodes of headache accompanied by other neurologic and gastrointestinal (GI) systems. Migraine presentation is multifaceted with symptoms emanating from multiple systems, including vascular, neurologic, GI, endocrine, and visual. There is general agreement that a comprehensive neuropsychiatric evaluation is required for all patients presenting with headache complaints.

Table 2.11–1.
Secondary Causes of Headache

Disorders of the Cranium or Face
- Cluster headache
- Cranial neuralgias
- Neck, eyes, ears, nose, sinus, teeth, mouth

Head Trauma
- Headache within 7 days

Intracranial Disorders
- Hemorrhage (subarachnoid; subdural)

Infections (Noncephalic)
- Fever, sinus, viral

Metabolic Disorders
- Arterial hypertension
- Cardiac cephalalgia
- Dialysis
- Fasting
- Hypothyroidism
- Hypoxia/hypercapnia (high altitude, diving, sleep apnea)

Substance Use or Withdrawal
- Caffeine, alcohol, other

Temporomandibular Joint Dysfunction
- Bruxism, joint injury, or inflammation

Vascular Disorders
- Arteriovenous malformation, stroke, vasculitis

www.konkur.in

Table 2.11–2.
ICHD-3 Criteria for Migraine without Aura

A. At least 5 attacks fulfilling criteria B-D
B. Duration between 4 and 72 hours (untreated or unsuccessfully treated)
C. At least 2 of the following:
   1. Unilateral
   2. Pulsating pain
   3. Moderate to severe intensity
   4. Aggravation by or causing avoidance of routine physical activity (walking or climbing stairs)
D. During headache at least one of the following:
   1. Nausea and/or vomiting
   2. Photophobia and phonophobia
E. Not better accounted for by another disorder

The ICHD-3 criteria for migraine with and without aura are presented in Tables 2.11–2 and 2.11–3. The core features of most definitions of migraine include a recurrent headache that is often unilateral, GI symptoms such as nausea or vomiting, and hyperesthesia manifested by photophobia or phonophobia. The headache generally has a pulsatile or throbbing quality, and the pain is exacerbated by routine physical activity involving movement of the head. The ICHD-3 criteria operationalize these features of a headache to draw common thresholds and distinctions between migraine and other types of headaches. Migraine was formerly divided into two major subtypes, common and classic, with the latter being distinguished by the presence of neurologic symptoms that precede the onset of the headache. The ICHD-3 no longer includes the common–classic distinction; instead, migraine is subtyped according to the presence or absence of aura symptoms (reversible neurologic dysfunction). Approximately 20% of migraine sufferers experience aura.

Despite recent progress in the standardization of the classification of migraine by the ICHD-3, the diagnostic criteria have not been subjected to intensive investigation with respect to reliability or validity. There are still several features unique to the headache syndromes that constitute impediments to developing a valid set of diagnostic criteria for headache syndromes that need to be addressed. These include the co-occurrence of multiple headache syndromes within individual persons; the tendency for

Telegram: @medical_k

www.konkur.in

headache characteristics to change across the life span; the effects of professional and self-treatment of headache in obscuring the manifestations of the underlying headache syndrome(s); and the lack of generalizability of treated samples from which the diagnostic criteria were derived. Specific areas of the classification system have also been identified as requiring additional clarification, notably the specification of procedures for ensuring standardized methodology for the ascertainment of the diagnostic criteria; methods for assessing and coding multiple headache syndromes within individuals; and the development of standardized methods for discriminating between primary headache syndromes and those for which the secondary etiology is known.

Table 2.11–3.
ICHD-3 Criteria for Migraine with Aura

A. At least 5 attacks fulfilling criteria B-D

B. Aura consisting of at least one of the following but no motor weakness:

1. Fully reversible visual symptoms including positive features (e.g., flickering lights, spots, or lines) and/or negative features (i.e., loss of vision)
2. Fully reversible sensory symptoms including positive features (i.e., pins and needles) and/or negative features (i.e., numbness)
3. Fully reversible dysphasic speech disturbance

C. At least two of the following:

1. Homonymous visual symptoms and/or unilateral sensory symptoms
2. At least one aura symptom develops gradually over 5 minutes and/or different aura symptoms occur in succession over 5 or more minutes
3. Each symptom lasts 5 or more minutes and less than or equal to 60 minutes

D. Headache fulfilling criteria B-D for migraine without aura begins during the aura or follows within 60 minutes

E. Not attributed to another disorder

Tension-Type Headache

Telegram: @medical_k

www.konkur.in

The definition of tension-type headache according to ICHD-3 criteria is presented in Table 2.11–4. Briefly, tension-type headache is characterized by episodes of stable bilateral pain lasting several days at a time. It is distinguished from migraine headaches by its generally longer duration, the lack of pulsating quality of the pain, the lack of worsening with physical activity, and the absence of GI concomitants. However, migraine and tension-type headaches may often coexist, either simultaneously or alternating over time. It is no longer believed that tension-type headache results from muscle tension. Indeed, neck pain may result from head movement to reduce headache pain.

Cluster Headache

Cluster headache is a distinct syndrome characterized by frequent intense attacks (often several per day) over a 1- to 2-month period, separated by headache-free intervals for as long as 1 or 2 years. Although it is commonly grouped with migraine, current evidence, including epidemiologic data, treatment response, and clinical features, suggests that cluster headaches may comprise a distinct syndrome.

Telegram: @medical_k

www.konkur.in

Table 2.11–4.
ICHD-3 Criteria for Tension-Type Headache

Frequent Episodic Tension-Type Headache

A. At least 10 episodes occurring on greater than or equal to one but less than 15 days per month for at least 3 months (greater than or equal to 12 and less than 180 days per year) and fulfilling criteria for B-D

B. Headache lasting from 30 minutes to 7 days

C. Headache has at least two of the following characteristics:

1. Bilateral location
2. Pressing/tightening (nonpulsating) quality
3. Mild or moderate intensity
4. Not aggravated by routine physical activity such as walking or climbing stairs

D. Both of the following:

1. No nausea or vomiting (anorexia may occur)
2. No more than one of photophobia or phonophobia

E. Not attributed to another disorder

Chronic Tension-Type Headache

A. Headache occurring on greater than or equal to 15 days per month on an average for more than 3 months (greater than or equal to 180 days per year) and fulfilling criteria B-D

B. Headache lasts hours and may be continuous

C. Headache has at least two of the following characteristics:

1. Bilateral location
2. Pressing/tightening (nonpulsating) quality
3. Mild or moderate intensity
4. Not aggravated by routine physical activity such as walking or climbing stairs

D. Both of the following:

1. No more than one of photophobia, phonophobia, or mild nausea
2. Neither moderate or severe nausea nor vomiting

E. Not attributed to another disorder

Cluster refers to a “clustering in time,” with the headache bouts occurring every day to several times a day over a period of days to weeks, followed by a lengthy headache-free interval. Cluster headache is generally retro-

Telegram: @medical_k

www.konkur.in

orbital in location and is accompanied by autonomic changes such as lacrimation, rhinorrhea, erythema of the eye, and agitation. Males tend to suffer more from cluster headaches than females. Patients with cluster headaches do not retire to dark rooms and lie down to avoid the stimulation but may, in fact, do quite the opposite, appearing almost manic in their agitation. The pain can be so intense that the sufferer may appear to be psychotic because of the screaming and thrashing that may be associated with the pain. Prior smoking and alcohol use has been associated with cluster headache, with alcohol often triggering the onset of the headache.

Chronic paroxysmal hemicrania is a type of cluster headache, specifically responsive to treatment with indomethacin and characterized by many daily focal attacks of pain lasting for short periods, generally about 15 or 20 minutes per attack.

Headache Attributable to Head or Neck Trauma

The key symptoms of ICHD-3 post-traumatic headache include a headache following head trauma that develops within 7 days after head trauma accompanied by a loss of consciousness, post-traumatic amnesia, and abnormal laboratory tests. Post-traumatic headache is variable in symptom presentation, severity, and duration.

Although a headache following a traumatic head injury has often been attributed to emotional factors, empirical evidence suggests that emotional factors are more likely to be a sequela rather than a cause of post-traumatic headache. Nevertheless, the pathogenesis of post-traumatic headaches is unknown. The major hypotheses include cerebral edema, cortical spreading depression, innate vulnerability to cerebral vasospasm, and transient elevation of intracranial pressure. There is no direct relationship between the prevalence or chronicity of post-traumatic headache and several indicators of the severity of the head injury, including duration of unconsciousness, post-traumatic amnesia, electroencephalographic abnormalities, presence of skull fracture, or the presence of blood in the cerebrospinal fluid. There appears to be an inverse relationship between the severity of the head injury and the development of posthead injury headache; post-traumatic headache is more common after injuries that do *not* result in a skull fracture.

The onset of typical migraine attacks following acute head trauma occurs so frequently that it has been hypothesized that head trauma serves as a trigger for migraine in persons with underlying susceptibility to migraine or with a personal or family history of migraine. Moreover, relatives of post-

Telegram: @medical_k

www.konkur.in

traumatic migraine subjects have an increased prevalence of neurologic symptoms, suggesting a propensity to neurologic manifestations of migraine.

EPIDEMIOLOGY AND COURSE

Prevalence

Headache is very common in the general population, with about 70% of adults endorsing a history of headaches in a given year. The average lifetime prevalence of migraine of about 12% in international studies has remained stable for the past several decades and is very close to the 10% to 12% rates in pre–ICHD-2 studies. By contrast, chronic migraine is quite rare, with an aggregate estimate of 0.5%. Recent reviews of the prevalence of tension-type headaches estimate the aggregate lifetime prevalence of tension-type headaches of about 30%. These rates are substantially greater than those of migraine, indicating that tension-type headache is the most frequent primary headache disorder in the general population.

Estimates of migraine incidence in the United States converge in demonstrating an earlier peak incidence of migraine, particularly migraine with aura in males in the midteens than in females in whom the peak incidence is in the early 20s. The disability of migraine is most significant in young adults from ages 20 to 30. Despite the high prevalence rates, only 20% continue to manifest chronic migraine over time. In general, both the frequency and duration of migraine decrease at midlife in both men and women and the symptomatic manifestations may change substantially over time.

The severity of migraine ranges from mild to nearly total disability. Over 80% of those with migraine report some degree of disability. Recent community studies have underscored the enormous personal and social burden of migraine in terms of both direct and indirect costs. Although there is an increasing proportion of those with headaches seeking professional treatment, only approximately one-half of those individuals who suffer from debilitating migraine seek professional help.

Migraine in childhood is more likely to be associated with gastrointestinal complaints, particularly episodic bouts of stomach pain, vomiting, or diarrhea, and the duration is shorter than that commonly observed in adults. In women, migraine is strongly associated with reproductive system function, with increased incidence during puberty and the first trimester of

Telegram: @medical_k

www.konkur.in

pregnancy, and is associated with exogenous hormone use. After menopause, the frequency of migraine attacks generally decreases dramatically unless estrogen replacement therapy is administered.

Aside from sex and age, a family history of migraine is one of the most potent and consistent risk factors for migraine. The results of twin studies implicate genetic factors underlying approximately one-third of the familial clustering of migraine, but the mode of inheritance is clearly complex. Despite an increasing number of candidate gene association studies of migraine, to date, no replicated linkage or associations between specific genes and migraine has emerged, except for hemiplegic migraine. To date, the application of genome-wide association studies in cases and controls has not identified significant associations between migraine and genetic markers.

Migraine is strongly associated with a variety of medical disorders, especially asthma, eczema, allergies, epilepsy, cardiovascular disease, cerebrovascular disease, and particularly ischemic stroke. Anxiety and mood disorders are strongly associated with migraine. Prospective data from community studies of youth reveal that anxiety in childhood is associated with the subsequent development of headaches in young adulthood.

There have been numerous factors that have been consistently implicated as precipitants of acute headache attacks, including hormonal changes, stress, or its cessation, fasting fatigue, oversleeping, particular foods and beverages, drug intake, chemical additives, bright light, weather changes, and exercise, but these agents/situations vary dramatically within and between individuals in prospective research. Many of these factors may be nonspecifically related to headaches in general rather than migraine. There has been a growing effort to examine the role of sleep and circadian rhythms in both migraine pathogenesis and incident attacks.

The prevalence of tension-type headaches is greater in women, but the sex difference is far less pronounced than that of migraine. Although tension-type headache is most common in young adults, there is a less steep decrement in prevalence with age.

By contrast, post-traumatic headache is quite rare in the general population (i.e., about 1% lifetime prevalence). However, it is likely that this is an underestimate because of the lack of systematic data on post-traumatic headaches in population-based samples. Based on retrospective reports of those who suffer from a severe head injury, the prevalence of severe and chronic headaches ranges from 28% to 62%. Children and

Telegram: @medical_k

www.konkur.in

young adults appear to be particularly susceptible to the development of headaches after head trauma.

The results of prospective studies of the incidence of headache following severe head injury, usually defined as postconcussion headache, reveal that approximately 50% of each series of admissions continue to suffer from headache at the time of discharge from the index admission, with a gradual dissipation to 20% 1 year later. Persistence of headache has been related to female sex, age over 45, the presence of dizziness, lack of skull fracture, intracranial hematoma, disorders of smell, hearing, or vision, depression, and impaired concentration.

The population prevalence of cluster headaches is very low (less than 1% of the general population) and occurs nearly exclusively in males. The age at onset of cluster headache is somewhat later than that of migraine and tension-type headache; the first attack of cluster usually begins in the late 20s or 30s and may recur intermittently throughout life. Risk factors include smoking and heavy alcohol use. There is some family study and twin research demonstrating the role of genetic factors underlying the etiology of cluster headache.

Comorbidity

Although comorbidity of migraine and numerous other conditions has long been reported in clinical samples, etiologic inferences are precluded by the role of comorbid disorders in treatment seeking for primary disorders. There is now strong evidence from population-based surveys regarding associations between migraine and musculoskeletal conditions, cardiovascular disease, particularly ischemic stroke, asthma, allergies and other immune and inflammatory disorders, and epilepsy. However, the only comorbid condition that appears to be specifically associated with migraine is cardiovascular disease. By contrast, the association between migraine and obesity has been shown to be attributable to headaches in general rather than migraine specifically.

Comorbidity between migraine with mental disorders has also been well established in population samples of adults and children. About 40% of young adults with major depression and/or anxiety have migraine, and about 60% of those with migraine have a lifetime history of either anxiety or mood disorder. The presence of a pre-existing physical or medical disorder may also elevate the risk of migraine. Prospective research of both adults and children demonstrates that migraine is associated with an increased risk for the development of depression rather than the converse. However,

Telegram: @medical_k

www.konkur.in

anxiety disorders, particularly phobias, are associated with an increased risk of incident migraine in prospective research. This link may be a manifestation of underlying autonomic reactivity that may represent a common underlying diathesis for migraine. The elevated rates of infantile colic in children in treatment for migraine would be consistent with this explanation. As such, comorbid disorders may reflect underlying etiology rather than environmental triggers of migraine. Several studies have now confirmed that there is a syndromic association between migraine, depression, and anxiety, with anxiety preceding the onset of migraine followed by the subsequent development of mood disorders. Studies that investigated the specificity of these associations have concluded that migraine was specifically associated with phobias and hypomania/bipolar spectrum conditions, whereas the association with depression was found for headaches in general. Prospective studies of children with headaches have indicated an increased risk for both headaches and somatic and psychiatric symptoms in adulthood. Research into the possible mechanisms underlying these associations, however, remains limited. Studies examining the order of onset and cross-transmission of migraine and psychiatric disorders in controlled family studies have been unable to clearly distinguish between causal and common etiologic models of association.

Comorbidity has a major impact on migraine sufferers' quality of life and disability and is associated with a poorer course and outcome of migraine. As such, comorbidity may comprise an index of the severity of migraine. For example, simultaneous investigation of somatic and psychiatric comorbidity in headaches and migraine has demonstrated greater health care utilization and negative health perception among those with comorbidity. In fact, about 65% of migraine-associated disabilities can be attributed to comorbid physical and mental disorders.

Impact and Health Seeking of Migraine

Community studies of migraine have documented the enormous personal and social burden of migraine in terms of both direct and indirect costs. Over 80% of those with migraine report some degree of disability. The finding that young adults with migraine suffer from migraine for an average of 1 month of every year across 30 years of prospective follow-up highlights the cumulative impact of migraine during the peak period of attainment of educational, occupational years, and social milestones of adult life. About one-third of people in the general population with active

Telegram: @medical_k

www.konkur.in

migraine tend to have three or more attacks per month, and more than half reported severe impairment requiring bed rest. Children with migraine have been consistently shown to have more school absences, decreased academic performance, social stigma, and impaired ability to establish and maintain peer relationships. In fact, the quality of life in children with migraine is impaired to a degree similar to that in children with arthritis or cancer.

Severe headaches and migraine not only have a substantial impact on the affected person, but they also have a major economic impact due to medical expenses and employer costs. The bulk of the expenses attributable to migraine derives from its high population prevalence and indirect costs. There have also been expanded efforts to characterize the magnitude of migraine in areas of the world that had been previously underrepresented.

Despite the high magnitude of disability associated with migraine, only approximately one-half of those individuals who suffer from debilitating migraine seek professional help. The gap in treatment is remarkably similar across the world despite variations in health systems across the world. Of those who do seek treatment, many do not continue in treatment. Only a minority of those with migraine in the general population ever seek treatment with clinicians with expertise in headaches. As expected, those who seek professional treatment are characterized by greater severity, longer duration, more disability, and more comorbidity. In light of the overwhelming evidence regarding the tremendous burden of migraine, leaders in the headache field have called for increased awareness of the availability of preventive efforts. Operational criteria for prevention have been developed based on headache frequency and attack-related disability, yet few of those with migraine have received preventive interventions. For example, only 25% of those with migraine in the general population of the United States seek professional treatment and receive appropriate medications, whereas a much smaller proportion (e.g., 11% to 12%) of those with tension-type headaches seek treatment specifically for headaches.

ETIOLOGY

Although the etiology of the major types of headaches is still unknown, recent advances in brain imaging have advanced our understanding of the pathogenesis of migraine. Most theories of migraine focus on the activation

Telegram: @medical_k

www.konkur.in

of the trigeminovascular system and its central projections. Functional imaging studies have shown that migraine is associated with brainstem activation, particularly the dorsolateral pons. Diffusion tensor imaging studies demonstrate abnormalities in primary and modulatory components of the central nociceptive pathways, such as the periaqueductal gray, an important central modulatory component of the pain pathway, the somatosensory cortex, and in the occipital lobe in subjects with migraine with aura. What remains unclear, however, is whether these findings represent causative abnormalities or whether they have occurred as the consequence of frequent repetitive attacks in migraine sufferers.

Psychophysiologic studies have also contributed to a better understanding of mechanisms underlying migraine pathogenesis. In particular, interictal abnormalities of evoked and event-related potentials have been reported for different **cortical** areas in migraineurs, such as the sensory cortices. Several studies suggest that the excitability of neurons in the visual cortex plays a fundamental role in the brain's susceptibility to **migraine** attacks. Other reports include increased amplitudes of visual-evoked potentials, reduced habituation of **cortical**-evoked responses, and an increased contingent negative variation in migraine patients.

Current theories of the etiology of cluster headaches posit that hypothalamic and central pain control regions trigger a cascade of events in the brain stem comprising afferent pain and efferent parasympathetic pathways. Positron emission tomography (PET) has shown vasodilatation of the major basal arteries during the acute pain attack in cluster headaches, representing the first convincing demonstration of the activation of neuronal vasodilator mechanisms in humans.

Far less is known about the etiology of tension-type headaches. It is clear, however, that tension-type headache is a misnomer since there is no evidence that muscle tension is the underlying cause of this headache subtype.

DIFFERENTIAL DIAGNOSIS AND CLINICAL EVALUATION

A very skillful workup is essential because headache is such a nonspecific complaint with an enormous number of etiologies ranging from trivial to acutely life-threatening. A thorough examination should include a description of the type and location of pain, timing, precipitants, prodromal events, and associated symptoms. Although diaries of headache

Telegram: @medical_k

www.konkur.in

symptoms have been widely used in the treatment of migraine for several decades, the availability of smartphone applications that can be used to track symptoms, triggers, and treatments is expected to revolutionize our ability to develop individualized treatments in the future. Factors that should be evaluated in the diagnosis of migraine include the following: (1) onset; (2) frequency; (3) location; (4) duration; (5) quality; (6) severity; (7) precipitants (factors that may elevate the risk of a migraine attack such as sleep deprivation or stress); (8) precursors (changes that may occur early in the development of an episode of headache such as visual symptoms or yawning); (9) triggers (factors that precipitate an acute attack such as dietary agents, exposure to particular smells or light); (10) phenomena that worsen or relieve the pain; (11) warning signs (specific precursors particularly visual changes); (12) specific symptoms including visual changes, GI symptoms, or neurologic symptoms; (13) sensitivity to light, noise, sounds, or touch; mood changes; and (14) cognitive changes. In addition, it is important to obtain a detailed family history, description of course, and a history of previous evaluation and treatment. Differential diagnosis of headache is based on a neurologic examination to rule out pathognomonic signs that might indicate other brain disorders. Some of the signs and symptoms that should signal immediate evaluation of headache include first headache, particularly in midlife, worst headache of a person's life, gradual worsening over days and weeks, vomiting prior to the headache onset, abnormal neurologic evaluation, particularly hemiplegia, ongoing systemic illness, onset after age 50, accompanied by fever, or occurs during sleep.

A migraine is more than a headache. There are a variety of manifestations of migraine that may mimic several neurologic or psychiatric disorders, including epilepsy, psychosis, and functional neurologic disorder. Visual and auditory hallucinations may occur, especially in children. Migraine may have autonomic manifestations suggesting cardiac disease, irritable bowel syndrome, or even acute abdominal emergency. Migraine may be associated with irritability, mood swings, and in some cases, impulsive temper outbursts. In a sense, migraine may be considered as lying on a continuum between the rapid neurophysiologic changes of epilepsy and the less rapid state changes of bipolar disorder. Basilar artery migraine, defined by a particular vascular distribution, may produce stupor and coma or paralysis, blindness, ataxia, dysarthria, or perceptual abnormalities. The extent to which such manifestations may be attributed to comorbid disorders has not been established.

Telegram: @medical_k

www.konkur.in

In addition to a history and physical examination, laboratory studies are critical. Even if the results are negative and do not uncover a metabolic, endocrine, or autoimmune etiology, this information may serve as a baseline for subsequent drug therapy. Headache onset over age 50 is particularly ominous and requires careful investigation. Temporal arteritis, or giant cell arteritis, must be ruled out, as it has the potential to cause stroke or blindness if not urgently treated. A sedimentation rate and serum alkaline phosphatase are useful screening tests followed by corticosteroids and antiviral medication. Application of the ICHD-3 requires that all the potential causes of headaches shown in Table 2.11–1 be considered. The diagnosis of headache requires the exclusion of other conditions, including structural lesion, vascular malformation, viral or bacterial meningitis, or encephalitis, intracranial abscess or hemorrhage, cerebral contusion, metabolic disorders (urea cycle disorders, aminoacidopathies, mitochondrial disorders), pseudotumor cerebri, vasculitis, brain tumors, sinusitis, or ocular disorders, any of which may be concurrent rather than causal. One of the most important findings of the past decade is the converging evidence that there is an increased risk of ischemic (but not hemorrhagic) stroke among young women with migraine. This finding supports the importance of the reduction of other stroke risk factors, including oral contraceptive use, hypertension, and smoking among young women with migraine.

Although imaging procedures may not be considered necessary in the evaluation of primary headache syndromes, an image of the brain is mandatory for the evaluation of patients with severe or persistent headaches, the “first” or “worst” headache, or when a subdural hematoma is suspected. An abnormal neurologic examination or seizure mandates brain imaging. A CT scan is indicated to rule out acute hemorrhage, while magnetic resonance imaging (MRI) is indicated when hydrocephalus, brain tumor, sinusitis, vasculitis, or posterior fossa lesions are suspected. X-rays of the jaw and cervical spine are useful to rule out malocclusions and degenerative changes of arthritis.

TREATMENT OF HEADACHE SYNDROMES

Migraine

The mainstay of migraine treatment is pharmacologic intervention. Treatment of migraine is divided into medications that prevent future

Telegram: @medical_k

www.konkur.in

attacks (prophylactic treatment) and interventions during the acute attack that provide symptom relief and/or progression.

Pharmacologic Prevention Treatments. Preventative treatment of migraine should be instituted when either the frequency or severity of migraine attacks leads to impairment in functioning. As shown in Table 2.11–5, the major classes of drugs that have been investigated in the prophylaxis of migraine include antidepressants, antiseizure medications, β-adrenergic blocking agents, triptans, and Omabotulatxin A. The recent introduction of a new class of drugs, calcitonin gene-related peptide antagonists (CGRP), known as the gepants, has now expanded our ability to both treat and prevent migraine.

Clinical trials of migraine treatment are complicated by the high placebo response rate among subjects with migraine, the heterogeneity of diagnostic subtypes of headache, the intermittent nature of the condition, and the frequent use of additional analgesics to treat headache pain. Due to the highly variable placebo effect in prophylactic migraine RCTs, the European Medicines Agency and the International Headache Society have recommended the inclusion of a placebo in comparative RCTs of migraine prophylaxis.

PHARMACOLOGIC TREATMENTS. Antidepressants have been a mainstay of preventative treatment of migraine for more than 30 years, yet there have been a limited number of controlled trials of either tricyclics or monoamine oxidase inhibitors that were reported to be the most efficacious treatments of migraine, even in the absence of comorbid mood disorders. The two drugs that have shown some evidence of superior performance over a placebo are amitriptyline and venlafaxine. The secondary amines (e.g., nortriptyline and desipramine) that have been shown to be efficacious in the treatment of depression but have fewer side effects than do the parent tertiary amines (e.g., amitriptyline, imipramine) have also been shown to reduce headache in patients with depression. However, the relative efficacy of the various tricyclic antidepressants in migraine prevention has not been examined. The more widely used selective serotonin uptake inhibitors do not have demonstrated efficacy in migraine. In fact, many patients complain of headaches as a secondary effect of the latter class of drugs. Headache is a common symptom encountered in clinical psychiatric practice, particularly among patients with anxiety and depression. This association should be systematically evaluated because headaches can be

Telegram: @medical_k

www.konkur.in

a side effect of many psychotropic drugs or could be a comorbid condition. If patients with anxiety and/or depression suffer from migraine, it is critical to treat the entire syndrome rather than limiting the treatment goal to headache cessation. In general, comorbid depression and anxiety are more important in the selection of migraine prophylaxis than in the treatment of an acute attack of migraine. The use of prophylactic medications with side effects of lassitude, fatigue, or depression should be avoided, if possible. If not, careful clinical evaluation of the above-cited manifestations of depression, including anergia, hypersomnia, and irritability, should be monitored. Given the overlap of symptoms of the actual migraine episode, including acute changes in energy, appetite, mood, and level of anxiety, as well as those that occur between attacks, and those on the anxiety/depression spectrum, it is not surprising that similar pharmacologic agents have been successfully employed in the treatment of migraine and anxiety/depression.

Table 2.11–5.
Pharmacologic Treatments for the Prevention of Migraine

Class	Established Efficacy	Probable Efficacy
Antidepressants	—	Amitriptyline Venlafaxine
Antiseizure	Divalproex sodium Topiramate Valproate sodium	
β-Blockers	Metropolol Propranolol Timolol	Atenolol Nadolol
CGRP monoclonal antibody	Eptinezumab Fremanezumab Galcanezumab	
CGRP receptor monoclonal antibody	Erenumab	
Neurotoxins	OnabotulinumtoxinA	
Triptans	Frovatriptan	

Telegram: @medical_k

www.konkur.in

Three antiseizure drugs that have shown superior efficacy to controls are divalproex sodium, topiramate, and valproate sodium. However, the side effects of these agents often lead to discontinuation, so they, therefore, require careful monitoring.

The three β-blockers that have been shown to be efficacious in migraine are metoprolol, propranolol, and timolol, and there is probable efficacy for atenolol and nadolol. This class of medications has few side effects and is particularly helpful among patients with high levels of autonomic reactivity.

One of the most exciting developments in the treatment of migraine over the past few years has been the development of agents that work directly on the CGRP level or its receptor that is involved in the reactivity of the vasculature. There are now three FDA-approved CGRP monoclonal antibody agents (i.e., eptinezumab, fremanezumab, and galcanezumab) and another CGRP receptor monoclonal antibody named erenumab. Their use has grown rapidly in specialty headache clinical settings because they are reported to have moderate efficacy yet limited side effects, yet their comparative efficacy both within this class and between other prophylactic agents has not yet been demonstrated.

OnabotulinumtoxinA has also been effective for a variety of headache conditions and has primarily been used in controlled trials of chronic migraine. Finally, the only 5-HT 1B agonist that has been shown to be superior to a placebo in the prevention of migraine is frovatriptan. As described below, this class of drugs has been most widely used to treat acute attacks of migraine.

Treatment of Acute Migraine Attacks. Table 2.11–6 shows the current treatments for acute attacks of migraine. The choice of treatment should be based on the severity of the attacks, history of treatment, concomitant conditions, and susceptibility to side effects. The three main classes of treatments are the triptans (5-HT 1B/1D agonists), ergot alkaloids including intranasal dihydroergotamine and ergotamine, the nonsteroidal anti-inflammatories (NSAIDs) including diclofenac potassium, naproxen and aspirin, and acetaminophen. Doses shown in the table are those that yielded significantly better efficacy than placebo in controlled trials. There are multiple triptans that have been introduced, and all appear to have about equivalent efficacy in reducing the acute symptoms of migraine attacks compared to placebos. The NSAIDs and acetaminophen are in widespread over-the-counter use for pain in general. However, they all can

Telegram: @medical_k

www.konkur.in

have serious side effects, particularly when used in higher doses and over longer periods than indicated.

Table 2.11–6.
Acute Treatment of Migraine

CLASS	Drug (Dose/mg)
Triptans (5-HT 1B/1D Agonists)	Sumatriptan (25; 50) Zolmitriptan (2.5; 5) Naratriptan (2.5) Rizatriptan (5; 10) Eletriptan (20; 40; 80)
Ergot Alkaloids	Dihydroergotamine (intranasal) Ergotamine
NSAIDs	Diclofenac potassium (50–150) Naproxen (500–550) Aspirin (325)
Acetaminophen	Acetaminophen (1,000)

NSAIDs, nonsteroidal anti-inflammatory drugs.

Drug Treatment for Children and Adolescents. There are few well-designed large clinical trials that have examined the efficacy of prophylactic migraine drugs for children. The only effective agents that have been effective in migraine prophylaxis for children in multiple controlled trials are topiramate and flunarizine. The remainder of the studies failed to show the superiority of migraine treatments over placebo or were open-label studies or retrospective reviews. Despite the lack of robust evidence, cyproheptadine is commonly used as a preventative medication in this age group, particularly for children under 12 years of age.

Nonpharmacologic Treatments. There has been substantial research on the use of behavioral treatments, including biofeedback, relaxation training, and cognitive behavioral therapy (CBT), for migraine prevention. Although most of the studies show greater reductions in migraine for the intervention compared to the no-treatment group, the lack of both clinician and patient blinding in these studies diminishes the extent to which such studies may provide conclusive evidence for efficacy. Likewise, herbal

Telegram: @medical_k

www.konkur.in

treatments such as feverfew (*Tanacetum parthenium*) and dietary supplements such as magnesium and vitamin D have only been assessed in a few studies. Finally, whereas massage and relaxation therapy have been shown to be equivalent to propranolol and other medications in the management of migraine, there is no evidence from controlled trials for cervical manipulation in the treatment of migraine.

The American Academy of Neurology and the American Headache Society developed the latest practice recommendations for pediatric migraine prevention, in 2019, based on a review of 15 class I to III studies. They found that topiramate and cinnarizine (an antihistamine), compared to placebo, caused a decrease in the frequency of migraine or headache days. Similarly, propranolol, compared to placebo, caused a 50% reduction in headache attacks. While amitriptyline alone was not shown to be efficacious in migraine prevention, compared to placebo, children and adolescents with chronic migraine who receive amitriptyline and CBT are more likely than those who receive amitriptyline and headache education from having a reduction in headache frequency. There is insufficient evidence to support the use of onabotulinumtoxinA in adolescents with chronic migraine.

Disease prevention must remain the cornerstone of migraine management in youth. Multiple behavioral factors are known to influence headache frequency. Recurrent headache in adolescents is associated with increased BMI, caffeine and alcohol use, lack of physical activity, poor sleep habits, and tobacco exposure. Headache disability is higher among adolescents with depression. In addition, weight loss can decrease the headache burden in children who are overweight. Thus, recognition and avoidance of factors that contribute to headache risk can reduce migraine frequency.

Tension-Type Headache

Pharmacologic Treatments. At present, ibuprofen (800 mg), which is associated with the lowest risk of GI bleeding or perforation, is the first choice for acute treatment of tension-type headache followed by naproxen sodium (825 mg) which has a higher risk of GI bleed. These recommendations are based on several drug trials that fulfilled the criteria set by the International Headache Society. Taken together, these studies suggest that although aspirin (500 or 1,000 mg) and various NSAIDs are more effective than placebo in aborting tension headaches, the

Telegram: @medical_k

www.konkur.in

effectiveness of aspirin is comparable to that of paracetamol (500 to 1,000 mg) while that of NSAIDs is superior to simple analgesics. The combination of analgesics and caffeine, sedatives, or tranquilizers might be more effective in some patients than simple analgesics or NSAIDs. The adjunction of caffeine (130 or 200 mg) significantly increases the efficacy of simple analgesics and ibuprofen in controlled trials.

Individuals with chronic tension-type headaches can use preventative treatments such as amitriptyline or topiramate. The initial dose of tricyclic antidepressants should be low (10 to 25 mg amitriptyline or clomipramine before bed) and increased gradually. The average required dose of amitriptyline for patients with chronic tension-type headaches, however, is 50 to 75 mg per day.

Most authorities recommend the discontinuation of treatment after 6 months, regardless of efficacy. A decrease in the daily dose by 20% to 25% every 2 to 3 days might avoid rebound headaches. The mode of action of antidepressants in chronic tension-type headaches is unclear. Tricyclic antidepressants' effect on increasing serotonin and endorphin levels, or inhibiting NMDA receptors, all important chemical components of the pain pathway, might all play a role in alleviating pain in tension-type headaches. Selective serotonin reuptake inhibitors (SSRIs) have not yet been convincingly proven effective for the prevention of tension-type headaches, however.

Nonpharmacologic Treatments. There are numerous behavioral treatments that have been tested in the treatment of tension-type headaches, including relaxation and biofeedback alone or in combination. Cognitive behavioral treatments, such as stress management, are also effective in treating tension-type headaches, especially when combined with biofeedback or relaxation therapies in subjects with high levels of stress.

The improvements produced by behavioral treatment might appear slowly compared with those produced pharmacologically; however, improvement is maintained for longer periods—up to several years—without monthly sessions or contact with the therapist.

The combination of stress management techniques and tricyclic antidepressants has been shown to be superior to either treatment alone in treating chronic tension-type headaches.

A systematic review of randomized clinical trials with physiotherapy and spinal manipulation in patients with tension-type headaches suggests that

Telegram: @medical_k

www.konkur.in

there is insufficient evidence to support the effectiveness of such techniques. Treatments such as massage, transcutaneous electrical nerve stimulation, and the application of heat or cold, have not been shown to be effective in the long-term treatment of tension-type headaches either. In addition, as already mentioned in the section on nonpharmacologic treatments for migraine, cervical manipulations are associated with the possibility of vertebral artery dissection.

Cluster Headache

First-line abortive therapy is subcutaneous sumatriptan, with most people obtaining relief quickly. Home oxygen can be very useful at high flow, 100% concentration via a nonrebreathable mask at 12 to 15 L/minute for up to 20 minutes. Transitional treatments, such as oral steroids, can help the patient through the acute phase while starting preventative strategies. Prophylactic medicine is almost always indicated for treating cluster headaches because of the extreme severity of pain induced by an acute attack, which often occurs at night. Medications that have been shown to be effective in preventing attacks of cluster headaches are lithium, corticosteroids, methysergide, calcium channel blockers, β-blockers, and valproic acid. Side effects can be severe, and combinations of these agents are often necessary to achieve success. Some may benefit from adjuvant topiramate. Histamine desensitization (that involves the repeated intravenous administration of low dose of histamine in an inpatient setting) and surgical intervention are options upon exhaustion of traditional agents.

Post-Traumatic Headache

There have been no randomized, double-blind, placebo-controlled studies of post-traumatic headaches in either adults or children. Therefore, treatment should be tailored to the symptoms of the individual patient. Most people with post-traumatic headaches have characteristics of either tension-type headaches or migraine, and so treatment is directed toward those entities. If a peripheral mechanism, such as muscular or ligamentous changes, is identified, physical therapy may be indicated. Clinicians should be aware of legal action that may diminish the motivation of the patient to improve.

2.12 Neuropsychiatric Aspects of Neuromuscular Diseases

Timothy P. Wuerz, D.O., M.Sc., Rajeet Shrestha, M.D., and Alan J. Lerner, M.D.

The peripheral nervous system (PNS) is a complex system of interconnected motor, sensory, and autonomic nerves and pathways that allow for rapid information passage to and from the central nervous system (CNS). In daily life, it subserves vital functions, including sensation leading to perception, movement around joints throughout the body, and coordination of automatic functions.

A wide variety of disorders occur in the PNS, and two major classes of neuropsychiatric aspects can be considered. Some disorders, such as amyotrophic lateral sclerosis (ALS) or systemic vasculitis, may affect both PNS and CNS simultaneously. Other disorders, such as myasthenia gravis

Telegram: @medical_k

www.konkur.in

(MG), affect the PNS solely, and their neuropsychiatric aspects arise directly from the disabling injury, its treatment, or its psychosocial effects. Medications and toxic exposures may also affect both systems. This chapter will cover the structure of the PNS and major disorders with neuropsychiatric aspects important for clinical practice.

STRUCTURE OF THE PERIPHERAL NERVOUS SYSTEM

The traditional separation of the nervous system into PNS and CNS is not always anatomically straightforward and at times results in ambiguous distinctions. Some portions of the PNS have their cell bodies located in the CNS (e.g., anterior horn cells or motor neurons that innervate skeletal muscle fibers), whereas other neurons originating in the PNS (e.g., sensory neurons located in the dorsal root ganglia) project axons into the CNS where they synapse in the dorsal horn of the spinal cord (e.g., ascending nerve tracts in the spinal cord). The autonomic nervous system can be divided into sympathetic and parasympathetic units and has central and peripheral components. Nevertheless, this imperfect separation is well established and has resulted in distinct neurologic subspecialties, including those related to peripheral neuromuscular diseases and clinical electrodiagnostic medicine. Advances in diagnostic testing such as neuroimaging are providing new insights into nervous system structure, which may change how we understand and categorize CNS and PNS structures.

Telegram: @medical_k

www.konkur.in

FIGURE 2.12–1. Peripheral nervous system (*Netter's Neurology*. 2nd ed.) (Asset provided by Anatomical Chart Co.).

The PNS is defined to include the motor neurons and their axons projecting into the periphery through peripheral nerves, the neuromuscular junction, and the innervated musculature. A motor unit encompasses all muscle fibers innervated by a single motor axon. This may vary from a few fibers in an eye muscle to several hundred in the quadriceps, allowing for graded contraction responses. The peripheral sensory system consists of various modality-specific receptors, including touch, pain, temperature, vibration and joint position sense, afferent sensory axons, their cell bodies in the dorsal root ganglion, and the portion of the axon projected centrally that comprises the dorsal nerve roots.

The ventral (motor) and dorsal (sensory) segmental nerve roots merge to form the segmental spinal nerves, which in turn combine to form the brachial and lumbosacral plexuses before dividing into the individual peripheral nerves (sensory, motor, or mixed sensorimotor) and their

Telegram: @medical_k

www.konkur.in

autonomic nervous system components. The cranial nerves (except olfactory and optic nerves) are similar to the segmental nerves, comprising peripheral and central segments but traversing or originating in the brainstem instead of the spinal cord (Fig. 2.12–1).

NEURONOPATHIES AND DISORDERS OF THE DORSAL ROOT GANGLION

Poliomyelitis and Other Disorders of Anterior Horn Cells

Poliomyelitis has been eliminated throughout much of the world, although pockets of infection remain in rural areas in Pakistan, Afghanistan, and scattered cases in the Middle East and Africa. Polio is the quintessential lower motor neuron disease (MND) affecting motor neurons in the spinal cord, although bulbar symptoms may occur. Syndromes similar to polio may occur with arthropod-borne diseases such as West Nile virus (WNV) infection and with idiopathic cases of flaccid paralysis. WNV may be limited to a segment of the spinal cord with concomitant weakness, but encephalitis with mental status changes and coma may occur. The prognosis for recovery from WNV infection is guarded, and supportive care and counseling throughout are important components of care for patients with this condition.

Postpolio Syndrome

Postpolio muscle dysfunction disorder has an unclear etiology. A consensus workshop in 1996 proposed the following diagnostic criteria: (1) history of paralytic Polio: confirmed or not confirmed with partial or fairly complete functional recovery; (2) after a period of functional stability of at least 15 years, development of new muscle dysfunction emerges; (3) muscle weakness; (4) muscle atrophy; (5) muscle pain; and (6) fatigue. Neurologic examination in postpolio muscle dysfunction should be compatible with prior poliomyelitis with lower motor neuron lesion, decreased or absent tendon reflexes, no sensory loss, and compatible findings on electromyography (EMG) and/or MRI.

Postpolio syndrome can lead to significant distress, anxiety, and depression as the pain and fatigue cause marked changes in the level of functioning. In a sample of polio survivors, more than a quarter had depression, while those with postpolio syndrome and lower family functioning were at higher risk of depression. It is important to carefully

Telegram: @medical_k

www.konkur.in

assess postpolio patients for psychiatric complications and to consider interventions, including counseling and antidepressants. Sedatives and alcohol should be avoided due to the increased risk of falls and hypoventilation. Physical rehabilitation may provide benefit, and seral medications have been used empirically without clear sustained benefit.

Amyotrophic Lateral Sclerosis

Long considered a very rare disease, ALS, the most common MND, has an annual incidence of roughly 2 per 100,000 and a prevalence of 6 per 100,000 persons. The typical clinical presentation is the combination of both upper motor neuron and lower motor neuron signs. Rarer forms include prominent bulbar dysfunction and pure lower- or upper-motor neuron presentation at least initially. Lower motor signs include weakness, muscle atrophy, and the presence of fasciculations, which are painless spontaneous discharges of motor units and involuntary rapid twitches in limb or trunk muscles. EMG and nerve conduction studies (NCS) play critical roles in the evaluation and may reveal fibrillations, a sign of active denervation. Upper motor neuron signs include spasticity, loss of dexterity, hyperreflexia, and pseudobulbar palsy. Death from respiratory failure or aspiration typically occurs within 3 years of diagnosis, although occasionally, patients may have a prolonged course, particularly if a decision is made by the patient to accept respiratory support. Because of the uniformly fatal course of ALS, a wide-ranging differential diagnosis should be considered, encompassing virtually the entire neuraxis.

The pathology of ALS involves degeneration of the motor neurons of the spinal cord (anterior horn cells) and brainstem, as well as the upper motor neurons of the cerebrum. Gliosis and neuronal loss occur in superficial layers of the dorsomedial neocortex of the frontal lobes and may occur in the hippocampal and parahippocampal regions in the temporal lobes. About 5% to 20% of cases are familial, and several different genes have been found in association with ALS. These include *SOD1, C9ORF72, VCP, TARDBP, FUS, CHMP2B*, and *ATXN2*.

There has been increasing recognition of the neuropsychiatric aspects of ALS, most notably its association with frontotemporal degeneration (FTD). FTD and ALS occur on a spectrum, and detailed examination may show a cognitive decline in patients presenting with classic ALS symptoms. FTD is clinically heterogeneous and may present as a behavioral and dysexecutive syndrome, primary progressive aphasia, or parkinsonism, with features of progressive supranuclear palsy or corticobasal syndrome

Telegram: @medical_k

www.konkur.in

(Table 2.12–1). ALS may develop in patients with previously diagnosed FTD or vice versa. Patients with the *C9ORF72* expanded hexanucleotide repeat mutation may present with behavioral syndromes, especially psychosis and agitation. These seemingly disparate disorders are linked by genetic and pathologic commonalities, with ubiquitin-positive neuronal cytoplasmic inclusions in lower motor neurons, hippocampus, and neocortex in both conditions. Gliosis and neuronal loss in superficial layers of the dorsomedial neocortex of the frontal lobes also occur across the FTD-ALS spectrum.

One-third to one-half of patients with ALS perform poorly on neuropsychological testing compared with matched control subjects. The pattern of cognitive change generally includes mild memory loss, associated word finding and semantic fluency difficulties, and executive function impairments. Facial emotional recognition is also impaired in ALS patients. These patterns of cognitive impairment differ substantially from that seen in Alzheimer disease, wherein memory loss and apraxia predominate. The presence of cognitive impairment has been associated with decreased survival time. Acetylcholinesterase inhibitors are of doubtful value in individuals with cognitive impairment in this population.

Pseudobulbar affect (PBA) is a syndrome of disinhibited affective display in which patients demonstrate inappropriate and exaggerated laughing or weeping responses to environmental stimuli and may affect up to 50% of ALS patients. The behaviors are not usually associated with disturbances of the underlying mood, and the behavioral phenotype tends to be stereotypical for each patient. Successful treatment of PBA in ALS patients has been reported with tricyclic compounds or selective serotonin reuptake inhibitors. A combination of dextromethorphan and quinidine (Nuedexta) has been found to be effective in many cases and is U.S. Food and Drug Administration (FDA) approved for the treatment of PBA.

There are several medications approved by the U.S. FDA for ALS treatment. Riluzole blocks glutamate release and prolongs survival by about 3 months in clinical studies. Tiglutek is a thickened liquid formulation of Riluzole designed to avoid problems that may be caused by crushing tablets. Riluzole's side effects include bladder pain, dark urine and difficulty, burning, or painful urination, tachycardia, malaise, cough, itching skin, and muscle aches and pains. Riluzole overdose may cause agitation.

Edaravone is administered intravenously at a dose of 60 mg according to the following schedule: an initial treatment cycle with daily dosing for 14 days, followed by a 14-day drug-free period. Subsequent treatment cycles

Telegram: @medical_k

www.konkur.in

with daily dosing for 10 days out of 14-day periods, followed by 14-day drug-free periods. Clinical studies favored Edaravone on the ALS Functional Rating Scale-Revised (ALSFRS-R). The ALSFRS-R scale consists of 12 questions evaluating fine motor, gross motor, bulbar, and respiratory function of patients with ALS (speech, salivation, swallowing, handwriting, cutting food, dressing/hygiene, turning in bed, walking, climbing stairs, dyspnea, orthopnea, and respiratory insufficiency). Each item is scored from 0 to 4, with higher scores representing greater functional ability.

Repeated exposure via “glue sniffing” leads to cognitive deficits, motor and sensory neuropathy, cranial nerve and autonomic dysfunction.	Cessation of hexacarbon exposure.

Spinal Muscular Atrophies

Spinal muscular atrophies (SMAs) are disorders with lower motor neuron dysfunction due to the loss of anterior horn cells. The syndromes may present in infancy (Werdnig–Hoffman syndrome; SMA I), childhood (chronic infantile; SMA II), adolescence (Kugelberg–Welander disease, SMA III), or adulthood (SMA IV). Developmental arrest and limited survival are features of SMA type I and II. SMA is an autosomal recessive disorder, with an incidence of about 1 per 10,000 live births. The differentiation of these complex disorders is increasingly being done by genetic analysis. The autosomal recessive proximal SMAs have been linked to mutations or deletions in the survival motor neuron (SMN) gene on chromosome 5q11.12–13.3. Variants of SMA also linked to chromosome 5q include SMA with arthrogryposis and a very severe form with survival measured in weeks after birth. There are also SMA syndromes, often with other neurologic features, that are not linked to 5q mutations. These include Kennedy disease (X-linked bulbospinal muscular atrophy with androgen resistance), Fazio–Londe (progressive bulbar atrophy of childhood), late-onset Tay–Sachs disease, focal atrophy syndromes, and distal SMAs

Telegram: @medical_k

www.konkur.in

("spinal" Charcot–Marie–Tooth disease, and autosomal dominant adult-onset SMA).

Long considered completely untreatable, a remarkable development is a new treatment for SMA with nusinersen, a survival motor neuron-2 (SMN2)-directed antisense oligonucleotide indicated for the treatment of SMA in pediatric and adult patients. SMA gene therapy is a one-time intrathecal infusion that replaces the defective or missing *SMN1* gene with a working copy. This new gene increases SMN protein levels, which improves motor neuron function and increases the likelihood of survival. Other gene-directed therapies are in development.

Dorsal Root Ganglion Disorders

Disorders of the dorsal root ganglia present as pure sensory syndromes. Paraneoplastic sensory neuropathies due to inflammation of the dorsal root ganglion may be associated with the production of other autoimmune antibodies producing paraneoplastic encephalomyelitis. Symptoms of encephalomyelitis include cognitive and behavioral disturbances (also seen in limbic encephalitis), ataxia, seizures, cerebellar ataxia, opsoclonus, myoclonus, and gut dysmotility.

Table 2.12–2.
General Categories of Sensory or Sensorimotor Neuropathies

Acute	Subacute/Chronic	Subacute/Chronic
Guillain–Barré syndrome (acute inflammatory demyelinating polyneuropathy [AIDP])	Vitamin B_{12} deficiency	Cryoglobulinemia
Toxic	Environmental toxicity (arsenic, lead, N-hexane, organophosphates, taxol, pyridoxine, cisplatin, vincristine, dapsone, chloroquine, many other medication and toxins)	Acromegaly
HIV-associated AIDP	Paraneoplastic	Graft vs. host disease
Vasculitis	Diabetes	Thiamine deficiency
Lyme disease	Hypothyroidism	Gastric bypass
Acute pandysautonomia	Monoclonal gammopathies (especially associated with multiple myeloma or other neoplasms)	
Porphyria	Sarcoidosis	
Critical illness neuromyopathy	Connective tissue disorders (SLE, Sjogren, scleroderma)	
	Hereditary (Charcot–Marie–Tooth, Fabry disease, Tangier disease)	
	POEMS syndrome	
	Amyloidosis	

SLE, systemic lupus erythematosus. POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, skin abnormalities.

PERIPHERAL NEUROPATHIES

There are many ways to classify peripheral neuropathies. A clinically useful two-pronged approach is to consider (1) the onset and course as acute, subacute, or chronic; (2) and whether the involvement is pure motor, mixed motor and sensory, or pure sensory, and with or without autonomic involvement. This classification applied to specific disorders is presented in Table 2.12–2.

Telegram: @medical_k

www.konkur.in

Sensory or Sensorimotor Neuropathies

Neuropathies involving sensory nerves or their cell bodies typically present with symptoms and signs of sensory loss involving the distal limbs. Sensory symptoms are very hard to describe in ordinary language: symptoms described as “burning,” “freezing,” or “cutting” may represent identical pathophysiology and, indeed, may be described alternately or even simultaneously in the same patient. Despite decreased sensation, patients paradoxically show hyperesthesia and often complain of uncomfortable sensations, characterized as burning and tingling, spontaneously or in response to a stimulus such as light touch. Traditional modality-specific sensory testing is quite crude and is aimed primarily at detecting changes in sensory thresholds. Clinical testing does not address the stimulus–response relationship, which may help explain this apparent paradox of decreased sensation and hyperesthesia. Most neuropathies are sensorimotor in nature, as most peripheral nerves subserve both functions.

Diagnosis of Neuropathies

The diagnostic evaluation of neuropathy is a highly specialized process, with a bewildering number of conditions possible with overlapping clinical phenotypes (Table 2.12–2). The clinical history may suggest positive family history, the presence of early onset, and slow progression, consistent with an inherited etiology. History may also suggest toxic exposures and systemic conditions (neoplasms, autoimmune disorders, and medications) associated with neuropathies. A thorough examination can help identify symptom patterns to aid the diagnostic process. The American Academy of Neurology recommends initial screening for diabetes, checking serum electrophoresis for underlying monoclonal gammopathy and vitamin B_{12} level, and using electrodiagnostic testing such as NCS and EMG for further classification. Nerve and muscle biopsy may be indicated in certain situations, and skin biopsy may help confirm small fiber neuropathy. Nonetheless, some neuropathies may remain undiagnosed. Neuromuscular ultrasound is being increasingly recognized as a valuable adjunct to NCS/EMG. It can show local pathologies, impacting nerve structure and function that would not otherwise be suspected, especially in focal syndromes such as entrapment neuropathies, traumatic injuries, and plexopathies.

Treatment of Neuropathies

Telegram: @medical_k

www.konkur.in

Treatment of neuropathy is primarily directed at treating the underlying cause. Neuropathic pain is one common problem associated with neuropathies. Treatment of neuropathic pain is typically resistant to traditional analgesics (i.e., NSAIDs or opiates) and requires a multimodal approach, often involving adjunctive pain medications. Antidepressants with mixed pharmacologic effects are useful in chronic pain syndromes, including the pain associated with some peripheral neuropathies. Amitriptyline (Elavil) is inexpensive and effective for this indication and is favored by many as a first-choice agent. Doses in the range of 25 to 75 mg per day are usually sufficient to generate some symptomatic improvement. Imipramine may also be used and has fewer anticholinergic adverse effects. Duloxetine (Cymbalta) is FDA approved in the United States for the treatment of painful diabetic neuropathy. Daily doses for duloxetine range from 30 to 120 mg per day. Venlafaxine has also been recommended as a first-line treatment for neuropathic pain at doses similar to those used for the treatment of depression. Pregabalin (Lyrica) is indicated for several neuromuscular conditions, specifically, management of neuropathic pain associated with diabetic peripheral neuropathy, management of postherpetic neuralgia (PHN), management of fibromyalgia, and management of neuropathic pain associated with spinal cord injury. Neuropsychiatric adverse effects of pregabalin include mood changes, anxiety, panic attacks, sedation or insomnia, impulsivity, agitation or aggression, and suicidal ideation. Dosage ranges from 50 mg three times daily up to 100 mg three times a day are used in patients with creatinine clearance of at least 60 mL/min, with reduced dosage based on renal function. In addition to being frequently used for neuropathic pain, gabapentin (Neurontin) is also indicated for usage in PHN at doses ranging from 100 mg/day up to 600 mg three times daily and must be adjusted for renal insufficiency. The neuropsychiatric side-effect profile is similar to that seen with pregabalin.

Clinicians must be aware that the approved indications for the use of duloxetine, pregabalin, and gabapentin with regard to neuropathic pain are limited. Their usage, or the use of many antidepressant medications for modulation of neurotransmitter systems involved in pain transmission and perception, in other pain syndromes, other neuropathies or for vague indications, is encountered commonly and may be of limited efficacy. Correction of metabolic abnormalities, removal of toxic exposures, and nonpharmacologic approaches such as physical therapy, psychological interventions, and exercise need to be integrated into a holistic care model.

Telegram: @medical_k

www.konkur.in

Physical and occupational therapy can address motor weakness and provide techniques and adaptive equipment to help overcome sensory loss.

Diabetic Neuropathy

Diabetes mellitus is the most common cause of sensory or sensorimotor neuropathy in the United States. In primary care settings, more than half of diabetic patients have symptoms and signs of peripheral neuropathy, and diabetes may be newly diagnosed during the evaluation of a new-onset painful neuropathy. Improved glycemic control slows the progression of diabetic neuropathy, but symptomatic improvement of unpleasant sensory symptoms remains a major clinical challenge.

Guillain–Barré Syndrome

Guillain–Barré syndrome (GBS) is an acute inflammatory demyelinating polyneuropathy (AIDP). It is classically described as ascending paralysis, frequently with sensory loss and autonomic instability. The pattern of presentation is somewhat variable and may be misdiagnosed as a nonspecific illness at first. Onset may follow a nonspecific illness, such as an upper respiratory infection. Cases of GBS, especially those associated with *Campylobacter jejuni* infection, may have an axonal injury in addition to demyelinating features. The presence of axonal injury and loss may predict a poorer prognosis. During the acute phase, the disorder can be life-threatening, with about a quarter requiring admission to an intensive care unit (ICU) for mechanical ventilation. The majority of individuals affected with GBS recover and similar degrees of improvement rate are seen with both γ-globulin infusions and with plasmapheresis. Both plasmapheresis and intravenous γ-globulin are used to hasten the return of nerve function caused by GBS, whereas steroids have not proven efficacious in this regard.

It is important for the psychiatrist to be aware of the associated neuropsychiatric manifestations both directly and indirectly from an acute GBS syndrome with a resulting ICU admission in terms of anxiety, acute stress disorder, depressive episodes, and brief reactive psychosis. Psychotic episodes are strongly associated with severe quadriparesis, artificial ventilation use, and multiple cranial nerve dysfunctions. Patients express that experiencing and coping with the loss of communication is the most difficult aspect of GBS. Therapeutically, patients often feel reassured

Telegram: @medical_k

www.konkur.in

by the ICU environment and contact with relatives and visitors is helpful. Supportive counseling is a valuable adjunct, in addition to psychopharmacologic measures, in helping patients cope with this illness, which can be devastating in its effects despite a good long-term prognosis.

Chronic Inflammatory Demyelinating Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy (CIDP) is an immune-based neuropathy of unknown cause and may resemble GBS in its early stages. Both cellular and humoral components of the immune response contribute to pathogenesis, although the precipitating antigen(s) is unknown. There is a breakdown of the blood–nerve barrier and recruitment of macrophages. Secretion of toxic factors then damages myelin sheaths and may produce axonal injury. In HIV-positive patients, there may be as many as 50 WBC/cubic mm in the CSF, mimicking a chronic CNS inflammatory process.

CIDP may occur at any age and may occur in connection with other autoimmune disorders and monoclonal gammopathy of unknown significance. Successful treatments of CIDP with corticosteroids, immunoglobulin infusions, plasmapheresis, and immunosuppressants have been reported. The uncertainties regarding prognosis present a special challenge to the patients, and dealing with these iatrogenic and situational problems can benefit from psychiatric consultation.

Nutritional and Alcoholic Neuropathies

Alcohol can affect every level of the PNS and CNS. Persons with alcohol-related neuropathies frequently have a history of alcohol dependence and other comorbid vitamin and nutritional deficiencies. Alcohol-related major neurocognitive disorder is complicated by the various syndromes described in individuals who abuse alcohol, as well as other possible comorbidities contributing to cognitive dysfunction in these individuals, including vitamin B_{12} deficiency, head injuries and subdural hematomas cerebrovascular disease, and so forth. It is also unclear to what degree alcohol-related major neurocognitive disorder overlaps with Wernicke–Korsakoff syndrome. Alcohol-related major neurocognitive disorder is diagnosed much more often than Wernicke–Korsakoff syndrome, but many people diagnosed with alcohol-related syndromes have a thiamine deficiency often missed by treating health professionals. Research has identified other metabolic disturbances that result in functional thiamine deficiency.

Telegram: @medical_k

www.konkur.in

Knowledge about whether alcohol abuse may be a risk factor for other dementias such as Alzheimer disease is also sparse.

Vitamin B_{12} deficiency affects multiple levels of the nervous system, which may present as peripheral neuropathy, myelopathy, or cognitive syndrome. Vitamin B_{12} is essentially found only in animal products, and deficiency can be due to decreased intake or failure of absorption since intrinsic factor is a gastric protein important for facilitating dietary absorption. Sensitivity in determining vitamin B_{12} deficiency may be enhanced by the measurement of intermediate metabolites such as methylmalonic acid and serum homocysteine. Rapid repletion of vitamin B_{12} is usually accomplished by intramuscular administration of 1 g daily for a week, then weekly for the first month, followed by maintenance therapy on a monthly basis. Chronic oral repletion is possible, even in patients with low intrinsic factor activity, through a low-affinity uptake mechanism.

Cranial Nerve Disorders

The 12 cranial nerves are largely analogous to the segmental peripheral nerves and have their cell bodies within the CNS. A variety of conditions can selectively affect cranial nerves, and occasionally these are associated with neuropsychiatric complications. Examples include cranial neuropathies secondary to concomitant meningeal inflammation, which may occur with granulomatous diseases such as tuberculosis or sarcoidosis. Cranial neuropathies may be associated with acute or subacute alterations in baseline mental status, hydrocephalus, or major neurocognitive disorder.

A clinical challenge may occur with cranial neuropathies in association with neurodegenerative disorders. Anosmia (olfactory nerve: CN I) may occur years before the classic motor symptoms of Parkinson disease or memory loss in Alzheimer disease. Visual hallucinations or complex visuospatial disturbances, seen in major neurocognitive disorder secondary to Alzheimer disease or dementia with Lewy bodies, often calls for ophthalmologic investigation of retinal and optic nerve (CN II) function as part of the neuropsychiatric treatment plan. Visual hallucinations can occur in the visually impaired and are termed Charles Bonnet syndrome (CBS). The visual impairment in CBS can be secondary to any cause of visual impairment and is considered to be a cortical release phenomenon. Patients with pre-existing neurodegenerative disorders may be predisposed to CBS. The treatment of CBS is based on the improvement of vision impairment.

Telegram: @medical_k

www.konkur.in

The importance of sensory loss due to hearing loss and visual loss (e.g., cataracts, macular degeneration, and sensorineural hearing loss) is being increasingly recognized as an important component of multidisciplinary evaluations since memory is critically dependent on sensory input for later recall.

Peripheral Nerve Injury

Traumatic peripheral nerve injuries range from stretch injury without rupture of the nerve sheath (e.g., foot drop after hip surgery) to complete transection of the affected nerve(s). While neural repair with reinnervation of affected nerves and their targets often occurs, the estimated daily repair rate is about 1 mm/day; thus, the time required for full functional return may be weeks to months. Patient expectations and secondary mood adjustments may respond to psychiatric interventions.

Concomitant traumatic brain injury (TBI), spinal cord, or severe musculoskeletal injury greatly complicates peripheral nerve injury, particularly in the acute post-traumatic period. Concurrent therapies are frequently needed as the presence of multiple injuries is often associated with greater mood effects; the range of symptoms with TBI include altered mental state, psychosis, disinhibition, mood effects, and focal neurologic injuries and should be treated as appropriate.

Metabolic, Endocrine Neuropathies, and Ischemic Neuropathies

This diverse group of disorders is of interest to psychiatrists because of concurrent psychiatric comorbidity. Metabolic and endocrine disorders associated with neuropathy include uremia, hepatic failure, hyper- and hypothyroidism, and neuropathy associated with acromegaly. Pituitary tumors, in general, are often associated with psychiatric symptoms, including depression, anxiety, apathy, behavioral and personality changes, and cognitive impairment. Changes in attention, memory, and executive function have been reported to be common in acromegalic individuals.

Environmental and Toxic Neuropathies

Toxic neuropathies can be caused by exposure to substances, including chemicals or heavy metals (Table 2.12–1). These exposures may be accidental (in the workplace or through drinking water) or intentional (homicide or suicide). Most toxic neuropathies produce symmetric deficits, but the symptoms and signs may vary based on dose and the intensity or

Telegram: @medical_k

www.konkur.in

duration of exposure to the toxic substance. A clue to toxic exposures is that the symptoms usually involve multiple organ systems and rarely present as an isolated peripheral neuropathy. The first step in identifying a neuropathy as toxin related is simply having a high degree of suspicion.

Frostbite

Frostbite is an ischemic neuropathy, and high-risk groups include outdoor workers, the older adults, the homeless, drug or alcohol abusers, psychiatric diseases, high-altitude or cold-weather athletes, and military personnel. It should be easily diagnosed, although several grades of severity are recognized. Psychiatric illness is very pervasive in victims of frostbite, and psychiatric screening for patients with frostbite has been highly encouraged. Acute treatments include rewarming and treatment of ischemic injury, often resulting in the need for amputation. Long-term consequences include sensitivity to cold and chronic limb pain.

Lead. Lead toxicity is a well-known cause of neurologic dysfunction. Potential for exposure is usually via inorganic lead and may occur in automobile factory workers, plumbers, exposure to outdated paint products, and consuming illegal “moonshine” whiskey. Exposure via lead-contaminated drinking water led to widespread population exposure in Flint, Michigan. Lead intoxication in children is most commonly associated with CNS dysfunction. This may lead to chronic cognitive dysfunction (developmental delay or loss of milestones) or acute encephalopathy with ataxia, tremulousness, choreiform movements, and hallucinations, which may progress to seizures, coma, or death. Acute or chronic exposure in adults can also lead to encephalopathy. Chronic lead exposure presentation usually includes gastrointestinal (GI) disturbance, anemia, weight loss, fatigue, renal dysfunction, and bluish discoloration of the gums (“lead lines”), in addition to a neuropathic picture. Porphyria should be included in the differential. Treatment consists of utilizing chelating agents and preventing or minimizing exposure.

Arsenic. Arsenic is famous as a poison used for suicide or homicide, usually resulting from massive ingestion, although it can also result from chronic low-grade exposure from the smelting of lead and copper ore, contaminated well water (a common occurrence in Bangladesh), tainted illicit drugs, and burning of preserved wood. High-level acute exposure causes multiple organ dysfunction, organic psychosis, CNS dysfunction,

Telegram: @medical_k

www.konkur.in

and possible death. Peripheral neuropathy manifests within weeks and may continue for a period of weeks after removal of the exposure. Peripheral neuropathy symptoms include burning and numbness of the feet followed by hands. Treatment of acute ingestion requires ICU care. Chronic exposure treatment includes chelating agents and education of those at risk.

Mercury. Mercury toxicity can be of several types: (1) elemental mercury found in outdated thermometers, barometers, and other gauges; (2) organic mercury found in latex paints as a preservative or as an environmental pollutant, exemplified by the so-called “Minamata disease” following massive organic mercury pollution in Japan; (3) and inorganic mercury salts used in the manufacture of chlorine, in dental amalgam, and in the natural gas industry.

Intoxication with mercury results in predominantly CNS dysfunction (encephalopathy [“mad as a hatter”], ataxia, dystonic movements, numbness in the hands and feet, general muscle weakness, narrowing of the field of vision, and damage to hearing and speech). Associated systemic toxicity includes GI symptoms and nephrotic syndrome. PNS dysfunction is seen in all forms of mercury poisoning. Treatment of mercury intoxication is primarily by removal from exposure, use of chelating agents, and preventive education.

Carbon Disulfide. Carbon disulfide is a clear liquid that vaporizes at room temperature and is readily absorbed by inhalation but is also absorbed via the GI tract and skin. It is also a major metabolite in the breakdown of the drug disulfiram (Antabuse). Acute or subacute exposure to high levels of carbon disulfide causes CNS dysfunction, including memory impairment, confusion, hallucinations, and emotional lability primarily. Pyridoxine may have a role in treatment.

Organophosphates. Organophosphorus (OP) compounds are used as insecticides, flame retardants, various other industrial manufacturing components, and in chemical warfare. Accidental exposure from agricultural spraying is the most common cause of individual intoxication. OP compounds are a frequent agent for suicide and are implicated in almost 20% of suicides in India.

The sarin gas attack in the Tokyo subways has been well studied, and a small number of survivors had a short-lived neuropathy. Post-traumatic

Telegram: @medical_k

www.konkur.in

stress disorder was common in those survivors. OPs have also been implicated in the Gulf War syndrome, with various combinations of PNS and CNS symptoms.

OPs prevent the degradation of acetylcholine (ACh) by disrupting acetylcholinesterase resulting in excessive stimulation of both muscarinic and nicotinic receptors. There are acute (type I) and intermediate (type II) cholinergic syndromes depending on which receptor is preferentially affected. Type I results from excessive stimulation of muscarinic cholinergic receptors. An acute syndrome frequently begins hours after exposure and always within 1 day. Symptoms include GI effects, micturition, sweating, and tachycardia or bradycardia. CNS involvement includes emotional lability, decreased alertness, cognitive impairment, convulsions, and coma in extreme cases. Type II occurs within 12 to 96 hours after exposure and is due to nicotinic ACh receptor activation in skeletal muscle. The initial feature is usually respiratory insufficiency, followed by weakness of the neck flexors and proximal muscles. The cranial muscles, including the extraocular muscles, may be involved. Dystonic posturing may be seen. This neuropathy has been labeled the organophosphate-induced delayed polyneuropathy (OPIDP) since there is an interval of 7 to 21 days after exposure before peripheral neuropathy symptoms are seen. Although less common than the cholinergic syndromes, OPIDP causes significant morbidity, including foot drop, claw hand deformity, or atrophy in extreme cases of severe neuropathy. Administration of atropine only treats the muscarinic type I syndrome and does not prevent the intermediate type II nicotinic cholinergic syndrome. Reactivation of acetylcholinesterase may be accelerated by the administration of pralidoxime. Cathartics and gastric lavage are indicated in the case of acute ingestion. Chronic low-level exposure to OP can result in mood dysregulation, increased risk of suicidality, and increased impulsivity. Psychiatric and psychological support is an important adjunct to more direct treatments and should be initiated early in the treatment regimen.

Hexacarbons. Hexacarbons are components of glues and lacquers, and solvents. Hexacarbon exposure occurs in the production and refining of petroleum products, and high-level exposure also occurs with intentional inhalation such as “glue sniffing.” Acute exposure causes CNS depression and stupor. Repeated exposure via “glue sniffing” leads to cognitive deficits, motor neuropathy, and cranial nerve and autonomic dysfunction. Severe neuropathies can result in sensory loss, atrophy, and distal

Telegram: @medical_k

www.konkur.in

weakness. The only treatment is the cessation of hexacarbon exposure. Psychiatric concerns from “glue sniffing” include the emergence of violent behavior and/or self-mutilation, functional deterioration, impairment of intelligence, and possible development of psychosis. Glue sniffing is often considered a “gateway drug” to other forms of substance abuse, and specialized addiction treatments should be considered in these cases.

Vasculitic Neuropathies and Neuropathies of Connective Tissue Disorders. Systemic disorders, especially primary vasculitides and connective tissue disorders (many of which are autoimmune in etiology), often affect peripheral nerves. Concomitant neuropsychiatric complications may be primary such as vasculitis affecting CNS structures, or secondary to treatment (e.g., steroid-related mood disturbance) or adjustment to severe chronic illness. Prominent syndromes affecting the CNS are systemic lupus erythematosus (SLE), Sjögren syndrome, giant cell arteritis, and disorders of circulating autoantibodies, especially the antineutrophil cytoplasmic antibodies (ANCA) classically seen in granulomatosis with polyangiitis (Wegener granulomatosis).

Infectious and Granulomatous Neuropathies. The infectious and granulomatous neuropathies result from a variety of inflammatory conditions. Peripheral nerve involvement in these disorders may manifest clinically as mononeuropathy, mononeuropathy multiplex, polyneuropathy, or polyradiculopathy. Nerve pathology may result from an inflammatory reaction induced by the infection and from the host’s immunologic reaction.

HIV-ASSOCIATED NEUROPATHIES. More than one-third of AIDS patients are estimated to have peripheral neuropathy. HIV neuropathy may affect proximal and distal components of the motor, sensory, and autonomic PNS. Other AIDS-related neurologic conditions, such as myelopathy, myopathy, and dementia, may coexist.

The diagnosis of HIV-associated neuropathy may be particularly complicated and challenging, as a wide range of potential etiologies underlies peripheral neuropathy in HIV-infected patients. Etiologies of HIV-associated neuropathy include cytotoxic effects due to direct HIV infection, cytokine dysregulation, opportunistic infection, neoplastic processes, autoimmune disorders, metabolic abnormalities, and toxic effects of medications.

Telegram: @medical_k

www.konkur.in

AIDS patients present with a variety of PNS syndromes. Distal symmetrical polyneuropathy (DSP) is a painful neuropathy occurring in 30% of AIDS patients. Patients complain of numbness, burning, and paresthesias of the feet, with pain usually beginning in the toes and soles of the feet. Inflammatory demyelinating polyneuropathy produces rapidly progressive muscle weakness of two or more limbs, often starting in distal muscles and may resemble GBS or CIDP. Mononeuropathy multiplex is a neuropathy that affects single or multiple nerves causing asymmetric motor and sensory complaints presenting with weakness or dysesthesias in the distribution of cutaneous nerves, mixed nerves, and nerve roots. Progressive polyradiculopathy is a serious condition presenting as a rapidly progressive cauda equina syndrome, characterized as leg weakness, difficulty walking, bowel and bladder dysfunction, low back pain, and leg paresthesias.

Prompt recognition and treatment of neuropathy may significantly benefit a patient's quality of life. Possible etiologies range from relatively benign facial neuropathy to severe opportunistic infections, including lymphomatous meningitis, CMV encephalitis, and *Cryptococcal* meningitis. In addition, cranial neuropathies occasionally are caused by primary CNS lymphoma, non-Hodgkin lymphoma, or brain stem glioma. Treatable conditions in HIV populations include B_{12} deficiency, ethanol abuse, neurotoxic medications, uremia, or diabetes.

Evaluation of AIDS or HIV-related neuropathies consists of ancillary tests, including NCS, EMG, autonomic testing, and blood, CSF, and neuroimaging studies. Treatment of HIV-related peripheral neuropathy depends on etiology but has four main components to be considered: antiviral treatment, immunomodulation, treatment of underlying causes, and symptom reduction.

HIV-associated peripheral neuropathy is often refractory to standard treatments for pain. For example, a placebo-controlled study of amitriptyline (tricyclic antidepressant) and mexiletine (antiarrhythmic) in patients with HIV-associated peripheral neuropathy found no significant improvement in pain intensity relative to placebo with either treatment. Similarly, a randomized, placebo-controlled study of the efficacy of acupuncture, amitriptyline, and a combination of the two treatments for pain relief in patients with HIV-associated peripheral neuropathy found that none of the treatments worked better than placebo. However, one study showed that lamotrigine worked significantly better than a placebo to decrease neuropathic pain. Severe rash, an important adverse effect of lamotrigine

Telegram: @medical_k

www.konkur.in

treatment, occurred more frequently than in studies of lamotrigine treatment for epilepsy. Studies suggest initial trials of gabapentin may be helpful, titrated up to 1,200 or 2,400 mg per day, divided into two or three times daily doses. Topical capsaicin can be used in cases that have contraindications, cannot tolerate, or prefer to avoid systemic medication.

LEPROUS NEUROPATHY. Leprosy is caused by *Mycobacterium leprae,* an acid-fast bacillus, and is characterized as a chronic infectious disease that affects the skin and peripheral nerves. The prevalence of leprosy has declined greatly in developed countries and is seen only rarely in immigrants from endemic areas. Sensory loss due to intracutaneous nerve damage is the hallmark of leprous neuropathy. The goal of treatment for leprous neuropathy is the eradication of *M. leprae.* The prognosis for neuropathy depends on the type of leprosy, the time of diagnosis, chemotherapeutic response, and reactive sites.

LYME NEUROPATHY. Lyme disease, the most common tick-borne disease in the United States, is caused by *Borrelia burgdorferi,* a gram-negative spirochete, and transmitted by *Ixodes dammini* and related species. After the incubation period of 3 to 30 days, three stages emerge. Stage I is characterized by a rash at the tick attachment site, causing constitutional symptoms, although many patients do not recall a tick bite. Neurologic complications develop during stages II (early) and III (late). Lymphocytic meningitis and lymphocytic meningoradiculitis (LMR) are common in early neuroborreliosis. Patients with LMR usually have variable motor and sensory involvement of multiple nerves, and symptoms may wax and wane over several months. Focal and multifocal peripheral and cranial nerve involvement is observed in half of patients. Facial nerve paralysis is the most common sign.

In Europe, neuroborreliosis has a somewhat different presentation with meningoradiculoneuritis, characterized by severe radicular pain with or without paresis. Late neuroborreliosis is marked by peripheral neuropathy and encephalomyelitis. The PNS abnormalities of this late stage last for weeks to months. Predominant sensory neuropathy may be seen in up to two-thirds of untreated patients. Stage III is characterized by asymmetric oligoarthritis, cardiac involvement, and a variety of CNS syndromes. Evaluation of Lyme disease consists of a laboratory two-test protocol (ELISA) and Western blot performed on serum or CSF. PNS complications

Telegram: @medical_k

www.konkur.in

of Lyme disease are treated by Borrelia eradication. Neurologic manifestations carry a good prognosis after antimicrobial therapy.

HERPES ZOSTER NEUROPATHY. Approximately 95% of the U.S. population has been infected with VZV, a Herpes virus that is the causative agent for chickenpox. Latent, lifelong infection persists in sensory nerve ganglia and can reactivate to cause zoster neuropathy, or “shingles.” VZV neuropathy results from the reactivation of latent virus from a primary infection. VZV infection is more commonly recurrent and chronic in AIDS and cancer patients receiving chemotherapy and radiotherapy. The most common PNS manifestations of VZV infection include PHN, radiculopathy, zoster sine herpete (zoster without rash), and cranial nerve palsies. PHN can be diagnosed when pain persists more than 4 months after VZV eruption and is more common in older adults. Vaccines are available for the prevention of chickenpox in children and for risk reduction of zoster and PHN in adults. Antiviral treatment is also available for acute attacks, prophylaxis against recurrent attacks, and decreasing the incidence of HSV. Antidepressants, such as amitriptyline, desipramine, and nortriptyline, may relieve pain associated with PHN, but the side-effect risks limit their use. Anticonvulsants are of limited value in the management of neuritic pain. Opioids are the most effective agents for severe neuritic pain. In addition, topical lidocaine 5% gel or patch, nerve blocks, skin infiltration, transcutaneous electrical nerve stimulation, IV lidocaine, and capsaicin dermal patch have been shown to provide adjunctive relief in severe PHN.

COVID-19–RELATED NEUROMUSCULAR DISORDERS

Adults. The COVID-19 pandemic has resulted in numerous unusual neuromuscular disorders both in children and adults. It is also associated with substantial worsening in patients with pre-existing neuromuscular disorders, especially those who have pre-existing breathing or swallowing dysfunction. A wide variety of neuromuscular disorders have now been associated with COVID-19, although the precise etiology and pathophysiology are often unclear.

There have several case reports of GBS with COVID-19, and GBS can be seen in conjunction with several viral diseases. Molecular mimicry between viral proteins and peripheral nerve epitopes on gangliosides has been postulated to underlie this association. There have been few clear-cut

Telegram: @medical_k

www.konkur.in

cases of motor neuron invasion or inflammation, as can be seen with WNV or poliomyelitis.

Myopathy may be a common problem, with reports from China of frequent increased serum creatine kinase, and myositis is common in conjunction with other coronaviruses. Critical illness neuromyopathy in ICU patients with prolonged sedation with nondepolarizing neuromuscular blockade is possible, and weakness from disuse atrophy in patients with prolonged illness is also likely. Fatigue is common after COVID-19 infection in symptomatic patients and may be due to a combination of factors of both PNS and CNS origin, as well as nonneurologic factors such as reduced pulmonary function.

COVID-19 therapies may also increase the risk of neuromuscular dysfunction. Patients may be on prior immunosuppressive therapies, and protease inhibitors may increase the risk of neuropathy in HIV patients. Chloroquine and hydroxychloroquine have been discredited as COVID-19 treatments, but both may be associated with a slowly progressive syndrome of proximal weakness affecting legs more than arms.

Children and Adolescents. A multisystem inflammatory syndrome in children (MIS-C) has been detailed, and diagnostic criteria have been published. The CDC definition includes clinically severe illness requiring hospitalization; and multisystem (two or more) organ involvement (cardiac, renal, respiratory, hematologic, GI, dermatologic, or neurologic). MIS-C has some features similar yet distinct from other childhood multisystem inflammatory disorders such as Kawasaki syndrome and toxic shock syndrome.

Neurologic manifestations may affect as much as 50% of MIS-C patients. These may be of CNS origin (headache, encephalopathy) or PNS such as severe proximal weakness with reduced reflexes. In a series of 82 children from New York City early in the pandemic, 43% had neurologic signs and symptoms. Neuromuscular complications included fatigue in 25% and weakness in 14%, and three patients with cranial nerve VI palsy. Most had evidence of recent or ongoing COVID-19. The full spectrum of this unusual disorder remains to be fully appreciated as cases accumulate in the ongoing COVID-19 pandemic.

SARCOID NEUROPATHY. Sarcoidosis is a multisystem granulomatous disorder that affects young and middle-aged adults and is manifested clinically with bilateral hilar adenopathy, pulmonary infiltration,

Telegram: @medical_k

www.konkur.in

reticuloendothelial system, ocular, and cutaneous involvement. It is estimated that neurosarcoidosis affects 5% to 16% of sarcoidosis patients, and of these, the PNS is affected in approximately 85% of patients. Sarcoid neuropathy can affect large nerve fibers or small nerve fibers. Large fiber neuropathy may present as cranial neuropathy, mononeuropathy multiplex, radiculopathy, or symmetric polyneuropathy. It may mimic GBS or CIDP or cause a small fiber neuropathy with neuropathic pain or autonomic symptoms. Cranial neuropathy is most common and often involves the facial nerve, which may be bilateral. The optic nerve may be affected, and hearing loss is not uncommon. Intra- and extradural granulomatous masses may cause radiculopathy. Endocrine dysfunction may occur due to the involvement of the hypothalamus or pituitary gland. Focal-onset or generalized tonic–clonic seizures may also occur. Neuropsychiatric symptoms include memory loss, changes in mood or behavior, delirium, and psychosis. The diagnosis of sarcoid neuropathy is straightforward when accompanied by recognized systemic involvement. In spite of their potential side effects, corticosteroids remain the mainstay of therapy.

NEUROMUSCULAR JUNCTION DISORDERS

Myasthenia Gravis

MG is the most common disease of the neuromuscular junction. MG is an autoimmune disease, with several identified autoantibodies directed mainly against postsynaptic ACh receptors on the muscle membrane. Two major clinical subtypes are ocular myasthenia and generalized myasthenia. Most frequently, cranial nerves are affected initially, especially extraocular muscles presenting as fluctuating double vision, facial weakness, or difficulty swallowing. Ocular MG may progress to generalized MG or remain an isolated syndrome.

Weakness in MG is classically effort dependent, so weakness increases with exertion and frequently worsens as the day progresses. MG severity also fluctuates over time with frequent remissions and exacerbations, and there are no objective findings on standard neurologic examination such as muscle atrophy or altered reflexes. Perhaps for these reasons, patients with MG frequently are thought to have psychiatric or psychological conditions or even seemingly unlikely diagnoses such as “psychogenic respiratory arrest” before the appropriate tests establish the diagnosis (e.g.,

Telegram: @medical_k

www.konkur.in

elevated ACh receptor antibody levels, abnormal response to repetitive motor nerve stimulation, or abnormal single-fiber electromyogram).

Just as the fatigable weakness of MG should not be casually attributed to psychiatric disorders, vague symptoms such as “tiredness” or “fatigue,” which can be seen in many psychiatric conditions, should not necessarily be considered a manifestation of MG. Patients with somatization disorder have been misdiagnosed as MG, sometimes with disastrous outcomes.

Dysphagia is a prominent and sometimes isolated symptom in early MG. Dysphagia is a nonspecific symptom and is frequently associated with many anxiety disorders, and several figures of speech recognize this connection between anxiety and difficulty swallowing (“I choked,” “I had a lump in my throat,” “I can’t swallow that”). Accompanying facial weakness characterized by intermittent ptosis, disconjugate gaze, and inability to express facial expression is seemingly inconsequential compared to the life-threatening components of MG. However, for many patients, these cosmetic and communicative features are far more disconcerting, often reaching pathologic levels and requiring psychiatric support. Myasthenic patients demonstrate high rates of anxiety symptoms when followed longitudinally through the course of their illnesses, especially anxiety symptoms focused on respiratory status. Research does not presently view these psychiatric symptoms as generated directly by the neurobiology of MG.

Acute episodes of worsening (myasthenia crises) can be life-threatening if they involve respiratory paralysis or dysphagia with aspiration. MG treatment involves the use of anticholinesterase medications to prolong the availability of ACh in the neuromuscular junction, increasing the likelihood that the transmitter will find an available ACh receptor and the use of long-term immunosuppressant medications, most commonly corticosteroids, with their attendant adverse behavioral side effects. Many medications can exacerbate weakness in MG, and clinicians should always check new medications to determine if they may worsen neuromuscular transmission in patients with MG. Lists of these medications to be avoided or used cautiously in MG patients are widely available, or clinicians should coordinate care with a treating neurologist.

Eculizumab is an FDA-approved monoclonal antibody for generalized myasthenia in antibody-positive patients and is also indicated for paroxysmal nocturnal hemoglobinuria (PNH) to reduce hemolysis atypical hemolytic uremic syndrome (AHUS), and neuromyelitis optica spectrum disorder in adult patients who are anti–aquaporin-4 antibody positive.

Telegram: @medical_k

www.konkur.in

Neuropsychiatric side effects may include headache, nausea, vomiting, or fatigue.

Lambert–Eaton Myasthenic Syndrome

Lambert–Eaton myasthenic syndrome (LEMS) is sometimes confused with either MG, chronic fatigue syndrome, or fibromyalgia. LEMS is an autoimmune paraneoplastic syndrome that results in progressive weakness frequently with autonomic symptoms and may progress to respiratory insufficiency. The majority of LEMS patients have a circulating voltage-gated calcium channel antibody. LEMS may be a presenting symptom of a neoplasm, with small-cell lung cancer and breast cancers most common. Although LEMS is not associated with psychiatric symptoms, weakness may be misattributed to psychiatric disorders. Amifampridine phosphate is a newly FDA-approved treatment for LEMS. Side effects may include seizures, allergic reactions, paresthesias, and insomnia and should not be used in addition to other aminopyridine compounds. Many medications lower seizure thresholds, and they should be used with caution in this context to prevent epileptic seizures.

MUSCLE DISEASES

Myotonic Dystrophy

Myotonic dystrophy, the most frequent *adult* muscular dystrophy, is often easily recognized in adults by the characteristic facial features, grip myotonia (e.g., difficulty releasing the hand grip), percussion myotonia (percussion of a muscle evokes myotonia), and distal weakness. Myotonic dystrophy occurs in 15 of 100,000 live births and is autosomal dominant with incomplete penetrance; heterozygotes may present at any age. The genetic basis for myotonic dystrophy type I is an expanded trinucleotide repeat in a protein kinase gene on chromosome 19. The rarer myotonic dystrophy type 2 (DM2) presents with proximal weakness and maps to chromosome 3. *Anticipation* may occur with the development of more severe symptoms in successive generations due to expansion of the length of trinucleotide repeat between generations. Systemic manifestations of myotonic dystrophy include cataracts, diabetes, temporal baldness, and testicular atrophy. Cardiac conduction defects, cardiomyopathy, and potentially fatal arrhythmias may occur and should be treated aggressively.

Telegram: @medical_k

www.konkur.in

Respiratory muscle weakness may develop later in the illness and is often the cause of death.

The interference in ribonucleic acid (RNA) processing resulting from expanded trinucleotide repeats accounts for the peripheral manifestations and the behavioral syndromes that appear predictably among patients with the disease. Cognitive impairment of variable severity occurs in patients with myotonic dystrophy. The pattern of cognitive impairment most commonly includes personality change, alterations of visuospatial and constructional abilities, and prefrontal or executive cognitive domains. The severity of cognitive impairment does not correlate with age or severity of muscle disease but correlates most closely with the length of the trinucleotide repeat expansion in the kinase gene. The cognitive impairment syndrome may remain stable over a prolonged period. Along with cognitive dysfunction, a range of personality traits from avoidant to obsessive-compulsive and passive-aggressive tendencies may be found.

Patients with myotonic dystrophy frequently complain of excessive daily sleepiness (hypersomnia), sleeping 12 or more hours per day. They may have hypnagogic hallucinations upon awakening and may resemble narcolepsy. As many as 39% of myotonic dystrophy patients have such symptoms, and there is a positive correlation between complaints of hypersomnia and functional disability due to muscular impairment. Central and obstructive sleep apnea with chronic hypercapnia may further complicate excessive daytime somnolence in myotonic dystrophy patients. The neurophysiologic basis of this complaint is somewhat similar to that found in narcolepsy, with reports of decreased hypocretin-1 in cerebrospinal fluid, suggestive of dysfunction of the hypothalamic hypocretin system. Therapy of hypersomnolence has generally relied on stimulants such as modafinil (Provigil) or methylphenidate. Many drugs have been used for myotonia, but large-scale randomized clinical trial data are lacking.

Dystrophinopathies

Different mutations in the dystrophin gene on the X chromosome produce Duchenne muscular dystrophy (DMD) and the milder Becker muscular dystrophy phenotype. Dystrophin is one component of a glycoprotein complex located in the sarcolemmal membrane of muscle fibers. In DMD, dystrophin is virtually absent, while in Becker dystrophy, there is a partial deficiency of dystrophin. Since dystrophin is X linked, males are predominantly affected, while female carriers are typically asymptomatic.

Telegram: @medical_k

www.konkur.in

DMD affects 1 of 3,500 live male births. Up to one-third of cases of DMD are sporadic.

Symptoms in DMD start with proximal muscle weakness and calf muscle hypertrophy developing at 3 to 4 years of age. Weakness is progressive and becomes more diffuse, with loss of ambulation by 12 years of age and death by the age of 20 due to respiratory failure. In Becker dystrophy, the clinical syndrome is less severe, with symptomatic weakness beginning between ages 5 and 15. Loss of ambulation typically occurs after 15 years of age, and death often occurs in the third or fourth decade. A mild form of Becker dystrophy may present in middle age with myalgias and exertional muscle cramping. Either disorder may be associated with symptomatic or asymptomatic cardiomyopathy.

Although usually considered an isolated muscle disease, a variety of cognitive and behavioral syndromes among patients with dystrophinopathies may be directly related to the neurobiology of the diseases. The dystrophin gene product is expressed in the brain as well as in muscle, although its CNS function is unknown.

A range of depressive and even psychotic syndromes has been reported. Approximately 30% of Duchenne patients have cognitive impairments by comparison with age-matched controls, but also by comparison with matched subjects with other spinal muscular disorders. Verbal function is more affected than visuospatial functions. Prior studies reported an average intelligence quotient (IQ) of 85 in Duchenne patients. The cognitive deficit is usually not progressive.

A glucocorticoid with anti-inflammatory and immunosuppressive properties, Deflazacort, is approved for the treatment of DMD in patients 5 years of age and older. Glucocorticoids can change the natural history of DMD, prolonging independent ambulation, preserving cardiac and pulmonary functioning in the teen years, and preventing severe scoliosis. However, side effects may include mood swings and difficult behavior. While anecdotal accounts suggest that these negative reactions may improve over time, they continue to remain one of the primary reasons for the discontinuation of therapy.

The impact of treatment with steroids on learning and memory is currently unclear. Acute steroid treatment for any condition has been shown to result in reversible impairment of long-term memory functions and retrieval of negative words, suggesting that emotional material is especially sensitive to the memory-modulating effects of steroids. Some research

Telegram: @medical_k

www.konkur.in

indicates that glucocorticoid-associated memory effects may be dose dependent.

Several medications have been approved that target increase in normal intracellular dystrophin levels in DMD patients with specific mutations amenable to exon skipping (exons are pieces of DNA that provide information for making proteins in a person's genome). The following medications are available: Eteplirsen for those with confirmed dystrophin mutations amenable to exon 51 skipping, Golodirsen for those with mutations amenable to exon 53 skipping, and Casimersen for those patients with a mutation amenable to exon 45 skipping. A clinical benefit of these medications, including improved motor function, has not been established. Nonetheless, consideration of the potential risks associated with these medications, the life-threatening and debilitating nature of DMD, and the lack of available therapy has opened new hope for what has been considered an incurable and untreatable disorder.

Inflammatory Myopathies

There are three major syndromes of inflammatory myopathies: polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM). All may be associated with autoimmune disorders such as SLE, and DM, in particular, may be associated with occult neoplasms, suggesting a paraneoplastic syndrome. Neuropsychiatric complications may occur secondary to the associated autoimmune disorder. The weakness in PM/DM is usually symmetric and proximal, whereas weakness in IBM may be asymmetric and distal, with prominent early involvement of quadriceps, finger and wrist flexors, and ankle dorsiflexors. The weakness is usually slowly progressive, serum creatine phosphokinase (CPK) level is elevated, and many patients are not diagnosed for years after onset. PM and DM are treated with steroids, immunosuppressant agents, and γ-globulin, with their attendant neuropsychiatric risks, whereas IBM responds less well to immunosuppression.

Inclusion Body Myositis. IBM is a disease of adults, most commonly over the age of 50 years. It affects men more than women. The nature of the inclusion bodies and the finding of β-amyloid in muscle fibers has led to theories that IBM may be a degenerative disorder of muscle (with homologies to Alzheimer disease) or possibly of viral origin. Rarely, IBM may be familial. Familial IBM is associated with Paget disease of bone, and frontotemporal dementia is associated with valosin-containing protein

Telegram: @medical_k

www.konkur.in

(VCP) gene mutations. Neuropsychiatric features of this syndrome may include behavioral variant FTD, primary progressive aphasia, and MND. Although no approved treatments are available, a study of Rapamycin showed promise on several secondary endpoints in a small clinical study.

Mitochondrial Myopathies

Muscle tissue, unlike peripheral nerves, is very energetically active. A number of myopathies, collectively called mitochondrial myopathies, can present with symptoms from childhood onward. Mitochondria are the "powerhouse of the cell" and contain their own DNA, which is uniquely transmitted by the mother (since sperm do not contribute mitochondria), so family histories show no male-to-male transmission. However, many mitochondrial proteins are of nuclear origin and show classic Mendelian inheritance, so not all mitochondrial myopathies are due to intrinsic mitochondrial gene mutations. Mitochondrial disorders affect bioenergetic processes with dysfunction in multiple body systems, resulting in effects such as developmental short stature, learning deficits, visual loss and blindness, eye movement abnormalities, deafness, cardiomyopathy and conduction defects, diabetes, liver and kidney problems, GI motility defects, and stroke-like symptoms.

Psychiatric features are found within the clinical spectrum of mitochondrial syndromes. Case reports have linked depression and obsessive-compulsive disorder to specific mitochondrial mutations. It is increasingly recognized that mitochondrial dysfunction may be associated with neuropsychiatric abnormalities such as dementia, major depression, and bipolar disorder. Furthermore, several lines of evidence suggest that there is mitochondrial dysfunction in schizophrenia, including documented alterations in brain energy metabolism, electron transport chain activity, and expression of genes involved in mitochondrial function. Treatments for mitochondrial disorders include coenzyme Q10 and the amino acid L-arginine. Patients with mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS) who also have muscle weakness have defective respiratory chain enzymes, resulting in a high $NADH/NAD^+$ ratio that inhibits the nitric oxide (NO) synthetase reaction to cause a decreased production of NO in vascular endothelium or arterial smooth muscle. Low plasma concentration of L-arginine, a potent donor of NO, has been observed in patients with MELAS, suggesting the possibility of L-arginine's therapeutic potential.

Telegram: @medical_k

www.konkur.in

Endocrine Myopathies

Endocrine myopathies include weakness due to hormonal imbalance in the pituitary, adrenal, thyroid, or parathyroid glands. Examples of this class of muscle disorders include steroid myopathy with weakness caused by either endogenous or exogenous glucocorticoid; psychiatric comorbidities of mood or thought disturbance are common. Adrenal insufficiency is associated with generalized weakness and fatigue. Treatment is aimed at normalizing hormonal levels or removal of toxic compounds as tolerated while working with the patient and medical team to optimize quality of life.

MISCELLANEOUS NEUROMUSCULAR DISORDERS

Stiff-Person Syndrome

Stiff-person syndrome is a rare disorder of the CNS, characterized as having progressive and fluctuating muscle rigidity with painful spasms. The spasms may occur at rest and may be triggered by sensory stimuli. The etiology of stiff-person syndrome is autoimmune and is often associated with type 1 diabetes and with dysfunction in the GABA inhibitory system. A majority of patients have autoantibodies to glutamic acid decarboxylase (GAD-65). Psychiatric symptoms in this disorder are prominent anxiety, probably mediated by changes in the GABAergic system.

Treatment is symptomatic, and high-dose benzodiazepine like diazepam, up to 100 mg/day or clonazepam, up to 6 mg/day, is usually the first-line treatment. Other GABA-mediating drugs such as baclofen, vigabatrin, tiagabine, and valproic acid (the latter up to 3,000 mg/day in divided doses) may also be helpful. Levetiracetam or pregabalin may be used if symptoms persist. Immunotherapies have included rituximab and tacrolimus. For patients with refractory disease, intrathecal baclofen, intravenous immunoglobulin (IVIG), or plasmapheresis may be administered.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is usually conceived of as a syndrome of fever, and catatonic rigidity, with increased serum CPK levels in the setting of neuroleptic administration or its rapid withdrawal. The etiology of this disorder is obscure, and the lack of consistent case definitions has hampered the fuller study of this syndrome. The initial description of NMS referred to it as pallor and hyperthermia and isolated

Telegram: @medical_k

www.konkur.in

primary symptoms of fever, akinesia or stupor with hypertonicity, and pulmonary congestion. Since then, a number of diagnostic criteria have been proposed. In essence, the syndromic definitions stress the presence of rigidity, fever, and autonomic changes in the presence of neuroleptic exposure. Alteration in sensorium is also a common feature of several of these criteria. Conditions with clinical similarity to NMS include serotonin syndrome (SS), malignant hyperthermia, drug toxicity (e.g., lithium), heat stroke and related syndromes, and malignant catatonia. Treatment of NMS involves immediately discontinuing the offending agent, aggressive supportive care to manage and prevent complications, and pharmacologic therapy. Bromocriptine mesylate, a dopamine agonist, and dantrolene sodium, a muscle relaxant, are most commonly used. If NMS is due to the rapid dopaminergic medication withdrawal, prompt and rapid medication reinstitution may improve symptoms.

Serotonin Syndrome

SS occurs due to excessive serotonergic activity in the CNS and PNS, usually in the context of initiation or dose increase of a serotonergic agent. Although this may occur with a single agent, it is usually the result of a combination of medications, supplements, illicit drugs with serotonergic activity (e.g., LSD), or proserotonergic foods. The symptoms fall under three broad categories—altered mental status, neuromuscular hyperactivity, and autonomic instability. Altered mental status may range from hyperactivity, anxiety, restlessness, mood elevation and excitement to lethargy, confusion, disorientation, hallucinations, and coma. Neuromuscular hyperactivity can manifest as myoclonus, hypertonicity, ocular clonus, hyperreflexia, and tremors. Autonomic instability may include diaphoresis, tachycardia, hypertension, and in moderate or severe cases, hyperthermia. In severe cases, symptoms can progress to generalized tonic–clonic seizures, multiorgan failure, and coma. Although clinical criteria such as Sternbach criteria and Hunter Serotonin Toxicity Criteria exist, there is not much concordance among these criteria. A heightened awareness of signs and symptoms, obtaining a detailed medication history, and conducting a careful physical examination are crucial for diagnostic discrimination of SS and other similar syndromes such as NMS, malignant hyperthermia, and anticholinergic toxicity. Treatment of SS involves cessation of the offending agent, supportive therapy, and use of the serotonin antagonist cyproheptadine. Given the widespread use of serotonergic antidepressants and the large number of substances that

Telegram: @medical_k

www.konkur.in

have been implicated in SS, it is of paramount importance that clinicians thoroughly evaluate the indication for adding a serotonergic agent to a medication regimen that might already contain serotonergic agent(s) and monitor closely for signs and symptoms of SS in those who are at increased risk.

Fibromyalgia

Fibromyalgia is a syndrome characterized by chronic widespread pain localized in various muscle groups, accompanied by fatigue, sleep disturbances, mood changes, and cognitive deficits. It is thought of as a centralized pain state in that it involves the central amplification of peripheral nociceptive stimuli. It is more common in females in their 30s to 50s. The provisional diagnostic criteria for fibromyalgia published by the American College of Rheumatology in 2010 are shown in Table 2.12–3.

Table 2.12–3. 2010 Fibromyalgia Diagnostic Criteria

Criteria

A patient satisfies diagnostic criteria for fibromyalgia if the following 3 conditions are met:

1. Widespread pain index (WPI) ≥7 and symptom severity (SS) scale score ≥5 or WPI 3–6 and SS scale score ≥9.
2. Symptoms have been present at a similar level for at least 3 months.
3. The patient does not have a disorder that would otherwise explain the pain.

Ascertainment

1) WPI: note the number of areas in which the patient has had pain over the last week. In how many areas has the patient had pain? Score will be between 0 and 19.

Shoulder girdle, left	Hip (buttock, trochanter), left	Jaw, left	Upper back
Shoulder girdle, right	Hip (buttock, trochanter), right	Jaw, right	Lower back
Upper arm, left	Upper leg, left	Chest	Neck
Upper arm, right	Upper leg, right	Abdomen	
Lower arm, left	Lower leg, left		
Lower arm, right	Lower leg, right		

2) SS scale score:
   Fatigue
   Waking unrefreshed
   Cognitive symptoms

   For each of the 3 symptoms above, indicate the level of severity over the past week using the following scale:

   0 = no problem
   1 = slight or mild problems, generally mild or intermittent
   2 = moderate, considerable problems, often present and/or at a moderate level
   3 = severe: pervasive, continuous, life-disturbing problems

   Considering somatic symptoms in general, indicate whether the patient has[a]:

   0 = no symptoms
   1 = few symptoms
   2 = a moderate number of symptoms
   3 = a great deal of symptoms

The SS scale score is the sum of the severity of the 3 symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent (severity) of somatic symptoms in general. The final score is between 0 and 12.

[a]Somatic symptoms that might be considered: muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, headache, pain/cramps in the abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

There is significant overlap and comorbidity between symptoms of fibromyalgia and psychiatric disorders such as depression and anxiety. The

Telegram: @medical_k

www.konkur.in

shared putative mechanisms underlying depression, anxiety, and pain, namely dysregulation of serotonergic, noradrenergic, and dopaminergic neurotransmitter systems, may explain the co-occurrence of these disorders. This has important treatment implications—antidepressants that modulate the serotonin and norepinephrine neurotransmitter systems have been found to be effective in treating symptoms of fibromyalgia; furthermore, the secondary psychiatric syndromes can provide therapeutic targets for psychopharmacology. There is also significant comorbidity between patients with fibromyalgia and rheumatologic disorders, such as rheumatoid arthritis, systemic lupus, and others.

There is a significant disability associated with fibromyalgia, with 35% of patients receiving Social Security disability income in one study. Although treatment with multiple modalities may lead to improvements in symptoms and quality of life, their impact on functional recovery is limited. Duloxetine, milnacipran, and pregabalin have been approved by the U.S. FDA for the treatment of fibromyalgia. Duloxetine and milnacipran are both SNRIs that mediate the antinociceptive effect through modulation of serotonin and norepinephrine in the synaptic cleft, whereas pregabalin modulates neuronal calcium influx by binding to α_2-δ subunits of voltage-gated calcium channels. Duloxetine is also approved for other psychiatric and pain conditions, while milnacipran is only approved for the treatment of symptoms in fibromyalgia. Other pharmacologic agents that have been shown to improve symptoms include tricyclic compounds such as amitriptyline and nortriptyline, cyclobenzaprine, and selective serotonin reuptake inhibitors. The choice of medication should be based on targeting predominant symptoms and side-effect profiles. Nonpharmacologic treatment plans include graded exercise regimens, rehabilitation programs, cognitive behavioral therapy, and patient education.

Myalgic Encephalomyelitis/Chronic Fatigue Syndrome

Myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS) is a multisystem disorder of unknown etiology. A more recent term used for this condition is systemic exertional intolerance disease (SEID). This complicated entity has an unclear relationship to other disorders such as fibromyalgia or myofascial pain syndrome. It is estimated to affect about 2 million people in the United States.

ME/CFS is characterized by extreme fatigue lasting more than 6 months, without a clear explanation as due to another underlying medical condition.

Telegram: @medical_k

www.konkur.in

The fatigue worsens with mental or physical exertion and is not improved with rest. Besides unrefreshing sleep, there is prominent difficulty with memory, attention and concentration, and dizziness that worsens with moving from lying down or sitting to standing. Other physical examination findings may include sore throat, headaches, enlarged regional lymph nodes, and muscle or joint pain.

Despite extensive investigations, the etiology of ME/CFS is unknown. It may occur at any age, but most often in young to middle-aged adults. There is a gender disparity with ME/CFS diagnosed much more often in women than men, but this may be confounded by ascertainment bias.

Possibilities etiologies include infections such as Epstein–Barr virus, Human Herpes virus 6, undiagnosed HIV infection, COVID-19, Lyme disease, autoimmunity or immune system imbalance, hormonal imbalance, neoplasms or paraneoplastic processes, functional and psychological stress, or some combination thereof. Physical or emotional trauma has been implicated in some, but not all cases, in temporal proximity to syndrome onset. Genetic susceptibility is also suspected in some cases. Diagnostic testing can rule out some disorders, but there is no single confirmatory test. Treatment for ME/CFS focuses on improving symptoms. There are multiple published diagnostic criteria, and many criteria have been used to assess “recovery,” leading to more confusion for both healthcare providers and patients.

Treatment with cognitive behavioral therapy and graded exercise therapy have been the most widely used treatment modalities and provided some patient responses, although many patients do not achieve sustained benefit. The medical literature abounds with small studies of limited duration, leading to inconclusive results in diagnosis, treatment, and recovery.

ME/CFS is a debilitating disorder, and as the name suggests, it is a chronic disorder frequently lasting many years. There are frequent lifestyle restrictions due to fatigue and inability to work, resulting in the need for disability assistance. Social isolation and depression are common. Severe cases can lead to being bedbound with severe neurologic deficits. It is important to understand that despite the lack of a defined cause, suggesting that symptoms are of psychological origin (“it’s all in your head”) is fraught with complications. This simplistic formulation could be simply wrong, and patients often feel rejected by the medical system where they are seeking a diagnosis, explanation of symptoms, and treatment. Patients seeking “alternative” medical solutions such as holistic healing,

Telegram: @medical_k

www.konkur.in

homeopathic remedies, acupuncture, invasive treatment, multiple supplements, unproven therapies, medical marijuana, etc., are frequent and may help some obtain temporary relief but add a layer of complexity to an already complicated medical and psychosocial picture.

FUTURE DIRECTIONS

Advances in the understanding of the molecular and structural basis of many neuromuscular diseases and their relationship to neuropsychiatric symptoms have ushered in a new era in psychiatry. The natural history and prognosis of these disorders are generally well understood. Even in less well-understood conditions such as fibromyalgia, the focus should be on using available clinical evidence and building excellent physician–patient relationships, a key factor in providing improved neuropsychiatric outcomes. Further advances and insights into the integrated neurobiology of these disorders raise hope that psychiatrists will find themselves intimately involved in all phases of care targeting these challenging disorders.

2.13 Psychiatric Aspects of Child Neurology

JEFFREY E. MAX, M.D., M.B.B.CH., SARAH MATTSON, PH.D., YVONNE E. VAUCHER, M.D., M.P.H.J., SHARON NICHOLS, PH.D., AND MARK P. NESPECA, M.D.

The topic "Psychiatric Aspects of Childhood Neurology" is large, and for justice to be done, a textbook is required. However, the approach taken in this chapter was to succinctly provide an updated review of five common and important pediatric neurologic conditions rather than review a much higher number of related topics in a cursory fashion. The topics (primary authors) chosen for this chapter are (1) Fetal Alcohol Spectrum Disorders (Sarah N. Mattson, Ph.D.); (2) Premature Birth and Low Birth Weight (Yvonne E. Vaucher, M.D.); (3) Human Immunodeficiency Virus (Sharon Nichols, Ph.D.); (4) Epilepsy (Mark P. Nespeca, M.D.); (5) Traumatic Brain Injury (Jeffrey E. Max, MBBCh). The focus of the chapter is on psychopathological sequelae, although mention will be made of associated problems in other domains of function.

FETAL ALCOHOL SPECTRUM DISORDERS

Children born to women who consume alcohol during pregnancy are at risk for physical, behavioral, and cognitive changes that can affect everyday function. These functional effects are collectively termed fetal alcohol spectrum disorders (FASD). The United States prevalence of FASD is between 1.1% and 5.0%, though estimates vary based on sampling techniques and study population. Criteria for diagnosis were first set forth by Jones and Smith in 1973 and have been updated by the Institute of Medicine and Hoyme. While multiple methods exist for clinical diagnosis, those set forth by Hoyme et al. will be described here. FASD includes five subdiagnoses: fetal alcohol syndrome (FAS), partial fetal alcohol syndrome (PFAS) with or without documented prenatal alcohol exposure, alcohol-related neurodevelopmental disorder (ARND), alcohol-

Telegram: @medical_k

www.konkur.in

related birth defects (ARBD), and neurobehavioral disorder associated with prenatal alcohol exposure (ND-PAE). ARBD is primarily a physical diagnosis and will not be described here.

www.konkur.in

Table 2.13–1.
Summary of Diagnostic Features That Comprise Fetal Alcohol Spectrum Disorders (FASD)

Telegram: @medical_k

www.konkur.in

Domain	Feature	Requirement	Additional Detail
Prenatal alcohol exposure		Indication of documented prenatal alcohol exposure as evidenced by maternal report or a reliable collateral report	Can include drinking levels reported by the mother 3 months before pregnancy recognition
Face	Characteristic pattern of minor facial anomalies	Requires two or more facial features:	
	Palpebral fissures	≤10th centile	
	Thin vermilion border	Rank 4 or 5 on a racially normed lip/philtrum guide	
	Smooth philtrum	Rank 4 or 5 on a racially normed lip/philtrum guide	
Growth	Pre- or postnatal growth deficiency	Requires one or more indicators:	
	Height or weight	≤10th centile	
Brain	Deficient brain growth, abnormal morphogenesis, or neurophysiology	Requires one or more indicators: Head circumference ≤10th centile Structural brain abnormalities	

Telegram: @medical_k

www.konkur.in

		Recurrent nonfebrile seizures	
Neurobehavioral impairment	Cognitive or behavioral impairment	Requires either cognitive or behavioral impairment	
	Cognitive impairment	Global impairment OR	GCA or IQ estimate ≥1.5 SD below mean
		One or more neurobehavioral domain ≥1.5 SD below mean	Executive functioning, specific learning impairment, memory impairment, or visual–spatial impairment
	Behavioral impairment (without cognitive impairment)	One or more behavioral domain ≥1.5 SD below mean	Self-regulation: mood or behavioral regulation impairment, attention deficit, or impulse control

GCA, general cognitive ability; IQ, intelligence quotient.

Diagnostic Criteria

The diagnoses under the umbrella of FASD share five critical domains. These are documentation of prenatal alcohol exposure, a characteristic pattern of facial anomalies, growth deficiency, deficient brain growth or

Telegram: @medical_k

www.konkur.in

abnormal morphogenesis, and neurobehavioral impairment. These domains are defined in Table 2.13–1. The diagnoses each require a different configuration of these domains, as indicated in Table 2.13–2. At the severe end of the spectrum, heavy prenatal alcohol exposure can cause characteristic facial features, resulting in a diagnosis of FAS. A diagnosis of FAS requires four diagnostic domains. Because of the specificity of this combination, documentation of confirmed prenatal alcohol exposure is not required. A diagnosis of partial FAS (PFAS) can be made with or without documentation of prenatal alcohol exposure. When alcohol exposure is confirmed, facial anomalies and neurobehavioral impairment are required. When alcohol exposure is not confirmed, impairment in either growth or brain growth is additionally required. A diagnosis of ARND is made in the absence of physical indicators (face and growth) and requires confirmed prenatal alcohol exposure and neurobehavioral impairment. Thus, ARND is intended to capture the broader population of children affected by prenatal alcohol exposure.

Table 2.13–2.
Summary of Criteria for Disorders Included in FASD

Diagnosis	Confirmed Prenatal Exposure to Alcohol	Facial Anomalies	Growth Deficiency	CNS Abnormalities	Neurobehavioral Impairment
Fetal alcohol syndrome (FAS)[a]	Not required	Required	Required	Required	Required
Partial FAS with documented exposure[a]	Required	Required	Not required	Not required	Required
Partial FAS without documented exposure[a]	Not required	Required	One or more required		Required
Alcohol-related neurodevelopmental disorder (ARND)[a]	Required	Not required	Not required	Not required	Required
Neurobehavioral disorder associated with prenatal alcohol exposure (ND-PAE)[b]	Required	Not required	Not required	Not required	Required

[a]Hoyme et al., 2016.
[b]Diagnostic and Statistical Manual (American Psychiatric Association, 2013).

ND-PAE has been proposed as an addition to those specified by Hoyme et al. The most recent revision of the Diagnostic and Statistical Manual (DSM-5) includes ND-PAE in the appendix under Conditions for Further Study. This proposed diagnosis reflects the importance of the neurobehavioral difficulties caused by prenatal alcohol exposure and addresses the critical need to better identify children affected by prenatal alcohol exposure. The proposed criteria for ND-PAE are listed in Table 2.13–3. ND-PAE fills a diagnostic gap by providing specific criteria

Telegram: @medical_k

www.konkur.in

for the neurobehavioral and cognitive effects seen in children affected by prenatal alcohol exposure. The specification of these criteria enables a clinical diagnosis for these children, which can improve identification, aid in treatment planning, as well as provide an etiologic context for behavioral concerns. Importantly the diagnosis of ND-PAE is independent of the diagnosis of FAS (i.e., it can occur in exposed children with or without the FAS).

Table 2.13–3.
Criteria for Neurobehavioral Disorder Associated with Prenatal Alcohol Exposure (ND-PAE)

Criterion	Requirement
Prenatal Alcohol Exposure	More than minimal prenatal alcohol exposure required
Neurocognitive impairment	**One or More Required** Impairment in global intellectual functioning Impairment in executive functioning Impairment in learning Impairment in memory Impairment in visual–spatial reasoning
Self-Regulation Impairment	**One or More Required** Impairment in mood or behavioral regulation Impaired attention Impairment in impulse control
Adaptive Functioning	**Two or More Required**[a] Impairment in communication Impairment in social interactions and communication Impairment in daily living skills Impairment in motor skills
Developmental Timing	Onset of symptoms in childhood required

[a]Two or more adaptive function difficulties required for diagnosis, but see also Kable and Coles, 2018.

Behavioral Findings

Telegram: @medical_k

www.konkur.in

Disordered behavior is characteristic of FASD and may represent the most clinically relevant deficit. Parent reports of behavioral disturbance are pervasive and severe. Many studies indicate the presence of behavioral problems in children with FASD, including issues with impulsivity, rule-breaking, anxiety, and social interactions, which persist even when compared to IQ-matched controls. Adaptive behavior deficits have also been noted across all domains of adaptive function: communication, socialization, and daily living skills. In particular, deficits in socialization and communication appear to worsen with age. As a result, behavioral problems in childhood may translate into difficulties in adulthood, including legal problems, substance abuse, psychiatric disorders, and elevated suicide risk.

Cognitive Findings

The cognitive effects of prenatal alcohol exposure are well documented. Deficits occur in multiple domains, including general intellectual function, verbal learning, executive function, language, visual–spatial, attention, and academic function. Children with FASD have a broad range of IQ scores, ranging from severely intellectually deficient to average, although the majority of children do not have IQ scores below 70. The average IQ score for children with FAS is around 72, while that for children with heavy prenatal alcohol exposure without FAS is somewhat higher at around 80, although there is considerable variability in both groups.

In addition to overall intellectual performance, children with FASD also display a broad array of neuropsychological and cognitive deficits. Verbal learning and memory are consistently impaired in this population, with deficits occurring predominantly in encoding with relatively intact retention. Repeated exposure and implicit strategy aid in improving performance on learning and memory tasks. Attention is a hallmark deficit of FASD. Children in this population typically display deficits in vigilance, reaction time, and information processing across multiple tasks, although visual attention may be more impacted than auditory. Deficits in attention are supported by both laboratory measures (e.g., continuous performance testing) and parent reports. Other aspects of executive function are also impacted in children with FASD. This domain has been particularly well-studied, and deficits occur in planning, working memory, response inhibition, set-shifting, concept formation, and verbal and nonverbal

Telegram: @medical_k

www.konkur.in

fluency. Deficits in executive function appear especially useful in the identification of alcohol-affected children.

Academic achievement is one domain that requires further study. Increased school failure has been documented, and limited research indicates deficits in reading, spelling, and mathematic achievement. Two studies support deficits across these three domains and provide additional details on underlying mechanisms. Results indicated that deficits in reading and spelling may relate to working memory deficits, and deficits in mathematics may relate to spatial processing deficits.

Comorbidity

Children with FASD are often diagnosed with psychiatric disorders and have elevated rates of concurrent psychiatric disorders, especially in younger children and boys. Across multiple studies, the most common psychiatric diagnosis made in children with FASD is attention-deficit/hyperactivity disorder (ADHD); the prevalence of ADHD in this population ranges from 44% to 96%. Other than ADHD, the most common conditions are oppositional defiant disorder (ODD), conduct disorder, depressive and anxiety disorders.

Because ADHD is so common in children with FASD, several studies have compared children with FASD to children with idiopathic ADHD (i.e., without FASD or prenatal alcohol exposure). These studies have examined adaptive behavior, psychopathology, and neuropsychological functioning (e.g., executive function, verbal learning and memory, and attention). Although some similarities between FASD and ADHD have been noted, e.g., performance on the Wisconsin Card Sorting Test and parent reports of attention, more studies show differences between these clinical groups. For example, group differences have been noted in overall IQ, verbal fluency, trail making, verbal encoding, attention, and adaptive behavior; generally, children with FASD perform worse than children with idiopathic ADHD. On measures of attention, children with FASD show deficits in shifting between attentional sets or types of stimuli and encoding information, while those with ADHD have more difficulty focusing and sustaining attention, although differences between groups may also relate to the timing of stimuli and regulation of activation. On parent reports of adaptive function, children with FASD, but not idiopathic ADHD, show arrested development of socialization and communication skills, failing to improve with age. In one study, even though IQ and

Telegram: @medical_k

www.konkur.in

adaptive function profiles were similar, children with FASD and ADHD had worse cognitive functioning than those with idiopathic ADHD. Thus, overall, it appears that the cognitive-behavioral profiles of FASD show more impairment than what is seen in ADHD.

Another important question is whether the presence of ADHD in many children with FASD affects behavioral or neuropsychological outcomes. That is, do children with FASD and ADHD have greater impairment than either condition alone. Three studies compared children with FASD with and without ADHD, children with idiopathic ADHD, and children with neither ADHD nor prenatal alcohol exposure. Both studies used a 2 (exposure: yes/no) × 2 (ADHD: yes/no) factorial design. In the first study, parent reports of psychopathology and problem behaviors were compared. Results suggested that the presence of ADHD in children with FASD elevated rates of conduct disorder and externalizing behaviors. A second study of adaptive behavior, using the same design, indicated that children with both ADHD and FASD had the greatest impairment in the communication domain of adaptive behavior, while the effects in socialization and daily living skills suggested independent effects of both ADHD and FASD. In contrast, the third study of this type examined a broad neuropsychological test battery and did not support an additive or synergistic effect of FASD and ADHD on neuropsychological functioning. Instead, neuropsychological performance was similar in the alcohol-exposed groups, regardless of ADHD diagnosis. An additional study documented similar results with children with FASD or FASD and ADHD demonstrating greater cognitive deficits than children with ADHD alone.

Summary

Research conducted over nearly 50 years has demonstrated that alcohol is a potent physical and behavioral teratogen. While some children will not be affected by the physical manifestations of this exposure, all children with histories of prenatal alcohol exposure are at risk for cognitive and behavioral impairment at great personal and societal cost. Debate continues over whether any safe amounts or periods of alcohol exposure exist, while empirical data clearly show that the effects of this exposure can be devastating. Additional research is needed on long-term outcomes for individuals with FASD. Limited research suggests continued negative outcomes, while some anecdotal reports suggest that more positive outcomes are possible.

www.konkur.in

PREMATURE BIRTH AND LOW BIRTH WEIGHT

Ten percent (383,061) of U.S. children in 2019 were born prematurely between 23 and 37 weeks gestation, of whom 52,330 (1.38%) were very low–birth-weight (VLBW), weighing less than 1,500 g at birth, and 24,758 (0.66%) were extremely premature (EP), born before 28 weeks gestation (Table 2.13–4).

More than 90% of these premature newborns, including the majority of EP children born at 24 weeks gestation, now survive as the result of remarkable medical advances in neonatal care over the past 30 years. However, those born prematurely are at increased risk for adverse neurologic, cognitive, neurosensory, behavioral, and psychiatric outcomes (Table 2.13–5). The risk is multifactorial, influenced by numerous antenatal, intrapartum, and postnatal factors. Major independent determinants of short-term adverse outcomes include gestational age, birth weight, gender, intrauterine growth restriction, severity and type of neonatal illness, and neonatal brain injury. Barring significant brain injury, socioeconomic factors and maternal education become the most important predictors of long-term neurodevelopmental outcomes.

Despite significant advances in medical care and dramatically improved survival over the past 60 years, the incidence of adverse neurologic, cognitive, behavioral, and psychiatric outcomes, with the possible exception of decreased clinically significant cerebral palsy in the most immature, has remained essentially unchanged, raising the question of whether being born preterm independently influences normal brain development. Preterm infants are born into a dramatically different vestibular, motor, and neurosensory extra-uterine environment. The extent to which this alters subsequent brain development is unknown. In addition, all premature organ systems are physiologically immature and vulnerable to injury after birth. The resulting medical problems, such as chronic lung disease, patent ductus arteriosus, sepsis, necrotizing enterocolitis, intracranial hemorrhage, white matter injury (WMI), and retinopathy of prematurity, are each associated with adverse neurodevelopmental outcomes. At the time of their child's preterm birth, parents are primarily concerned about survival and the risk of severe motor or cognitive impairment. The latter is apparent within the first 24 months after birth. However, the more frequent behavioral, emotional,

Telegram: @medical_k

www.konkur.in

psychiatric, and educational problems are usually not evident until later in childhood.

Table 2.13–4.
Common Nomenclature for Preterm Infants

Weight	
Low–birth-weight (LBW)	<2,500 g
Very low–birth-weight (VLBW)	<1,500 g
Extremely low–birth-weight (ELBW)	<1,000 g
Gestational age	
Late preterm	34 $^{0/7}$ to 36 $^{6/7}$ weeks
Moderate preterm	32 $^{0/7}$ to 33 $^{6/7}$ weeks
Very preterm (VP)	28 $^{0/7}$ to 31 $^{6/7}$ weeks
Extremely preterm (EP)	<28 $^{0/7}$ weeks

Table 2.13–5.
Adverse Neurodevelopmental and Psychiatric Outcomes of VLBW Children

Cerebral palsy
Developmental coordination disorder
Minor neurologic dysfunction

Brain Development

Preterm infants are born from the end of the 2nd through the 3rd trimester when the brain is undergoing very rapid growth and organization. Between 25 weeks and term, the cerebral cortical volume increases fourfold. At 35 weeks gestation, the brain is one-third smaller than it will be at term. Neurons proliferate primarily in the 1st trimester and migrate radially outward from their origin in the subependymal germinal matrix beneath the floor of the lateral ventricles to the cerebral cortex during the 2nd trimester. A smaller wave of neuronal proliferation and migration occurs from 20 to 27 weeks gestation, overlapping the time when the most immature preterm infants are critically ill and receive medical care in neonatal intensive care units. The 3rd trimester is characterized by active neuronal organization and exponentially increasing synaptic connectivity, which is dependent upon complex interrelationships between structural relationships, functional activity, sensory input, growth factors, hormonal and neurotransmitter activity. This is also a critical period, between 24 and 32 weeks gestation when transient subplate neurons are in place just beneath the cerebral cortex, waiting to connect with and guide late ascending neurons from the thalamus and commissural axons to the cortex. By 36 weeks gestation, these thalamocortical axons, callosal, and corticocortical association afferents have reached their ultimate destination in the cortex.

Neuronal survival and function are dependent upon the glia, the most common cell type in the brain. Glia determine and maintain the structural and functional integrity of the neurons, mediate the inflammatory response, and facilitate neuronal communication. Specifically, astrocytes transfer nutrients from capillaries to neurons, modulate the strength of synaptic transmission, and participate in synaptic repair; oligodendrocytes are responsible for axonal myelination, and microglia mediate the inflammatory response. Glia creates the topographic boundaries and maintains the structure of the white matter projection, commissural, and association axon tracts. Immature, preoligodendrocytes predominate from 23 to 32 weeks gestation and are extremely vulnerable to inflammatory, excitotoxic, and free radical injury due to hypoxemia, ischemia, hemorrhage, cytokines, and the toxic by-products of neuronal injury, all of which may result in acute glial cell injury or death as well as later apoptosis, delayed or abnormal maturation, and impaired function. Lack of glial support and hypomyelination results in neuronal injury, loss, and

Telegram: @medical_k

www.konkur.in

dysfunction. A reciprocal relationship between neuronal and glial injury has been proposed by Volpe, whereby injury to the glia leads secondarily to injury to the neuron and vice versa. He proposes that this "encephalopathy of prematurity," a combination of primary destructive disease and secondary trophic and maturational disturbances, is responsible for the adverse neurodevelopmental outcome.

The cerebellum also undergoes very active development between 24 to 40 weeks gestation, increasing fivefold in volume and 30-fold in surface area, with peak cerebellar growth, differentiation, and neuronal migration occurring from 30 to 40 weeks gestation. Hemorrhagic injury, arising in the cerebellar germinal matrix, is more often unilateral and asymmetric, whereas ischemic infarction is more likely to be bilateral. The sequence of events is similar to that of cerebral injury-acute destruction, resulting in focal or diffuse volume loss with impaired neuronal development and hypomyelination. Trophic interaction (crossed diaschisis) between the contralateral cerebellar and cerebral hemispheres is such that injury to one is associated with decreased volume in the other, which may explain why cerebellar injury is associated with a wide range of cognitive, language, and motor deficits.

Preterm Brain Injury

Intracranial or intraventricular hemorrhage (IVH) currently occurs in approximately 25% of all VLBW infants. The widespread use of antenatal steroids to accelerate lung maturity has had the additional benefit of reducing the incidence of intracranial hemorrhage by half. Hemorrhage occurs within the first few days after birth, originating from the fragile capillaries in the subependymal germinal matrix just under the floor of the lateral ventricles at the caudo-thalamic groove. IVH is most often unilateral and, when bilateral, usually asymmetric in size. The mildest form (Grade 1 IVH) is contained within the subependymal germinal matrix (Fig. 2.13–1). The hemorrhage may rupture through the floor into the lateral ventricle (Grade 2 IVH) and may become large enough to distend the lateral ventricles with blood (Grade 3 IVH). The most severe form of IVH occurs when a large subependymal hemorrhage occludes the terminal vein draining the adjacent periventricular white matter resulting in intraparenchymal venous infarction (Grade 4 IVH, intraparenchymal hemorrhage [IPH] or periventricular hemorrhagic infarction [PVHI]). The associated white matter destruction may evolve into many small cysts, a

Telegram: @medical_k

www.konkur.in

large porencephalic cyst, or into an irregular outpouching of the ventricle into the adjacent area of white matter volume loss (Fig. 2.13–2). Blood within the ventricular system, especially with Grade 3 IVH, may result in posthemorrhagic hydrocephalus.

The majority (~85%) of hemorrhages are in Grades 1 or 2. Approximately 10% are Grade 3, and 5% are Grade 4 IVH/IPH. As expected, severe IVH/IPH (Grades 3 and 4) occurs most frequently in the smallest and most immature infants, affecting about 20% of those born at 23 to 24 weeks gestation. Fortunately, Grades 1 to 2 IVH are not associated with an increased risk of motor impairment. For infants with Grades 3 and 4 IVH/IPH, however, the risk of cerebral palsy is much higher–35% and 80%, respectively. Neurologic sequelae of IVH are primarily due to associated white matter damage, although free iron may also contribute to cellular injury. Almost all hemorrhages, except the most massive, are clinically silent, being recognized only by cranial imaging. Except for those in the posterior fossa, intracranial hemorrhages are easily visualized by cranial ultrasound. It was not until the advent of MRI that the incidence of cerebellar hemorrhage, occurring in up to 15% of VLBW infants, was appreciated.

FIGURE 2.13–1. Types of intraventricular hemorrhage (IVH). **A:** Grade 1 IVH **(left)**, Grade 2 IVH **(right)**. **B:** Grade 3 IVH **(right and left)**; Grade 4 IVH-Periventricular Intraparenchymal infarction **(left).**

FIGURE 2.13–3. White matter injury (WMI)/periventricular leukomalacia (PVL) Coronal sections. **A:** Acute, focal, bilateral, white matter infarction (WMI); plus bilateral Grade 3 IVH. **B:** Subacute, focal, bilateral white matter loss with cystic degeneration. **C:** Chronic, diffuse, bilateral white matter loss with marked ventricular dilatation and brain atrophy.

Periventricular leukomalacia (PVL) or WMI occurs in the white matter without associated hemorrhage and is symmetric, bilateral, and clinically silent. Watershed areas with a decreased arterial blood supply in the region of the internal capsule near the angles of the lateral ventricles are especially vulnerable to ischemic injury. Acute ischemia results in focal necrosis and the formation of transient cysts; moderate ischemia results in more gradual injury due to maldevelopment and diffuse apoptosis with varying degrees of progressive brain atrophy due to glial and axonal loss associated with low pressure, ventricular dilatation into the areas of volume loss (Fig. 2.13–3). Macroscopic cyst degeneration, visible on

Telegram: @medical_k

www.konkur.in

cranial ultrasound, occurs in 5% of VLBW infants. However, microscopic cystic degeneration is much more common, affecting about 50% of VLBW infants. In one study, over 70% of infants born at ≤30 weeks gestation had abnormalities in the white matter detected by MRI at term equivalent gestation. Whereas focal necrosis with loss of all cellular elements is more likely to result in spastic cerebral palsy due to the destruction of the motor tracts crossing through the area of acute injury, diffuse white matter loss is associated with more generalized cognitive and behavioral deficits. Signs of white matter and associated axonal loss include thinning of the corpus callosum, delayed myelination, immature gyral development, enlarged subarachnoid space, and volume loss in the cortical and deep grey matter, peristriatal regions, and the temporal lobes.

A unifying, common path for brain injury may be antenatal, intrapartum, or postnatal hypoxia, ischemia, or inflammation, which in turn results in brain, especially white matter, injury in the physiologically vulnerable, preterm group. Subsequent adverse neurodevelopmental outcomes, including cerebral palsy, epilepsy, and cognitive impairment, are all thought to relate primarily to the adverse effects of WMI on both glial and neuronal structure, maturation, and function.

Role of Brain Imaging

Detection of neonatal brain injury after preterm birth relies on neonatal cranial ultrasound and MRI imaging. Although both modalities comparably identify severe cerebral brain injury, neonatal MRI also detects cerebellar abnormalities as well as more subtle signs of brain injury. Neonatal imaging abnormalities, including moderate to severe intracranial hemorrhage, PVL, and ventriculomegaly, are highly predictive of cognitive, motor, and behavioral outcomes at 2 years of age in very preterm (VP) children. By 10 years of age, however, moderate-severe neonatal brain injury predicts only poorer cognitive outcome. There are no specific neonatal anatomical markers for later behavioral, socio-emotional, and psychiatric problems. Despite advances in neonatal neuroimaging, it is not possible to accurately predict the long-term neurodevelopmental outcome for an individual child.

In later childhood, structural and functional MRI studies demonstrate substantial differences in regional brain volumes and neural connectivity, including the smaller hippocampal, thalamic, caudate, corpus callosum, and cerebellar volumes, as well as thinner cortices in infants, children,

Telegram: @medical_k

www.konkur.in

and adolescents born preterm. Disorganization of tracts in the internal capsule and posterior corpus callosum reflects widespread alterations in neural connectivity. Functional MRI DTI studies demonstrate that preterm children utilize novel neural pathways to complete tasks suggesting the development of alternative networks to compensate for abnormal brain development or injury.

Neurodevelopmental Outcome

The risk of adverse neurodevelopmental outcome increases progressively with increasing prematurity, with the lowest risk for those born nearest term at 36 weeks gestation and the highest risk for those born at the margins of viability at 22 to 23 weeks gestation. Thus far, overall individual outcomes during infancy and childhood appear to be longitudinally stable.

The best outcome studies are prospective and comprise large, population or geographically based cohorts followed longitudinally from infancy through adulthood. Comparison of outcomes with normal birth-weight (NBW), term-born, control children is critical. Most such studies have been performed in high-resource countries where children can be tracked easily within a national healthcare system over long periods of time (e.g., Australia, Canada, Scandinavia, and Great Britain). However, reports from single centers, cross-sectional and smaller samples are remarkably congruent with the results from larger, longitudinally followed cohorts.

The majority of neurodevelopmental outcome studies have focused on the highest risk preterm infants-either VLBW (<1,500 g), ELBW (<1,000 g), VP (<32 weeks gestation), or EP (<28 weeks gestation) in very early childhood at 2 years of age. Approximately one-third of EP children born at 25 weeks gestation demonstrate moderate-severe neurodevelopmental impairment at this time. Multinational outcome studies for EP children in midchildhood, now becoming available, report similar rates of impairment. Recently more attention has been paid to the neurodevelopmental outcomes of larger, more mature, moderate, and late preterm children born at 32 to 36 weeks gestation whose risk of adverse cognitive and behavioral outcomes, while substantially lower than that of more immature preterm infants, is significantly higher than that of term infants. Due to their much greater numbers representing over three-quarters of all preterm newborns, moderate to late preterm children contribute

Telegram: @medical_k

www.konkur.in

disproportionately to the burden of adverse neurodevelopmental outcomes associated with preterm birth.

A myriad of demographic, antenatal, intrapartum, and postnatal variables have been associated with adverse neurodevelopmental and psychiatric outcomes. Many of these factors, such as SES, parental stress, maternal depression, and infection, are also associated with an increased risk of preterm birth. Epigenetic markers of prenatal and postnatal environmental exposures also likely influence brain development and neurodevelopmental outcome. Whether there will be substantive differences in long-term outcomes based on birth before and after the currently widespread use of antenatal steroids, intrapartum neurologic protection, and postnatal surfactant beginning in the early 1990s remains to be seen. Whereas studies of childhood and adolescent outcomes reflect current obstetrical and neonatal practice, most adult outcome studies are derived from the earlier time period. Of note, although antenatal steroids decrease the risk of severe illness in preterm newborns, a recent population-based study in Scandinavia found that whereas antenatal steroids decreased the risk of intellectual disability, the risk of mental and behavioral disorders in preterm children was increased.

Despite the physical, emotional, behavioral, and cognitive adversities facing many children and adults born prematurely, the majority self-report a satisfactory quality of life. Often self-perception is more positive than parent or teacher reports, particularly with regard to ADHD and depression. Whether this is a lack of self-awareness or reflects resilient coping mechanisms is not clear. The majority of preterm adults are able to compensate for their difficulties and go on to lead full, productive lives.

Cognitive Outcomes

Both the risk and magnitude of cognitive deficits are inversely correlated with gestational age. VLBW or VP children have a decrement of 0.8 SD on measures of IQ and an increased risk of moderate to severe cognitive deficits. Moderate and late preterm children born at ≥32 weeks gestation score an average of 8 points lower, VP children born from 28 to 31 weeks gestation score 11 points lower, and EP children born at <28 weeks gestation score 14 points lower—a decrease of approximately 1.5 IQ points/week if born before 33 weeks gestation. EP/ELBW are two to three times more likely to have impaired attention than term controls with deficits including delays in selective, sustained, encoding, divided, and

Telegram: @medical_k

www.konkur.in

shifting attention. Processing speed, the time required to interpret and respond to incoming stimuli, is also slower. Compared to term controls, VP/VLBW children are 2 to 3.5 times more likely to have deficits in all aspects of memory, including short-term working memory, long-term episodic (events) memory, and semantic (facts) memory. Impaired visual acuity and visual/perceptual processing problems are common. It is, therefore, not surprising that executive function is also often impaired. These deficits do not appear to improve over time. Some, such as difficulties related to attention and executive function, tend to worsen as intellectual challenges become increasingly complex throughout childhood and adolescence.

Academic performance, especially for EP/ELBW children, is moderately to severely affected and due in part to specific learning disabilities in mathematics, reading, and spelling, often being worse than expected for a given IQ. In one study, compared with term controls, children born at <26 weeks gestation were more likely to have impairment at 11 years of age in reading (52% vs. 11%) and mathematics (70% vs. 14%). In another study, 65% of ELBW children at 8 to 9 years of age had at least one learning disability compared to 13% of those born at term. Although many VP/VLBW children may require some special educational resources at some point in their education, most VP/VLBW children are in mainstream classes and graduate from high school; many attend college and pursue postgraduate degrees.

Family Impact of Preterm Birth

The emotional effect of preterm birth, especially extremely preterm (EP) birth, on sibling and parental behavior and emotional well-being may be profound and pervasive, including post-traumatic stress disorder, anxiety, depression, family dysfunction, and divorce. Preterm birth is traumatic for parents, disrupting the cultural idealization of the perfect child, the competent mother, and the protective father. Physical separation and medicalized parenting interfere with normal parent–infant bonding. The most immature preterm infants are critically ill for many weeks, with multiple ups and downs involving difficult decisions by both the family and the medical team. EP children are often survivors of multiple gestations, adding the burden of grieving a fetal or neonatal loss to the family dynamic. Parents of preterm infants are more likely to report moderate to severe anxiety, depressive symptoms, and higher levels of parenting

Telegram: @medical_k

www.konkur.in

stress many years after their VP child's birth. Maternal depression not only increases the risk of preterm delivery but also is associated with internalizing behavior, anxiety, depression, and low social competence in their offspring. Maternal and paternal emotional distress related to preterm birth persisting for many years may negatively affect family function, parental perceptions of their child, long-term parent/child relationships, and child development.

Psychopathologic Outcome

Behavioral and socio-emotional problems are three to eight times more common in the preterm child compared to their term counterparts. Preterm children are more likely to have persistent internalizing and less likely to have externalizing problems. The preterm behavioral phenotype has been described as being inattentive, anxious, and socially withdrawn. At 4 years of age, poor social competence in VP children was associated with birth at <28 weeks gestation, socioeconomic disadvantage, the severity of brain injury, and early exposure to high maternal anxiety and negative parenting. Poor peer relationships and bullying are reported more often by preterm children.

Studies of preterm young adults compared with their term-born peers have noted decreased risk-taking behavior, delinquency, and incarceration and an increased risk of depression, anxiety, and social difficulties, including introversion, autistic features, and neuroticism. The reasons for less high-risk behavior are unclear but may reflect a lack of interest or opportunity, decreased social interactions, or increased protection by the family. Unlike term-born adults, longitudinal studies of ELBW adults found no decrease over time in internalizing problems from midchildhood to young adulthood. Behavioral and psychiatric diagnoses in preterm children are generally stable through adolescence.

Being born preterm substantially increases the risk of psychopathology, especially anxiety, depression, ADHD, and Autism. As with other outcomes, the risk increases with decreasing gestational age, rising sharply for those born before 31 weeks gestation. The risks of autism spectrum disorder (ASD) and emotional and behavioral problems are each 10 times higher if born at 23 to 27 weeks compared to ≥37 weeks gestation. VP children are two to three times more likely than moderate to late preterm children to have nonaffective psychosis, depressive disorder, and bipolar disorder. From a Scandinavian National Registry database,

Telegram: @medical_k

www.konkur.in

the risk of hospitalization for any psychiatric diagnosis doubles below 33 weeks gestation. Psychiatric disorders are often comorbid with other preterm-related cognitive, motor, and neurosensory impairments making diagnosis and treatment more difficult.

In midchildhood, compared to term-born children, EP children are approximately 3 times as likely to have a psychiatric diagnosis, 4 times as likely to have ADHD, 2.6 times as likely to have emotional disorders, and 8 times as likely to have ASD. In a U.S.-based longitudinal study, extremely low gestational age newborns (ELGAN) at 10 years of age were much more likely to screen positive for internalizing disorders (i.e., anxiety, dysthymic disorders, and social phobias) and other psychiatric disorders (i.e., ASD, ADHD) compared to NBW controls. Overall, 29% screened positive for one to four psychiatric disorders and were four times more likely to be taking prescribed psychotropic medications. In this same cohort, ASD determined by validated diagnostic criteria was highest (15%) in the ELGANS born at 23 to 24 weeks gestation, decreasing to 3% in those born at 27 weeks gestation.

In a meta-analysis including five studies of LBW, preterm adolescents, one in four had a psychiatric diagnosis (OR 3.66). In another study of midadolescent VLBW children, whereas 11% had cerebral palsy and 18% had moderate intellectual deficiency, 46% had emotional or behavioral problems and 25% had psychiatric symptoms fulfilling at least 75% of diagnostic criteria.

For moderately preterm young adults, the prevalence of a psychiatric disorder at 19 years of age was higher than their full-term counterparts (30% vs. 19%). The primary disorders were mood, ADHD, and antisocial personality, with males and females being equally affected. The risk of having a psychiatric problem increased from 11 to 19 years. More than 50% of those with a disorder at 19 years had not had a psychiatric diagnosis when seen at 11 years of age.

Anxiety/Depression. In a recent longitudinal U.S. study of an EP cohort at 10 years of age, parent and teacher reports of anxiety and depression were associated with the increased degree of prematurity, public insurance, Hispanic ethnicity, obesity, and physical health. Compared to term controls, a multicultural meta-analysis of VLBW adult cohorts born between 1977 to 1988 reported more internalizing and avoidant personality problems and less externalizing and antisocial

Telegram: @medical_k

www.konkur.in

personality problems. In LBW (<2,500 g) preterm adolescents, the attributable risk for depression in female adolescents based on psychiatric assessment was 18% to 24% of LBW females versus 3% of NBW females. LBW adolescent females were also found to be less resilient than their NBW peers. Compared to NBW females, LBW females have more risk factors associated with depression: (i.e., 20% of LBW vs. 5% of NBW for one risk factor and 85% of LBW vs. 20% of NBW for two risk factors). In this study and others, the risk of depression was not increased in preterm male adolescents. Absolute rates of adolescent depression were slightly lower in an Australian population-based cohort where 15% of preterm LBW adolescent girls and 1% of preterm LBW adolescent males had stable depression in comparison to 2% of term females and 0.25% of term male adolescents. The OR for LBW adolescents developing a stable depressive disorder was 11.6 after adjustment for background confounders. Other studies indicate that moderate to late preterm young adults born at 32 to 36 weeks gestation are 2.7 times more likely, and VP young adults born before 32 weeks gestation are 7.4 times more likely to develop bipolar disorder.

Attention-Deficit/Hyperactivity Disorder. The prevalence of ADHD is 2 to 4 times greater in preterm children and occurs most often in the most premature children. The majority of preterm children are more likely to have the inattentive ADHD subtype rather than combined or hyperactive/impulsive subtypes. In one large population-based study, EP children had a high rate of generalized attention impairment at 11 years of age–77% were impaired in at least one area of attention, and 50% were impaired in 2 areas. In the same cohort seen at 17 years of age, 18% had clinical ADHD compared to 7% of the term adolescents. Unlike in term children, where there is a male predominance, preterm girls and boys are equally affected. Specific neonatal factors are weak predictors of attention impairment and ADHD although poor intrauterine growth may contribute to the risk of hyperactivity. In a large twin study, the lower–birth-weight twin scored higher on a hyperactivity scale. In preterm children with ADHD, neuroanatomical and functional abnormalities are present on MRI in specific structures and in the fronto–striatal–cerebellar circuitry with evidence of hyperactivation in some areas and decreased activation in others.

Telegram: @medical_k

www.konkur.in

Autism/Autism Spectrum Disorder. The prevalence of autism in preterm children is two to three times the prevalence in the overall population. There is a gradual increase in the risk of ASD associated with decreased length of gestation, with the most immature and the smallest at the highest risk. Clinically, preterm and LBW children have predominately social and communication problems, with less stereotypic, repetitive movements and more motor and cognitive delays.

Although a high proportion (21% to 41%) of VP children fail the Modified Checklist for Autism in Toddlers (MCHAT) screener at 18 to 24 months of age, these results are strongly influenced by concomitant cognitive, motor, and neurosensory impairments. The percentage of positive screens is much lower following confirmatory interviews. In later childhood and adolescence, the prevalence of ASD fulfilling diagnostic criteria is 5% overall in LBW children and up to 8% in EP children. Although the prevalence of autism is four times higher in males, the risk is higher for preterm females born at less than 33 weeks gestation. Preterm females are also more likely to have comorbid conditions.

Many variables that have been associated with ASD occur more frequently with preterm delivery. See Table 2.13–6 for a list of these risk factors. Most of these variables are either primarily or secondarily associated with hypoxic/ischemic, inflammatory, or toxic brain injury. Both genetic and environmental components of autism have been demonstrated in twin studies which have high rates of concordance in identical but not dizygotic twins. When identical twins are discordant for ASD, the smaller twin, presumably with the less optimal intrauterine environment, is more likely to be affected. Autism is associated with neonatal cranial imaging abnormalities, including ventricular dilatation, intracranial hemorrhage, parenchymal white matter volume loss, isolated cerebellar injury, and hypoplasia of the cerebellar vermis.

Telegram: @medical_k

www.konkur.in

Table 2.13–6.
Risk Factors Associated with Autistic Spectrum Disorder

Risk Factors		
Maternal/Antenatal	**Fetal/Intrapartum**	**Neonatal/Postnatal**
Gestational diabetes	Preterm delivery	Low Apgar score
Advanced maternal age	Fetal distress	Need for intensive care
Maternal hypertension	Breech presentation	Hypoxemia
Maternal antidepressants	Umbilical cord complications	Respiratory distress
Antenatal bleeding	Intrauterine growth restriction	Meconium aspiration
Antenatal infection	Twin gestation	Jaundice
	Birth order	Anemia
	Induced labor	Hemolytic disease of newborn
	Summer delivery	Lack of human milk feeding
		Congenital malformation

Psychotic Disorders. Given the low prevalence of nonaffective psychosis, little information is available. The few studies from mental health or large birth registries associate preterm birth, hypoxia, and related obstetrical complications (e.g., perinatal asphyxia), fetal undergrowth, and pre-eclampsia with schizophrenia. Moderate to late preterm young adults born at 32 to 36 weeks gestation are 1.6 times more likely, and VP young adults born before 32 weeks gestation are 2.5 times more likely to develop nonaffective psychosis. Brain abnormalities associated with schizophrenia include cerebellar hypoplasia, severe IVH, and ventricular dilatation.

In conclusion, psychopathology, including behavioral problems, depression, anxiety, autism, ADHD, and nonaffective psychosis, are all more prevalent in children, adolescents, and adults born prematurely. The risk increases steadily with increasing prematurity such that those born at less than 28 weeks gestation are at the highest risk. Abnormalities in brain structure and function incurred as a result of preterm birth have been implicated in adverse neurodevelopmental and psychiatric outcomes.

HUMAN IMMUNODEFICIENCY VIRUS IN CHILDREN AND ADOLESCENTS

Epidemiology

The human immunodeficiency virus type-1 (HIV) is a retrovirus acquired through exposure to infected bodily fluids, most commonly in adults via unprotected sexual contact or injection drug use; infection via blood products, a significant route of exposure early in the epidemic, has been reduced to negligible levels in the United States by donor screening and treatment of donated blood. For infants born to a woman with HIV, exposure can occur in utero, during birth, or via breastfeeding. There is regional variation in the most common route of infection and the population affected; in the United States, new infections are most likely among men who have sex with men (MSM). HIV primarily infects and destroys $CD4^+$ T-lymphocytes and, untreated results in progressive immunosuppression and vulnerability to opportunistic infections and neoplasms. Centers for Disease Control (CDC) surveillance classification of disease severity assigns categories according to age-specific $CD4^+$ T-lymphocyte count and whether an opportunistic infection has been diagnosed; Stage 3, or acquired immunodeficiency syndrome (AIDS), refers to $CD4^+$ count below 200 or diagnosis of a Stage 3-defining opportunistic infection. The development of effective antiretroviral therapy (ART), particularly combinations of ARTs from different drug classes, has resulted in a dramatic decrease in AIDS incidence and increased focus on more subtle effects of HIV, such as those in the brain; long-term toxicities associated with ART; interactions of HIV with other comorbidities such as substance use, depression, concomitant infections, and aging; and functional cure of HIV through the elimination of viral reservoirs. A discussion of virology and pathogenesis-related to HIV, as well as neuropsychiatric findings in adults, are presented in the chapter in this volume, “Neuropsychiatric Aspects of HIV Infection and AIDS.”

Over the more than 30 years of the HIV epidemic, children and adolescents have been significantly affected. Globally, an estimated 37.7 million people, including 1.7 million children under 15 years of age, were living with HIV in 2020, with 1.5 million new infections and 680,000 deaths from AIDS-related illnesses that year. Since the administration of ART during pregnancy and to the infant after birth was discovered to prevent

Telegram: @medical_k

www.konkur.in

most cases of mother-to-child HIV transmission, the incidence of new infant infections has dropped dramatically in high-resource environments such as the United States, with the majority of perinatal infections occurring in limited resource settings, particularly sub-Saharan Africa. However, in all settings, numbers of older perinatally infected children and youth have grown as effective ART has extended their lives; many of them are now adolescents or young adults and experiencing long-term neurodevelopmental, behavioral, and mental health issues associated with HIV as well as mental health and substance use problems common to their age group and/or demographic. Among individuals who acquire HIV infection postnatally, adolescents (age 15 to 24) have a relatively high rate of infection.

If taken appropriately, ART can suppress HIV to undetectable levels in the blood for most people across the lifespan, preventing immunosuppression with its associated health risks, some of which remain following immune reconstitution, and dramatically reducing the risk of transmitting HIV to others. Currently, recommendations for initiating ART include all individuals upon diagnosis, including infants at birth. In order to reap the benefits of ART and achieve viral suppression, however, an individual must first be identified as HIV infected, linked to and engaged in medical care, prescribed ART, and maintain high ART adherence (the so-called HIV treatment cascade). Youth aged 13 to 24 with HIV have lower rates of success at all stages of the treatment cascade than other age groups, and as a result, only an estimated 33% in the United States were virally suppressed in 2018, according to the CDC. Globally, access to ART continues to be lower for youth than for adults, and HIV is among the leading causes of death for adolescents.

Mental Health and Psychiatric Disorders

The interconnections of HIV with mental health and psychiatric disorders, including neurocognitive impairment, psychopathology, and substance use, are well established in the adult population but are less well understood among children and youth. The likelihood of sexual and injection drug use risk behaviors associated with HIV acquisition, as well as other infections, is already greater among youth by virtue of the age-typical tendency toward risk-taking and is increased in the presence of mental illness and substance use. Conversely, HIV infection increases the risk for mental health and substance use problems both directly in the

Telegram: @medical_k

www.konkur.in

case of neurocognitive decline and indirectly through the emotional and psychosocial impacts of having HIV. Furthermore, neurocognitive and psychiatric disorders complicate health and medication management for individuals with HIV, increasing morbidity and likelihood of HIV transmission, and the presence of multiple comorbidities challenges healthcare systems, particularly in lower resource settings. This suggests the important role of psychiatrists and other mental health professionals in preventing HIV infection as well as increasing the quality of life in those already infected. Addressing the gap in mental health care for individuals with HIV is a necessary component of reducing and ultimately eliminating the HIV epidemic.

Adolescents with Behaviorally Acquired HIV

Neurocognitive Impact of HIV. The neuropathogenesis, as well as neurocognitive and psychiatric sequelae of HIV in adults, are reviewed in detail in the chapter “Neuropsychiatric Aspects of HIV Infection and AIDS” and will be summarized only briefly here, along with differences between youth and adults. The CNS is vulnerable to HIV, and neuropsychiatric sequelae of HIV have been described since the beginning of the epidemic. The virus can enter the CNS early in infection via infected monocyte-derived macrophages and lymphocytes and establish a locally productive infection that may be relatively independent of other loci, representing a viral reservoir. The effects of HIV on neural functioning are largely indirect, through exposure to viral proteins, production of proinflammatory cytokines by infected or activated monocytes and other cells, and alteration of the blood–brain barrier rather than through direct infection of neurons. HIV can lead to a dynamic state of chronic inflammation and immune activation that impacts the CNS and other systems and may be influenced by other lifestyle factors such as substance abuse and may interact with neurodevelopment in perinatally infected children and possibly in adolescent infection. HIV-related immune activation and inflammation may become established early in infection and persist despite viral suppression using ARTs.

Before the advent of highly active ART, HIV-associated dementia occurred in 20% to 30% of adults with HIV by the time of death, typically in the context of significant immunosuppression, where it can still occur. In addition, opportunistic infections in the CNS, such as progressive multifocal leukoencephalopathy, can occur with immunosuppression.

Telegram: @medical_k

www.konkur.in

Amongst severely immunocompromised individuals, delirium, coma, seizures, and intracranial hypertension can be seen. In the era of ART, the incidence of HIV dementia and other severe sequelae has declined dramatically; however, the prevalence of milder impairments continues to be high and is particularly likely in individuals who have experienced profound immunosuppression at some point despite later immune reconstitution (i.e., “legacy” effect). Preventing long-lasting effects of immunosuppression, as well as the establishment of inflammation, have led to the recommendation to initiate ART upon diagnosis with HIV, including in infants.

A “subcortical” presentation, with slowing, impaired retrieval from memory but more intact recognition, fine and gross motor impairment, apathy, and decrease in emotional expressivity, has been described among individuals with untreated HIV. With ART, impairments are more subtle and have been suggested to have a more “cortical” presentation, with executive function difficulties assuming more prominence. Several mechanisms have been proposed to explain the presence of impairments in virally suppressed or early-infected individuals, including inflammation and higher viral activity in the CNS than in the periphery. Although it is often assumed that behaviorally HIV-infected adolescents and young adults would follow the course typically seen among older adults, the few studies of this population suggest some differences in presentation. In particular, striking impairments in verbal and nonverbal learning, and lesser difficulties in other cognitive domains, have been observed among young adults with behaviorally acquired HIV. The presence of some associations with HIV disease severity and markers of inflammation and immune activation raises the question of subtle, HIV-associated neurocognitive function in this population, but associations with demographics and psychiatric and educational covariates suggest that other, possibly pre-existing causes for the impairments are contributory. Distinguishing subtle HIV-associated impairments from those related to comorbidities such as depression or substance use requires careful assessment. Regardless of their origin, however, neurocognitive impairments have been found to be associated with poorer daily functioning and medication adherence; monitoring is indicated in all individuals with HIV. This is particularly true since viral suppression through good medication adherence is an important tool for preventing HIV transmission. Because both reduced medication adherence and

Telegram: @medical_k

www.konkur.in

increased risk behaviors are more likely among adolescents, adherence interventions take on increased importance for this population. Unfortunately, efforts to develop CNS-specific therapies have been disappointing, and results of using ART with greater penetrance across the blood–brain barrier into the CNS have been mixed. Although cognitive impairments have shown modest improvement with ART and systemic viral suppression in some studies (however, findings for adolescents are less compelling), choosing regimens with less potential neurotoxicity is of particular relevance for this population facing many decades of therapy. Nevertheless, at this time, viral suppression with ART is considered the most effective prevention and treatment for HIV-associated neurocognitive disorders.

Mental Illness and Substance Use. Though prevalence estimates vary across settings and populations, in general, the literature demonstrates a higher prevalence of mental health disorders among adolescents and adults with HIV than among the general population, with rates up to 75% to 83% in some studies. Several classes of disorders are of particular concern due to their prevalence or potential to impact health outcomes or HIV transmission.

DEPRESSION. Depression is a common referral issue for mental health treatment for individuals with HIV, with reported prevalence rates two to three times higher than among the general population and a significant unmet need for treatment, particularly among minority youth. Assessment of depression is important in the clinical care of youth with HIV for several reasons, even in the absence of depression as the presenting complaint. The American Academy of Pediatrics notes the higher rates of depression and suicidal ideation among sexual minority (lesbian, gay, bisexual, transgender, and questioning) youth and the mental health treatment disparities resulting from discrimination and stigma related to sexual orientation and gender identity, and recommends screening for depression as part of a complete psychosocial history. Depressive symptoms can be a side effect of certain antiretroviral medications (e.g., efavirenz) and indicate the need for a change of medication regimen. Untreated depression can contribute to sexual and substance use risk behaviors and to poorer adherence and engagement in care, thus increasing morbidity and HIV transmission likelihood and suicide. Finally,

Telegram: @medical_k

www.konkur.in

cognitive symptoms associated with depression (e.g., psychomotor slowing, apathy) can be similar to those of HIV-associated neurocognitive disorders, and thus, depression must be considered as a differential diagnosis during the neuropsychological assessment.

Pharmacologic treatment of depression in youth with HIV can follow principles and guidelines for other populations since there is no evidence of differential efficacy or side effect profiles in the presence of HIV; however, attention to potential interactions with ART is important (below). As in other populations, psychopharmacologic treatment can be combined with other supportive and evidence-based therapies. Evidence-based treatments such as cognitive behavior therapy have been adapted to incorporate concerns relevant to youth with HIV and address associated issues such as medication adherence.

ANXIETY DISORDERS. Although the lifetime prevalence of anxiety disorders may be higher in adults with HIV, anxiety disorders have not received as much focus in studies of HIV. In a survey study of youth with HIV, 16% to 17% reported clinically significant symptoms of anxiety. The exception is post-traumatic stress disorder, which appears to have a higher prevalence (30% to 64%) among adults with HIV than in the general population in North America and Africa. Youth with HIV may have been premorbidly subject to chronic stress associated with discrimination as members of racial and sexual minority groups, poverty, histories of physical or sexual abuse, immigrant or refugee status, and in some cases, homelessness, among other stressors. Following their diagnosis, they may experience trauma related to receiving the diagnosis and anxiety related to HIV stigma, disclosure to sexual partners and others, and fear of HIV sequelae and mortality. The association of stress and trauma with inflammation and decreased immune functioning amplifies concern about trauma, stress, and PTSD in youth with HIV. Individual and group therapy for anxiety and PTSD should be sensitive to the acute and chronic stresses common to this population. Recommendations regarding pharmacotherapy are based largely on studies with non-HIV–infected populations, but clinicians should be aware of the possibility of additional confusion or sedation in individuals with HIV-associated cognitive impairment.

PSYCHOSIS. Individuals with chronic mental illness have an increased risk of becoming infected with HIV. Those with substance use or unstable

Telegram: @medical_k

www.konkur.in

housing may exchange sex for money or drugs or have decreased access to condoms or clean needles. HIV screening, risk reduction counseling, and, where needed, substance abuse treatment should be considered for this population. Although less commonly relevant for adolescent populations, new-onset psychotic symptoms or mania can occur in late-stage disease as part of HIV disease or opportunistic infections in the CNS; these symptoms may respond to low-dose neuroleptics.

SUBSTANCE USE. Injection drug use is a vector for HIV infection, particularly in South and Southeast Asia but to varying degrees worldwide. In addition, substance use is relevant for adolescents with HIV as a common comorbidity of other psychiatric disorders as well as a disorder in its own right, as a factor in sexual risk behaviors and poor medication management, and because of its potential interactions with immune and neurocognitive functioning. Among adults, some substances, such as alcohol and methamphetamine, have been found to exacerbate HIV-associated neurocognitive impairment. Less research on this topic has been done with adolescents; however, studies showing the increased vulnerability of the developing adolescent brain to the effects of substance use raise concern, and one study showed that HIV and alcohol risk interacted in association with cognitive functioning in youth with HIV. Furthermore, drugs of abuse may interact with some ARTs. Screening for substance use is a critical part of psychiatric and primary care for youth with HIV.

Although estimates vary, substance use overall is generally found to be more prevalent among adults with HIV than among uninfected adults. Among HIV-infected youth engaged in care, the most common substances of abuse have been reported to be cannabis, tobacco, and alcohol; however, the use of other drugs such as methamphetamine, opioids, club drugs, and cocaine varies regionally and represents a significant concern. Cannabis is of particular interest due to its wide availability, including legal use in some states; its increasing acceptability, particularly among youth; immune interactions and unknown interactions with cognitive impairment; use by some individuals to manage HIV symptoms and ART side effects; and, specifically for youth, the literature suggests a long-term impact of cannabis use during adolescence on continuing neurodevelopment.

Telegram: @medical_k

www.konkur.in

Facilitating engagement in the care of youth with substance use is vitally important for clinical and public health reasons. Examples of strategies to encourage engagement in care include integrating treatment for substance use disorders with mental health treatment and HIV services where possible and reducing the stigma of acknowledging substance use to adolescent providers. Where abstinence is not achievable, harm reduction (e.g., reducing behaviors with the potential to transmit HIV) is an applicable strategy. Evidence-based youth-friendly therapeutic approaches such as motivational interviewing can be implemented in a variety of settings.

Children and Youth with Perinatally Acquired HIV

Neurocognitive Impact of HIV. Our understanding of the neurodevelopmental effects of HIV among perinatally infected children is complicated by the changing state of their CNS and the numerous other developmental risks present in this population. These can be environmental (e.g., economic and educational disadvantage, chronic stress related to poverty), genetic (e.g., familial psychiatric and learning disorders), prenatal or birth-related (e.g., low–birth-weight, prenatal exposure to substances of abuse and ARTs, other congenital infections such as cytomegalovirus), or related to their own and/or caregivers' chronic illness (e.g., death or changes in caregiver, missing school). Prior to the advent of combination ART, progressive HIV encephalopathy characterized by delay or loss of developmental milestones or cognitive functioning, pyramidal tract motor deficits, and microcephaly (or atrophy in older children) was seen in 24% to 35% of children with HIV. A plateau course with deviation from the expected developmental trajectory rather than a loss of milestones or decline in cognitive functioning was also seen. Currently, as with adults, encephalopathy is less common (2% to 15%), and impairments are most likely in children or youth who have had immunosuppression sufficient for an AIDS diagnosis in the past, regardless of current immune functioning, particularly if the most severe disease impact was early in life (e.g., prior to age 3) or encephalopathy was present. Although most studies have utilized measures of global cognitive functioning such as I.Q., impairments in specific cognitive domains such as language, executive functions, or processing speed have been noted. According to some studies, children and adolescents who have had consistently good viral control perform at a level

Telegram: @medical_k

www.konkur.in

comparable to those who were perinatally exposed to HIV but uninfected, with both groups performing in the low average range overall, possibly due to the other developmental risks outlined above. However, the role of prenatal exposure to HIV and ARTs cannot be ruled out by these studies.

Mental Illness and Substance Use. Children and youth with perinatally acquired HIV face numerous risks for emotional and behavioral issues. These include high rates of familial mental illness and substance use, potential or actual death of a parent, concerns about HIV-related stigma and disclosure to others, and living with the actual or potential effects of HIV itself, such as illness, cognitive impairment, delayed puberty, pain, and death. Perinatal HIV differentially affects minority and economically disadvantaged populations who may, as a result, already be subject to high levels of chronic stress. Reviews by Mellins and Malee, 2013 and Vreeman et al. noted higher rates of psychiatric disorders and behavioral problems in children and youth with perinatally acquired HIV than seen in the general population. Studies using diagnostic tools such as structured interviews have found that up to 70% have met the criteria for a nonsubstance-use psychiatric diagnosis at some time point, most commonly anxiety, ADHD, disruptive behaviors, and depression. However, some studies have found similar rates among youth who were perinatally HIV-exposed but uninfected, bringing into question the relationship between the high rate of diagnoses to HIV infection. Similarly, the results of studies using caregiver- or youth-report symptom checklists vary, some demonstrating higher rates of reported mental health problems than in the general population or comparison groups, with others showing no differences or even lower ratings of mental health problems among infected youth, possibly reflecting the close monitoring of and availability of resources for youth with PHIV in some settings.

Only in recent years have significant numbers of youth with perinatally acquired HIV survived into adolescence and reached the age of substance use initiation. They have been found to initiate substance use at similar rates as other adolescents, with higher severity of emotional symptoms or meeting symptom criteria for ADHD, major depressive disorder, and oppositional or conduct disorder associated with a greater likelihood of substance use.

Regardless of the origin of mental health problems in this population, the research demonstrates a clear need for intervention. In addition to the

Telegram: @medical_k

www.konkur.in

importance of intervention for decreasing suffering and improving quality of life, as youth with perinatally acquired HIV grow into adolescence, those with mental health problems are more likely to engage in substance use and sexual risk behaviors and to have difficulty adhering to their medication regimens. Thus, the intervention has the potential to improve long-term health outcomes and reduce HIV transmission. Mental health services are commonly provided by pediatric and adolescent HIV programs. However, little data exists regarding the differential effects of either pharmacologic or behavioral treatment in perinatally infected youth compared to uninfected youth.

Factors that have been found to increase the risk for mental health problems in the context of perinatally acquired HIV include caregiver psychiatric disorder and limit-setting problems, lower child cognitive functioning, and exposure to stressful life events. Conversely, resilience to mental health problems has been associated with higher self-esteem, positive caregiver–child relationships and parental monitoring and involvement, and family, peer, and community support. Thus, points of intervention can be multisystemic and include, for example, family-based therapy to facilitate communication, including disclosure of the child's or mother's HIV infection, peer support groups, and community programs to reduce HIV stigma. At the individual level, interventions to boost resilience through increasing coping skills and self-esteem can complement the use of pharmacologic and evidence-based therapeutic approaches.

Issues Related to Psychopharmacologic and Antiretroviral Treatment

Key issues for psychiatrists monitoring youth with HIV and prescribing psychopharmacologic medications are potential psychiatric side effects of ART and interactions between ART and psychotropic medications. Psychiatric side effects of some antiretroviral agents are well known; the use of efavirenz, in particular, can be associated with mood disturbance, insomnia and vivid dreams, impaired concentration, and in some cases, hallucinations, among other symptoms. Familiarity with the side effect profiles of patients' ART regimens is critical for the treating psychiatrist. An important issue for psychiatrists is the common pharmacokinetic and pharmacodynamic interactions between psychopharmacologic and antiretroviral agents. Some antiretroviral medications, such as protease inhibitors and non-nucleoside reverse transcriptase inhibitors, involve the CYP450 system and thus have the potential to affect drug levels of

Telegram: @medical_k

www.konkur.in

antidepressants and other medications. An additional consideration in prescribing psychopharmacologic treatments in the context of HIV is that individuals using specific ARTs or who have neurocognitive impairment may be more sensitive to the side effects of psychiatric medications. In general, the treating psychiatrist is advised to take a careful drug history, anticipate drug interactions and toxicities, start with lower dosages, and take a cautious approach when increasing them. Drug interactions are discussed in detail in the chapter "Neuropsychiatric Aspects of HIV Infection and AIDS."

EPILEPSY

Seizures and Epilepsy Syndromes in Children

It is estimated that 1% to 1.5% of children will have a nonfebrile seizure at some time in their life. The most common seizure condition in pediatric medicine is febrile seizures which can occur in 4% of infants, toddlers, and preschoolers overall, with some ethnic groups, such as Japanese (10%) and Guamanians (20%), having a much higher incidence. Seizures can begin at any time of a child's life, from prenatally to perinatal to onset in late adolescence. Epilepsy has been defined in the past as having two or more unprovoked seizures. A slightly different operational definition of epilepsy has recently been stated by the International League against Epilepsy, along with an updated Classification of Seizure Types.

Based on this new definition, epilepsy is a disease of the brain defined by any of the following conditions:

1. At least two unprovoked (or reflex) seizures >24 hours apart.
2. One unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures occurring over the next 10 years.
3. Diagnosis of an epilepsy syndrome.

Child neurologists and epileptologists consider in their evaluation of a child with a single or recurrent seizures the historical and examination findings, seizure type, age at onset, and EEG findings. In doing so, roughly 50% of children can be characterized as having a particular epilepsy syndrome. Making a syndrome diagnosis can provide prognostication and often guides discussion about therapeutic options.

Telegram: @medical_k

www.konkur.in

The latter is based upon accumulated experience, clinical trials of single agents versus placebo, or rarely as in the case of childhood absence epilepsy, well-conducted comparative clinical trials. Table 2.13–7 provides information about seizure type classification, and Table 2.13–8 provides a list of pediatric epilepsy syndromes.

In past decades epileptologists and geneticists hoped for a single gene to be associated with electroclinical epilepsy syndrome, but as data have accumulated over the past 25 or more years, this idea has not been supported by available data from genetic association studies. Many individual electroclinical syndromes have been found to be associated with a given single gene mutation–often de novo, while a particular electroclinical syndrome may be associated with two or three or more different genetic mutations. Knowledge of the specific gene mutation for a given epilepsy syndrome has largely failed to inform the optimal choice of therapy. Exceptions to this include SLC2A1 mutation (glucose transporter deficiency) and SCN1A mutation associated with Dravet syndrome. The former condition responds to ketogenic diet therapy, and the latter is often worsened by lamotrigine therapy which is usually avoided in such patients.

Epidemiology of Psychiatric Issues in Childhood Epilepsy

The best prospective assessment of psychiatric issues in pediatric epilepsy comes from a multiyear study of new-onset seizures/epilepsy in Connecticut. In this study, 501 children were enrolled and followed for several years. One hundred fifty-nine children were judged to have a "complicated" profile with either a brain lesion evident on imaging or an IQ less than 80 or both. When brain MRI showed no etiologic structural lesion and IQ was 80 or higher in 342 children, this constituted the "uncomplicated" group.

	Complicated *N* = 159	**Uncomplicated *N* = 342**	***P*-Value**
No psychiatric disorder	98 (62%)	251 (73%)	0.008
Psychiatric disorder present	61 (38%)	91 (27%)	

Internalizing disorders (depression, bipolar disorder, obsessive-compulsive disorder, schizophrenia) were reported in 17% of the complicated group and 15% of the uncomplicated group. Externalizing disorders (ADHD, ODD, and conduct disorder) were present in 31% of the complicated group and 18% of the uncomplicated group ($P < .002$).

When specific features were evaluated, it was found that the age of seizure onset influenced the occurrence of any psychiatric disorder. Of those with onset <2 years old, 11% had a psychiatric disorder with onset at 2 to 5 years old, 24% had a psychiatric diagnosis, and if onset was >10 years old, 36% had a psychiatric disorder. Sex was not a factor influencing the incidence of psychiatric disorders. Of those children who had childhood absence epilepsy, 23% had a psychiatric diagnosis. Thirty

Telegram: @medical_k

www.konkur.in

percent of children who had benign epilepsy with centro-temporal spikes (aka Benign Rolandic Epilepsy) had a psychiatric diagnosis. Thirty-seven percent of children with juvenile absence epilepsy and juvenile myoclonic epilepsy had a psychiatric diagnosis.

More recently, questions have been raised regarding parental/proxy reporting of mood and anxiety symptoms in children with epilepsy. The point is made that when parental factors of stress and parental mood disorders are factored into the assessment of a child's behavioral problems, the differences in reported psychiatric diagnoses among different childhood epilepsy syndromes may not be apparent. Therefore, caution is advised when relying solely on parental reporting of behavior for both research and clinical assessments.

Depression and Anxiety in Pediatric Epilepsy

In the population-based study referenced above, often patients in both the complicated and uncomplicated groups had more than one psychiatric diagnosis–most often depression + anxiety or ADHD + anxiety or depression. A surprising finding in this study was no increase in the occurrence of psychiatric disorders in children who had failed >2 antiseizure medication trials versus those well-controlled on the first or second medication used.

Other studies have found by KSADS (Kiddie Schedule for Affective Disorders and Schizophrenia) assessment of children with focal unaware seizures and absence seizures, 12% and 13%, respectively, had features of depression. When assessed by the Children's Depression Inventory, 25% of children in a community-based cohort of 115 had depression, and this did not differ from those in a tertiary referral center.

Surveys of the general childhood population have shown 9.5% to have an anxiety disorder, and in children with epilepsy, figures have ranged from 5% to 49%. A wide array of disorders has been identified, including generalized anxiety disorder, specific phobias, and social anxiety, with one study finding specific phobias to be the most common. No specific data regarding optimal therapy of anxiety disorders in pediatric epilepsy have been published as of this writing, though cognitive behavioral therapy is usually recommended as first-line treatment and consideration of combined CBT with an SSRI if needed.

Data regarding the incidence/prevalence of obsessive-compulsive disorder or psychosis in children who have epilepsy have not been

Telegram: @medical_k

www.konkur.in

published to date.

Interictal and Postictal Psychosis

Only anecdotal reports are available about psychosis in childhood epilepsy, and we must turn to the adult literature for more informative and relevant data. Up to 9% of adults who have temporal lobe epilepsy will have an associated interictal psychosis, and this has been observed to be more common with left versus right temporal lobe seizure origin. Such patients most often display positive symptoms with delusions and may demonstrate hallucinations in the setting of otherwise clear consciousness. They often have the absence of a formal thought disorder, a better premorbid state, and less personality deterioration.

An uncommon situation in which psychosis coincides with improved seizure control, often with improved EEG findings via medication, vagal nerve stimulation, or resective surgery, has been termed “forced normalization” and seems to be a rare and controversial phenomenon. Great variability (<1% to 28%) has been reported in the occurrence of de novo psychosis after epilepsy surgery. When this occurs, it usually begins within 5 months and is more likely to occur in individuals who have a family history of psychosis or are older than 30 years of age at the time of surgery.

Proposed criteria for defining postictal psychosis include the following:

1. within one week of a seizure or seizure cluster
2. duration >1 day and <3 months
3. disorientation, delusions, delirium, or hallucinations in clear or clouded consciousness
4. no evidence of anticonvulsant toxicity, nonconvulsive status epilepticus on EEG, prior interictal psychosis, recent head trauma, or drug/alcohol intoxication (reference)

Postictal psychosis has been sparsely reported in children and adolescents. In the adult epilepsy literature, the risk of postictal psychosis is increased with age >30 years old, male gender, focal seizures, rapid secondary generalization of focal seizures, prior encephalitis, slowing on EEG, and prior personal or family history of psychosis. Thought insertion, commenting/command hallucinations, and negative symptoms are rare. While there are literature reports of levetiracetam, vigabatrin, and

Telegram: @medical_k

www.konkur.in

zonisamide therapy started vigorously for repeated new onset seizures as a cause for psychosis, child neurologists and consulting child psychiatrists must consider that in some patients, new onset repetitive seizures may be a presenting feature of NMDAR antibody encephalitis, and there may be an alternate explanation for psychotic behavior in a child with new-onset seizures.

It is advisable to avoid as much as possible the use of clozapine, chlorpromazine, and loxapine for pharmacologic therapy of psychosis in patients with epilepsy due to their risk of lowering seizure threshold and association with seizure occurrence in individuals not known to have epilepsy. It is important to be aware of potential drug-drug interactions when neuroleptic agents are used; for example, ziprasidone levels are reduced by enzyme-inducing antiseizure medications such as carbamazepine, phenytoin, and phenobarbital.

Aggression

Little data about aggression is reported in the pediatric epilepsy literature. Up to 5% of adults with epilepsy have problems with aggressive behavior. Risk factors include intellectual disability, onset of seizures earlier than age 10 years old, traumatic brain injury (TBI), psychosis, and lower socioeconomic status. Medications, including gabapentin, phenobarbital, lamotrigine, and levetiracetam, have been associated in case series with the occurrence of aggressive behavior that improves after cessation of that particular medication. Ictal and postictal aggression are a rare phenomenon, and in video-EEG studies, they have been associated primarily with staff or family member physical restraint attempts.

Attention-Deficit Hyperactivity Disorder and Sorting Out Staring Spells

Even prior to the initiation of antiseizure medication, symptoms of attention deficits are commonly present in children who develop epilepsy. Most studies have found approximately a 30% to 35% prevalence of attention deficit in children with epilepsy versus a 5% prevalence in the general childhood populations. A prospective cohort study of baseline neuropsychological testing in children with new onset seizure(s), including half not yet started on antiseizure medication compared with unaffected siblings, found a significantly worse performance on Conners Continuous Performance Task III in patients versus nonaffected siblings. Medication

Telegram: @medical_k

www.konkur.in

may exacerbate or precipitate attentional problems, such as has been demonstrated in a large comparative blinded trial of valproate, ethosuximide, and lamotrigine in the therapy of childhood absence epilepsy. Thirty-six percent of 393 children with new onset childhood absence epilepsy had attention deficit as gauged by Conners Performance Test II. After 16 to 20 weeks of the assigned antiseizure medication, 49% of the valproate group showed attention deficits compared to 32% of the ethosuximide and 24% of the lamotrigine-treated groups. This was statistically significant for valproate versus others, but no significant difference was present between the lamotrigine and the ethosuximide group.

In the past, there have been statements advising the avoidance of stimulant medication in children who have seizures. Numerous open-label studies and two randomized placebo-controlled studies, however, have failed to show a worsening of seizures in children with epilepsy taking either methylphenidate or atomoxetine. Although the issue has not been well studied in pediatric epilepsy patients with unstable, poorly controlled seizures, stimulant medications have been well tolerated when introduced to children taking antiseizure medications.

Not uncommonly, children who have ADHD present to healthcare providers with a history of staring spells. When observant parents or teachers can provide a detailed history, it is usually found that the staring off does not interrupt ongoing speech, play, eating, walking, or running as is usually the case in absence or focal unaware types of seizures. When staring spells are brief, on the order of seconds, and not associated with versive head or eye movements or somnolence/confusion after and there is concern that a child might have absence seizures, a routine awake EEG with two periods of hyperventilation will detect generalized 3 Hz spike-wave activity of absence seizures in 95% of affected children. If there is lingering doubt, long-term ambulatory EEG or inpatient VEEG may be required to settle the issue but will be most helpful only if the staring spells occur on a daily basis.

Psychogenic Nonepileptic Seizures

Estimates from epilepsy centers caring for children using video EEG (VEEG) for documentation of psychogenic nonepileptic seizures (PNES) indicate an estimated prevalence of PNES to vary between 1% to 9%. This is lower than 15% to 20% incidence of PNES in patients referred to

Telegram: @medical_k

www.konkur.in

adult epilepsy centers for VEEG monitoring for refractory seizures. Nonepileptic events in children vary according to age and can include syncope, parasomnias, various movement disorders, inattention/daydreaming, breath-holding spells, hypnic jerks, and sleep myoclonus. In general, the older the child, the greater likelihood that an event is a psychogenic nonepileptic event as opposed to one of the above. Older children are more likely to have motor features of their PNES, and these may have a variety of manifestations–focal, upper or lower extremities alone, whole body, etc. Clinical videography of such events to determine if the habitually observed characteristics of true epileptic seizures are a critical part of the evaluation. Younger children have been found to more often simply display a behavioral pattern of staring and unresponsiveness without motor features.

The gold standard in diagnosing PNES is VEEG monitoring with capture of a typical episode in VEEG with semiologic features not seen in epilepsy with normal EEG at the time of the event. Such patients will usually have preservation of normal EEG background rhythms and be nonresponsive to commands during PNES spells. Behavioral characteristics of PNES often include longer duration of events (>10 minutes), fluctuating course during events, side-to-side head or body movements, pelvic thrusting, asynchronous movements (excluding abrupt asymmetric tonic postures as are seen in frontal lobe partial seizures), crying during the event, eyes remaining closed during the event and memory recall within the event. Tongue biting, incontinence, flailing or thrashing movements, opisthotonus, and gradual onset of events may occur in either epileptic seizures or psychogenic nonepileptic events. They usually arise from an awake state or from apparent sleep that is not corroborated by EEG. Some patients presenting to emergency rooms may receive multiple doses of antiseizure medications or even be intubated. For convulsive events, a major rise in serum CPK 8 to 16 hours after a convulsive event supports that an event was epileptic. The absence of such a CPK rise argues against such an event being a tonic–clonic epileptic seizure but would not exclude such a possibility. Prolactin measurements comparing a baseline nonictal sample to a sample drawn 10 to 20 minutes after the onset of the seizure may be of help when the postictal prolactin measure is twice that of the baseline measure. Results may be unreliable in the setting of dopamine antagonist or agonist use, tricyclic antidepressant use, breast stimulation, and syncope.

Telegram: @medical_k

www.konkur.in

Unfortunately, surveys of psychiatrists reveal that a substantial portion of psychiatrists believe that VEEG monitoring is not an accurate tool for determining if an event is a psychogenic nonepileptic seizure. A well-explicated characterization of the level of certainty in making the diagnosis of PNES is detailed in an ILAE task force report and can be applied in a variety of different scenarios, including healthcare facilities that do not have VEEG capability.

As most teens and adults who have PNES appear to have somatic symptom disorders as opposed to major depressive, anxiety, or bipolar disorder, psychopharmacologic therapy often has a limited role in habilitating such patients. Psychiatric consultation is sought to determine in a structured psychiatric interview if other diagnoses are present such as depression or anxiety, which may respond to psychopharmacologic intervention. Such consultation, however, is often of great benefit in identifying precipitating factors. In published studies, factors include school-related difficulties (9% to 46%); stressful family environment (8% to 67%); sexual/physical abuse (8% to 38%); fear of rejection/attention-getting (19% to 26%), and no precipitant found in 12% to 29% in various studies. DSM IV and ICD-10 psychiatric diagnoses have been reported in 6 studies. Results indicate 19% to 62% were found to have depression or anxiety, 7% to 41% had separation anxiety/school phobia, 8% to 12% have panic disorder, 6% to 12% have an exclusive general anxiety disorder, 2% to 8% have PTSD, and 16% to 59% had no psychopathologic diagnosis or was not reported in others.

A key element in the treatment of PNES is making a firm diagnosis of the habitual type of spell. This should be presented in a positive fashion to the parent or parents by the child neurologist/epileptologist. At the same time, it must be communicated to the family and child is not “faking” their seizures and that these involuntary symptoms have a biopsychosocial basis. Treatment in some situations may be as easy as simply identifying the nonepileptic nature of the events. Some series report a high rate of resolution within a few weeks of diagnosis of PNES. There should be clear communication that the treatment program must focus on the underlying psychological causes. In adults, multimodality therapies, including cognitive behavioral therapy (once weekly for 12 weeks), have been found to be more effective, with or without sertraline, compared to sertraline alone or treatment as usual. It may be important for some patients to continue to see the child neurologist to wean off antiseizure

Telegram: @medical_k

www.konkur.in

medications. Of course, ongoing care by neurology is required when patients have both PNES and epileptic seizures, which is not uncommon. Primary care physicians, school personnel, and social groups should be engaged in providing support to the treatment effort. This often requires communication about the appropriate response to the PNES spells in environments outside the home. Psychiatrists can play a critical role in the habilitation of such children not only by providing psychopharmacological treatment but also by assisting the neurology team in identifying appropriate local resources for cognitive behavioral therapy. Interventions in addition to cognitive behavioral therapy have included other modalities, including hypnosis, occupational therapy, art therapy, music therapy, and family therapy. Despite such efforts, some patients may still be refractory to treatment. Nonresponder rates are often lower in children and teens than in adults. It is reasonable in such situations to ask the neurologist/epileptologist to reassess the patient in light of the lack of improvement, especially if new symptoms arise.

Presurgical Psychiatric Evaluation

In surveys of Epilepsy Centers, 20% performed presurgical psychiatric evaluations on all patients prior to resective epilepsy surgery. Forty-five percent of centers referred for psychiatric evaluation only if prior psychiatric history is present or if presurgical neuropsychological evaluation advised psychiatric evaluation. One-fourth of such centers had their own dedicated psychiatrist, while 45% utilized different psychiatrists for this purpose. The rationale for performing such evaluations is that postoperative psychiatric complications are not rare, and identification of personal or family history of prior psychoses, depression, and anxiety can aid in the evaluation and therapy of any postoperative psychiatric disorder. Decades ago, some patients were denied epilepsy surgery if there was a major psychiatric disorder, but this is no longer judged to be a specific contraindication to surgery in an otherwise good surgical candidate. One study found, however, that the presence of major depression was a significant factor in reducing the likelihood of seizure freedom after temporal lobectomy. A single-center study utilizing both CBCL (Child Behavior Checklist) and clinical psychiatric diagnostic evaluation reported results on 40 children (aged 6 to 17 years who also had IQ above 70) who were undergoing evaluation for surgery for refractory partial epilepsy. Eighty-two percent had at least one axis I psychiatric diagnosis based on

Telegram: @medical_k

www.konkur.in

the clinical interview. ADHD was found in 40%. Anxiety was found in 32%, and depression was found in 20%. Two or more diagnoses were found in 28% of this group. The use of CBCL found broadband categories to be in the clinically significant range of 35% for internalizing problems and 25% for externalizing problems. Analysis of temporal lobe versus extratemporal foci in this group revealed that a similar proportion of both groups had attention and anxiety diagnoses, whereas CBCL data revealed that the temporal lobe foci patients had higher scores in depression-specific categories.

Adjustment Issues

Surveys have found that children with epilepsy have lower self-concepts and lower self-esteem than children with other chronic illnesses, such as diabetes or asthma. Lower social competence has been associated with lower IQ range, prior disruptive behaviors, and not so much with seizure variables. Half of the teens who have epilepsy state they do not feel stigmatized. However, they still often “keep it a secret.” Surveys of childhood and teen peers about epilepsy indicate major misperceptions supporting such stigmatization. Forty-six percent were not sure if epilepsy was contagious. Forty percent were not sure if people with epilepsy are dangerous, and only 31% would date a peer who is known to have epilepsy. Unfortunately, one survey revealed that 24% of parents believed that having a child with epilepsy in their own child’s classroom would be disruptive. Teachers tend to underestimate the learning abilities and athletic abilities of students with epilepsy and commonly report a lack of knowledge about how to handle a seizure in the classroom. As a consequence, many teachers and school personnel often advise unnecessary restrictions for students who have epilepsy. Many local chapters of the Epilepsy Foundation of America, many pediatric epilepsy centers, and other organizations provide educational programs for school nurses and school staff and offer teen and child support groups, parent support groups, and summer camp programs to help children with epilepsy overcome such stigma and promote a better quality of life.

TRAUMATIC BRAIN INJURY

TBI in children and adolescents is a major public health problem. The annual incidence of TBI in this age group is 400/100,000, and the

Telegram: @medical_k

www.konkur.in

male:female incidence ratio is at least 1.8:1. Incidence rates are related to median family income independent of age, race, or ethnicity. The proportion of TBI caused by motor vehicle accidents increases with age. The mechanism of injury in infants, toddlers, and young children is related to child abuse or falls in almost 50% of cases. Injury severity may be classified as mild (90%), moderate (7% to 8%), and severe (5% to 8%).

Pathophysiology

Diffuse injury and brain swelling that result in intracranial hypertension is more common in children than adults whereas focal injuries including intracerebral, subdural, and epidural hematomas are less common in children versus adults. Children have a higher frequency than adults of lesions in frontal white matter, orbitofrontal, and dorsolateral frontal regions. The reader is referred to a review by Serpa et al. on the pathophysiology of pediatric TBI.

Relationship of Psychiatric Disorders and Pediatric TBI

This review of psychiatric disorders in relation to pediatric TBI focuses primarily on studies that have used gold-standard psychiatric interview research assessments and less so on studies relying on parent reports and self-reports of behavior.

Preinjury Psychiatric Disorders. Prospective studies that used standardized psychiatric interviews found that 33% to 52% of consecutively treated children had a preinjury lifetime psychiatric disorder. Birth cohort prospective data have also supported a disproportionate increase in preinjury behavior problems in children who go on to have an injury compared with uninjured children. This finding may be related to higher impulsivity and risk-taking in children with externalizing disorders.

Postinjury Psychiatric Disorders. New-onset psychiatric disorders, termed “novel psychiatric disorders,” are characteristically heterogeneous. The term novel psychiatric disorders originated in the late 1990s, specifically in contrast to the term “new psychiatric disorder” used by Michael Rutter and his team in the 1970s and 1980s. New psychiatric disorders had been defined as psychiatric disorders which developed only in children with no preinjury psychiatric disorder. Novel psychiatric disorders could also occur in children with a preinjury psychiatric disorder

Telegram: @medical_k

www.konkur.in

if the child developed a different psychiatric disorder after the injury. At least one-third of children who incur a TBI have a preinjury psychiatric disorder, and therefore the broadening the definition of the population of children who might develop psychiatric complications after TBI resulted in more representative research samples. The only disorder that is unique to brain injury is personality change due to TBI, which will be discussed below. Novel psychiatric disorders have been documented to be related to injury variables. For example, they occurred in 54% to 83% of children after severe TBI, in 7% to 25% after mild/moderate TBI, and in 3% to 14% of children with orthopedic injuries without TBI. The finding that a novel psychiatric disorder is related to lower fractional anisotropy in bilateral frontal and temporal lobes, bilateral centrum semiovale, and bilateral uncinated fasciculi suggests that diffuse white matter damage is central to the emergence of psychiatric disorders after TBI. Recently it was reported that gray matter lesions of the superior frontal gyrus, and orbital gyrus, in addition to frontal white matter lesions, were independently significantly associated with novel psychiatric disorders. Noninjury variables have also been related to novel psychiatric disorders, and these included preinjury psychiatric disorders, socioeconomic status/preinjury intellectual function, preinjury adaptive function, preinjury family function, and family psychiatric history. The relationship between novel psychiatric disorders or worsening of behavioral symptomatology and family function has been shown to be a bidirectional process. Across the range of injury severity, family outcome is associated with lower preinjury family function, the presence of novel psychiatric disorders, fewer sources of support, and more stressors. The only long-term prospective longitudinal psychiatric interview study of pediatric TBI found that a novel psychiatric disorder that was present at a 24-year follow-up was independently significantly related to the severity of the injury and preinjury lifetime psychiatric disorder. These findings are consistent with findings from a Swedish birth cohort study encompassing 13 years, over one million individuals, 9% of whom had a registry entry of at least one TBI. Mean follow-up from age 8 to 26 years found that TBI contributed to absolute risks of over 10% for specialist diagnoses of psychiatric disorders and low educational attainment, about 5% for disability pension, 2% for premature mortality, and a high relative risk for psychiatric inpatient hospitalization

Mild TBI in children and adolescents has become an area of public concern, especially in the area of sports injury. Recently, the first

Telegram: @medical_k

www.konkur.in

prospective controlled longitudinal psychiatric interview study of mild pediatric TBI versus orthopedic injury showed that novel psychiatric disorders occurred at a significantly higher frequency in the first 3 months postinjury, even when analyses were adjusted for potential confounders. Multipredictor analyses found that aside from mild TBI, other variables independently accounting for novel psychiatric disorders were preinjury lifetime psychiatric disorder, high versus low family psychiatric history, and worse socio-economic status. After the first 3 months postinjury, mild TBI no longer exhibited a higher frequency of novel psychiatric disorders. These new findings add to those of a 2016 systematic review which found that psychiatric and psychological problems were more prevalent when the mild TBI was associated with hospitalization, when the evaluation occurs earlier in the recovery phase, when there were multiple previous mild TBIs, in children with pre-existing psychiatric disorders when outcomes depended on retrospective recall, and when the comparison group was uninjured children rather than children with injuries not involving the head, for example, orthopedic injuries. It has been demonstrated that children with mild TBI are more likely than orthopedically injured controls to display transient or persistent increases in postconcussive symptoms in the first year after injury, especially with more serious injuries. The families of children with mild TBI experienced more distress and burden than their orthopedic injury counterparts, and this was closely related to postconcussive symptoms.

Specific Novel Psychiatric Disorders

PERSONALITY CHANGE DUE TO TRAUMATIC BRAIN INJURY. Personality change due to TBI (PC) is the most common and important novel psychiatric disorder, especially after severe TBI. Despite its name and relatively new classification under personality disorders in DSM5, it is arguably not a personality disorder but rather a disorder of clinically significant emotional and/or behavioral problems, including affective instability, aggression, disinhibition, apathy, and paranoia. Persistent PC has been found in approximately 40% of consecutively hospitalized children with severe TBI in an average of 2 years postinjury. PC (diagnosed by waiving a 1-year duration criterion) occurred in 5% of mild/moderate TBI but was always transient, suggesting that the duration of symptoms criterion has validity. The most common subtypes are those with significant affective instability,

Telegram: @medical_k

www.konkur.in

aggression, and disinhibition presentations. The severity of the injury and superior frontal gyrus lesions are related to PC in the first year postinjury, consistent with models of affective regulation implicating failure of dorsal prefrontal cortex modulation of affect generated from a ventral brain network. Second-year postinjury correlates of PC include the severity of the injury, frontal white matter lesions, and preinjury adaptive function, suggesting that recovery is limited by network damage and related to a preinjury reserve of functioning. PC is significantly comorbid with postinjury or secondary ADHD. The neurocognitive profile of PC that emerged from research comparing children with TBI meeting diagnostic criteria of PC versus no PC was characterized by lower performance on attention, processing speed, verbal memory, IQ, and executive function measures.

SECONDARY ATTENTION-DEFICIT/HYPERACTIVITY DISORDER. Secondary ADHD (SADHD) is the term given to ADHD that develops after TBI. The phenomenology includes all subtypes of ADHD, although inattentive symptomatology is the most pronounced. SADHD is related to the increasing severity of the injury and the concurrent adaptive and intellectual function, memory deficits, and family dysfunction in samples ranging from severe to mild TBI. In samples limited in range from moderate to severe, the findings are mixed except for adaptive function differences being still evident. The categorical diagnosis of SADHD, as well as postinjury ADHD symptoms, have been associated with greater psychosocial adversity and poorer preinjury family function. Imaging correlates of SADHD included orbital frontal gyrus, right putamen, and thalamic lesions, suggesting that damage to different locations along the same cortico-striatal-pallidal-thalamic loop can result in a similar phenotypic expression. A study of neurocognitive correlates of SADHD has shown that children with SADHD exhibited deficient attention, working memory, and psychomotor speed compared to children with preinjury ADHD. In addition, children with SADHD and the injured children who had neither SADHD nor preinjury ADHD were impaired compared to the children with preinjury ADHD with regard to planning. There were no group differences related to response inhibition which is considered a signature deficit in pre-injury ADHD.

Telegram: @medical_k

www.konkur.in

OPPOSITIONAL DEFIANT DISORDER/CONDUCT DISORDER. Novel ODD and conduct disorder have been associated with preinjury psychosocial adversity, lower socio-economic status, worse preinjury family function, lower early postinjury processing speed, lower preinjury adaptive function, and concurrent emotional lability symptoms. ODD symptoms have also been found to be associated with preinjury ODD symptoms, social class, and preinjury family function. Severity of injury predicted ODD symptoms after the first year postinjury and significantly accounted for change in ODD symptoms from before injury.

POST-TRAUMATIC STRESS DISORDER. Post-traumatic stress disorder (PTSD) can occur notwithstanding neurogenic amnesia. Studies have documented that new-onset PTSD occurs in 4% to 13% of pediatric TBI but that the presence of subsyndromal PTSD symptoms is quite common (68%) in the weeks after injury before declining to 12% by 24 months postinjury. PTSD symptoms were related to preinjury anxiety or mood disorder/symptoms, greater injury severity, postinjury anxiety and depressive symptoms, female gender, preinjury psychosocial adversity, and nonanxiety psychiatric disorders. Re-experiencing symptoms were associated with relatively intact right cingulum and hippocampus possibly because these structures are necessary in the elaboration of these particular symptoms. Hyperarousal symptoms were associated with relatively intact left orbitofrontal lesions and were associated with left temporal lesions.

OBSESSIVE-COMPULSIVE DISORDER AND ANXIETY DISORDERS. Novel obsessive-compulsive disorder has been associated with frontal and temporal lobe lesions and has occurred in the absence of striatal injury. Novel obsessive symptoms were associated with psychosocial adversity, female gender, and mesial frontal and temporal lesions. Novel anxiety disorders have included specific phobia, generalized anxiety disorder, and separation anxiety disorder. Preinjury anxiety symptoms and younger age at injury were related to postinjury anxiety symptoms. In addition, postinjury levels of stress and severity of brain injury were associated with mood/anxiety disorders. Superior frontal gyrus lesions have been associated with postinjury anxiety symptoms suggesting that damage to this region can result in affective dysregulation that includes anxiety as well as the

Telegram: @medical_k

www.konkur.in

affective instability of PC. One study found an association between fewer anxiety symptoms and orbitofrontal lesions.

MANIA/HYPOMANIA. Manic and hypomanic syndromes have occurred after pediatric TBI documented in case reports and in a prospective study in 8% of consecutively injured children. Careful consideration of the overlapping and more common syndromes of PC and SADHD should be taken before diagnosing a manic syndrome. Manic/hypomanic syndromes have been associated with frontal and temporal lesions, greater severity of injury, and a family history of mood disorder. The episodes are usually long-lasting, and there has been a similar frequency of irritability versus elation as the primary form of affective symptomatology.

DEPRESSIVE DISORDER. Novel depressive disorder has occurred in 11% to 33% of previous studies. Children with social disadvantages were at higher risk of developing depressive symptoms. Novel depressive disorder can be classified as nonanxious depression (no comorbid new-onset anxiety disorder) or anxious depressive disorder (comorbid novel anxiety disorder). Nonanxious depression was related to left inferior frontal gyrus and left temporal tip lesions, whereas anxious depression was related to right frontal lobe white matter and left parietal lesions. Anxious depression was related to PC and a family history of anxiety disorder.

AUTISM AND PSYCHOSIS. Nonaffective psychosis has been documented in only two cases in studies of consecutive admissions of children with TBI that used standardized psychiatric interviews. Autism has not been described after pediatric TBI in contrast to other forms of early brain injury. It is important clinically to distinguish autism from qualitatively distinct aberrations of pragmatic communication and social communication that have been complications of severe TBI in young children.

Case Formulation

A useful model suggested by Asarnow et al. that has guided the clinical approach to the psychiatric formulation in the assessment of children and adolescents with a history of TBI involves six pathways. (1) The psychiatric problem predates the injury and may increase the risk of its occurrence postinjury. (2) A preinjury psychiatric problem is worsened by

Telegram: @medical_k

www.konkur.in

the TBI. (3) The psychiatric problem is a direct (biologic) effect of the TBI. (4) The psychiatric problem is an immediate secondary effect of the TBI (e.g., a traumatic emotional response to the incident, such as PTSD). (5) The psychiatric problem is a long-term secondary effect of the TBI (e.g., disruptive behavior problems and lowered motivation from frustration resulting from new-onset cognitive problems). (6) The psychiatric problems are caused by factors other than the TBI.

Intervention

Prevention. Prevention is the most critical intervention with regard to pediatric TBI. This includes education with respect to the use of bicycle helmets, improving motor vehicle safety, limiting alcohol-related motor vehicle accidents, and reducing the risk of child abuse and neglect.

Nonpharmacologic Treatment

FAMILY THERAPY. Web-based family and teen problem-solving therapies have been developed to target behavioral problems after TBI. These included Online Family Problem-Solving Therapy (F-PST), either self-guided or therapist-guided, resulting in similar improvement based on parent ratings of adolescent behavior and executive function, whereas the corresponding face-to-face treatment was not associated with improvement. Earlier iterations of this type of therapy included counselor-assisted problem solving (CAPS), which is a 6-month web-based, family-centered treatment that focuses on problem-solving, communication, and self-regulation. CAPS and a similar treatment called teen online problem solving (TOPS) have been effective in multiple ways, including improving parent-rated behavioral executive functioning and externalizing problems in the children, as well as enhancing problem-solving and decreasing depressive symptoms in parents. Pilot research has demonstrated that cognitive-behavioral therapy for insomnia (CBT-I) in children with sleep disruption and persistent postconcussion symptoms leads to improved sleep quality, shorter sleep-onset latency, better sleep efficiency, fewer dysfunctional beliefs about sleep, and longer sleep time compared with children receiving treatment as usual. Other effective approaches have included general cognitive behavioral therapy and the restructuring of the child's environment to optimize behavioral supports.

Telegram: @medical_k

www.konkur.in

SCHOOL. The Individuals with Disabilities Education Act entitles children, especially those with severe TBI, to services. Furthermore, special education interventions target poor academic function related to a variety of permutations of academic skills deficits and emotional and behavioral problems, which may compound corresponding preinjury problems. For a more detailed review of educational and neuropsychological correlates and interventions for pediatric TBI, the reader is referred to Crowe et al.

Pharmacologic Therapies. A comprehensive review of pharmacologic treatment in pediatric brain injury by Feinberg et al. has concluded that there was a limited number of high-quality, clinically meaningful studies in the acute stage of injury and, therefore, evidence-based analysis that would inform clinicians' decisions on medication management was not feasible. Anecdotal guidelines only are therefore noted here. Mood stabilizing antiseizure medications and selective serotonin reuptake inhibitors can be helpful together with behavioral treatment for affective instability and aggression typical in PC. The disinhibited type of PC is difficult to treat. Neuroleptic medication may be helpful for the agitated or paranoid patient when the behavior is complicating rehabilitation and recovery, although usage must be balanced against potential risks in the alteration of neuronal recovery. There have been several positive reports of stimulant use for children with ADHD-like symptoms after TBI, although overall findings are mixed. In the absence of research data, depressive disorders after TBI may be treated with selective serotonin reuptake inhibitors as in corresponding syndromes in the absence of TBI.

Conclusion

Pediatric TBI is a major cause of morbidity and mortality and is thus an important public health problem. Particularly with severe TBI, the sequelae may be life-long. Mental health professionals have a key role to play in this field because psychiatric disorders are common both before and after injury. As in circumstances unrelated to TBI, psychiatric disorders and family function have a close relationship. Novel psychiatric disorders are associated with injury and psychosocial variables that can be recorded soon after injury, and this opens potential options for secondary prevention and early recognition of predictable outcomes. Neurocognitive, school, and adaptive function problems often occur after severe TBI, and effective treatment for the patient must address each of

Telegram: @medical_k

www.konkur.in

these domains of function. Research in psychosocial treatments is more advanced than psychopharmacological approaches at this point.

OVERALL SUMMARY

There are several striking similarities and differences with regard to psychopathology in children and adolescents with varying brain injuries discussed in this chapter. Psychiatric disorders occur commonly in each of the brain injury groups we have reviewed. The rates of psychiatric disorders are at least 27% (in uncomplicated epilepsy) and generally higher in the range of 50% to 60% in children with the other kinds of brain injury reviewed. The psychiatric disorders that manifest are typically heterogeneous, that is, there is no signature disorder that occurs in all brain-injured children. Comorbidity is also the rule rather than the exception. The disorder specific to brain injury is Personality change due to a general medical condition. Aside from this disorder, it is quite clear that the most common disorder in brain-injured children is ADHD, typically around 25% to 30%, except for FASD, where ADHD occurs at at least double that rate. The very high rate of ADHD associated with prenatal alcohol exposure may be due to a confluence of factors that include a particularly virulent teratogen, genetic factors, and poverty. There is accumulating evidence that ADHD associated with brain injury has different neuropsychological characteristics compared with developmental ADHD. Other psychiatric disorders such as depressive, anxiety, and ODDs that are present occur at similarly high rates across brain injury categories. Of the brain disorders reviewed in this chapter, Autism is most closely associated with prematurity and low–birth-weight. While it is true that children with autism have a relatively high rate of epilepsy, only a small proportion of children with epilepsy have autism. Standardized psychiatric interviews are more sensitive in detecting psychiatric disorders compared with behavior checklists in brain-injured pediatric populations, possibly because parents who complete the checklists have accommodated their child's limitations and often do not keep in mind a normative expectation.

IQ tends to be low average in children who are significantly affected by the brain injuries discussed in this chapter. Intellectual disability or IQ ≤70 is unusual. Deficits occur in multiple neuropsychological domains and

Telegram: @medical_k

www.konkur.in

again there is no signature neuropsychological deficit profile across brain injury groups.

Treatment for the psychiatric disorders associated with the brain injury groups generally rely on treatments designed for children and adolescents in general or even those used in adults with brain injury. This will remain the standard of care until more intervention research is conducted. The public health impact of brain injury-related psychopathology in children and adolescents is high because of its high frequency as well as the many years of illness burden when brain injury is acquired at a young age. There is an exceptional need for mental health researchers and clinicians to understand, develop treatments, and to intervene to improve the lives of young people with brain injury.

2.14 Neuropsychiatry of Neurometabolic and Neuroendocrine Disorders

Mark Walterfang, M.B.B.S. (Hons), Ph.D., F.R.A.N.Z.C.P., Ramon Mocellin, M.B.B.S., M.Sc., F.R.A.N.Z.C.P., Olivier Bonnot, M.D., Ph.D., and Dennis Velakoulis, M.B.B.S., M.P.M., Dip.Crim., D.Med.Sci., F.R.A.N.Z.C.P.

Metabolic and endocrine disturbances can have wide-ranging effects on the central nervous system (CNS). Neurons, because of their high metabolic level of activity and demand, are often acutely sensitive to derangements in systemic metabolic processes. As a result, disorders affecting systemic metabolism often have a very high rate of associated CNS disturbance, ranging from the severe—with gross neurodevelopmental disruption, encephalopathy, seizures, delirium, and/or coma—to the mild, with subtle cognitive and behavioral disturbance. A number of these disorders cause recognizable and significant psychiatric illnesses, including psychotic disorders, affective disturbance, anxiety disorders, attention-deficit disturbance, and other behavioral disturbances such as apathy, dysexecutive syndromes, and catatonia. For the purposes of this section, those disorders of metabolism and endocrine function associated with significant CNS disturbance will be referred to as *neurometabolic* and *neuroendocrine* disorders, respectively, and those associated with major neuropsychiatric syndromes will be highlighted.

The relevance of recognition of neuropsychiatric comorbidity in neurometabolic and neuroendocrine syndromes has both diagnostic and treatment importance. A number of these disorders can produce an accurate *phenocopy* of psychiatric illness, where illness presentation carries most or all the characteristic features of a psychiatric diagnosis. For example, a schizophrenia-like psychosis may develop in metachromatic leukodystrophy (MLD) that is otherwise indistinguishable

Telegram: @medical_k

www.konkur.in

from “typical” schizophrenia, at least until other features more typical of the primary neurometabolic illness supervene. Awareness of the types of disorders that may present as psychiatric illness phenocopies and their associated physical, cognitive, or neurologic concomitants allows for the appropriate recognition and diagnostic confirmation of an underlying metabolic or endocrine illness. In some circumstances, this may mean medical treatment of an endocrine illness, enzyme replacement, or substrate reduction therapy for a metabolic illness. Failure to recognize the underlying illness while focusing on psychiatric treatment alone can delay the institution of appropriate management and result in potentially irreversible CNS changes. However, it is not uncommon for these disorders to present with associated, and often atypical, features—such as cognitive or motor impairment or other systemic organ involvement (such as hepatosplenomegaly)—and the recognition of “atypicality” in the presentation of psychiatric illness, and the associated disorders that may result in secondary atypical presentations, is an important skill for all psychiatrists working in healthcare settings.

Most clinicians will undertake a routine set of investigations for underlying “organic” causes of psychiatric illness at the initial presentation, including screening for thyroid illness, infective disease, electrolyte disturbance, and renal and kidney function, in addition to brain imaging and/or electroencephalography (EEG). Although these tests are relatively high yield and detect a number of illnesses producing secondary psychiatric syndromes, less common but no less significant conditions are often missed. Literally, hundreds of metabolic disorders have been described, and only a very limited number of these are screened for in the neonatal period (usually less than 10 in most centers). This may provide the clinician with a false assurance that any significant and/or serious metabolic disorders will already have been detected or excluded. This situation is further complicated by the fact that the age of onset and presentation, in addition to disease expression, vary greatly across and within these disorders, and disorders that present later or in a less severe form are often missed by screening processes during the neonatal and childhood periods, or are not suspected in the setting of non-specific presentations (e.g., recurrent emergency department presentations with abdominal pain in a patient with acute intermittent porphyria [AIP]).

Those metabolic disorders that present initially, or predominantly, with neuropsychiatric syndromes generally have their onset in the period of the

Telegram: @medical_k

www.konkur.in

life cycle associated with the onset of the majority of psychiatric illnesses, that is, adolescence or early adulthood—the “psychiatric window” where the majority of psychiatric illnesses manifest. The disorders that present during this window include inborn errors of metabolism that affect cellular function in the CNS. A wide range of phenotype–genotype correlations occur in such disorders, as differing mutations in the gene for the protein serving a key function in metabolism will result in different structural or conformational changes to the protein product and differential metabolic effects. For example, some mutations in the gene encoding for the NPC1 protein in Niemann–Pick disease type C are associated with an early onset of illness, severe intellectual disability, and death in childhood, whereas others are associated with a less significant deficit in the function of NPC1, and thus less disruption to intracellular cholesterol metabolism (even falling into the “normal” range), and a presentation in adolescence or early adulthood as opposed to early childhood. The adult-onset forms of these diseases often form a minority of cases of these disorders, although they will generally respond as favorably to primary treatments for the disorder; these late, “nonclassical” presentations are often, unfortunately, missed. Additionally, some carriers with autosomal recessive disorders who were previously considered asymptomatic (such as female carriers with adrenomyeloneuropathy) have been shown to have attenuated syndromes often involving subtle psychiatric disturbance. For most of these disorders, gross metabolic disturbance results in severe impairment of CNS function (such as delirium, seizures, or encephalopathic presentations), with moderate impairments often resulting in dementia (or intellectual disability in children) and movement disorders. More subtle impairments, however, are less likely to disrupt these core vegetative and functional systems of the brain but rather disrupt higher-order functions that are much more dependent on highly synchronous cortico-cortical and subcortical connectivity, with the result being a disturbance to higher cognitive functions and a predilection for major mood and psychotic disorders. As these systems tend to mature later in the brain’s neurodevelopmental trajectory, those disorders that alter or interrupt later neurodevelopment are more likely to cause neuropsychiatric syndromes. For progressive neurometabolic disorders, it is not uncommon for these disorders to present initially with a neuropsychiatric syndrome, which may be diagnosed and treated as a primary psychiatric illness. As the pathologic effect of the metabolic

Telegram: @medical_k

www.konkur.in

derangement impinges further on the CNS and begins to result in degenerative change, frank neurologic illness, and dementia often supervene.

In addition to those metabolic disorders that impact neurodevelopment, some metabolic disorders are associated with episodic but reversible metabolic disturbances (such as the acute porphyrias or urea cycle disorders [UCDs]). As opposed to impacting late-maturing developmental networks, these disorders impact metabolically on presumably mature or normally developed brain systems. Those disorders that show a predilection for neuropsychiatric disturbance are more likely to affect brain regions (such as the frontal or temporal cortical regions) or transmitter systems (particularly monoaminergic or glutamatergic systems) that are strongly associated with psychiatric illness. Similarly, the majority of major endocrine disorders that are associated with psychiatric disturbance do so in the setting of an otherwise intact CNS. These endocrine systems are crucially involved in energy metabolism, cell turnover, and downstream metabolic effects. Elevated rates of psychiatric disturbance in these disorders occur via a direct effect of the altered hormonal system on particularly vulnerable cellular populations or neurotransmitter systems, such as the effects of elevated cortisol levels on hippocampal neurons or thyroid hormone on serotonin turnover.

NEUROMETABOLIC SYNDROMES

Lysosomal Disorders

The lysosome is a subcellular organelle that is manufactured by the Golgi apparatus and contains a number of hydrolytic enzymes such as proteases, lipases, nucleases, and polysaccharidases. They function as the “garbage disposal” system of the cell via phagocytosis (digestion of extracellular material), endocytosis (digestion of cell surface proteins), and autophagy (digestion of old or damaged intracellular organelles or structures). Macromolecules (DNA, RNA, proteins, glycoproteins, lipids, and phospholipids) transported to lysosomes are degraded by enzymatic “factories,” which then pass out their monomeric components for reutilization. Impairment in the function of a lysosomal enzyme occurs if it is structurally altered, alteration occurs to a cofactor protein, or enzyme transport is affected. Each enzyme is specific for breaking a particular chemical bond, as opposed to a particular substrate macromolecule. Over

www.konkur.in

70 lysosomal enzymes are known, and more than 40 disease syndromes involving defective enzyme function have been characterized. Many of these disorders present both in childhood and adulthood, and for those that present in adolescence or early adulthood—the period of onset of most major psychiatric disorders—the rate of major psychiatric illness is not unexpectedly elevated, whereas childhood presentations commonly result in major intellectual disability and older adult presentations in dementia, in addition to frank neurologic disturbance. Of those lysosomal storage disorders (LSDs) that present in adult life, those strongly associated with neuropsychiatric presentations include those involving defective breakdown of sphingolipid components (MLD, Fabry disease, GM2-gangliosidosis/Tay–Sachs disease (TSD), Niemann–Pick type C disease), glycoproteins (α-mannosidosis [AM]), and cholesterol and lipids (neuronal ceroid lipofuscinosis [NCLs]).

Metachromatic Leukodystrophy

MLD is an autosomal recessive, incompletely penetrant genetic deficiency of the lysosomal enzyme arylsulfatase A (ASA) that occurs in 1.5 per 100,000 individuals and was first described in 1933. ASA hydrolyzes various sulfatides, including sulfate-containing lipids of the CNS. Lysosomal sulfatide accumulates in the brain, peripheral nerves, kidney, and gallbladder, but particularly in myelinated structures, seen as metachromatic granules on histologic examination and widespread loss of myelin. MLD is protean in its presentations such that in younger patients, seizures and motor symptoms predominate with psychiatric manifestations and dementia frequently occurring prior to the onset of motor symptoms in adult patients, particularly those with the I179S mutation; the severity is inversely correlated with the degree of residual ASA activity. The adult form appears to cleave into two distinct phenotypes, one with a predominantly motor cerebello-pyramidal presentation and the other with a predominantly psychiatric presentation. Up to half of the patients with illness onset between 10 and 30 years of age present with psychotic symptoms, including auditory hallucinations, systematized delusions, formal thought disorder, catatonic posturing, and inappropriate affect. As the illness progresses, other neurologic symptoms supervene, such as seizures, chorea, or dystonia. Dementia is an inexorably progressive component of the illness, initially presenting as attentional disturbance, reduced speed of processing and executive

Telegram: @medical_k

www.konkur.in

impairment, and may present as a phenocopy of frontotemporal dementia; if disinhibition is a prominent feature, it may present as a phenocopy of hypomania. Diagnosis is made by demonstrating reduced enzyme activity in leukocytes or skin fibroblasts. Magnetic resonance imaging (MRI) generally demonstrates typical periventricular white matter changes sparing subcortical U-fibers and often shows pathology with a frontotemporal preponderance (Fig. 2.14–1).

FIGURE 2.14–1. Two-axial FLAIR images from a 32-year-old male with genetically confirmed metachromatic leukodystrophy (MLD). White matter involvement is symmetrical, with an anterior preponderance superiorly, and characteristic involvement of the patient's corpus callosum. (Supplied by author.)

Treatment is generally symptomatic, although bone marrow transplantation has shown benefit in some patients, and intrathecal enzyme replacement therapy is in phase II trials. Adolescent/adult MLD provides an intriguing model for the understanding of the neurobiology of psychosis, as it interrupts myelinative processes that occur during this critical period of neurodevelopment, in particular frontotemporal myelination. As frontotemporal connectivity is known to be impaired at both functional and structural levels in schizophrenia, MLD appears to have an almost uniquely psychotogenic propensity in this age group and suggests that a neuropathologic process that interrupts the normal development of connectivity between these cortical regions in this crucial late neurodevelopmental window can result in psychosis. It has also been

Telegram: @medical_k

www.konkur.in

shown that some treatment-refractory schizophrenia patients have ASA pseudo-deficiency or intermediate ASA levels (assessable with leucocyte enzyme assay), suggesting that this may be a disease modifier or potentially an independent risk factor for the development of psychosis through its disruption of myelination.

Fabry Disease

Fabry disease is an X-linked recessive disorder of the lysosomal enzyme α-galactosidase A (GLA), resulting in the accumulation of the glycolipid globotriaosylceramide (Gb3) in blood vessels and other tissues (Fig. 2.14–2), which occurs in 1 in 40,000 to 60,000 males. Hemizygous males are particularly affected, with females varying from asymptomatic to severely affected due to the degree of X-inactivation. The major clinical manifestations of Fabry disease reflect the particular impact of the disorder on the vascular endothelium. Early clinical features with onset in childhood or adolescence include angiokeratomas and acroparesthesias. Angiokeratomas are dark, punctate vascular lesions most prevalent between the umbilicus and the knees but also seen on the oral mucosa and conjunctiva. Acroparesthesias are acute episodes of severe pain in the fingers and toes lasting days to weeks precipitated by exercise, fatigue, or fever, which are very disabling. Chronic pain syndromes associated with acroparesthesias may continue into adulthood and account for much of the associated psychiatric comorbidity. Corneal or lenticular opacities and hypohidrosis are also early manifestations, and patients may also develop tinnitus and hearing loss. Disease progression is marked by vascular disease, resulting in kidney impairment, cardiovascular disease, and stroke in adulthood. Brain MRI often demonstrates subcortical changes in periventricular white matter and the basal ganglia, thalamus, and brainstem. Cognitive impairment may be detected via formal neuropsychological testing and often presents as impaired processing speed, attention and executive functioning, likely reflecting the impact of subcortical vascular ischemia. Depressive disorders, often meeting the criteria for severe clinical depression, occur in up to half of all sufferers and are most strongly associated with the degree of peripheral pain and anhidrosis, suggesting that it reflects the burden of disease rather than being a poststroke phenomenon or associated with subcortical vascular change. Anxiety is also commonly reported; other psychiatric syndromes appear relatively rare. The severity

Telegram: @medical_k

www.konkur.in

of depression and anxiety also appears to predict the degree of social and occupational dysfunction. Symptomatic treatment of depression is often effective; however, enzyme replacement therapy with agalsidase-alpha or -beta may prevent some of the physical manifestations of Fabry disease that appear to be causally related to depression in this disorder; other treatments are symptomatic, including anticonvulsants, anticoagulants, and antihypertensives.

FIGURE 2.14–2. Fluid-attenuated inversion recovery magnetic resonance image demonstrating mild (*left*) white matter lesions (*arrows*) in a 39-year-old woman with Fabry disease, and more significant (*right*) white matter lesions in a 41-year-old woman with the same disease. White matter lesion severity in male and female patients with Fabry disease. *Neurology*. 2005;65(4):600, Figure 1, with permission. doi: 10.1212/01.wnl.0000173030.70057.eb. © American Academy of Neurology.)

Gaucher Disease

Gaucher disease (GD) is the most common hereditary LSD due to a deficiency in β-glucocerebrosidase (GBA1) occurring in 1 in 50,000 individuals, which results in the accumulation of glucocerebroside in macrophage lysosomes. GD carrier status has more recently been shown to be the most common genetic risk factor for Parkinson disease (PD) because of the molecular relationship between glucocerebrosides and

Telegram: @medical_k

www.konkur.in

alpha-synuclein. These are deposited in a variety of tissues, including marrow, liver, spleen, and brain. Type I GD is “non-neuronopathic” as the brain, and spinal cord are thought to be spared; this presents with hepatosplenomegaly, anemia, leukopenia, and thrombocytopenia in addition to skeletal bone lesions. Types 2 and 3 (“neuronopathic”) affect the CNS, with type II causing progressive severe disease in infancy and type III being more indolent and often associated with survival into adulthood, with the development of seizures, ataxia, and gaze palsy being common neurologic presentations. It is known, however, that even GD1 patients have some neuronal involvement, with astrogliosis and alpha-synuclein deposition occurring in neuronal populations, but with only type I patients being spared neuronal loss. GD1 patients may demonstrate subtle cognitive deficits, largely in attention and memory; in GD3 patients, cognitive function can vary widely—from severe impairment to normal functioning—according to the severity of the disease. Depression and anxiety are not uncommon in GD1 patients, at approximately three times the rate of the normal population. Depression in GD patients is known to respond to antidepressant medication. Enzyme replacement therapy in GD is associated with significant improvement in mood and psychological functioning, with similar improvements reported in quality of life, even though intravenous enzyme therapy does not significantly cross the blood–brain barrier. Notably, heterozygosity for GBA1 disease-causing mutations is now known to be the most significant genetic predisposition to PD, with 5% of PD patients carrying a GBA1 mutation, compared to 1% of the healthy population.

GM2 Gangliosidosis (Tay–Sachs Disease)

TSD is an autosomal recessive lipid storage disorder caused by the accumulation of GM2-gangliosides within neurons due to a deficiency in β-hexosaminidase A (HEX-A) and occurs in 1 in 300,000 individuals, although it is as common as 1 in 3,000 in the Ashkenazi Jewish population—and thus is part of carrier screening for some individuals prior to childrearing. HEX-A deficiency in lysosomes impairs the catabolism of gangliosides from the neuronal cell membrane, resulting in the accumulation of lysosomal gangliosides (Fig. 2.14–3). This leads to secondary axoneuronal changes, particularly axon hillock outgrowth to form “meganeurites” with ectopic dendritogenesis and focal axonal enlargements known as *axonal spheroids*, both of which may alter

Telegram: @medical_k

www.konkur.in

neuron-to-neuron microconnectivity. Additionally, ganglioside accumulation results in direct neurotoxicity, altered neuronal electrical properties, inappropriate apoptosis, or an inflammatory response. In infantile or childhood forms, severe neurologic impairment usually results in death within 3 to 10 years. A later, or adult-onset, form of TSD has been described and may be associated with having at least one allele (most commonly the G269S mutation) associated with residual enzyme activity. In this late-onset form, psychiatric symptoms may co-present with or predate the development of neurologic disturbances in early adulthood. Patients present with a speech disorder, gait disturbance, saccadic eye movement abnormalities and tremor, with normal or near-normal cognitive function, although subtle deficits in executive function, processing speed, and memory may be present in up to half of patients. Brain MRI often shows significant cerebellar atrophy, although cortical atrophy may also be seen. Neuropsychiatric presentations occur in up to half of late-onset TSD patients, predominantly psychosis, which may occur in 30% to 50% of adult patients, marked by disorganization, auditory and visual hallucinations, and catatonia. Affective disorders, including mania and depression, have been occasionally reported. Patients only partially respond to neuroleptics or lithium and are often very sensitive to motor side effects of these medications; neurologic worsening has been described with typical antipsychotics and tricyclic antidepressants (TCAs). Importantly patients with psychotic illness appear to respond to electroconvulsive therapy (ECT).

Neuronal Ceroid Lipofuscinosis

Telegram: @medical_k

www.konkur.in

The NCLs, sometimes referred to as Batten disease in childhood, are a group of neuronal storage disorders that are collectively the most common neurodegenerative disorders in childhood, with a frequency of 1 in 20,000 to 40,000. Accumulation of abnormal lipopigments with characteristic ultrastructure in lysosomes, particularly in neurons, characterizes NCLs. Mutations in at least 10 genes that encode for a range of proteins, all involved in lysosomal catabolism and recycling of proteins and lipids, have been shown to be responsible for this group of disorders. These include lysosomal enzymes and proteins (CNL1, 2, 5, 10, and 13), membrane-associated cytoplasmic proteins (CLN4 and 14), a range of transmembrane proteins (CLN3, 6–8 and 12) and a soluble lysosomal protein (CLN5). Lipopigment accumulation diffusely affects cortical and subcortical neurons, but particularly the hippocampus and entorhinal cortex, and is associated with significant glial activation that precedes rather than follows neuronal loss. Alteration in axonal and synaptic function due to ultrastructural change occurs across the NCLs.

Adult neuronal ceroid lipofuscinosis (ANCL), also known as Kufs disease, is generally inherited in a recessive fashion (with the rare dominant Parry disease [CLN4] being dominantly inherited) and makes up between 2% and 10% of all NCLs, and unlike childhood forms of the disease, adults rarely have retinal pathology. Dominant pedigrees have been shown to have pathogenic variants in the *DNAJC5* gene, and recessive pedigrees have variants in *CLN6* or *CTSF* and less commonly in *GRN* or *CLN5*. Symptoms most commonly appear at the beginning of the fourth decade but may be present early in the second decade. Two clinical forms of ANCL have been described: a progressive myoclonic epilepsy form associated with debilitating action myoclonus, photosensitivity and ataxia (type A), typically associated with pathogenic variants in *CLN6* or *DNAJC5*, and a neuropsychiatric/cognitive form (type B) characterized by dementia, psychiatric disturbance, and dyskinesia, with epilepsy usually absent, usually due to pathogenic variants in *CTSF*.

Psychosis occurs in up to 25% of patients, particularly in adolescent and early adult patients, with characteristic hallucinations, delusions and thought disorder, and occasionally catatonia. A mood disturbance is particularly common, and OCD has also been described. Patients present cognitively with slowing, attentional disturbance, and impaired new learning; older patients may present with a frontotemporal dementia-like picture or a Kluver–Bucy type syndrome.

Telegram: @medical_k

www.konkur.in

Diagnosis traditionally rested on the identification of characteristic inclusions in brain or skin punch biopsy, but pathologic interpretation in peripheral tissues can be challenging and is being supplanted by molecular genetic diagnosis. MRI often shows cerebral and cerebellar atrophy, and callosal thinning, while SPECT shows regional cortical hypoperfusion. Treatment is symptomatic, although they may be sensitive to extrapyramidal side effects such as dystonia and neuroleptic malignant syndrome, as NCL patients may have muscle membrane pathology comorbid with changes in the CNS.

α-Mannosidosis Type II

AM is a recessively inherited and rare LSD that results from a deficiency of α-mannosidase, which causes lysosomal accumulation or undigested oligosaccharides, with a frequency of 1 in 500,000 individuals. AM is characterized by mild to moderate intellectual disability, hearing loss, skeletal changes, and recurrent infections secondary to immunodeficiency, with an indolent form (type II) occurring in the minority of patients who survive to adulthood. The deficiency of AM results in the intralysosomal accumulation of mannose-rich oligosaccharides and the formation of storage vacuoles in neuronal and glial cells, which impairs myelin formation. Neuropathologically, AM appears to initially affect myelinated structures before progressing to involve the neuronal body. In type II AM, the predominant clinical features are cerebellar ataxia, hearing loss, neuropsychological impairment, and retinopathy. Diagnosis rests on the demonstration of a pattern of urinary oligosaccharides and reduced enzyme activity in leukocytes or fibroblasts. MRI scanning shows periventricular T_2 hyperintensities and cortical and cerebellar atrophy (Fig. 2.14–4) and may show iron accumulation in the basal ganglia. Up to 25% of type II AM patients over the age of 15 develop clear psychiatric illness, predominantly a psychotic disorder characterized by delusions, hallucinations, and confusion. Generally, psychosis presents with neurologic manifestations, although it may rarely present as a prelude to frank neurologic disturbance. Like many LSDs, bone marrow or peripheral blood cell transplantation is the only current viable treatment option, although enzyme replacement therapy using velmanase-α, a recombinant form of the enzyme, may assist patients with mild to moderate disease.

Peroxisomal Disorders

Telegram: @medical_k

www.konkur.in

The peroxisome is a subcellular organelle that plays a role in the breakdown of fatty acids, the degradation of hydrogen peroxide (released via oxidation of fatty acids), membrane phospholipid and cholesterol synthesis, and the metabolism of amino acids. Unlike lysosomes, the peroxisomes bud off from the endoplasmic reticulum. Disorders of biogenesis (formation) of the peroxisome are generally fatal during infancy. Defects in single enzymes of the peroxisome may also cause disease compatible with survival well into adult life, and at least one of these, X-linked adrenoleukodystrophy (X-ALD), the most common peroxisomal disorder, is known to be associated with psychiatric illness.

X-linked Adrenoleukodystrophy. X-ALD is an X-linked recessive disorder occurring in 1 in 20,000 births and is caused by mutations to *ABCD1*, the gene for a peroxisomal membrane protein that β oxidizes very–long-chain fatty acids (VLCFAs). This leads to the accumulation of saturated VLCFAs in brain white matter and adrenocortical cells predominantly, which impairs membrane stability, but oxidative stress and bioenergetic failure, particularly in mitochondria, are thought to play major roles in the pathophysiology of the disease. It predominantly affects males, although some female carriers can be affected. In adults, it presents in either a predominantly cerebral form (5% of cases), marked by an inflammatory demyelinating process, or an adrenomyeloneuropathic form (AMN, 45% of cases), in which neuronal dysfunction is predominantly a distal axonopathy affecting the dorsal columns and corticospinal tract. The majority of other presentations are of the childhood cerebral form, which is rapidly progressive over 2 to 3 years. Both adult forms also present with adrenocortical insufficiency, often indistinguishable from primary Addison disease. The adult cerebral form shows a predilection for neuropsychiatric presentations, although the neurobiology of this is unclear. Demyelinative changes are most prominent in the parietal and occipital cortex as well as the thalamus, callosum, and brainstem (Fig. 2.14–5), although more anterior cortical regions may be involved. MRI frequently shows symmetrical white matter hyperintensity that begins in the splenium of the corpus callosum and spreads into neighboring posterior regions on T_2-weighted imaging. At presentation, a significant proportion of adult-onset patients present with psychiatric disturbance, most commonly behavioral changes. Mania and affective psychosis appear to be the most common neuropsychiatric

Telegram: @medical_k

www.konkur.in

presentations, more so than schizophreniform illnesses, although the latter does occur. Early attentional and executive changes are also common. When white matter changes occur in a more anterior distribution, patients may even show a frontotemporal dementia-like presentation. Psychiatric presentations may precede motor or cognitive changes by some years, and as in other organic psychiatric illnesses, patients often show treatment resistance. The AMN form, the most common form of ALD among adults, was thought to affect only the peripheral nervous system; however, subtle cerebral manifestations of the disorder are often present, and the rate of depressive illness appears to be elevated at least twofold. Some patients may present with mood changes subsequent to adrenal insufficiency, which reverse with appropriate corticosteroid replacement therapy. AMN patients may also show subtle neuropsychological changes that affect the speed of processing and executive functioning. There is no primary treatment for X-ALD, although bone marrow transplantation has provided some stabilization in younger patients with early disease, and the oral administration of 4:1 glyceryl trioleate and glyceryl trierucate ("Lorenzo's Oil") normalizes plasma VLCFA levels but does not improve neurologic function in already symptomatic or adult patients. A current trial is examining the role of pioglitazone, an agonist of the PPARγ pathway of mitochondrial biogenesis which has been shown to halt axonal degeneration in a mouse model of the disease in X-ALD patients.

Other Enzyme Deficiency Disorders

Acute Intermittent Porphyria. AIP is one of the porphyria disorders group, where defects in heme biosynthesis result in excessive secretion of urinary porphyrins and their precursors; a number of heme synthesis pathway intermediates are neurotoxic. Most of the porphyrias are inherited in a dominant fashion. The incompletely penetrant, autosomal-dominant AIP results from defects in the enzyme porphobilinogen (PBG) deaminase, which speeds the conversion of PBG to hydroxymethylbilane, and occurs in 1 in 20,000 individuals. Deficient activity of this enzyme results in the accumulation of porphyrin precursors PBG and aminolevulinic acid (ALA), which are thought to be neurotoxic. This enzymatic deficit becomes apparent in situations that require an increase in heme synthesis, including fasting, menstruation, intercurrent medical illness, and drugs that induce the cytochrome P450 system, such as alcohol estrogens, barbiturates, and sulfonamides, and presents most

Telegram: @medical_k

www.konkur.in

commonly in women of child-rearing age. Coproporphyria, a dominantly inherited deficiency of coproporphyrinogen oxidase, can present identically to AIP in addition to cutaneous findings (bullous lesions, skin fragility, and scarring).

The periodic “madness” of King George III has in recent decades been considered to be secondary to AIP, in addition to being implicated as illnesses affecting the work of Van Gogh and Soren Kierkegaard. AIP has been shown to be significantly overrepresented in a sample of 4,000 psychiatric inpatients (1 in 500 compared to a community rate of 1 in 100,000), emphasizing its predilection for psychiatric illness. The “classical triad” consists of abdominal pain, psychiatric disturbance, and peripheral neuropathies (mostly motor and often mimicking Guillain–Barré syndrome) during episodes, although psychiatric symptoms alone may be the single presenting feature. Of clinically symptomatic cases, a psychiatric disturbance occurs in up to half of all cases, half of which are psychotic episodes, although depression, anxiety, and delirium may also be the main presenting symptoms. The intermittent “attacks” of neuropsychiatric disturbance may result in a misdiagnosis of schizophrenia; additionally, the high likelihood of abdominal pain during attacks can result in a diagnosis of a somatoform disorder. More chronic porphyrias have been associated with elevated rates of anxiety and depression. How PBG and ALA accumulation causes neuropsychiatric disturbance is unclear. Explanatory hypotheses have included oxidative stress, vascular change, and demyelination, although it may be that ALA’s structural similarity to γ-aminobutyric acid (GABA) results in an impaired release of GABA from synapses of GABAergic inhibitory neurons and reductions in heme-dependent enzymes causing increased serotonin turnover and reduced nitric oxide activity.

Diagnosis of AIP rests on the demonstration of elevated urinary ALA and PBG and red cell PBG deaminase activity; for coproporphyria, urinary coproporphyrin levels should be assessed. Gross elevations of urinary ALA and PBG will often turn urine amber or purple in direct sunlight; it is imperative to collect specimens carefully (such as a 24-hour collection of urine in light-protected containers and correctly preserved). Management involves correct identification and avoidance of precipitants if possible. During an attack, treatment includes the reversal of contributing illnesses, intravenous hydration, carbohydrate loading to inhibit heme synthesis, and hematin or heme arginate to provide negative feedback to the heme

Telegram: @medical_k

www.konkur.in

synthetic pathway. Psychopharmacological management of AIP involves judicious use of medication that will not worsen the biochemical deficit, which for psychosis includes chlorpromazine (Thorazine) and droperidol (Inapsine), fluoxetine (Prozac) for depression, lithium for mania, and lorazepam (Ativan), triazolam (Halcion), and temazepam (Restoril) for anxiolysis and sedation.

Phenylketonuria. Phenylketonuria (PKU), an autosomal recessive disorder with an incidence of 1 in 10,000 to 20,000, is caused by mutations in the gene for phenylalanine hydroxylase (*PAH*) that converts the amino acid phenylalanine (PhE) to tyrosine. Mutations in both copies of the gene for *PAH* result in inactive or deficient enzyme levels, and accumulated PhE is converted to phenylketones, which are detectable in the urine. Resultant low levels of tyrosine, the precursor for the monoamines dopamine and serotonin, causes monoaminergic depletion in the CNS and severely disrupt normal neurodevelopment. Additionally, reduced large neutral amino acid (LNAA) availability causes reduced protein and cholesterol synthesis, impaired synaptogenesis and myelination, and altered glutamatergic neurotransmission. Hypomyelination occurs in untreated and early-treated patients; increased T_2 signal on MRI scanning is seen in most patients in frontal but particularly parieto-occipital zones with magnetic resonance spectroscopy (MRS) demonstrating increased cerebral PhE that tightly correlates with serum PhE levels. Functional MRI demonstrates altered connectivity within and between prefrontal cortical regions; diffusion tensor imaging (DTI) has also demonstrated impairments in white matter integrity, and these appear to underpin the executive deficits seen in PKU patients.

PKU sufferers require an individually tailored diet of foods low in PhE and supplemented with tyrosine. Routine screening of newborns and the universal initiation of dietary restriction within the first 3 months of life have essentially eliminated the severe, irreversible cognitive deficits, and behavioral disturbance associated with untreated PKU. A reduced PhE diet maintained for the first decade of life is associated with essentially normal cognitive outcomes, although some controversy exists as to whether relaxing dietary restrictions in the preadolescent phase ("early treated" patients) is associated with greater psychiatric disturbance than in PKU sufferers in whom dietary control is not relaxed ("consistently treated" patients). Early treated patients are described as showing elevated rates

Telegram: @medical_k

www.konkur.in

of depression, anxiety disorders (particularly agoraphobia), attention-deficit disorder, and more nonspecific psychosocial adjustment issues in adolescence when compared to matched healthy individuals. Compared to individuals with chronic illnesses such as diabetes, they show elevated rates of anxiety disorders, suggesting that this is unlikely to be an effect of adjustment to chronic illness. Elevated rates of psychiatric and cognitive illness appear to directly negatively affect psychosocial outcomes, with a higher proportion of PKU patients remaining unmarried, childless and/or living with their parents than their unaffected peers. Cognitive impairment also relates directly to the degree of past treatment, with untreated patients showing intellectual disability and developmental delay; early-treated patients may show subtle reductions in IQ and executive and attentional impairment. Prefrontal dopaminergic neurons are particularly vulnerable to decreased tyrosine availability, and mild elevations in PhE to tyrosine ratios (a marker of dopamine availability) in these patients in whom a dietary restriction is not maintained are associated with executive impairment and may underpin the adolescent and early adulthood psychiatric disturbance seen in these patients. Acute tyrosine depletion in healthy adults is associated with depression, anxiety, and executive disturbance and may provide a model for psychiatric and cognitive disturbance as a result of a prefrontal hypomonoaminergic state as a result of elevated PhE. Additionally, impairment of oligodendrocyte function may impair myelination in PKU (Fig. 2.14–6). Frontotemporal myelination, in addition to the dopaminergic innervation of the prefrontal cortex, peaks during adolescence, and the disruption of these processes may result in neuropsychiatric illness in this patient group. Animal models show that hypomyelination has been partially restored with dietary control, and some human studies show an improvement of psychiatric, cognitive, and imaging parameters with improved dietary control—even in individuals who have been “off diet” for years. However, perhaps less than 20% of adults maintain dietary control throughout adulthood, with the impact of diet on social interactions being the most commonly reported impediment for patients; discontinuation in adulthood is associated with poorer social, educational, and health outcomes, but re-engagement of “lost” patients may allow for some reversal.

Urea Cycle Disorders. UCDs result from aberrant metabolism of waste nitrogen, created by the breakdown of proteins and related nitrogenous molecules; the cycle is dependent on six co-ordinated enzymes and two transporters within the mitochondria and the cytosol and are found in hepatocytes only. They are recessive disorders, other than OTC deficiency (see below), which is an X-linked disorder; their prevalence varies from 1 in 10,000 to 35,000. While a third of patients present early in life, the remainder present outside the postnatal period, and adult presentation—particularly with neuropsychiatric illness—is not uncommon. The cardinal biochemical manifestation is hyperammonemia, and in the neonatal period—when the deficit is usually severe—this may present with somnolence and failure to feed, progressing to seizures and cerebral edema. When the biochemical deficit is milder, it may present only in situations of metabolic stress (such as systemic infection or pregnancy) and hyperammonemia when milder is associated with vomiting, headache, lethargy, sleep disturbance, and a range of neuropsychiatric symptoms, including agitation, psychosis, and confusion.

Telegram: @medical_k

www.konkur.in

In very mild patients, the diagnosis is often missed, but a clue can be the avoidance of a high-protein diet, with some patients becoming vegetarian due to the association between protein intake and mild encephalopathic states, or the use of valproate which can trigger hyperammonemia in mild UCD patients. Acutely, sodium phenylbutyrate or sodium benzoate is used to scavenge ammonia; and chronically, UCD patients utilize urea cycle precursors such as arginine and citrulline to reduce ammonia levels.

Acute hyperammonemia results in neuronal damage akin to that seen in hypoxia or stroke. The insular cortex is vulnerable early, with other cortical regions affected with prolonged hyperammonemia; after severe decompensation, occasionally gliosis and atrophy occur. On neuroimaging in less severely affected adults, T_2-weighted imaging may show hyperintensities and reductions in white matter integrity detected using DTI. Even mildly or minimally affected adults may develop executive and/or attentional deficits in the setting of mild and/or intermittent hyperammonemia.

Psychiatric symptoms are common in UCDs, and often present comorbid with neurologic symptoms such as ataxia, lethargy, and seizures. Agitation and hallucinations are common during hyperammonemic states; in patients with mild disease, when not grossly hyperammonemic, patients may be diagnosed with anxiety, depression, anorexia (often driven by protein avoidance) or somatization.

Ornithine transcarbamylase (OTC) deficiency is the most common UCD and is an X-linked disorder that usually presents in young male children up to 5 years of age with encephalopathy, ataxia, and focal neurologic signs; in heterozygous females, it often only presents during periods of metabolic compromise and high protein diet, and females are often asymptomatic for years, making diagnosis difficult. It is not uncommonly diagnosed as postpartum psychosis in females.

A 33-year-old married mother of two children (7 and 2) and a graduate nurse was diagnosed in childhood with OTC deficiency following maternal diagnosis. She had two significant episodes of hyperammonemia during pregnancy; in the first, she suffered from confusion, headache, and vomiting in the setting of mild hyperammonemia (130–160 μmol/L); in the second, with more significant hyperammonemia (>220 μmol/L), she required an intensive care admission, a PEG for amino acid infusions due to persistent vomiting, and then developed an acute psychotic episode which resolved without antipsychotic treatment. She was, however, referred in the setting of persistent anxiety, which began in her mid-teens and which had been treated with serotonergic antidepressants since the age of 18 at slowly escalating doses. Because of the association between food and the symptoms she experienced during metabolic crises, she at times became anxious about food intake and would struggle to maintain food intake and manage her citrulline and arginine supplementation. Her anxiety appeared to worsen at times when her ammonia levels were slightly increased (50 to 100 μmol/L). She ultimately improved with the addition of pregabalin to her antidepressant treatment, which allowed her to resume more regular supplementation and lower her ammonia level.

Carbamoyl phosphate synthetase I (CPSI) deficiency is a recessive disorder affecting the first enzyme in the cycle, located in the mitochondria that commonly presents in infancy with severe encephalopathy progressing to coma; however, milder forms present later in childhood or adulthood and may be asymptomatic until triggered by metabolic stress.

Citrullinemia (CTL1) is also recessive and caused by a deficiency in arginosuccinate synthetase (ASS). It similarly presents severely in neonates with typical findings of a UCD but can present as an asymptomatic illness punctuated by encephalopathy during times of metabolic stress in mildly affected adults. It has been known to present with schizophrenia-like psychosis but also as psychosis during pregnancy.

Maple Syrup Urine Disease. Maple syrup urine disease (MSUD) is an autosomal recessive disorder caused by a defect in the branched-chain α-ketoacid dehydrogenase enzyme complex, with resultant abnormalities in

Telegram: @medical_k

www.konkur.in

branched-chain amino acid (BCAA) catabolism. In adult-presenting disease, altered leucine metabolism results in impaired glial function, reduced synaptogenesis and dendritic arborization, impaired myelination and the induction of neuronal apoptosis. Additionally, elevated leucine reduces transport across the blood–brain barrier of large neutral amino acids, including most monoamine precursors, which results in disruptions to dopaminergic, noradrenergic, histaminergic, and serotonergic transmission. Altered BCAA metabolism also results in depletion of glutamate, GABA, and aspartate, which alters excitatory/inhibitory transmission throughout the CNS. Although quite rare, occurring in 1 in 185,000 individuals, the incidence is significant (1 in 200) in Amish and Mennonite populations. Clinical manifestations include body fluid odor that resembles maple syrup and overwhelming illness in the first week of life, beginning with vomiting and lethargy and progressing to seizures, coma, and death if untreated. In milder forms of the disease, the illness may manifest symptoms only during stress (such as infection or following surgery). MSUD is diagnosed by elevated plasma BCAAs, particularly leucine, and profound ketosis and acidosis. Long-term management is via restriction of dietary BCAAs, although small amounts are required for normal metabolic function. Decompensation can be prevented in some patients via liver transplantation. Like PKU, the advent of dietary restriction has modified the illness course significantly, and MSUD patients who survive into adulthood have demonstrated subtle cognitive deficits and an elevated rate of some neuropsychiatric disorders. Like PKU, adult neuropsychological impairment appears more related to age at the institution and adherence to treatment rather than persistent BCAA levels. Whereas in PKU, the relative tyrosine deficiency results in altered myelination and monoaminergic transmission, in MSUD, the BCAA-restricted diet results in chronic cerebral valine deficiency, which itself may impair neuronal and oligodendrocyte function. Similar to PKU, however, hyperleucinemia inhibits the transport of tyrosine and tryptophan, which results in reduced monoamine production, and the ketoacid derivative of leucine causes glutamate depletion. Bioenergetic and osmotic dysregulation also occurs, particularly in encephalopathic states, which results in cerebral edema. Despite strict metabolic control, many children suffer from attention-deficit disorders, whereas adolescents and adults commonly present with depression and anxiety. These are described as responding to psychostimulants and antidepressants, respectively.

Telegram: @medical_k

www.konkur.in

Cognitive impairment is usually seen in executive and attentional domains.

A 32-year-old partnered mother of an 11-year-old child was referred for assessment of mood, anxiety, and cognition. She worked in a factory steaming second-hand clothes and making manila folders 3 days per week. She was diagnosed with MSUD at the age of 17 days old in the setting of persistent vomiting and failure to thrive, spent the first 3 months of her life in hospital care, was managed on a low BCAA diet throughout childhood, and suffered epilepsy throughout her development. She had struggled with dietary compliance in adulthood and frequently presented to the hospital emergency department with nausea, abdominal pain and vomiting, and at other times with obtundation and seizures. In between encephalopathic episodes, she suffered from significant worsening anxiety and panic, triggered by social conflict, medical procedures and enclosed spaces, and road travel. Neuropsychological assessment revealed mild intellectual disability (full-scale IQ of 62) with particular difficulties in memory, executive function, and attention. She was prescribed escitalopram syrup but struggled to remain compliant.

Cerebrotendinous Xanthomatosis. Cerebrotendinous xanthomatosis (CTX) is an autosomal recessive disorder of cholestanol metabolism caused by mutations in the sterol-27 hydroxylase gene (*CYP27A1*) on chromosome 2. It is exceptionally rare, with a frequency of 1 in 1 million, but is much more frequent in the Moroccan Jewish population. CTX was first described in 1937 and is also known by the eponymous name of van Bogaert disease. Since then, over 300 patients with CTX have been described, and about 50 mutations have been identified in the *CYP27A1* gene, just under half the mutations being missense mutations. Deficiency of the mitochondrial enzyme sterol 27-hydroxylase leads to reduced hepatic production of bile acid and reduced chenodeoxycholic acid (CDCA) production. The absence of CDCA-driven negative feedback on bile acid synthesis results in the accumulation of cholestanol precursors, increased cholestanol and 7-hydroxycholesterol production. Accumulation of cholestanol and cholesterol in the eyes, tendons (often the Achilles, but also elbow/hand extensor tendons, patellar and neck tendons), and brain

Telegram: @medical_k

www.konkur.in

—particularly the cerebellar hemispheres (Fig. 2.14–7) lead to the classic clinical triad of juvenile cataracts, adult tendinous xanthomas, especially of the Achilles tendon, and progressive neurologic impairment. The neurologic manifestations are due to the deposition of large granulomatous lipid deposits in basal/cerebellar nuclei and cerebral white matter or to demyelination and include peripheral neuropathy, intellectual disability, seizures, cerebellar ataxia, pyramidal signs, and dementia. Early-onset illness tends to present with behavioral and personality changes associated with intellectual disability, whereas later-onset illness is characterized by neuropsychiatric illness associated with frontal, frontotemporal, or orbitofrontal syndromes. Psychiatric presentations include depression, psychosis, and personality or behavioral change. Case series of CTX patients with psychiatric disturbance have described 3 of 35 cases as suffering a neuroleptic-responsive psychotic disorder; 7 of 10 CTX patients demonstrated agitation and psychosis; and a series of 13 patients at a single site found 6 presented with an organic psychiatric presentation, usually associated with dementia. A review of 425 published CTX cases found that 54 presented with neuropsychiatric illness, and in a series of 78 patients, 10 had a confirmed retrospective diagnosis of an autism spectrum disorder (ASD)—suggesting that ASD symptoms may be present in childhood and herald later neuropsychiatric illness. Accelerated cardiovascular disease can result in strokes, further impacting cognitive and psychiatric function.

Telegram: @medical_k

www.konkur.in

A 47-year-old woman with a 2-year history of treatment-resistant depression, unusual behavior, and memory problems was referred for neuropsychiatric assessment. On admission, she fluctuated between periods of withdrawal and noncommunicativeness and periods of joviality associated with child-like comments and fatuous affect. She was unable to provide a detailed history and responded in a stereotyped way with single sentences: “I am confused,” “This is what I am like at the moment.” Cognitive assessment was not possible. Her past history included cataracts and a hip fracture. Physical examination revealed enlarged, thickened Achilles tendons bilaterally (Fig. 2.14–7). Neurologic examination revealed primitive reflexes and clonus in the right ankle, together with a right plantar response. A diagnosis of cerebrotendinous xanthomatosis was made on the basis of the clinical picture and elevated cholestanol levels. Treatment with chenodeoxycholic acid was instituted.

The diagnosis of CTX in adults should be suspected when the clinical picture includes cataracts, xanthomas, chronic diarrhea, and progressive neurologic or cognitive impairment. In the presence of the typical clinical picture, the identification of elevated plasma cholestanol levels with low or normal cholesterol levels plus reduced urinary excretion of bile alcohols is usually sufficient to confirm the diagnosis. MRI using fluid-attenuated inversion recovery (FLAIR) sequences can identify bilateral hyperintensities of the cerebellar dentate nuclei that mirror the known neuropathologic site of disease involvement (Fig. 2.14–7), usually associated with folia atrophy and lesions in the brain stem and periventricular regions. Global gray and white matter volume is frequently reduced. Treatment consists of lifelong replacement of CDCA (750 mg per day, often combined with a statin) and is aimed at limiting the long-term damage caused by cholestanol and cholesterol deposition, which improves neurologic and neuroradiologic markers of disease, particularly when initiated at an early stage. Treatment with CDCA alone has also been shown to result in an improvement in psychiatric symptoms and cognition in CTX patients.

Tetrahydrobiopterin Deficiency. Tetrahydrobiopterin deficiency (THD) is an extremely rare recessive disease (1/ 500,000 to 1,000,000

Telegram: @medical_k

www.konkur.in

newborns) caused by the mutation of several genes, in particular GCH1, PCBD1, SPR, PTS, and QDRP, which encode enzymes involved in the production and recycling of tetrahydrobiopterin (BH4). BH4 is an essential cofactor for numerous enzymes involved in the synthesis and maintenance of monoaminergic neurotransmitters (via tyrosine-3-hydroxylase and tryptophan-5-hydroxylase), the regulation of nitric oxide synthesis, and the modulation of glutamatergic transmission. It is also a cofactor for the enzyme PAH, impairments that cause PKU. Mutations in MTHFR and DHFR genes can also cause a mild deficiency. Impaired enzymatic function leads to altered levels of PhE and central monoamines. PhE hydroxylase, tyrosine hydroxylase, and tryptophan hydroxylase all require BH4 as a cofactor. Inherited defects that reduce the concentration of BH4, therefore, lead to PKU and to reduced CNS levels of dopamine and serotonin, as tyrosine hydroxylase and tryptophan hydroxylase are enzymes required for the synthesis of these neurotransmitters.

Classical symptoms are progressive and include intellectual disability (IQ between 60 and 90 in most patients), movement disorder, dysphagia, seizures, developmental delay, and behavioral disturbance in younger patients. Various psychiatric symptoms (including depression, anxiety, psychosis, obsessive-compulsive features, impulsivity, and attention-deficit disorder), as well as sleep disturbance, are reported infrequently in all of the THDs. However, psychiatric and behavioral problems are likely underdiagnosed, except in sepiapterin reductase deficiency, where they were documented in around 45% of patients. BH4 deficit has been associated with depression and psychosis, and reduced BH4 levels have been demonstrated in both schizophrenia and schizoaffective disorder, and supplementation with the BH4 analog sapropterin is being investigated as a potential therapeutic agent in psychotic disorders.

Hyperprolinemia. Hyperprolinemia (HP) is a recessive disease caused by mutation of either of the two genes, *ALDH4A1* and *PRODH*. These genes code for pyrroline-5-carboxylate dehydrogenase and proline oxidase, respectively, which are implicated in the degradation of proline. Proline is converted to glutamate, and HP thus alters glutamatergic transmission, alters synaptic activity, and thus impacts cognition. HP, which has no definitive treatment, is divided into two subtypes based on the severity of biochemical deficit; HP2 (with proline blood levels elevated

Telegram: @medical_k

www.konkur.in

10–15X) is considered more severe in patients presenting in childhood with seizures and mild intellectual disability. In HP1 (proline levels elevated 3–10X), patients have few symptoms or may be asymptomatic—rendering the true frequency of HP difficult to determine. Neuroimaging is often normal. There has long been a speculative association between HP1 and psychosis; the 22q11 deletion, known for its strong association with schizophrenia, results in a hemizygous deletion of the PRODH gene, and up to 50% of patients with the 22q11 deletion have elevated plasma proline levels. In a recent study, schizophrenia patients demonstrated a mild to moderate increase in serum levels of proline when compared to sex and gender-matched controls, and in a large study of patients with major psychiatric illness, HP due to missense mutations or deletions in *PRODH* was found to be a risk factor for schizoaffective disorder (OR = 4.6). A recent systematic review of 35 case reports and case-control studies found a common psychiatric phenotype of developmental delay, intellectual disability, autism spectrum and psychotic disorders.

Propionic Acidemia. Propionic acidemia (PA), also called ketotic glycinemia and propionic aciduria is a recessive disorder affecting 1:100,000 births, caused by the deficiency of activity of the enzyme propionyl CoA carboxylase, a mitochondrial biotin-dependent enzyme that is essential for the catabolism of the amino acids threonine, methionine, isoleucine, valine, as well as cholesterol and some fatty acids. This results in a buildup of organic acids in blood and tissues, in particular propionic acid. Patients with early-onset PA present with acute metabolic decompensation in childhood. Late-onset PA, still largely a childhood disorder, is more heterogeneous and may fluctuate (particularly in times of increased metabolic demand), with symptoms including vomiting and feeding difficulties with impairment in psychomotor development and movement disorders such as choreoathetosis and dystonia.

Acute acidosis with encephalopathy and hyperammonaemia may occur, during which brain MRI often demonstrates cortical edema and signal changes in the basal ganglia. It may rarely present in the third or fourth decade of life. Diagnosis requires urine organic acid analysis and a plasma or blood spot acylcarnitine profile, and treatment is largely symptomatic. PA has been associated with adolescent or young-adult psychosis, isolated visual hallucinations, associated with metabolic decompensation, and with ASD in preadolescent patients. In pediatric

Telegram: @medical_k

www.konkur.in

patients, it has been associated with ASD-type presentations in a significant majority of patients. Treatment with antipsychotics may require careful consideration as patients may have long QT syndrome.

AMACR Deficiency. Alpha-methylacyl-CoA racemase (AMACR) deficiency is an exceptionally rare and recently discovered recessive disorder caused by mutations in the *AMACR* gene and has no specific treatment. The AMACR enzyme is found in mitochondria and peroxisomes. In peroxisomes, lack of AMACR leads to elevation of pristanic acid, a fatty acid usually supplied from meat and dairy foods in the diet. The role of AMACR in mitochondria is felt to relate to the breakdown of molecules derived from pristanic acid. Accumulation of pristanic acid influences functions of brain cells, leading to neuronal and glial cell death and leads to alterations of brain structure with encephalopathy, progressive demyelinating neuropathy and xanthomas with sterol storage in the CNS. Diagnosis is made by demonstrating elevated pristanic acid in plasma. The disorder can present across the lifespan but usually presents in early adulthood with cognitive decline, seizures, and migraine; acute decompensations may present as stroke-like episodes. More chronic neurologic signs, such as ataxia, spasticity, and sensorimotor neuropathy, may also present, and it has been associated with late-onset ataxia presenting in the 5th decade. MRI tends to demonstrate increased T_2 signal in cerebello-thalamic pathway structures.

Disturbances in fatty acid and oxidative phosphorylation pathways have been described in brain regions of patients with schizophrenia, including the prefrontal cortex. The AMACR gene is also located on chromosome 5p13, a locus that has been shown to be a putative schizophrenia susceptibility locus in a large sample of patients from Puerto Rico with 3 missense variants segregating with schizophrenia. A larger study of exome sequences of multiplex and multigenerational families has also implicated the AMACR gene in schizophrenia.

Cerebral Creatine Deficiency Syndrome. The cerebral creatine deficiency syndromes (CCDS) encompass two autosomal-recessive creatine biosynthesis disorders: GAMT deficiency and L-arginine:glycine amidinotransferase (AGAT or GATM) deficiency, and the X-linked creatine transporter (SLC6A8) deficiency. Intellectual disability and seizures are

Telegram: @medical_k

www.konkur.in

common in all three CCDS. Creatine plays a key role in cellular energy availability through the regeneration of ATP and is partly synthesized endogenously and supplemented by dietary intake. Creatine is synthesized from L-arginine, glycine, and methionine through a two-step process involving AGAT and GAMT. When synthesized, creatine is then transported to tissues with a high-energy demand via the creatine transporter (SLC6A8). A diagnosis is suggested by a reduction or absence of the creatine peak visualized by proton MRS and increased urinary creatine excretion.

Almost all patients with GAMT deficiency have a behavioral disorder that may include autistic behavior and self-mutilation associated with pyramidal and extrapyramidal signs, with onset usually between the ages of 3 months and 3 years. Patients present with mild intellectual disability and speech delay to severe intellectual disability, seizures, and behavioral disorders that may become more marked during the course of the disease. AGAT deficiency usually presents as intellectual disability, autistic behavior and severe language disorder without epilepsy. Autistic behavior is also a common feature in SLC6A8, although presentation tends to occur later in childhood or even in adulthood. SLC6A8 deficiency is the cause of approximately 2% of X-linked intellectual disabilities. Clinical characteristics include psychomotor and expressive speech delay, autism, epilepsy, and muscle hypotonia and hypotrophy. Semantic pragmatic language disorders and oral dyspraxia have been described. CCDS patients may also present with a choreoathetoid movement disorder associated with dystonia and/or ataxia, and patients may demonstrate abnormal signal intensities in the basal ganglia with or without myelination changes on MRI although imaging may also be normal. Patients are often treated with supplementation with creatine monohydrate (and, in GAMT, L-ornithine), although SLC6A8 deficiency has no treatment.

Glycine Encephalopathy. Glycine Encephalopathy, also known as nonketotic hyperglycemia (NKH), is caused by mutation of the glycine ecarboxylase (GLDC, 80% of NHK) or aminomethyltransferase (AMT, 10% to 15%) genes; its prevalence is estimated at 1:75 000 newborns. These genes produce proteins implicated in the glycine cleavage enzyme complex that is responsible for breaking down glycine. A dysfunction in this complex leads to a toxic level of glycine in various tissues. As glycine,

Telegram: @medical_k

www.konkur.in

an amino acid is also a neurotransmitter, the brain is a key site of toxicity. The classical form of glycine encephalopathy appears shortly after birth presenting with lethargy, feeding difficulties, hypotonia, abnormal movements and breathing and is not infrequently fatal. Outside the neonatal period, individuals may present with profound intellectual disability and treatment-resistant seizures. The chief clinical phenotype is intellectual deficiency and childhood ADHD. Due to the intrinsic role glycine plays in excitatory neurotransmission by modulating the activity of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors, it has been suggested that NKH theoretically could present with psychosis in older patients, although there are no published reports associating psychosis and NKH. Biologic diagnosis is made by glycine measurement in the CNS and confirmed by mutation analysis of the GLDC and AMT genes. Treatment is with sodium benzoate, which reduces serum glycine levels, and dextromethorphan (and ketamine) can be utilized to reduce excessive NMDA-mediated glutamatergic activity.

SSADH Deficiency. Succinic semialdehyde dehydrogenase (SSADH) deficiency is a rare recessive metabolic disorder with a nonspecific and variable phenotype characterized by reduced activity of the enzyme SSADH, involved in the degradation of GABA, leading to an accumulation of γ-hydroxybutyric acid (GHB) and coded for by the ALDH5A1 gene. It is suggested to occur in 1: 1,000000 individuals. GABA is the major inhibitory neurotransmitter in the brain (although it is excitatory in the embryo) and is derived from glutamate, the major excitatory neurotransmitter. Impairments to SSADH activity result in an alteration of the balance between excitatory and inhibitory neurotransmission. Diagnosis rests on the demonstration of elevated urinary GABA and leukocyte SSADH assay. MRI commonly shows T_2 hyperintensity in the pallidum, dentate nucleus and white matter, and in 2/3 of patients, EEG shows background slowing and spike discharges (Fig. 2.14–8).

Patients with SSADH deficiency present intellectual disability with deficits in expressive language, hypotonia, choreoathetosis, nonprogressive ataxia, and hyporeflexia. Neuropsychiatric symptoms are prominent and include sleep disorders, inattention, hyperactivity, autism-like behavior and anxiety or obsessive-compulsive symptoms. Symptoms occur before age 4 in most cases, although diagnosis has been made as late as the third decade. Developmental delay is present in all cases, and

Telegram: @medical_k

www.konkur.in

10% of patients will present movement disorders such as chorea, myoclonus and dystonia. Delayed language is very common and frequently associated with intellectual disability. A recent study on a sample of transcortical sensory aphasia (TSA) patients (n = 187) found two patients with SSADH deficiency, suggesting enrichment of this disorder in some clinical populations. In a review of 37 cases of SSADH deficiency with psychiatric symptoms (70% of 53 patients), hyperactivity was present in 40% of patients, inattention in 50%, OCD in 35% and aggressive behavior in 15%. Four patients in this sample also had hallucinations. The majority of neuropsychiatric presentations were seen in older children and adults, and these symptoms tended to respond to stimulants, serotonergic medication and antipsychotics. The enzyme deficiency itself has no specific treatment, although trials of vigabatrin, an irreversible inhibitor of GABA transaminase (which thus inhibits the formation of succinic semialdehyde), led to improvement in some patients but worsening in others.

Telegram: @medical_k

www.konkur.in

FIGURE 2.14–8. SSADH. Global pallidal lesions in SSADH, seen on axial T_2-weighted FLAIR image. A 26-year-old woman with SSADH deficiency, obsessive-compulsive disorder and seizures.

Serine Deficiency Syndrome. Serine deficiency syndromes (SDS) are a group of threee diseases implicating disturbance in the L-serine synthesis pathway. Three serine-deficiency syndromes have been described: 3-phosphoglycerate dehydrogenase (3-PGDH) deficiency, 3-phosphoserine phosphatase (3-PSP) deficiency, and phosphoserine

Telegram: @medical_k

www.konkur.in

aminotransferase (PSAT) deficiency. L-serine plays a key role in the development of the CNS. Its conversion to glycine provides a source of one-carbon units for methylation processes, nucleotide and phospholipid synthesis, and cell proliferation; it also facilitates the role of glycine and D-serine in excitatory neurotransmission through activation of NMDA receptors.

Neurodevelopmental disorders are associated with SDS, and clinical presentations differ according to the enzyme affected. PSAT deficiency patients present with acquired microcephaly, psychomotor retardation, treatment-resistant seizures, and hypertonia. PSH deficiency patients have congenital microcephaly and intrauterine growth retardation, feeding difficulties, and psychomotor retardation, and the disorder has been associated with Williams Syndrome. The infantile form of 3-PGDH deficiency presents akin to PSH deficiency, whereas the juvenile form is more insidious with absence seizures, moderate developmental delay and abnormal behavior. This last clinical form may be seen by child psychiatrists in adolescence with developmental delay and aggressive behavior with no clinical neurologic signs.

Diagnosis is made by demonstration of low plasma and CSF serine; treatment with L-serine (+/– glycine) improves seizures and behavioral disturbance but not developmental delay.

Cerebral Folate Deficiency. Cerebral folate deficiency is defined as any neurologic syndrome where CNS levels of 5-methyltetrahydrofolate are low in the presence of normal extra-CNS levels of folate. The two main causes are autoantibodies to the folate receptor that transports folate (also known as vitamin B_9) into the CSF or a mutation in the gene encoding this receptor; it has also been described in Aicardi and Rett syndromes and mitochondriopathies. Folate plays a key role in myelination, in the generation of biogenic amines and pterins, and is involved in the production and repair of DNA and gene expression. CFD is generally treated with folinic acid, which ameliorates symptoms if initiated early.

Cerebral folate transport deficiency (CFTD) is a rare recessive disorder caused by a mutation in the *FOLR1* gene encoding for the folate receptor FR1 that allows folate to enter the cell and is found on the basolateral endothelial surface of the choroid plexus. Impaired function of (or antibodies blocking) this receptor prevents the receptor-mediated

Telegram: @medical_k

www.konkur.in

endocytosis of folate and thus its entry into the CSF. Symptoms of CFTD do not begin until late infancy as until this period the folate receptor FR2 is responsible for folate transport before birth and in early infancy. Affected children have onset of the disease classically around age 2 with psychomotor delay and regression, speech difficulties, seizures and ataxia. Leukodystrophy is usually apparent on MRI scanning secondary to marked impairment of myelination. Folate deficiency may also interact with a polymorphism in the MTHFR gene to increase the risk of ASD in CFD patients.

Autoimmune cerebral folate deficiency (ACFD) is an acquired disorder with a wider spectrum of age of onset of disease and has been reported in children, adolescents, and rarely in adults. The vast majority are infants who develop symptoms after 4 months of age with irritability, sleep disturbance and then dyskinesia, ataxia and seizures. A number of patients present with autistic behavioral features, and in adolescents, it has been associated with catatonic schizophrenia. In these patients, FR1 and FR2 receptor encoding are normal, but autoantibodies develop in the receptors. It has been suggested that this may develop via induction by soluble folate-binding proteins in cow's milk in infants or by sensitization by other similar epitopes in older patients. In one sample of ASD patients, FR1 and FR2 autoantibodies were found in almost 75% of patients, and folinic acid treatment improved one-third of patients. Similarly, FR1/2 autoantibodies were detected in 80% of a small sample of treatment-resistant schizophrenia patients, a number of whom showed symptomatic improvement to treatment with folinic acid.

Other Neurometabolic Disorders

Niemann–Pick Disease Type C. Niemann–Pick type C disease (NPC) is an autosomal recessive neurovisceral disorder of lipid storage with a frequency of 1 in 100,000 live births, with 95% of sufferers having aberrations on the *NPC1* gene (18q11–12) and 5% on the *NPC2* gene (14q24.3). It is biochemically and phenotypically distinct from Niemann–Pick diseases type A and B, which result from a deficiency of lysosomal sphingomyelinase. *NPC1* and *NPC2* are involved in the cyclical movement of sterols within cells, and their impairment results in late endosomal accumulation of cholesterol and gangliosides; excess GM2 and GM3 gangliosides cause ultrastructural change to neurons, and disrupted cholesterol metabolism results in altered tau and beta-amyloid

Telegram: @medical_k

www.konkur.in

processing (with Alzheimer-like neurofibrillary tangles, NFTs), and disrupted calcium and metal metabolism. Axonal structures are particularly vulnerable and are affected early with subsequent involvement of cerebellar Purkinje cells, basal ganglia, and thalamic neurons, followed by hippocampal and neocortical regions later (Fig. 2.14–9). The most fulminant neuronal loss occurs in the cerebellum, causing early cerebellar signs. Diagnosis is usually confirmed by demonstrating a low esterification rate of exogenous cholesterol in fibroblasts or by testing for lysosomal accumulation of free cholesterol by filipin staining (Fig. 2.14–10); more recently, oxidized cholesterol levels in plasma and/or direct NPC1 sequencing have been utilized. NPC may present in infancy, adolescence, or adulthood with a clinically variable picture, although its core features include dementia, dysarthria, ataxia, vertical supranuclear ophthalmoplegia, and hepatosplenomegaly. Seizures, dysphagia, and pyramidal signs may appear with disease progression. Psychosis occurs in 25% to 40% of adolescent and adult-onset cases and may precede motor and cognitive disturbance by many years. Some cases have been described with onset in middle age associated with cognitive impairment alone. MRI often shows diffuse cerebral and/or cerebellar atrophy, atrophy of the striatum, hippocampus and thalamus, and thinning of the callosum. Positron emission tomography (PET) imaging often shows fronto-thalamic hypometabolism and has also demonstrated significant neuroinflammation and NFT accumulation in frontotemporal regions. Executive function is impaired early in adults, before memory impairment and speed of processing becomes impaired. The co-occurrence of vertical gaze palsy and psychosis should prompt the clinician to consider NPC, so that appropriate treatment can be instituted. Psychosis may require higher doses of antipsychotics and may require treatment with a combination of neuroleptics and mood stabilizers. The development of substrate reduction therapy using the imino sugar miglustat (Zavesca), which penetrates the blood–brain barrier and reduces ganglioside accumulation, has shown promise in reversing the motor and cognitive deficits in NPC and may also reduce or prevent psychiatric disturbance in this disorder, and current trials are underway involving intrathecal and intravenous cyclodextrin, a toroidal sugar that appears to restore the biochemical cholesterol trafficking deficit in animal and cellular models, and acetyl-L-leucine, a modified amino acid that appears to stabilize Purkinje cell function in NPC and other ataxias.

A 26-year-old man presented with movement disturbance and dysarthric speech following a 10-year history of a treatment-resistant psychotic disorder. He suffered persistent auditory hallucinations and referential and persecutory delusions, which only abated when treated with olanzapine (Zyprexa) 60 mg per day and valproic acid (Depakene) 2,000 g per day. On examination, he showed dysarthric speech, gait ataxia, and disturbed eye movements with jerky saccades and grossly impaired downgaze. He was cognitively rigid with significant memory and executive impairment. Tests for Tay–Sachs disease and other enzyme disorders were negative. Filipin staining of cultured fibroblasts showed an elevated number of cells, demonstrating perinuclear filipin staining of cholesterol (60% to 70%, normally less than 5%), and cholesterol esterification rate was mildly abnormal (2.9 pmol/hr/mg; less than 2 abnormal, 2 to 3 equivocal, greater than 3 normal). Mutation analysis of the NPC1 gene revealed a compound heterozygote status of G992R/R1186H, genetically confirming the diagnosis of Niemann–Pick disease type C.

Telegram: @medical_k

www.konkur.in

FIGURE 2.14–9. Filipin staining on fibroblasts for three patients with Niemann–Pick disease type C. *Top left* stain on healthy control reveals lack of filipin staining of accumulated cholesterol; on three other cases, each of whom presented with psychosis, punctate perinuclear accumulation of cholesterol is identified.

Pelizaeus-Merzbacher Disease. Pelizaeus-Merzbacher disease (PMD) is an X-linked recessive disorder with a frequency of 1:200,000 to 1:500,000 due to abnormalities in the gene encoding for the proteolipid protein (PLP), the major structural protein of CNS myelin, resulting in patchy myelin loss as a result of oligodendrocyte apoptosis and/or axonal damage. PMD is also variable in its onset and clinical manifestations, with childhood-onset PMD resulting in intellectual disability, nystagmus, and spastic paraparesis, and adult-onset cases most commonly associated with mild, adult-onset lower limb spastic paraparesis. Dementia and psychiatric dysfunction, including psychosis, are common in adult-onset cases, often associated with subtle or partial interruption to myelination

Telegram: @medical_k

www.konkur.in

(Fig. 2.14–11), although adult-onset PMD is rare. Psychosis, when reported, occurs in the fourth or fifth decade. PLP has been implicated in schizophrenia: downregulation of the gene encoding PLP has been reported in schizophrenia and in animals treated with NMDA antagonists in experimental models of schizophrenia, implicating abnormal formation of myelin in psychosis. Treatment of PMD is symptomatic and supportive.

FIGURE 2.14–10. Magnetic resonance image scans on two individuals with Niemann–Pick disease type C who presented with major psychiatric disorders. *Left*, T_2-weighted axial image of a young adult male who presented with psychosis at age 16 prior to the onset of neurologic disturbance at age 25, showing frontal atrophy, ventricular enlargement, and a cavum septum pellucidum. *Right*, a coronal T_1-weighted image of a young male who presented with a rapidly cycling bipolar disorder in his early 20s. Note the disproportionate hippocampal atrophy in comparison to subtle global cerebral atrophy.

Chorea-Acanthocytosis. Chorea-acanthocytosis (ChAc) is a form of neuroacanthocytosis, a group of disorders that present with neurologic and psychiatric manifestations secondary to changes in the basal ganglia

Telegram: @medical_k

www.konkur.in

and acanthocytes: spiculated red blood cells. ChAc is an autosomal recessive disorder associated with mutations or deletions in the *VPS13A* gene on chromosome 9q, which codes for the membrane protein chorein, a protein expressed in all tissues but particularly in the brain, skeletal muscle, and erythroid cell precursors. The loss of function of chorein, which interacts with the membrane cytoskeletal proteins adducing and actin, causes destabilization of the membrane skeleton in red blood cells and neurons; additionally, adducing and actin are also crucially involved in synaptic function and plasticity, and synaptic vesicle trafficking. Cell loss and astrocytic gliosis then occur in the basal ganglia in ChAc patients, most particularly in the caudate, but also the ventrolateral substantia nigra and globus pallidus (Fig. 2.14–11).

The onset of neurologic disturbance in ChAc is usually between the third and fifth decades, commonly with limb and orobuccal chorea that may be indistinguishable from Huntington chorea. It can be differentiated from the other main neuroacanthocytosis disorder, McLeod syndrome, by the absence of Kell antigens in red blood cells and the presence of cardiomyopathy in the latter. Patients with ChAc frequently present with mutilation of the tongue, lips, and cheeks, which is generally not a feature of Huntington chorea and can help to clinically distinguish the two disorders. Seizures, dystonia, and denervation atrophy occur in up to half of patients. Significant psychopathology is common in ChAc patients, occurring in up to two-thirds, and may precede the onset of frank neurologic disturbance by up to a decade. In the original series of 19 individuals described by Hardie et al. (of a mixed ChAc-dominant group of neuroacanthocytosis patients), the most prominent psychiatric feature was a behavioral and cognitive change (apathy, disinhibition, and poor judgment and planning) consistent with a dysexecutive syndrome in more than half the patients, with obsessive-compulsive disorder-like symptoms occurring in two patients. When psychiatric symptoms precede frank neurologic disturbance, an overrepresentation of OCD-type disorders occurs, in addition to behavioral syndromes secondary to frontal lobe disturbance. These both appear to be the result of the predilection of neuropathology in ChAc for the head of the caudate nucleus, which is a key relay in a basal ganglia–thalamocortical loop known as the lateral orbitofrontal loop. This circuit integrates information from the anterior cingulate, orbitofrontal, and dorsolateral prefrontal cortex to determine behavioral and motor programs that occur to resolve conflict or facilitate

Telegram: @medical_k

www.konkur.in

decision-making. Disruptions to this circuitry lead to apathy, disinhibition, and poor judgment and planning. The motor compulsions seen in many ChAc sufferers may be secondary to behavioral dysregulation of motor acts through a loss of motor inhibition. Less commonly, patients with ChAc have been known to present with a schizophrenia-like psychosis. When compulsive disorders occur in ChAc, they have been known to respond to both selective serotonin reuptake inhibitors (SSRIs) and TCAs. The disorder itself usually responds to antiseizure medication, and dopamine blockers/depleters for chorea, in addition to deep brain stimulation and botulinum toxin treatment.

A 38-year-old woman with a history of focal seizures with impaired awareness with secondary generalization since the age of 21 presented with a history of movement disorder. She first presented at age 16 with contamination fears and compulsive picking at her skin, which responded to antidepressant treatment. At the age of 27, she developed involuntary movements of the limbs, head, and neck, which were severe at the time of assessment. MRI demonstrated gross bilateral caudate atrophy, particularly affecting the head of the caudate, and a blood film showed 5% acanthocytes (Fig. 2.14–12). A Western blot on peripheral blood demonstrated the absence of normal chorein, confirming the diagnosis of neuroacanthocytosis. Her cognitive function deteriorated, and she remained on antidepressant medication while haloperidol (Haldol) was added, which significantly improved her worsening chorea. Her cognitive and behavioral decline continued over subsequent years, and she died of an unrelated medical illness 2 years later.

Cysteine and Homocysteine Disorders

Homocystinuria. Disorders that lead to increased blood and urinary levels of homocysteine are grouped under the term homocystinurias. The classic form of homocystinuria is an autosomal recessive disorder caused by a defect in the chromosome 21 gene coding for cystathionine beta-synthase, an enzyme that converts homocysteine and serine into cystathionine. This leads to the accumulation of homocysteine and methionine. Excessive homocysteine disrupts the structure of fibrillin-1, an

Telegram: @medical_k

www.konkur.in

extracellular matrix protein, and leads to damage of collagen and elastic fibers; this leads to significant arterial and venous diseases such as stroke, myocardial infarction or venous thrombosis. In neurons, it alters the release of monoamines and may potentiate neurotoxicity through NMDA receptor agonism; it can also induce DNA strand breakage and cellular apoptosis. The primary clinical effects of the disorder reflect this pathology. The presenting features are usually developmental delay or intellectual disability associated with optic lens dislocation within the first 10 years. Optic lens dislocation is seen in almost 100% of patients older than 10, and other ophthalmologic complications may ensue, such as cataracts, glaucoma, and optic nerve atrophy. Intellectual disability is seen in about half of the patients, and intellectual decline tends to be slowly progressive. Patients may appear Marfanoid with a long narrow head, arachnodactyly, kyphoscoliosis, and pectus excavatum. Patients will often have pale, pink skin together with fine, fragile, light-colored hair and malar rash. Abnormalities in the clotting cascade and increased platelet adhesiveness lead to occlusion of and thromboembolism from arterial and venous vessels, with very high mortality. Other neurologic complications include seizures and dystonias. Although early case reports identified patients with psychosis and homocystinuria, studies investigating large case series of patients have reported that personality disorder, behavioral disturbance (such as aggression), depression, and OCD are the most common psychiatric findings and that aggression and behavioral disturbances were more common in patients with intellectual disability. The diagnosis of classic homocystinuria is made on the basis of elevated plasma methionine and elevated plasma and urine homocysteine. Brain imaging may show the effects of cerebrovascular accidents, atrophy, or venous occlusions. Treatment with methionine restriction and cysteine supplementation will generally prevent any long-term sequelae if the disorder is diagnosed at birth. Oral pyridoxine (vitamin B_6), which remethylates homocysteine to methionine, leads to a reduction in levels of methionine and homocysteine in about half of patients, while the addition of folic acid and B_{12} may be of further benefit.

(See Color Plate.)

The metabolic pathway that converts homocysteine and serine to cystathionine is the most common pathway for the metabolism of homocysteine (Fig. 2.14–13). Other autosomal recessive homocystinurias are caused by defects in an alternative remethylation pathway in which homocysteine is catalyzed to methionine by either methionine synthetase or methylenetetrahydrofolate reductase (MTHFR). An inherited defect in methylcobalamin (methyl-B_{12}) that acts as a cofactor for methionine synthetase will also result in homocystinuria, together with methylmalonic aciduria. Deficiencies in these enzymes will lead to high levels of homocysteine but, in contrast to cystathionine synthase deficiencies, low levels of methionine. The clinical picture of these enzyme defects is one of intellectual disability, seizures, and hypotonia, while megaloblastic anemia is an additional feature of the disorder of methionine synthetase deficiency. The less severe form of MTHFR deficiency has been strongly associated with psychosis in adolescents and adults; this may be underpinned by alterations to dopamine synthesis and myelination. The C677T variant of the MTHFR gene, which causes a 35% reduction in enzyme function, has been shown to be an independent risk factor for the development of psychosis. The clinical course and MRI findings can resemble that seen in childhood leukodystrophies in these two disorders. Neuropsychiatric symptoms figure most prominently in the presenting symptoms of patients with methyl-B_{12} deficiency, with delays of up to 13

Telegram: @medical_k

www.konkur.in

years between the onset of neuropsychiatric symptoms and the ultimate diagnosis.

Mitochondrial Diseases

Mitochondrial diseases are a heterogeneous group of diseases caused by defects in oxidative phosphorylation. They are characteristically multisystem disorders that overlap clinically and should be considered as a differential diagnosis across a range of neurologic and neuropsychiatric presentations. The genetic and phenotypic complexity of these disorders can be best understood in the context of a description of the mitochondrial genome, which is inherited maternally. Each human cell has up to several thousand copies of the mitochondrial genome, which is organized into a circular double-stranded structure. Human mitochondrial DNA was first sequenced in 1981 and consisted of 37 genes, with no introns and a small noncoding portion. Thirteen proteins, translated from mitochondrial DNA, are involved in the respiratory chain/oxidative phosphorylation system. The mitochondrial respiratory chain consists of five enzyme complexes (complexes I, II, II, IV, V) made up of polypeptides encoded by nuclear and mitochondrial genes, except for complex II, which is entirely encoded in the cell nucleus. As a result, the mitochondrion is under the genetic control of both nuclear and mitochondrial DNA, and mitochondrial disorders can result from mitochondrial or nuclear DNA mutations. These enzyme complexes participate in a chain of metabolic processes that lead to ATP production, the overall process being referred to as oxidative phosphorylation. ATP is used in the vast majority of cellular metabolic processes as an energy source, and the respiratory chain responds to the energy needs of cells, which in some cases may be quite stable, while in others (e.g., muscle), they may vary dramatically over time. Other functions of the mitochondria include cellular homeostasis, fatty acid oxidation, the urea cycle, intracellular signaling, calcium storage and signaling, apoptosis, and the metabolism of amino acids, lipids, cholesterol, steroids, and nucleotides.

The genetics of mitochondrial disorders are complex, but the following principles can be generally applied:

Telegram: @medical_k

www.konkur.in

1. Mitochondrial disorders may be sporadic, maternally inherited, or inherited in an autosomal recessive or dominant pattern.
2. Due to the polyploid nature of the mitochondrial genome, the one cell may include normal and mutated mitochondrial DNA (heteroplasmy), and thus siblings may show a very broad range of clinical variability due to differences in the inheritance of such heteroplasmic mitochondria. The mitochondrial function will generally begin to fail once the proportion of mutated mitochondrial DNA has crossed a threshold of 70% to 80%.
3. Mitochondrial respiratory chain disorders will mostly affect tissues with high metabolic needs such as muscle, central and peripheral nervous system, heart, endocrine and eye.
4. The clinical expression of mitochondrial disorders may vary widely from individual to individual with the same mutation depending on the proportion of mitochondria affected in different tissues, the interaction of that individual with the environment, and the differential metabolic energy needs of different tissues within the one individual.

Mitochondrial diseases are the most common inborn errors of metabolism, accounting for 1 in 5,000 live births with nearly 300 causative genes identified. One-third of these genes have been identified through next-generation sequencing in the last decade. About 15% of these genes are mitochondrial genes, with the remainder being genes encoded in the nucleus. For the reasons outlined above, there is no clear genotype–phenotype relationship for mitochondrial genome disorders. Clinical features common to all mitochondrial disorders include dysfunction of endocrine (short stature, diabetes, thyroid and adrenal disorders), neurologic (deafness, myopathy, peripheral neuropathy, retinopathy, optic atrophy, ophthalmoplegia, seizures, ataxia, dementia), and cardiac (cardiomyopathy, cardiac block) systems. The patterns of clinical presentation vary significantly with regard to the age of onset, the temporal order of symptoms and conditions, and the progress of the disorders. The combination of maternal history, multisystem involvement, and a progressive course should arouse clinical suspicion of a mitochondrial disorder. In patients with atypical psychiatric presentations, physical signs such as muscle weakness, hearing loss, seizures, short stature, diabetes, Wolff–Parkinson–White syndrome, or migraines should alert clinicians to the possibility of a mitochondrial disorder. The disorders reviewed below are not an exhaustive review of mitochondrial diseases

Telegram: @medical_k

www.konkur.in

and are restricted to those disorders with clinical neuropsychiatric phenotypes.

Mitochondrial Encephalomyopathy, Lactic Acidosis, and Stroke-Like Episodes (MELAS). MELAS, the most common of the mitochondrial disorders, presents before early adulthood after a period of normal development. The majority (about 80%) of MELAS cases are due to an A to G substitution at nucleotide 3243 of tRNA leucine (A3243G $tRNA^{Leu(UUR)}$). A further 10% of mutations are in other regions of this same gene, while the remaining 10% of mutations occur in six other mitochondrial genes. The onset is most common in childhood but can first present in early adulthood. The characteristic features of MELAS are stroke-like episodes whose lesions do not conform to vascular territories and may involve gray or subcortical white matter. They typically occur in tempero–parieto–occipital regions, basal ganglia, brainstem, and cerebellum and lead to hemiparesis, hemianopia, and cortical blindness. Other clinical features include short stature, migraines, vomiting, and seizures. Lactic acid levels are elevated and have been correlated with the level of neurologic symptoms. The course of MELAS is highly variable, ranging from single stroke-like episodes to a progressive course characterized by one or more multiple strokes, deafness, diabetes, retinopathy, seizures, and cardiac abnormalities. Cases of schizophrenia or schizophrenia-like psychosis associated with MELAS have been reported. Such cases typically show onset in the third decade, several years to a decade before the clinical diagnosis of MELAS is made. Similar cases of depression, obsessive-compulsive disorder, bipolar disorder, and borderline personality disorder have been reported, but like the schizophrenia cases, the course of the illness is not typical. A retrospective review of the patient's history will often reveal previously unappreciated features of MELAS, such as short stature, diabetes, or unexplained somatic symptoms. The development of neurologic signs or symptoms, cognitive decline, and evidence of strokes on imaging usually leads to the definitive diagnosis.

Telegram: @medical_k

www.konkur.in

FIGURE 2.14–14. Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS). *Left*, axial fluid-attenuated inversion recovery magnetic resonance image scans of a patient at age 43 and age 47, showing early gliosis of anterior temporal and parietal zones (*top*) with progression over 2 years to more advanced gliosis and cortical volume loss (*bottom*). *Right*, skeletal muscle from a 29-year-old man with early-onset stroke. **A:** Gomori trichrome stain demonstrates the typical appearance of ragged red fibers, consisting of abnormal subsarcolemmal proliferation of mitochondria. **B:** Electron micrograph of skeletal muscle demonstrates "parking lot" inclusions, consisting of dystrophic mitochondria.

A 42-year-old man with deafness and diabetes was admitted with a confusional episode and found to have extensive posterior cortical and subcortical changes on MRI. The diagnosis of MELAS was confirmed by genetic testing. Five years later, he was rereferred due to altered behavior, aggression, and having become very "fixed" in his ideas. He performed poorly on bedside executive function tests. Repeat MRI revealed extensive inferior frontal and parietotemporal atrophy (Fig. 2.14–14).

The diagnosis of MELAS is based on the clinical syndrome, elevated serum lactic acid levels, muscle biopsy showing ragged red fibers and molecular genetic testing. Ragged red fibers are muscle fibers exhibiting mitochondrial proliferation in response to mitochondrial failure. MRI scanning typically shows cerebral stroke-like lesions. There is currently no

Telegram: @medical_k

www.konkur.in

available treatment for MELAS. A study of 13 patients treated with oral or intravenous L-arginine during acute stroke-like episodes identified a reduction in their frequency and severity but did not alter the disease trajectory over the 9-year follow-up period. Antioxidants, respiratory chain substrates, and cofactors have been studied in trials with varying results. Symptomatic treatments for MELAS include cochlear ear implants for deafness, anticonvulsants, antipsychotics and diabetic treatments. Antipsychotics with a higher risk of glucose intolerance (e.g., olanzapine) should be avoided or used with caution.

Myoclonic Epilepsy With Ragged Red Fibers (MERRF). MERRF typically begins in middle adulthood with photosensitive myoclonic seizures and is associated with limb-girdle weakness, dementia, cerebellar ataxia, cardiac abnormalities, and neuropathy. Muscle biopsy reveals ragged red fibers, and the electroencephalogram (EEG) is usually abnormal. In 90% of cases, the causative mutation is an A8344G transition in the tRNA *lysine*. There is no specific treatment, but appropriate management of the epilepsy is critical to clinical outcome, with levetiracetam and clonazepam recommended as first-line treatments.

Mitochondrial Diseases with Progressive External Ophthalmoplegia. Progressive external ophthalmoplegia, a clinical syndrome of progressive ptosis with paresis of eye movement, is associated with a number of mitochondrial diseases. Mutations in the nuclear PLOG1 gene are the commonest causes of the syndrome with a phenotype of adult presentation, dementia, depression, parkinsonism, ataxia, and occipital seizures. Kearns-Sayre syndrome (KSS) is a sporadic mitochondrial deletion disorder characterized by a triad of onset before 20, progressive external ophthalmoplegia plus one of the following: pigmentary retinopathy, heart block, cerebellar ataxia, or elevated cerebrospinal fluid (CSF) protein. It is associated with short stature, cognitive impairment, and death due to cardiac or neurologic morbidity before the age of 40. Muscle biopsy reveals ragged red fibers, and serum lactate is often elevated. MRI will often show diffuse central white matter abnormalities and basal ganglia calcification.

Mitochondrial Diseases With Cerebral White Matter Disease. Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is an autosomal recessive disease caused by mutations in the thymidine

Telegram: @medical_k

www.konkur.in

phosphorylase gene (TYMP), leading to the accumulation of thymidine. The clinical presentation is in adolescence with gastrointestinal dysmotility symptoms, progressive external ophthalmoplegia, peripheral neuropathy, and leukoencephalopathy progressing to death in the fourth decade. Thymidine phosphorylase replacement with platelet or erythrocyte transfusion has been of limited value. Increasing thymidine clearance through hematopoietic stem cell transplantation and orthotopic liver transplantation has been associated with significant medical complications, particularly due to the need for life-long immunosuppression. Leber hereditary optic neuropathy (LHON) is a maternally inherited disorder presenting as bilateral visual neuropathy in young adults. Although usually confined to the optic nerve, it has been described together with white matter pathology. Maternally inherited Leigh syndrome (MILS), also known as subacute necrotizing encephalomyelopathy, is an infantile encephalomyopathy characterized by seizures, heart block, dystonia, and optic atrophy.

Many overlapping mitochondrial syndromes have been described that include features typical of MELAS plus one of the other syndromes (e.g., LHON/MELAS, MELAS/MERRF, Leigh/MELAS).

Wolfram Disease Type I and Type II. Wolfram disease Type I is an autosomal recessive disorder caused by a mutation on the short arm of chromosome 4 (4p16.1) in the *WFDS1* (wolframin) gene. The wolframin protein acts to regulate cellular calcium. Wolfram disease is also known by the acronym DIDMOAD (*d*iabetes *i*nsipidus, *d*iabetes *m*ellitus, *o*ptic *a*trophy, *d*eafness) and often displays characteristic atrophy of the optic tract and loss of signal of the neurohypophysis on MRI (Fig. 2.14–15). Neurologic symptoms include dysarthria, areflexia, epilepsy, and anosmia. In a 1991 study, 68 patients with Wolfram disease were reviewed. Sixty percent (41 of 68) had had psychiatric symptoms, and 25% (17 of 68) were classified as showing severe psychiatric illness. Eleven (16%) patients had a history of psychotic symptoms. Heterozygous family members exhibited a high rate of psychiatric illness, approximately eight times greater than for noncarriers of the wolframin gene. Subsequent studies and systematic reviews of the clinical phenotype have not replicated these high rates of psychiatric morbidity in patients with Wolfram syndrome.

Disorders of Metal Metabolism

Wilson Disease. Wilson disease is an autosomal recessive disorder caused by mutations in a copper transporting ATPase encoded by the *ATP7B* gene on chromosome 13q14.3. About 1% of the population carries an *ATP7B* mutation, of which almost 1,000 have been identified. The frequency of the disorder is estimated to be about 1 in 40,000. The gene defect leads to the accumulation of copper in the liver through impaired copper excretion and impaired binding of copper to ceruloplasmin. The subsequent catabolism of ceruloplasmin leads to low ceruloplasmin plasma levels and increased free copper. Free copper then accumulates in the brain and leads to the neurologic and neuropsychiatric manifestations of this disorder. Copper deposition occurs in astrocytes but

Telegram: @medical_k

www.konkur.in

not neurons or the extracellular matrix and is particularly evident in the basal ganglia.

The most common presentation of Wilson disease is hepatic disease anywhere between the first and fourth decades. About 50% of patients are symptomatic by age 15. Up to two-thirds of patients will present with neurologic disease in the second or third decade without clinical evidence of liver disease. The *dystonic* form is the commonest presenting neurologic syndrome with dysarthria, dysphagia, drooling, and a rigid open mouth. In the *pseudosclerotic* form, patients present with incoordination, clumsiness, unsteadiness of gait, or dysarthria. As the illness progresses, patients may exhibit features of both forms with rigidity, tremor, choreic, athetoid, or dystonic movements. Such movements may be exacerbated by stress in the early stages of illness and be interpreted as functional. In particular, the tremor associated with Wilson disease, the so-called wing beating, may be interpreted as a functional movement disorder. This tremor is characteristically absent at rest and develops after a short period of the arm extension. The arms beat in a wide violent arc, and the tremor may be altered by the position of the arms.

Wilson's original description in 1912 emphasized the importance of psychiatric changes in the disease. Since then, many authors have described the high prevalence of psychiatric symptoms, with estimates ranging from 30% to 100% of symptomatic patients experiencing psychiatric symptoms at some point during their illnesses. Up to two-thirds of patients with Wilson disease will present with psychiatric symptoms, and one-third will have received psychiatric treatment prior to the diagnosis being made. The most common reasons for psychiatric referral are behavioral and personality changes, with disinhibition, bizarre, or impulsive behavior being present in about a quarter of patients and depression in about one-fifth. Personality and behavioral changes, but not depression, correlate with the degree of neurologic impairment. Although early reports suggested that psychotic presentation was a feature of Wilson disease, more recent investigations have shown that psychotic symptoms are relatively rare. The importance of recognizing the early psychiatric presentations of Wilson disease lies in the proven benefits of early treatment intervention. Diagnostic delays may be exacerbated if extrapyramidal movements are attributed to psychotropic medications or interpreted as functional. Patients with neurologic involvement show a

Telegram: @medical_k

www.konkur.in

subcortical pattern of cognitive impairment with frontal executive deficits that correlate with the extent of cerebral involvement.

The presence of Kaiser Fleischer (KF) rings (copper deposits in the outer rim of the cornea that are brown or gray-green) on slit-lamp examination is the single most important clinical diagnostic sign and is observed in about half of patients with hepatic presentation and almost all patients with a neurologic or psychiatric presentation. Low serum levels of ceruloplasmin have high sensitivity (over 80%) and low specificity, and normal ceruloplasmin may occur in 10% of patients in the presence of high urinary copper excretion. Low serum copper or free copper and high urine copper can be seen but are less reliable. Liver biopsy with staining for total hepatic copper has a sensitivity of over 80%, but liver biopsy is subject to false-negative results due to sampling errors. Genetic testing of the ATP7B gene is the gold standard for diagnosis but requires direct sequencing of the entire gene and may detect variants of unclear significance. MRI shows reduced T_1 signal and increased T_2 signal in basal ganglia, thalamus, and brainstem (Fig. 2.14–16). The European Association for the Study of the Liver developed the Leipzig criteria, incorporating clinical and laboratory findings, in recognition of the variability of clinical and laboratory findings in Wilson disease. The criteria are valued in clinical and research settings. The aims of treatment in Wilson disease are to remove accumulated copper, prevent re-accumulation through maintenance treatment and reduce its absorption. Treatment with d-penicillamine combined with pyridoxine has been the mainstay of initial treatment but may lead to a worsening of neurologic symptoms in up to 50% of patients. This has led to the recommended use of less neurotoxic copper chelators such as trientine. Zinc acetate therapy which induces metallothionine in the gastrointestinal epithelium and inhibits copper absorption, has been used as a preventative treatment in patients who are presymptomatic and for maintenance treatment. Restriction of high copper foods (shellfish, liver, chocolate, nuts, beans, mushrooms) is encouraged. A liver transplant can restore normal copper excretion but is limited due to the need for lifelong immunosuppression and the complexity of the procedure. Neurologic and psychiatric symptoms will improve with copper chelation over 1 to 2 years, with regression of MRI lesions on serial imaging. In patients with neurologic forms of Wilson disease, the best outcomes are seen in patients with the pseudosclerotic form (82% symptom-free), with worse outcomes in

Telegram: @medical_k

www.konkur.in

patients with chorea (75% of patients), parkinsonism (63%), and dystonia (53%).

Neurodegeneration With Brain Iron (NBIA). Neurodegeneration with brain iron (NBIA) refers to a group of disorders that were previously referred to as Hallevorden–Spatz syndrome. Common to these disorders is the accumulation and deposition of iron in the brain in association with clinical, radiologic, and pathologic evidence of neurodegeneration. The clinical phenotype of these disorders include neurologic (parkinsonism, dystonia, choreoathetosis), cognitive impairment and neuropsychiatric symptoms. Five of the ten recognized NBIA disorders which have adolescent or adult-onset phenotypes are discussed below (PKAN, PLAN, MPAN, aceruloplasminemia, neuroferritinopathy).

Telegram: @medical_k

www.konkur.in

FIGURE 2.14–16. T_2-weighted axial magnetic resonance image of an adolescent patient with Wilson disease, showing characteristic bilateral hyperintensity of the thalamus, caudate, and putamen. A study of clinical, MRI and multimodality evoked potentials in neurologic Wilson disease. *Eur J Neurol.* 2007;14(5):498, with permission. © EAN. doi: 10.1111/j.1468-1331.2006.01676.x.)

PANTOTHENATE KINASE-ASSOCIATED NEURODEGENERATION (PKAN). The identification of mutations in the gene *PANK2* on chromosome 20p13 led to the descriptive term "pantothenate kinase-associated neurodegeneration" for what is recognized as the most prevalent form of

Telegram: @medical_k

www.konkur.in

NBIA. Pantothenate kinase 2 regulates the mitochondrial synthesis of coenzyme A (CoA), which is involved in energy and fatty acid metabolism. *PANK2* catalyzes the phosphorylation of pantothenate (vitamin B_5) to phosphopantothenate, which condenses with cysteine in the next step of CoA biosynthesis. Mutations in *PANK2* lead to an accumulation of cysteine, which binds iron and leads to free radical production, triggering cell membrane damage and death. The retina and basal ganglia appear particularly sensitive to these effects of PKAN mutations, and the primary clinical features reflect this retinal and basal ganglia involvement.

The clinical phenotype of *PKAN* can be divided into three types: The *classic* syndrome first described by Hallevorden and Spatz consisted of early childhood (3 to 4 years) onset of dystonia, dysarthria, rigidity, pyramidal signs, pigmentary retinopathy, and cognitive decline, and with a progressive fulminant course such that patients became nonambulatory by their mid to late teens. All patients with this classic phenotype have been found to have a *PANK2* mutation. The *atypical clinical phenotype* (about 25% of PKAN) is characterized by presentation in the early to mid-teenage years with palilalia, tachylalia, dysarthria, and psychiatric symptoms, including depression, emotional lability, personality changes, and cognitive decline. Extrapyramidal rigidity, dystonia, and pyramidal spasticity develop subsequently and result in progressive loss of mobility over 15 to 40 years. About one-third of this *atypical clinical phenotype* exhibit *PANK2* mutations. Interestingly, the patients with *PANK2* mutations and late-onset appear to be more likely to exhibit speech and psychiatric symptoms at onset. The third clinical phenotype, previously termed *HARP* (hypobetalipoproteinemia, acanthocytosis, retinopathy, and pallidal degeneration), has now been identified as being caused by a *PANK2* mutation. Together with a strongly suggestive clinical picture, the finding of the characteristic MRI “eye of the tiger” sign (a low signal intensity region caused by iron deposition and a high signal area that corresponds to the axonal spheroid formation, as seen in Fig. 2.14–17) is almost pathognomonic of a *PANK2* mutation and should lead to genetic testing. Treatment aimed at reducing iron levels using deferiprone, an iron chelator that crosses the blood–brain barrier, has been relatively ineffective in the classic phenotype but may slow progression in the atypical phenotype. A phosphopanthonate replacement trial using fosmetpantotenate did not improve function in PKAN patients (Table 2.14–1).

(From Hayflick SJ: Unraveling the Hallervorden-Spatz syndrome: Pantothenate kinase-associated neurodegeneration is the name. *Curr Opin Pediatr*. 2003;15[6]:572, with permission.)

PLA2G6-ASSOCIATED NEURODEGENERATION (PLAN). About 200 autosomal recessive mutations have been identified in the phospholipase A2 gene (PLA2G6, chromosome 22q13.11) and can lead to infantile, childhood-onset and adult-onset disorders. Pathologically this disorder is characterized by the accumulation of spheroids in peripheral axons and nerve terminals. The adult-onset disorder is typically one of dystonia-parkinsonism with associated abnormalities in eye movements, pyramidal signs, cognitive impairment, and psychiatric symptoms.

MITOCHONDRIAL MEMBRANE PROTEIN-ASSOCIATED NEURODEGENERATION (MPAN). MPAN is associated with approximately 50 mutations (autosomal recessive or dominant) in the (chromosome 19 open reading frame 12) gene. The function of the C19ORF12c protein, a mitochondrial membrane protein, remains unknown, as does the mechanism by which mutations

Telegram: @medical_k

www.konkur.in

lead to iron accumulation. The clinical phenotype is one of progressive dementia, pyramidal and extrapyramidal symptoms, optic atrophy, peripheral motor neuropathy, and neuropsychiatric symptoms.

ACERULOPLASMINEMIA. Aceruloplasminemia is an autosomal recessive disorder associated with reduced or absent levels of ceruloplasmin and tissue iron deposition. It can be caused by about 40 mutations in the ceruloplasmin gene on chromosome 3q25 and occurs in 1 per 2 million births. There are two types of ceruloplasmin. Serum ceruloplasmin is predominantly synthesized in the liver but does not cross the blood–brain barrier, while a second form (GPI-anchored form) is produced by astrocytes in the CNS. Ceruloplasmin promotes the loading of iron onto transferrin, allowing Fe^{3+} efflux out of cells and preventing oxidative damage caused by Fe^{2+}. GPI-anchored ceruloplasmin plays a key role in regulating iron levels in the CNS and in preventing free radical injury. The disease leads to the deposition of iron in the CNS, retina, pancreatic cells, liver, spleen, and ovaries. The major sites of CNS iron deposition in aceruloplasminemia are similar to the sites of greatest iron concentration in healthy individuals: the basal ganglia, cerebellar dentate nuclei, red nucleus, thalamus, and hippocampus.

Table 2.14–1.
Metabolic Disorders Presenting as Neuropsychiatric Syndromes, With Pattern of Inheritance, Gene Location, and Product, Prevalence, Onset, and Neuropsychiatric Features

Disorder	Inheritance	Location	Gene	Gene Product	Stored or Altered Substance	Prevalence per Million	Diagnosis	Onset	Neuropsychiatric Features
Metachromatic leukodystrophy	AR	22q13.31	ARSA	Arylsulfatase A	Cerebroside sulfate	5–25	Enzyme levels (leukocytes), genetic testing	Childhood–adulthood	Psychosis in adolescent onset/chorea/seizures/dementia
Fabry disease	X-linked recessive	Xq22	α-Gal	α galactosidase A	Globotriaosylceramide	25 (males)	Enzyme levels (leukocytes), genetic testing	Childhood–adolescence	Depression
Tay–Sachs disease	AR	15q23–q24	HEXA	β–hexosaminidase A	GM2-gangliosides	150–400 (Jewish) 3 (general population)	Enzyme levels (leukocytes), genetic testing	Childhood–adulthood	Psychosis in adult-onset, speech, gait disorder, tremor
Neuronal ceroid lipofuscinosis (Kufs)	AD/AR	Not yet identified	CLN4	Unknown—more than one may be involved (CLN1&2—lysosomal thioesterase and protease; CLN3&8 are membrane proteins of unknown function)	Unknown	1–2	Biopsy—muscle, vessel	Adult (Kufs)	Psychosis/depression/myoclonic epilepsy/dyskinesias
α-mannosidosis	AR	19q13.1	MANB	α-Mannosidase	Oligosaccharides	2	Enzyme levels (leukocytes), genetic testing	Childhood–adulthood	Psychosis in adult onset/ataxia/deafness/retinopathy
X-linked adrenoleuko-dystrophy	X-linked recessive	Xq28	ABCD1	ALDP peroxisomal membrane protein	Saturated very-long-chain fatty acids (VLCFAs)	50 (males)	Serum VLCFA levels, genetic testing	Childhood–adulthood	Affective psychosis in adult-onset/demyelination
Acute intermittent porphyria	AD	11q23.3	HMBS	Porphobilinogen-deaminase	Porphobilinogen/amino levulinic acid	40–100	Urine porphobilinogens	Adulthood	Psychosis/delirium/depression/peripheral neuropathy
Phenylketonuria	AR	12q23.2	PAH	Phenylalanine hydroxylase	Phenylketones	50–100	Phenylalanine levels	Childhood	Intellectual disability
Maple syrup urine disease	AR	19q13.1–13.2 6p22–p21 1p31	BCKDHA BCKDHB DBT	Branched-chain ketoacid dehydrogenase	Branched-chain amino acids (BCAAs)	5	Urine keto acids, serum BCAAs, genetic testing	Childhood–adulthood	Depression and anxiety in adults
NPC	AR	18q11–12 14q24.3	NPC1 NPC2	NPC1 NPC2	Cholesterol and gangliosides	10	Plasma oxysterols or lysosphingomyelin, genetic testing	Childhood–adulthood	Intellectual disability in childhood-onset/psychosis in adolescent-onset/dementia in adult-onset
Pelizaeus-Merzbacher Disease	X-linked recessive	Xq22	PLP1	Proteolipid protein	n/a	2–5	Neuroimaging, genetic testing	Childhood–adulthood	Intellectual disability in childhood-onset/psychosis and dementia in adult-onset
Cerebrotendinous xanthomatosis	AR	2q33	CYP27A1	Sterol 27 hydroxylase	Cholestanol and cholesterol	300 reported cases	Plasma cholestanol, genetic testing	Adulthood	Psychosis/agitation/depression
Cystinosis	AR	17p13	CTNS	Cystonin	Cystine	5	Cysteine levels (leukocytes), genetic testing	Childhood	Cystinosis encephalopathy
Homocystinuria	AR	21q22.3	CBS	Cystathionine synthase	Homocysteine and methionine	3–5	Plasma homocysteine, liver biopsy, genetic testing	Childhood	Intellectual disability/seizures/dystonias/personality change/behavioral disturbance/depression/OCD
Tetrahydrobiopterin deficiency	AR	Multiple	GCH1 PCBD1 PTS QDRP	Multiple	BH4	2	Urinary pterin levels, BH4 and PhE loading tests, genetic testing	Childhood–Adulthood	Behavioral disturbance, intellectual disability; adult mood and psychotic disorders

www.konkur.in

Hyperprolinemia	AR	1p36	ALDH4A1	Pyrroline-5-carboxylate dehydrogenase	Proline	<1	Plasma proline level, genetic testing	Childhood–adulthood	Intellectual disability, psychosis
Propionic academia	AR	13q32, 3q21-22	PCCA PCCB	Propionyl-CoA carboxylase	Propionic acid	10	Plasma propionyl-carnitine and methionine, genetic testing	Childhood–adulthood	Encephalopathy, intellectual disability, autism, psychosis
AMACR deficiency	AR	5p13	AMACR	α-Methylacyl-CoA racemase	Pristanic acid	<1	Plasma pristanic acid, genetic testing	Early adulthood	Cognitive decline, psychosis
Cerebral creating deficiency syndrome (CCDS)	AR and XL	19p13.3, 15q21.1, Xq28	GAMT AGAT SLC6A8	Guanidinoacetate N-methyl transferase, glycine amidinotransferase, sodium and chloride-dependent creatine transporter	Creatine	<1	Plasma/urine creatine, guanidinoacetate, creatinine; genetic testing	Childhood	Autism, self-mutilation, intellectual disability
Non-ketotic hyperglycinemia (NKH)	AR	9p22, 3p21.31	GLDC AMT	Glycine dehydrogenase, aminomethyltransferase	Glycine	20	Glycine levels in the blood, plasma, CSF; genetic testing	Childhood	Intellectual disability, attention deficit
SSADH deficiency	AR	6p22	ALDH5A1	Succinic semialdehyde dehydrogenase	GABA, GHB	<1	Urine levels of 4-hydroxy-butyric acid; enzyme levels (leukocytes); genetic testing	Childhood–adulthood	Intellectual disability, autism, OCD, psychosis
Serine deficiency	AR	1p12, 7p11.2, 9q21.2	PHGDH PSPH PSAT1	Phosphoglycerate dehydrogenase, phosphoserine phosphatase, phosphoserine aminotransferase	Serine	<1	Plasma/CSF serine levels; genetic testing	Childhood	Aggression, intellectual disability
Cerebral folate deficiency	AR, auto-immune	11q13.3	FOLR1	FR1	Folate	<1	CSF 5-methyl-tetrahydrofolate levels	Childhood, adulthood	Intellectual disability, autism, psychosis
MELAS	Maternal	mtDNA	MT-TL1	Mitochondrial tRNA leucine 1	n/a	60	Serum lactate/pyruvate, neuroimaging, genetic testing (leukocytes, urinary sediment, tissue)	Adolescence/early adulthood	Stroke-like lesions/psychosis/depression
Wolfram disease	AR/Maternal	4p/mitochondrial	WFS1	Wolframin	n/a	170 reported cases	Genetic testing	Childhood–adolescence	Schizophrenia
Wilson disease	AR	13q14.2–q21	ATP7B	Copper transporting ATPase	Copper	25	Serum copper and ceruloplasmin, urine 24-hour copper excretion, genetic testing, liver biopsy	Adolescence/early adulthood	Extrapyramidal movements/psychosis/parkinsonism/dysphagia/dysarthria
Aceruloplasminemia	AR	3q25	CP	Ceruloplasmin	Iron	.5	Serum ceruloplasmin, genetic testing, neuroimaging	Adolescence/early adulthood	Ataxia, dystonia, dyskinesia, subcortical dementia
Pantothenate kinase–associated neurodegeneration	AR	20p13	PANK2	Pantothenate kinase	Cysteine	1	Neuroimaging, genetic testing	Childhood–adolescence	Childhood dystonia, rigidity/adolescent pallidalia, dysarthria, depression, lability, personality change, cognitive decline

AR, autosomal recessive; AD, autosomal dominant; tRNA, transfer ribonucleic acid; ATP, adenosine triphosphate; MELAS, Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; OCD, obsessive-compulsive disorder.

FIGURE 2.14–18. Scans of a 22-year-old woman patient with aceruloplasminemia and a schizophrenia-like psychosis. Reduced intensity of the basal ganglia (*left*) and dentate nucleus of the cerebellum (*middle*) on axial T_2-weighted imaging representing iron deposition (*arrows*) and T_1-weighted sagittal scan demonstrating anterior callosal thinning (*right, arrow*).

Aceruloplasminemia presents with a triad of diabetes mellitus, retinal degeneration, and neurologic symptoms. Neurologic signs may be preceded for many years by diabetes mellitus and anemia due to inefficient iron delivery. Ataxia and extrapyramidal movements such as blepharospasm, dystonia, dyskinesia, grimacing, and parkinsonism usually develop in the fifth decade. A subcortical picture of cognitive decline then follows with personality change, amotivation, psychomotor

Telegram: @medical_k

www.konkur.in

slowing, and executive deficits. Psychosis has been reported, although psychiatric symptoms have not been commonly described in aceruloplasminemia due to the rarity of the disorder. MRI findings typically show marked T_2 hypointensity in the regions of maximal iron deposition, posterior white matter tract hyperintensity, and superficial cerebral and cerebellar cortical hypointensity.

A 21-year-old woman on treatment for aceruloplasminemia was referred for neuropsychiatric assessment. There was a family history of aceruloplasminemia, and the diagnosis was made 12 months earlier after she was found to have abnormal liver function tests. She now presented with an 18-month history of schizophrenia-like psychosis and declining function in the absence of neurologic signs. Neuropsychological testing showed significant dominant hemisphere deficits. MRI showed bilateral iron deposition in the cerebellar dentate nuclei and thalami, frontal atrophy, and periventricular white matter hyperintensities (Fig. 2.14–18).

The diagnosis of aceruloplasminemia can be made biochemically with findings of absent ceruloplasmin, low serum copper, normal serum total iron-binding capacity, and moderately elevated ferritin. Early treatment with the combination of the iron-chelating agent deferiprone and phlebotomy has been shown to delay the onset of neurologic symptoms in patients with early or pre-symptomatic disease.

NEUROFERRITONOPATHY. Neuroferritinopathy is an extremely rare autosomal dominant disorder with about 120 reported cases. It is caused by a mutation in the ferritin light chain (FTL) gene on 19q13.33, with 7 mutations identified to date. The FTL gene codes for the FTL, a subunit of ferritin, which plays a role in the storage and release of iron from cells. In neuroferritinopathy, ferritin is unable to store iron, and excess iron is deposited in brain cells, especially the globus pallidus, putamen and dentate nuclei of the cerebellum. The clinical phenotype begins in the third or fourth decade with extrapyramidal symptoms and signs including chorea, ataxia, dystonia, tremor, dysphagia, and dysarthria. This clinical syndrome may often be misdiagnosed as Huntington disease, but the presence of orofacial action-specific dystonia is characteristic of

Telegram: @medical_k

www.konkur.in

neuroferritinopathy. A review of the neuropsychiatric features of neuroferritinopathy described 22 cases. This review identified that subcortical type cognitive changes began about 4 years after the onset of motor symptoms (mean onset age 47.2). Individual cases of obsessive-compulsive disorder, psychosis, emotional lability and aggression were noted.

The clinical diagnosis of neuroferritinopathy should be suspected in cases of adult-onset movement disorder, MRI findings of excess iron deposition in basal ganglia or cystic degeneration on T_2* MRI images. The presence of cystic degeneration may help distinguish neuroferritinopathy from aceruloplasminemia. Serum ferritin may be low. The genetic diagnosis is based on the identification of a mutation in the FTL gene. Treatment using iron chelation (deferiprone or desferrioxamine) with phlebotomy has been unsuccessful. Symptomatic treatment of the movement disorder using conventional treatments (tetrabenazine, benzhexol, l-dopa, benzodiazepines) is variably successful. Botulinum toxin may be of benefit in dystonia.

Ion Channel Disorders

Disorders of ion channels, or channelopathies, have become an increasingly recognized group of disorders affecting cellular ion channels involving Na^+, Ca^{2+}, K^+, and Cl^- in electrically excitable tissue, such as heart, muscle, and brain. A number of genetic ion channel diseases have now been well described, such as the long QT syndrome (LQT), periodic paralysis, and a range of monogenic seizure syndromes. The cardinal feature of ion channel disease is the disturbance of rhythmic function, best illustrated by epilepsy, with an abnormally synchronous discharge causing a seizure; other rhythmic CNS disturbances include ataxia, paralysis, and sensorineural deafness. Additionally, the possibility of developing an *acquired* abnormality of ion channel function has been recognized, particularly in autoimmune disorders.

FIGURE 2.14–19. Voltage-gated potassium channel antibodies causing limbic encephalitis. *Left*, coronal fluid-attenuated inversion recovery magnetic resonance image shows bilateral mesial temporal hyperintensity. *Right*, identical coronal slice 3 months later, after treatment, shows resolution of hyperintensities but resultant hippocampal atrophy.

Voltage-Gated Potassium Channel Encephalopathy. Voltage-gated potassium channel (VGKC) antibodies are linked to a group of rare disorders characterized by abnormal neuromuscular excitability and CNS manifestations. These disorders form part of a larger group of CNS autoimmune disorders involving antibodies directed against targets on the neuronal surface. Isaac syndrome (acquired neuromyotonia) is associated with thymoma and VGKC antibodies but has no CNS manifestations. Morvan syndrome is a very rare disorder characterized by neuromyotonia, severe insomnia, excessive sweating, hypersalivation, and subacute encephalopathy commonly accompanied by psychotic features including delusions and hallucinations. High titers of VGKC antibodies are also detected. A group of patients with nonparaneoplastic limbic encephalitis have high titers of VGKC antibodies. This group presents with focal seizures with impaired awareness and a progressive amnestic syndrome with sleep disturbance as well as a fluctuating conscious state, personality change, and variable psychotic symptoms. MRI frequently demonstrates bilateral high signals in the hippocampal region. These symptoms are steroid responsive, including reversal of cognitive deficits and MRI changes once the diagnosis has been made (Fig. 2.14–19).

Telegram: @medical_k

www.konkur.in

Timothy Syndrome. Timothy syndrome is a relatively recently recognized multisystem Ca^{2+} channelopathy in which ASDs occur in 80% of affected individuals, alongside cardiac arrhythmias and syndactyly. The affected $Ca_V1.2$ gene is widely expressed, particularly in the heart, brain, smooth muscle, and pituitary and adrenal glands. In the CNS, the highest expression is in the granular layer of the dentate gyrus of the hippocampus and cerebellum. It is not clear how changes to neuronal tissue excitability contribute to the development of autism, but it is likely to represent the endpoint of the interaction between tissue excitability and normal neurodevelopment. A greater understanding of the pathophysiology of this disorder may open up new avenues of research into the possible contribution of ion channel disturbance to polygenic neuropsychiatric disorders.

NEUROENDOCRINE DISORDERS

Hypothalamic Disorders

The relationship between the hypothalamus and the pituitary gland is complex. In brief, the release of six anterior pituitary hormones prolactin (PRL), growth hormone (GH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), adrenocorticotrophin (ACTH), and thyrotropin or thyroid-stimulating hormone (TSH) is under the tonic influence of hypothalamic neuropeptides which travel from hypothalamic neurons via the portal system of the anterior pituitary to influence pituitary hormone-producing cells. AVP (vasopressin or ADH, antidiuretic hormone) and prolactin are produced in the hypothalamus and stored in the posterior pituitary. As a consequence of this relationship, endocrine abnormalities of the hypothalamus are largely manifest as abnormalities of pituitary function, as described below. However, the hypothalamus also has a number of nonendocrine functions that, when disturbed, may manifest as neuropsychiatric disorders.

The hypothalamus contains a number of unique neurons that create two neuropeptides known as *orexins* (formerly *hypocretins*). They are synthesized only in the hypothalamic neurons and share some homology to the gut hormone secretin. Orexinergic neurons project from the hypothalamus to a number of monoaminergic centers, including the locus ceruleus, raphe nuclei, and ventral tegmentum. A number of these

Telegram: @medical_k

www.konkur.in

monoaminergic systems are involved in the regulation of sleep, in which the hypothalamus is now recognized as a key center. The contribution of the hypothalamus is via sleep-promoting GABAergic neurons of the VLPO (ventrolateral preoptic area) and the wakefulness-promoting orexinergic neurons in the lateral hypothalamus. These pathways are closely linked to the circadian pacemaker in the suprachiasmatic nuclei and the regulation of other hypothalamic functions such as temperature, food intake, metabolism, and hormone secretion.

The orexinergic system is also important in the regulation of food intake and energy expenditure. Orexin production can increase food craving but is also inhibited by leptin, a hormone produced by adipocytes and stimulated by ghrelin. Ghrelin is secreted by the stomach just prior to a meal and is known to stimulate caloric intake. This provides a biochemical basis for the well-demonstrated phenomenon of sleep-deprivation-related catabolism despite adequate caloric intake described in animal models.

Narcolepsy

Narcolepsy is a sleep disorder characterized by excessive daytime somnolence, cataplexy (a sudden loss of muscle tone, often triggered by strong emotional reactions) and manifestations of disordered rapid eye movement (REM) sleep such as hypnogogic hallucinations, automatic behavior, and sleep paralysis. Although narcolepsy in dogs is linked to mutations in hypocretin-related genes, no such mutations have been described in humans, although in approximately 90% of patients, orexin levels in the CSF are low or nonexistent. Strong links to the human leukocyte antigen (HLA) system suggest an autoimmune basis. HLA-DR15 and HLA-DQ6 have been described in up to 85% of patients, but only 20% of controls and the DQB1*602 allele has been detected in 98% of patients with cataplexy. Gene–environment interaction is likely given the <25% concordance rate between monozygotic twins. Depression has been described in up to 25% of patients in some series, although others suggest a rate no higher than in the healthy population.

There appear to be three main groups of patients who experience psychosis in narcolepsy. First, sleep-related hallucinations have been described in up to 80% of patients with typical narcolepsy, most often nonverbal in form and associated with insight. It has been suggested that these symptoms are “narcoleptic” in origin and respond to treatment with stimulants and that REM-intrusion into wakefulness may be misdiagnosed

Telegram: @medical_k

www.konkur.in

as schizophrenia. Second, in an atypical form of narcolepsy, vivid hallucinatory experiences and daytime dream experiences associated with reduced insight may result in delusional preoccupations or misinterpretations resembling the delusional symptoms described in schizophrenia. Third, there is a small group of patients who have a dual diagnosis of schizophrenia and narcolepsy. The vast majority of psychoses associated with narcolepsy do appear to relate to stimulant use/misuse, as historically, dopaminergic agents such as dexamphetamine have been used to promote wakefulness. Newer agents such as modafinil may be less psychotogenic. Neuroleptics, however, worsen narcoleptic somnolence, as dopamine outflow is central to cortical wakefulness.

A 23-year-old man was referred for assessment of psychotic symptoms occurring in the setting of narcolepsy. At age 13, narcolepsy was diagnosed on the basis of daytime somnolence, cataplexy, sleep paralysis, and hallucinations. He showed an HLA-DR15 haplotype. He had begun dexamphetamine 2 years prior to assessment and started to experience auditory hallucinations, thought broadcasting, and a complex persecutory delusional system (whereby he was being studied through a device implanted in his head) within 6 months. His family described a precipitous psychosocial decline over 12 months, as the patient became unemployed, socially withdrawn, and increasingly disorganized. On mental state, he presented as fatuous and inappropriate, with a clear thought disorder. After commencing fluphenazine 4 mg and ceasing dexamphetamine, the hallucinations and delusions diminished, although he remained fatuous and amotivated. A diagnosis of narcolepsy-related psychosis secondary to dexamphetamine treatment was made, with a differential diagnosis of schizophrenia.

Hypothalamic Lesions

Hypothalamic obesity has been associated with lesions of the ventromedial nucleus and may initially involve aggressive behavior and hyperphagia until a new set weight is reached, at which time reduced appetite and activity may manifest. Rage reactions are also well described in animals with lesions in this region of the hypothalamus, although less

Telegram: @medical_k

www.konkur.in

so in humans with such lesions. Lateral lesions have been reported to result in an apathetic state. Thirst may also be impaired if ADH production is reduced by a hypothalamic lesion. Short-term memory dysfunction has been reported, particularly in lesions of the ventromedial and premamillary areas of the hypothalamus. Extensive hypothalamic lesions may produce features consistent with a dementing illness.

Hypothalamic disease may also result in abnormalities of thermoregulation. Temperature-sensitive neurons are located in the anterior hypothalamus, whereas the posterior hypothalamus mediates heat loss mechanisms. Acute lesions such as hemorrhage, infarction or those from surgical procedures may result in acute and paroxysmal hypothermia. Conversely, posterior hypothalamic lesions may result in paroxysmal hyperthermia with associated fevers and rigors.

Childhood tumors invading the anterior and basal hypothalamus, such as gliomas, midline cerebellar astrocytomas, and suprasellar ependymomas, may result in diencephalic syndrome which is manifested as motor hyperactivity, euphoria or inappropriate effect, increased alertness and emaciation despite normal caloric intake. If death does not ensue, the clinical picture may change to one of obesity and intermittent rage reactions. In adulthood, slower-growing tumors usually result in a dementia syndrome, endocrine dysfunction, and food intake dysregulation. More rapid or destructive processes present with disturbances of consciousness, temperature, and autonomic dysregulation. Craniopharyngiomas, germinomas, and gliomas are the most frequently reported tumors. Craniopharyngiomas, remnants of the embryonic Rathke pouch, can manifest in both childhood (most common) and adulthood, usually involving the posterior hypothalamus. As most are suprasellar, patients usually present with visual abnormalities and headaches. Hypogonadism, hyperprolactinemia, diabetes insipidus, and weight gain are common, as is cognitive deterioration and personality change without evidence of psychosis (Fig. 2.14–20).

Pituitary Disorders

The pituitary gland, or *hypophysis*, is an endocrine structure that sits in the midline sella turcica at the base of the brain in the middle cranial fossa and is covered by a dural fold (the *diaphragma sellae*). It secretes hormones regulating homeostasis and, through the release of trophic hormones, stimulates other distal endocrine structures. Its anterior lobe,

Telegram: @medical_k

www.konkur.in

the *adenohypophysis,* is under the direct functional control of the hypothalamus via the hypophysial-portal vascular connection in the pituitary stalk, through which stimulatory and inhibitory signals are sent to control the five distinct endocrine cell types that release pituitary hormones. The posterior lobe, the *neurohypophysis*, is predominantly a collection of axons from the supraoptic and paraventricular nuclei of the hypothalamus that secretes peptide hormones into the hypophyseal circulation. The posterior lobe is connected by the infundibulum in the pituitary stalk, and the release of oxytocin and vasopressin is controlled through the tuberoinfundibular pathway. Given the complex nature of the hypothalamic–pituitary axis, it is not surprising that clinical manifestations of pituitary disease are protean. Pituitary dysfunction may result from pituitary tumors or destructive disease processes.

FIGURE 2.14–20. Craniopharyngioma causing the diencephalic syndrome. T_1-weighted magnetic resonance imaging scans of a patient who presented with emaciation and features of the diencephalic syndrome. *Left*, axial image demonstrating a slightly hypointense tumor within the third ventricle accompanied by moderate dilation of the lateral ventricles. *Right*, sagittal image obtained after the administration of gadolinium revealing that the tumor is homogeneously enhanced and is entirely confined within the third ventricle. Diencephalic syndrome of emaciation in an adult associated with a third ventricle intrinsic craniopharyngioma: a case report. *Neurosurgery*. 2003;52(1):224, with permission. © Congress of Neurological Surgeons.)

Telegram: @medical_k

www.konkur.in

Pituitary Tumors

Pituitary tumors are found in up to 20% of adults at autopsy and are frequently incidental findings in neuroimaging. They may result in an increase or decrease of hormone levels and produce symptoms by invading surrounding structures such as the hypothalamus.

Prolactinomas. The most common secretory tumors are prolactinomas. Dysregulated secretion of prolactin results in amenorrhea, infertility and galactorrhea in women and impotence and occasionally galactorrhea or gynecomastia in men. Data regarding the neuropsychiatric manifestations of hyperprolactinemia are lacking. There is some evidence of increased aggression in lactating animals associated with elevated prolactin levels and in hyperprolactinemic human subjects. Depression and anxiety symptoms also occur with greater frequency in this group of patients, which may respond to treatment with the dopamine agonist bromocriptine. Psychotic symptoms have been described in neuroleptic naive patients with hyperprolactinemia at a case report level. Treatment with antipsychotic agents may then result in further elevation of prolactin. Psychotic symptoms have also been described in patients receiving bromocriptine for the treatment of a prolactinoma, with both delusions and hallucinations recorded. The incidental finding of a pituitary adenoma on neuroimaging can complicate the assessment of patients with a psychotic illness stabilized on an antipsychotic agent with hyperprolactinemia. Impulse control disorders such as pathologic gambling have also been reported in patients receiving cabergoline (a potent dopamine type II receptor agonist) therapy for pituitary adenomas.

Growth-Hormone Secreting Tumors. These are the second most common functional pituitary adenomas (Fig 2.14–21). In adults, they result in *acromegaly* with soft tissue and bone enlargement, particularly involving the hands, feet, jaw and tongue, with a characteristic overall coarsening of facial features. There may be associated hypertension, congestive cardiac failure and obstructive sleep apnea and hypersomnolence. A number of psychiatric symptoms have been associated with acromegaly, largely at the case report level. Acromegalic patients appear to have a lifetime increased risk of affective disorders when compared with control subjects with and without a chronic somatic disease. There is no evidence of a preponderance of psychotic

Telegram: @medical_k

www.konkur.in

symptoms, although these are well described when acromegalic patients are treated with bromocriptine resulting in delusional symptoms, schizophrenia-like presentations, and visual hallucinations.

ACTH Secreting Tumors. ACTH secreting tumors are the next most common pituitary tumor type, resulting in excessive cortisol production or Cushing disease. The neuropsychiatric manifestations of increased cortisol release are discussed below in the description of adrenal disease.

Other Pituitary Tumors. Clinical symptoms resulting from tumors producing LH or FSH are very rare. Increased TSH production can occasionally result in hyperthyroidism, the psychiatric aspects of which are discussed below. As many as 30% of pituitary tumors are non-secretory and are often larger at diagnosis because of the lack of endocrine manifestations. If large enough, pituitary tumors may impinge on surrounding structures resulting in the classic visual field defect of bitemporal hemianopia, oculomotor palsies headache and occasionally hypothalamic syndromes (see above). Visual hallucinations in the context of visual field defects related to pituitary tumors impinging the optic chiasm have been reported. More often, these are of the simple, non-formed type, are associated with insight and can be exacerbated by treatment with bromocriptine.

Telegram: @medical_k

www.konkur.in

FIGURE 2.14–21. Pituitary adenoma causing acromegaly. Gadolinium-enhanced magnetic resonance imaging of the brain showing a well-defined mass in the right lateral aspect of the sella with a lack of enhancement (see white arrow) compared with the normal pituitary gland. Endocrinologic evaluation revealed elevated human growth hormone and insulin-like growth factor levels consistent with acromegaly. (From Koo CW, Bhargava P, Rajagopalan V, Ghesani M, Sims-Childs H, Kagetsu NJ. Incidental detection of clinically occult pituitary adenoma on whole-body FDG PET imaging. *Clin Nucl Med.* 2006;31(1):42, with permission. doi: 10.1097/01.rlu.0000191779.75532.05.)

Hypopituitarism

Deficiency or dysfunction of one or more of the pituitary hormones is referred to as hypopituitarism. In adulthood, this is usually caused by an acquired destructive process that may be traumatic (related to head injury), inflammatory, immune-mediated, vascular or as the result of compression from an adjacent tumor. Clinical manifestations are

Telegram: @medical_k

www.konkur.in

dependent on the hormones involved. GH is often first affected, followed by the gonadotrophins with associated amenorrhea and infertility in women and reduced libido and body hair loss in men. Low TSH can result in hypothyroidism, ACTH deficiency in fatigue, reduced appetite, weight loss, and impaired stress response. Vasopressin deficiency may also ensue, resulting in polyuria and thirst. A number of neuropsychiatric manifestations have been described in hypopituitarism in the absence of delirium. Memory impairment, sleep disturbance and personality change are commonly but variably reported. Visual and auditory hallucinations have been described at a case report level, and several observers have reported an absence of affect on the mental state examination. A systematic study of psychiatric co-morbidity in hypopituitarism found more psychiatric symptoms than those expected in chronic diseases such as diabetes mellitus, most particularly depression and anxiety. Psychosis is uncommon, but depression appears to be more common in those who have hypopituitarism associated with a traumatic brain injury.

More specific symptoms are attributable to particular hormone deficiencies. GH deficiency may result in reduced energy, depressed mood, anxiety, emotional lability, and impulsivity or impaired self-control. Testosterone deficiency has been associated with depression, irritability and insomnia. Fatigue, social withdrawal and negativism have been reported when ACTH is low. Finally, as in hypothyroid states, fatigue, depression, insomnia or hypersomnia and psychotic symptoms have been described when TSH levels are low. There can be considerable variation in the type of psychotic symptoms described. In general, appropriate correction of the hormone deficiency and addressing the underlying cause results in the resolution of these features.

Thyroid and Parathyroid Disorders

Normal thyroid function involves the production of the two thyroid hormones, L-thyroxine (T_4) and 3,5,3′-triiodo-L-thyronine (T_3), which are required for the regulation of a number of metabolic processes. Increased thyroid hormone production results in hypermetabolism or increased caloric utilization and the other clinical features of hyperthyroidism. Hypometabolism and the features of hypothyroidism (sometimes referred to as myxedema) result from reduced hormone production. Psychiatric symptoms that accompany either of these states have been subject to

Telegram: @medical_k

www.konkur.in

more systematic study than those associated with pituitary disorders, as primary thyroid disorders have a much higher incidence in the population.

Hyperthyroidism. Hyperthyroidism is the result of the excessive production of thyroid hormones. This may result from a toxic multinodular goiter, a single functioning adenoma or from the presence of a thyroid stimulator, such as a thyroid-stimulating antibody in Grave disease. Exogenous thyroid hormone can produce a similar picture as can disorders of thyroid hormone storage consequent to autoimmune thyroiditis.

Depressive symptoms are not only the most common psychiatric features seen in hyperthyroidism, occurring in up to 30% of patients, but frequently occur prior to the onset of the other physical features. This includes lowering of mood as well as neurovegetative disturbance such as insomnia, reduced libido, weight loss, and fatigue. However, as distinct from depression, appetite is invariably increased in hyperthyroidism. The severity of the depressive symptoms has not been found to be related to the severity of hyperthyroidism as measured by subsequent thyrotoxic features and the extent of the biochemical abnormalities.

Older adult patients with thyrotoxicosis may present with predominantly apathy, depression, and weight loss rather than increased psychomotor activity. Typically this presentation is of slower onset, the neurologic and ophthalmologic features are less prominent, but cardiovascular events such as exacerbation of angina, cardiac failure, and atrial fibrillation are more prevalent. Anxiety symptoms presenting as generalized anxiety are also common, with a prevalence of between 10% and 20%, but panic and agoraphobia are relatively uncommon. Like depressive symptoms, anxiety may occur prior to the other features of hyperthyroidism but more often correlates with the severity of the thyrotoxic features. Anxiety and depressive features are often comorbid. Manic symptoms are less common in hyperthyroid states with a prevalence between 2% and 5% but may be difficult to distinguish from psychomotor agitation and anxiety. Psychotic symptoms, including paranoid delusions and auditory hallucinations, while historically reported as common, have a true prevalence of between 2% and 5%. The depressive syndrome seen in hyperthyroidism rarely requires treatment other than which is used to restore the euthyroid state. However, some features, such as anxiety,

Telegram: @medical_k

www.konkur.in

fatigue and loss of function, may persist for as long as 12 months after a euthyroid state has been achieved.

Cognitive dysfunction is reported between 5% and10% of patients with thyrotoxicosis, but to a lesser degree than seen in hypothyroidism. Patients may present with slow processing speeds, impairments in immediate memory, defective higher-level problem solving or frank delirium. Mild disorders of attention and concentration are common, but their severity does not always correlate with the severity of thyrotoxicosis. These deficits invariably respond to the reversal of the thyrotoxic state.

Hypothyroidism. The most common cause of hypothyroidism in adults is primary autoimmune hypothyroidism related to antithyroid antibodies. Other causes include treatment for hyperthyroidism, drug-related effects, and iodine deficiency. Supra-thyroid causes (hypothalamic or pituitary dysfunction) account for less than 5% of cases. The symptoms of hypothyroidism may include fatigue, lethargy, weight gain, constipation, cold intolerance, stiffness and cramping of muscles, hair loss, cognitive slowing, and depression. Signs include hypothermia, bradycardia, dry skin, sparse hair, periorbital swelling, thickening of the tongue, coarsening and deepening of the voice, and a characteristic prolonged relaxation phase of deep tendon reflexes. This clinical picture is often referred to as *myxedema*. Hypothyroid patients may present with a variety of psychiatric symptoms ranging from mild cognitive slowing and depression to frank encephalopathy, which often predates other physical features. Functional neuroimaging studies have demonstrated global hypometabolism and more specific areas of hypoperfusion in the posterior cingulate, insula, fusiform gyrus, and right parieto-occipital and primary motor cortex.

Cognitive deficits are the most common neuropsychiatric features of hypothyroidism, occurring in up to 50% of cases. Psychomotor speed, memory, and visual-perceptual skills are often impaired. Difficulties with constructional skills and reduced performance in trail-making and maze tasks also suggest prominent executive deficits. The severity of these disorders is correlated with the degree of biochemical abnormality, and although largely corrected by a return to a euthyroid state, some cognitive deficits may remain, particularly in the older adults or those with reduced cognitive reserve. Severe disturbance of consciousness, including coma and delirium, may be encountered but may be associated with other metabolic changes related to the hypothyroid state, such as

Telegram: @medical_k

www.konkur.in

hyponatremia. Depression is only slightly less common than cognitive disturbance, reported in approximately 40% of patients, but appears less closely related to the severity of biochemical hypothyroidism. Low mood, fatigue, anhedonia, reduced concentration, and hypersomnolence are the most commonly described features of the depressive syndrome in hypothyroidism. These features predictably respond to treatment of the hypothyroid state. The origin of depression in hypothyroidism appears to relate to the role of thyroxine in serotonergic transmission, such that reduced thyroid input reduces serotonergic tone and lowers the threshold toward the development of depressive symptoms. Conversely, thyroid replacement restores central serotonin activity in concert with improvement in depressive symptoms. This may also underpin the adjunctive antidepressant effect of thyroxine.

In contrast, manic and hypomanic symptoms have been infrequently reported in association with hypothyroidism. However, hypothyroidism may be a risk factor for the development of bipolar disorder, particularly the rapid cycling form and treatment of otherwise refractory mood disorders with thyroid hormones has occasionally been shown to be effective. Generalized anxiety symptoms are described in up to 30% of patients and are strongly correlated with depressive symptoms but not with biochemical severity. There is some evidence that hypothyroidism is a risk factor for suicidal ideation in patients with depression. Psychotic symptoms, including paranoid ideas, misidentification, visual and auditory hallucinations, and thought disorder, were originally thought to be common (and described as “myxedematous madness”) but likely occur in less than 5% of all patients with hypothyroidism and tend to emerge after the onset of physical symptoms. Although these symptoms also respond to appropriate thyroid hormone treatment within days to weeks, rapid titration of hormone doses may exacerbate psychosis. Careful addition of a low dose of antipsychotic to thyroxine has been reported to be well-tolerated and results in an earlier remission of psychosis.

“Subclinical” Hypothyroidism. Thyroid hormone abnormities may occur without overt functional hypothyroidism. Designated *subclinical hypothyroidism*, these scenarios can be further classified into elevated TSH without changes in thyroid hormones (Grade II hypothyroidism), abnormal TSH response to stimulation with TRH (Grade III) and the presence of antithyroid antibodies with no thyroid hormone system

Telegram: @medical_k

www.konkur.in

abnormalities (Grade IV). Grade II hypothyroidism has been associated with depressive disorders. Patients with major depressive disorders have an increased incidence of Grade II hypothyroidism, and some studies show these patients respond poorly to conventional treatment. Grade II hypothyroidism may be a risk factor for major depressive disorders. Cognitive disturbance, particularly memory and psychotic symptoms, have also been reported in Grade II hypothyroidism. Although there is some evidence of improvement in cognition, mood and psychosis, treatment of subclinical hypothyroidism is controversial.

Hashimoto Encephalopathy. Hashimoto encephalopathy (HE), also described as steroid-responsive encephalopathy associated with autoimmune thyroiditis (SREAT), is best defined as an uncommon autoimmune encephalopathy of unknown etiology associated with high titers of serum antithyroid (usually antithyroid peroxidase ± anti-thyroglobulin) antibodies. The role of antithyroid antibodies is controversial. There is no direct evidence that these auto-antibodies exert direct effects on CNS tissue, and they may be epiphenomena of another autoimmune process. Additionally, the base rate of elevations of these autoantibodies in the population is as high as 10%. Elevated serum antithyroid antibodies are associated with other thyroid disorders (Grave disease, de Quervain thyroiditis, primary hypothyroidism, and colloidal goiter) and other auto-immune disorders (including diabetes mellitus, Addison disease, and pernicious anemia).

HE is more common in women with a mean age of onset between 45 and 50 years. There may be a history of other autoimmune diseases. The clinical picture is one of encephalopathy with progressive cognitive decline, although the course may also be relapsing and remitting. Common features include seizures (>95% of cases), stroke-like episodes (> 65% of cases), and memory dysfunction. Neuropsychiatric features include agitation and restlessness, apathy, and social isolation. Visual hallucinations are frequently reported (>90%), as are other disorders of perception and delusions. HE may also present as a depressive illness, although typical presentations of psychiatric illness, such as depression, in the setting of mildly elevated antithyroid peroxidase antibodies are unlikely to be due to HE. However, when antithyroid peroxidase levels are very high (>1,000 IU/l), the likelihood of them being associated with neuropsychiatric HE is much greater.

Telegram: @medical_k

www.konkur.in

Routine investigations are often normal, although patients will often show slowing on EEG, with the degree of slowing being proportional to the clinical severity of the syndrome, and some patients may show triphasic waves (Fig. 2.14–22). The majority of patients respond to corticosteroid treatment with complete resolution of the neuropsychiatric symptoms.

A 66-year-old woman presented with a 4-month history of cognitive decline, including short-term memory and language deficits. She had a generalized tremor and developed a delusional belief that her husband wished to harm her. She became agitated and disoriented, particularly at night, and also described visual hallucinations of small animals in her room. No neurologic features, including myoclonus, were described. At this time, all routine blood investigations (including complete blood count, serum urea, electrolytes, creatinine, liver enzymes, thyroid hormone assays, folate and B_{12} level and CT brain) were normal. One month later, she suffered a generalized tonic–clonic seizure. Routine blood investigations and examination of the CSF were normal. Angiography of the anterior and posterior cerebral circulation was normal. MRI scan was normal, and EEG was unremarkable. On mental state examination, she was disoriented with impaired attention and markedly poor short-term memory (particularly nonverbal memory). Her speech was characterized by impaired verbal fluency and word-finding problems. There was a concrete thinking style with reduced abstract reasoning as well as poor judgment. There were no depressive or psychotic features at this time. Her then mental state rapidly deteriorated. She became virtually mute, with poor concentration and attention and required assistance with all aspects of personal care. She had bilateral grasp and pout reflexes as well as diffuse hyperreflexia. She also had bilateral and multifocal myoclonus. In the face of previously normal investigations, the diagnosis of Hashimoto encephalopathy was considered. Thyroid hormone (TSH, T4, T3) levels were within normal limits. Antithyroid peroxidase antibodies (anti-TPO) were raised in titer (640 IU/ml, normal <50 IU/mL), consistent with this diagnosis. A course of prednisolone 60 mg was commenced with marked improvement in her mental state within 2 weeks.

Parathyroid Disorders

The parathyroid glands are small accessory glands that are anatomically associated with but functionally distinct from the thyroid gland. Their sole function is to maintain serum calcium levels within a narrow range to permit optimum functioning of the nervous and muscular systems through the release of parathyroid hormone (PTH). The release of PTH increases serum calcium via stimulating osteoclasts in bone to release calcium and by increasing its absorption in the gut and kidneys.

Telegram: @medical_k

www.konkur.in

Hyperparathyroidism. Hyperparathyroidism is usually diagnosed after an incidental finding of hypercalcemia on routine blood tests, and 50% of patients with hyperparathyroidism are asymptomatic. Increased PTH release is usually caused by a single functioning adenoma, although multiple adenomas may occur as part of Multiple Endocrine Neoplasia Syndrome (MENS). Symptoms are principally those secondary to hypercalcemia. These include fatigue, general malaise, proximal muscle weakness, renal colic, abdominal pain, and cognitive decline. There is often little to find on examination, although real calculi, nephrocalcinosis, or bone changes (osteitis fibrosa cystica, now rare) may be seen on radiologic investigations ordered for other reasons. Although a number of psychiatric symptoms have been described in hyperparathyroidism (as part of the symptomatic tetrad of “bones, stones, moans and psychic groans”), the prevalence overall is likely to be less than 10%. These symptoms correlate with both the duration and severity of the associated hypercalcemia. Affective disorders predominately of the depressive type are the most frequently recorded, with anxiety often comorbid. Psychotic disorders are reported, although infrequent, with persecutory and paranoid delusions predominating. Cognitive changes, usually related to short-term memory loss, disorders of attention and acute confusional states often occur, and severe derangement of calcium metabolism may present with somnolence and coma. Neuropsychiatric symptoms are often the initial presentation in the older adults or those with limited cognitive reserve. The more severe the hypercalcemia, the more severe the psychiatric disturbance, but symptoms generally respond to appropriate treatment such as parathyroidectomy. When PTH levels are mildly raised in the setting of normocalcemia (most commonly due to vitamin D insufficiency, increasingly prevalent in developed countries), a psychiatric disturbance is uncommon.

Hypoparathyroidism. The most common cause of impaired PTH production in adults is inadvertent surgical removal during thyroid surgery or excessive removal for hyperparathyroidism. Clinical features related to hypocalcemia, particularly symptoms of neuromuscular excitability, including paresthesias, muscle cramps, carpopedal spasm, facial grimacing progressing to laryngeal spasm and convulsions. An examination may reveal features of tetany, reduced or absent deep tendon reflexes, papilledema, and QT interval prolongation on ECG.

Telegram: @medical_k

www.konkur.in

Delirium is now understood to be the most common neuropsychiatric manifestation. One large study available demonstrated cognitive impairment in 39% of patients, affective or neurotic symptoms in 12%, psychotic symptoms in 11% and nonspecific affective disturbance in 21% of patients. Again, the severity of symptoms directly relates to the degree of hypocalcemia and appropriate normalization results in the resolution of these symptoms, although persistent psychosis has been noted when associated hypomagnesemia was not addressed.

Adrenal Disorders

The adrenal glands produce both adrenal steroids from the cortex and catecholamines from the medulla. The adrenal cortex produces glucocorticoids, principally cortisol, under the stimulatory effects of ACTH from the anterior pituitary controlled by a negative feedback loop. Aldosterone, a mineralocorticoid, originates from the adrenal cortex but is controlled by the renin-angiotensin system influenced by body volume and potassium balance. Adrenal androgens, predominately DHEA (dehydroepiandrosterone), are also regulated by the ACTH system and undergo peripheral conversion to sex-determining androgens. Hyperfunction or hypofunction of these adrenal systems results in distinct clinical syndromes with complex physical and neuropsychiatric manifestations.

Hyperadrenalism. Hyperadrenalism (Cushing syndrome) occurs when the adrenal gland produces excess corticosteroids, usually as a result of ACTH overproduction from the anterior pituitary secondary to a pituitary adenoma (Cushing disease). Other causes include ACTH production from a non-endocrine tumor, an adrenal neoplasm or, most commonly, exogenous steroids, usually prescribed for treatment of a steroid-sensitive medical condition. Patients with Cushing syndrome present with the classic features of hypertension, muscle weakness and fatigue, osteoporosis, cutaneous striae and easy bruising. A characteristic pattern of obesity is seen involving the upper face (resulting in a “moon face”), back (“buffalo hump”), and mesentery resulting in truncal obesity. Women may experience hirsutism, acne and amenorrhea, men, decreased libido and impotence. Neuropsychiatric features are well described, with depression the most frequently noted psychiatric symptom in up to 70% of patients. Anxiety is commonly comorbid with depression in up to 50% of

Telegram: @medical_k

www.konkur.in

sufferers. Depressive symptoms may present prior to physical symptoms. They respond to treatment of the underlying cause, and the response correlates with lowering plasma cortisol levels. Elevated mood is infrequently reported in Cushing syndrome, reported in less than 10% in most case series. Delirium is also relatively uncommon and is usually a marker of a supervening infection or other metabolic disorder such as metabolic alkalosis. Although dramatic case reports of Cushing syndrome presenting with psychosis and obfuscating the underlying condition are reported, this form of presentation is rare. When present, psychotic symptoms are almost always mood-congruent delusional beliefs and derogatory auditory hallucinations associated with a depressed mood. Cognitive impairment occurs in over 50% of patients, presenting as deficits in verbal memory, attention, and visuomotor and visuospatial function. The degree of memory impairment, and its reversibility, appear to correlate with hippocampal volume, suggesting that cognitive impairment is partially driven by the effect of excess glucocorticoids on hippocampal neurons. A more general reduction in gray matter volume, cortical thickness, and white matter integrity has been demonstrated and can persist after correction of the hypercortisolism.

With exogenous administration of steroids, manic symptoms are most frequently reported, followed by delirium, depression, and psychotic symptoms. Mixed affective states also appear over-represented. The severity of these symptoms may be dose-related, reproducible in the individual and minimized with the use of divided doses of steroids.

Manic symptoms may respond to both cessation of the exogenous steroid administration and pharmacotherapy with mood-stabilizing agents such as lithium and valproate or treatment with antipsychotics.

Hypoadrenalism. Primary hypofunction of the adrenocortical system may result from a primary process at the level of the gland, such as destruction by an autoimmune process, referred to as Addison disease (most common), other inflammatory or destructive processes, or an inborn failure of enzyme function. It may also arise secondary to dysfunction of the hypothalamic–pituitary axis or withdrawal of exogenous steroids. The onset of symptoms is usually insidious with progressive fatigue, weakness, anorexia, nausea, abdominal pain, weight loss, cutaneous and mucosal pigmentation, hypotension and hypoglycemia. Other findings include hyponatremia, hyperkalemia, and metabolic acidosis. Reports of

Telegram: @medical_k

www.konkur.in

neuropsychiatric symptoms in Addison disease are uncommon, although the true prevalence is uncertain due to probable under-reporting. Depression, reduced motivation and energy and behavioral changes predominate. Memory dysfunction is the most common form of cognitive disturbance. Paranoid symptoms and delusions are less common. Catatonia and self-mutilation are rare but dramatic presentations. Auditory and visual hallucinations, changes in conscious state, irritability, insomnia, and nightmares often herald an addisonian crisis with frank delirium, coma, and seizures. Hyponatremia and metabolic acidosis may contribute to delirium and cognitive deficits. These symptoms appear to largely resolve, including those of adrenal crisis when treatment with adequate doses of corticosteroids is commenced. Recent data indicates that higher corticosteroid doses reduce the occurrence and severity of neuropsychiatric symptoms, particularly depressive symptoms. The use of other psychotropic agents is rarely indicated.

Hyperaldosteronism. Excess of the major adrenal mineralocorticoid aldosterone can arise from the adrenal gland (primary aldosteronism) or from an extra-adrenal site (secondary aldosteronism). Primary aldosteronism is usually due to an aldosterone-producing adenoma (Conn syndrome) or bilateral cortical hyperplasia. Secondary aldosteronism relates to disturbance of the renin-angiotensin system and hypovolemia. The characteristic features of Conn syndrome are hypokalemia, hypertension, muscle weakness, fatigue, polyuria, and polydipsia. Metabolic alkalosis and hypomagnesemia may also occur, and edema is characteristically absent. Depression has been identified as one of the major features, but more recent studies have demonstrated features of generalized anxiety with individual cases of associated depression, features of obsessive-compulsive disorder and panic without specific gender differences. Untreated primary hyperaldosteronism and resulting severe hypertension can result in vascular dementia if left untreated. Although treatments, such as surgical excision of a functioning adenoma, are effective in reversing the physical symptoms of hyperaldosteronism, the effect on anxiety and other symptoms is unknown.

FIGURE 2.14–23. Subcortical dementia due to hyperaldosteronism in a 48-year-old man with untreated hyperaldosteronism. Axial fluid-attenuated inversion recovery images show bilateral extensive periventricular and subcortical white matter hyperintensity with multiple lacunar infarcts in the basal ganglia, consistent with long-standing untreated hypertension.

Telegram: @medical_k

www.konkur.in

A 48-year-old man with no past psychiatric history had raised family concerns following 3 years of unusual behavior, social withdrawal, and poor self-care. He lost contact with friends, began to gamble heavily, had a number of car accidents, and was disinhibited and socially inappropriate. He had recently started a fire in his residence with one of many discarded cigarettes. On examination, he was hypertensive (240/120 mm Hg) and had signs of left ventricular hypertrophy but no neurologic abnormalities. On cognitive assessment, he had a marked dysexecutive syndrome. Serologically he had a mild metabolic alkalosis and hypokalemia (3.2 mmol/L). Serum cortisol, ACTH, and vasculitic screen were normal. ECG showed first-degree heart block and left ventricular hypertrophy, which was confirmed on echocardiography. There was a failure of aldosterone suppression with saline challenge and bilateral adrenal hyperplasia on abdominal CT. Brain MRI showed extensive severe periventricular and subcortical white matter disease (Fig. 2.14–23). He was diagnosed with Binswanger dementia secondary to hypertension associated with hyperaldosteronism.

Pheochromocytoma. Pheochromocytomas are tumors that secrete catecholamines and most commonly originate in the chromaffin cells of the adrenal medulla but may rarely arise from similar cells in sympathetic ganglia. Familial forms are associated with MENS type IIa and b and von Recklinghausen neurofibromatosis. Secretion of catecholamines may be continuous or sporadic, sometimes resulting in characteristic paroxysmal symptoms of headache, profuse sweating, palpitations, Raynaud phenomenon, tremor, nausea, vomiting, abdominal and chest pain. The triad of palpitations, headache, and profuse sweating is the most sensitive and specific for pheochromocytoma. Clinical findings include hypertension, pallor, postural hypotension, and signs of chronic hypertension such as retinopathy. Paroxysmal symptoms occur in 40% of pheochromocytomas and may present as a phenocopy of anxiety symptoms, particularly a panic episode, and are often diagnosed as such. These may occur spontaneously or may be precipitated by exercise, postural change, raised intra-abdominal pressure, or emotional excitement or shock. The severity of the episodes may also vary, and anxiety may persist for some time after the attack. Psychosis and

Telegram: @medical_k

www.konkur.in

cognitive deficits have not been described, although there are several case reports of a secretory pheochromocytoma causing a relapse of a previously treated or quiescent psychotic disorder. Diagnosis is made by detecting increased urinary secretion of catecholamines or catecholamine metabolites. Location of the underlying tumor and surgical excision with alpha-adrenergic blockade is effective in resolving most anxiety symptoms if paroxysmal episodes are terminated.

Neuroendocrine Tumors

While the term “neuroendocrine” is commonly used to refer to the interaction of the endocrine and nervous systems, histologically, it refers to a particular type of cell.

Neuroendocrine cells are cells that release a hormone or regulatory peptide into the circulation in response to a neural stimulus. The most extensive neuroendocrine system is in the gastrointestinal tract and associated organs, and when these tissues release excess hormones, a range of neuropsychiatric syndromes can occur.

Carcinoid Syndrome. A carcinoid is a neoplasm of neuroendocrine cells that synthesize and secrete serotonin in the respiratory system and gastrointestinal tract. The main symptoms are flushing (often severe facial flushing with bronchial tumors), diarrhea, wheezing, and hypotension. Although peripherally secreted serotonin does not cross the blood–brain barrier, a number of psychiatric symptoms have been described. These include depression (in up to half of patients), anxiety, sleep disorders and, rarely, psychosis. These symptoms may be more common with metastatic disease. A series of 23 patients found that over half experienced personality change consisting of increased irritability and impulsive aggressive thoughts or behavior, some meeting criteria for impulse control disorder. These changes often preceded the other physical symptoms. Depression was far less common, and psychotic symptoms were not detected.

Insulinoma. Insulinomas are functioning b islet cell tumors of the pancreas, which result in unregulated insulin secretion, at times with abrupt fluctuations. Clinical features include fasting hypoglycemia (relieved by glucose ingestion) and weight gain. Hypoglycemia is characterized by hunger, restlessness, palpitations, flushing and ataxia

Telegram: @medical_k

www.konkur.in

but may also include malaise, anxiety, depersonalization and derealization or seizures. Neuroglycopenic symptoms such as confusion, personality change, amnesia, and bizarre behavior are also reported. A more subacute syndrome consisting of clumsiness, disinhibited or aggressive behavior (and associated amnesia for these episodes) may mimic alcohol intoxication or a seizure disorder. Global and irreversible cognitive deficits may result if hypoglycemia and neuroglycopenia are long-standing. Surgical therapy is the most definitive treatment, but hyperglycaemic treatment with the somatostatin analog octreotide can be helpful.

Glucagonoma. This is a rare pancreatic islet cell that secretes glucagon. The presenting features are impaired glucose tolerance and diabetes, and a severe migratory and necrolytic erythema. Anxiety and agitation, as well as depression, may accompany these features.

FUTURE DIRECTIONS

An awareness of the relationship between neurometabolic and neuroendocrine disease and psychiatric illness by psychiatrists and other physicians provides for more diagnostic precision, in addition to allowing for improved treatment of psychiatric comorbidity in these disorders. Psychiatric symptoms can have a profound effect on long-term quality of life, and the recognition of a comorbid psychiatric illness in these disorders can improve health outcomes and quality of life for both patient and caregiver alike. As psychiatrists are best placed to manage major psychiatric disturbances, the involvement of a psychiatrist in the care of these patients is crucial, whether a psychiatric illness is the first or only presentation of illness or if it develops later in the course of the illness. In Table 2.14–1, we have included a summary of the key neurometabolic disorders, their presentation and diagnosis.

Recognizing, understanding, and exploring the links between neurometabolic and neuroendocrine disorders and major psychiatric syndromes can also provide insights into the neurobiologic basis of psychiatric illness. For example, the recognition of the elevated rates of schizophrenia-like psychosis in MLD has highlighted the possible role of myelinated structures as a possible anatomical substrate for the functional disconnectivity that has been well described in schizophrenia. Following a group of publications by Hyde and Weinberger on the links between

Telegram: @medical_k

www.konkur.in

schizophrenia and leukodystrophies, a large body of research in the subsequent 20 years has produced real insights into the role of white matter structures in schizophrenia at the genetic, developmental, and structural levels. Additionally, the emerging data on the exceedingly rare movement disorder ChAc suggesting significantly elevated rates of OCD and its unique predilection for neuropathology in the caudate and putamen has further highlighted the role of disturbed prefrontal-subcortical circuitry in OCD "proper." Further delineation of the neurobiologic link between the cellular and metabolic deficit in these syndromes and the psychiatric disturbance they are commonly associated with may yet yield further insights into the neurobiologic basis of those disorders that present most commonly in psychiatric practice but that have only yet afforded limited insights into their underlying pathophysiology.

2.15 Catatonia

JOSHUA J. RODGERS, M.D., AND THANH THUY TRUONG, M.D.

Telegram: @medical_k

www.konkur.in

Catatonia is a peculiar, fascinating, and important neuropsychiatric syndrome defined clinically by abnormalities in the initiation and/or termination of motoric and behavioral functions, but cognitive, emotional, and autonomic dysregulation can also be involved. Catalepsy (maintenance of fixed postures) and waxy flexibility are easily recognizable classic signs, but withdrawal, mutism, and negativism are more common features and may go overlooked. Catatonic features may be insidious or acute, transient or chronic, and persist for days to years. The seemingly contradictory features of stuporous (retarded) or hyperactive types, as well as the typically robust but paradoxical response to benzodiazepines, may be understood from a perspective of dysregulation of cortical–subcortical (direct and indirect pathways) circuits and cortical–cortical network functions. Neuroleptic malignant syndrome (NMS) can be understood as drug-induced catatonia, and there is also a syndromic and mechanistic overlap with akinetic Parkinsonism. These later syndromes reflect “bottom-up” subcortical–cortical disordered dopamine modulation of the involved circuitry, while catatonia reflects “top-down” cortical-subcortical disordered GABA modulation of the circuitry. Catatonia is nonspecific and may be associated with any psychiatric, neurologic, or general medical disorder that may cause dysfunction in these neural pathways. Catatonia is highly prevalent but often unrecognized and untreated, which can have fatal consequences. Fortunately, the gold standard intervention of electroconvulsive therapy (ECT) is highly effective, but unfortunately, unjustified legal regulations in many U.S. States make ECT very difficult to administer in the most vulnerable catatonic patients. Understanding the syndrome of catatonia as a deficit of “executive volition” and its underlying mechanisms may help elucidate the underlying mechanisms of such essentially human constructs of conscious awareness and free will.

BRIEF HISTORY AND NOSOLOGY

Catatonia has been interpreted through many lenses over the past century and a half, depending on the prevailing model of psychiatry at the time; in a way, the syndrome is a projective test for nosologic conflicts within the fields of psychiatry and neurology. Kahlbaum described mental illnesses as “state-course entities” and, in 1874, provided the first systematic description of catatonia as “tension insanity.” He described

Telegram: @medical_k

www.konkur.in

motoric, behavioral, and affective impairments that had a relapsing–remitting course with a good prognosis. He also documented the syndrome's association with mood disorders and organic (medical and neurologic) disorders. In 1886, Schüle differentiated "true" catatonia from catatonia secondary to organic causes. In 1899, Kraepelin included catatonia in "dementia praecox" and emphasized negativism/positivism signs over motor features. Unlike Kahlbaum, Kraepelin documented a chronic course with a poor prognosis. In the 1900s, Wernicke and other behavioral neurologists understood catatonia through a neurologic dysfunction model and focused on motor signs.

However, around this time, Bleuler, based on a psychoanalytic model, accepted only extreme subconscious ambivalence (conflicts) as the basis for catatonic features and largely rejected organic etiologies or pathophysiologic explanations. Bleuler considered catatonic features to be accessory symptoms of schizophrenia ("splitting of the mind"), his coined term and reconceptualization of dementia praecox. This view persisted for decades, even into the DSM-IV, which continued to describe catatonia as a subtype of schizophrenia, though also recognizing it as a specifier of mood disorders or as secondary to a medical disorder.

The use of sodium amobarbital for catatonia in the 1930s heralded the era of psychopharmacology, and together with a general failure to examine or recognize the motor signs of catatonia, led Mahendra and many in the field to believe that the syndrome of catatonia had disappeared.

Fortunately, in the 1970s and 1980s, several clinician-researchers, including Morrison, Abrams, and Taylor, maintained focus on catatonia and noted its common association with mood disorders rather than only schizophrenia. In 1976, Gelenberg revived the recognition of neurologic, general medical, and psychiatric etiologies to the syndrome, and in 1991, Taylor and Fink summarized the evidence supporting that the classification of catatonia should reflect its association with many illnesses and later continued to argue that it warrants recognition as an independent syndrome. Bräunig and Krüger reconciled the various views of catatonia by regarding it "… as part of a motor-behavior continuum … an independent dimension reflecting a disturbance of executive function that cuts across diagnostic categories." We suggest this dimension be called "executive volition" as it is the executive control of desired initiation and termination of motor, cognitive, and emotional functions which is

Telegram: @medical_k

www.konkur.in

disturbed in catatonia. The latest edition of the DSM (DSM-5-TR, released in 2022) defines catatonia as a distinct syndrome that can be a specifier of psychiatric disorders, secondary to a medical condition, or as “unspecified catatonia.”

EPIDEMIOLOGY AND ETIOLOGY

Catatonia is common and underdiagnosed. Reports on the incidence of catatonia vary widely depending on the population studied and the methodologies used. Incidence studies have found catatonia in 7% to 31% of psychiatric inpatients and 1.6% to 5.5% of psychiatric consultations in general medical settings. A research team using consistent standard screening instruments diagnosed catatonia nine times more than the admitting team in a psychiatric hospital.

Table 2.15–1 provides a partial list of the possible etiologies of catatonia. The underlying diagnosis in catatonic patients may be a psychotic disorder about 15% of the time (range 4% to 67%), a mood disorder about 30% of the time, with a bipolar mixed manic state constituting 14% to 71% of cases. Other associated psychiatric disorders include functional neurologic disorder, obsessive-compulsive disorder, personality disorder, and dissociative disorders. Neurologic and medical disorders account for 4% to 46% of cases of catatonia. Medications that increase the risk for drug-induced catatonia include typical and atypical neuroleptics and vesicular monoamine transporter 2 inhibitors (i.e., tetrabenazine). Withdrawal from substances such as benzodiazepines/sedative–hypnotics and dopaminergic agents (i.e., levodopa) can induce catatonic symptoms to emerge. Other agents associated with catatonia from use or withdrawal include alcohol, antidepressants, lithium, antiseizure medications (carbamazepine, primidone), aspirin, disulfiram, metoclopramide, morphine, steroids, hallucinogens, amphetamines, methylphenidate, and cocaine. Numerous medical conditions have been associated with catatonia (Table 2.15–1). Given the high frequency of catatonic features and their prognostic and treatment implications (see below), we suggest that clinicians look for and freely call out and note catatonic features when observed as they would for atypical or psychotic features of a mood disorder, for example.

DIAGNOSIS AND FEATURES

Telegram: @medical_k

www.konkur.in

None of the commonly used diagnostic schemas identify a cardinal feature of catatonia a notable absence that begs remedy. As noted above, catatonia is recognized as a cluster of objective signs (note the absence of symptoms in the diagnostic schemas, unique in psychiatric disorders) signifying dysfunction of what we suggest should be termed executive volition in motoric/behavioral, cognitive, and affective domains. Executive volition is a broadly distributed function of cortical–cortical, largely frontal lobe, and cortical–subcortical circuits. Dysfunction of these circuits is thought to result in the features of catatonia (discussed further below). Table 2.15–2 describes the subtypes of catatonia: retarded, excited, malignant, and periodic catatonia. Each may involve a disruption in specific circuits.

Diagnosis

DSM-5 criteria for the diagnosis of catatonia as a specifier of another mental disorder requires the presence of 3 or more of 12 signs: stupor, catalepsy, waxy flexibility, mutism, negativism, posturing, mannerisms, stereotype, agitation, grimacing, echolalia, and echopraxia. The same criteria are used for diagnosing catatonia due to another medical condition as long as there is sufficient evidence that the features are the direct physiologic consequence of a medical condition and not more likely due to a psychiatric disorder or delirium.

Multiple instruments and scales have been developed to assist with screening for catatonia and rating its severity. The most widely used clinically and in research is the Bush–Francis catatonia screening instrument (BFCSI) and rating scale (BFCRS) (Table 2.15–3). The BFCSI (14 items) and BFCRS (23 items) are accompanied by a standardized examination procedure to increase interrater validity and reliability. Screening can also be conducted using the DSM-5 criteria, which does not assess severity. Other scales include the Rogers Catatonia Rating Scale, designed to distinguish catatonia from depression and Parkinson disease; the Northoff Catatonia Rating Scale, which includes motor, behavioral, and affective domains; and the Braunig Catatonia Scale.

Table 2.15–1.
Potential Causes of Catatonia

Telegram: @medical_k

www.konkur.in

Psychiatric Conditions	Psychotic disorder about 15% of the time (range 4–67% depending on the population), mood disorder ~30% of the time, with a bipolar mixed manic state constituting 14–71%. Other associated psychiatric disorders include functional neurologic disorder, obsessive-compulsive disorder, personality disorder, and dissociative disorders
Medications/substances	Neuroleptics and vesicular monoamine transporter 2 inhibitors (i.e., tetrabenazine), benzodiazepines/sedative–hypnotics and dopaminergic agents, antibiotics (macrolides and fluoroquinolones) phencyclidine, ecstasy, synthetic cannabinoids
Poisoning	Coal gas, organic fluorides, tetraethyl lead poisoning
Neuromedical	Aneurysms, arteriovenous malformations, cerebral infarcts (temporal, bilateral, parietal, hemorrhagic), thrombosis, hemorrhage (subdural hematoma, subarachnoid hemorrhage, third ventricular hemorrhage), multiple sclerosis
Other central nervous system causes	Encephalitis, traumatic brain injury, alcohol degeneration Wernicke encephalopathy, epilepsy (nonconvulsive status epilepticus), tuberous sclerosis, frontal lobe atrophy, cerebellar degeneration, anoxia, hydrocephalus, basal ganglia lesions, narcolepsy, central nervous system lupus
Metabolic/endocrine	Diabetic ketoacidosis, acute intermittent porphyria, Addison disease, Cushing syndrome, pellagra, hepatic dysfunction, hyper and hypoparathyroidism, idiopathic hyperadrenergic state, thyrotoxicosis, pheochromocytoma
Neoplasm	Frontal lobe tumors, paraneoplastic encephalitis,

Telegram: @medical_k

www.konkur.in

	angioma, glioma, Langerhans cell histiocytosis, periventricular diffuse pinealoma
Infectious	Acquired immunodeficiency syndrome (AIDS), bacterial meningoencephalitis, viral encephalitis (i.e., herpes), sepsis, malaria, mono, tertiary syphilis, tuberculosis, typhoid, subacute sclerosing panencephalitis

Table 2.15–2.
Subtypes of Catatonia

Subtype	Symptoms
Stuporous	Mutism, withdrawal, negativism, inhibited movement, posturing, rigidity, and staring
Excited	Excessive and purposeless motor activity, restlessness, stereotypy, disorganized speech, disorientation, impulsivity, agitation, and combativeness
Malignant	Fever, autonomic instability (labile or elevated blood pressure, tachycardia, tachypnea, and diaphoresis), delirium, and rigidity. Mortality 75–100% before 1960 (before ECT); now ~10%
Periodic catatonia	Follows cyclical relapsing and remitting course with psychomotor symptoms, mixed stupor, and excitement. Autosomal dominant inheritance with variable penetrance; disease locus has been linked to chromosome 15q15. Chromosome 15 polymorphisms have also been associated with schizophrenia and autism.

Table 2.15–3.
Description of Signs of Catatonia

Telegram: @medical_k

www.konkur.in

Category	Sign Name	Description
Motor	Posturing°*+	Spontaneous maintenance of posture(s) for long periods
Motor	Catalepsy°*+	Passive induction (from an external person or object; >1 minute) of a posture with persistence/inability to return to initial posture
Motor	Stereotypy°*+	Inherently normal but repetitive (>3) and unchanged, non–goal-directed motor activity
Motor	Festination+	Paroxysms of involuntary, jerky, uncoordinated, inappropriate, hasty movements
Motor	Dyskinesias+	Abnormal involuntary fast movements
Motor	Athetosis+	Choreatic-like movements with a screw-shaped character
Motor	Mannerisms°*+	Inherently abnormal, odd, bizarre execution of purposeful movements with a disturbance in the harmony of movements

Telegram: @medical_k

www.konkur.in

Motor	Rigidity°+	Maintenance of a rigid position despite efforts to be moved
Motor	Muscular hypotonus+	Slack and loose active movement; decreased muscle tone in passive movements.
Motor	Sudden muscular tone alterations+	Rapid switches between muscular normotonus, hypotonus, and hypertonus, with or without apparent external trigger
Motor	Akinesia+	Complete absence or paucity of movements (for at least 30 minutes)
Motor	Waxy flexibility°* (Flexibilitas cerea+)	Initial resistance before allowing repositioning (like bending a candle)
Motor	Grasp reflex°	Reflexive bending of fingers in response to palmer tactile stimulation
Motor/Behavior	Mitgehen°+/Mitmachen+	Arm raising in response to light pressure despite contrary instruction (tone induced by passive manipulation going with the examiner)
Motor/Behavior	Gegenhalten°+	Resistance to passive movement

Telegram: @medical_k

www.konkur.in

		proportional to stimulus strength (tone induced by passive manipulation going against the examiner)
Behavior	Negativism°* Negativismus+	Resistance to instructions or attempts to move/examine patient. Contrary behavior does the opposite of the instruction
Behavior	Automatic obedience°+	Exaggerated cooperation with the examiner's request
Behavior	Mutism°*+	Persistent verbal unresponsiveness or minimal responsiveness (for at least 30 minutes+)
Behavior	Grimacing°*+	Maintenance of odd facial expressions
Behavior	Echopraxia°*+/echolalia°*+	Mimicking an examiner's movements/speech
Behavior	Verbigeration°+	Repetition of phrases or sentences (like a scratched record)
Behavior	Perseveration°+	Repeatedly returns to the same topic or movement; Non–goal-directed repetition of thoughts and/or actions

Telegram: @medical_k

www.konkur.in

Behavior	Abnormal speech+	Qualitative abnormalities in volume and intonation of speech
Behavior	Withdrawal° Autism/Withdrawal+	Refusal to eat, drink, or make eye contact Isolates from or avoids social contacts
Behavior	Immobility/Stupor°*+	Persistent extreme hypoactivity, immobility, minimal response to stimuli (for at least 30 minutes+)
Behavior/Affective	Loss of initiative+	Subjective/ objective (expressed or observed) loss of initiative concerning things they usually do/daily Routine/relation to the environment and/or other persons.
Behavior/Affective	Staring°+	Fixed gaze, decreased/no scanning of the environment, or blinking (at least 20 seconds+)
Behavior/Affective	Excitement° (agitation*+)	Uncontrollable extreme hyperactivity, constant motor unrest (nonpurposeful, not goal-directed, not akathisia; may be related to intense

Telegram: @medical_k

www.konkur.in

		emotional experiences[+])
Behavior/Affective	Impulsivity°[+]	Sudden inappropriate behaviors (running, taking off clothes)
Behavior/Affective	Compulsive behavior or speech[+]	Patient feels driven to perform repetitive patterns (i.e., >5 times) of behavior or speech that they cannot control or relate to themselves
Behavior/Affective	Ambitendency°/Ambivalence[+]	The appearance of being “stuck” in indecisive, hesitant movement; exhibits conflicting emotions and/or thoughts so that they appear “stuck,” indecisive, and hesitant[+]
Behavior/Affective	Combativeness°/Aggression[+]	Verbally or physically aggressive in an undirected manner—unable to explain, but apparently induced by internal emotional states or external events/triggers
Affective/Behavior	Affective related behavior[+]	Abnormal behavioral reactions apparently related to particular emotional states and/or discharges
Affective	Compulsive emotions[+]	Uncontrollable and ego-dystonic abnormal

Telegram: @medical_k

www.konkur.in

		affective reactions
Affective	Affective/emotional lability+	Unstable and quickly alternating affective reactions
Affective	Flat affect+	Considerable reduction in quantity and quality of emotional reactivity (i.e., flat facial expression, aprosodic speech)
Affective	Affective latency+	Delayed emotional initiation or reactivity to external stimulus
Affective	Anxiety+	Signs of intense, uncontrollable anxiety (i.e., facial expression, verbal, and/or vegetative (i.e., perspiration)
Autonomic	Dysautonomia° Vegetative abnormalities+	Abnormal temperature, blood pressure, heart rate, respiratory rate, diaphoresis

Signs marked * are included in the DSM-5 diagnostic schema, which requires three or more signs to diagnose Catatonia. See DSM-5 for details. American Psychiatric Association. DSM-5 Task Force. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. American Psychiatric Association; 2013.

Signs marked ° are included in the Bush-Frances Catatonia Rating Scale.

Signs marked + are included in the Northoff Catatonia Rating Scale.

Differential Diagnosis

Catatonic features are nonspecific. When a patient presents with catatonic features, the clinician must have a broad differential in mind. There is substantial symptom overlap between several disorders, including serotonin syndrome, NMS, akinetic mutism, and disorders of consciousness (DOC). Distinguishing between these presentations is essential to guide the next steps in management (Table 2.15–4). For

Telegram: @medical_k

www.konkur.in

example, a patient presenting with catatonic features may have been recently prescribed neuroleptics in their history. Likewise, NMS is differentiated from serotonin syndrome by the latter exhibiting hyperreflexia rather than hyporeflexia, myoclonus, and gastrointestinal distress.

Telegram: @medical_k

www.konkur.in

Table 2.15–4.
Differential Diagnoses for Patients Presenting with Possible Catatonia

Telegram: @medical_k

www.konkur.in

Differential Diagnosis	Features
Neuroleptic malignant syndrome (NMS)	Drug-induced malignant catatonia caused by neuroleptic (antipsychotic) medications; presents after high doses of neuroleptics are given
Malignant hyperthermia	Rare genetic disorder with exposure to inhaled anesthetic (e.g., halothane) or a depolarizing muscle relaxant (e.g., succinylcholine)
Serotonin syndrome	Distinguished by the prominence of hyperreflexia, myoclonus, nausea, vomiting, and diarrhea
Akinetic mutism	Unlike catatonia, there is no posturing, echolalia, or echopraxia, and it is not responsive to benzos. Medial frontal lesions are usually detectable on imaging. Dysfunction is of motivation and not executive volition.
Selective mutism	Patients can be observed to be mute with some and not others; does not exhibit other catatonic features. Presentation is seen in personality disorders and major stressful periods.
Nonconvulsive status epilepticus	EEG would show epileptic activity, whereas there is no specific EEG abnormality in catatonia.
Locked-in syndrome	Presents with immobility and mutism but no other catatonic features; neuroimaging shows brainstem lesions. The patient may make attempts to communicate.
Stiff-person syndrome	Rigidity, dysautonomia, and response to benzodiazepines. However, this is differentiated by a fixed deformity of the spine and the presence of anti-GAD antibodies. There is no mutism, posturing, and other catatonic features.
Parkinson disease	Characteristic stooped posture, not odd. No benzodiazepine response. Presence of resting tremor, postural instability, response to levodopa.

Telegram: @medical_k

www.konkur.in

Stroke	Focal neurologic signs, neuroimaging.
Delirium	No posturing, rigidity, or negativism; generally worsens with benzos.
Dementia	No posturing, rigidity, or negativism generally worsens with benzos.

GAD, glutamic acid decarboxylase.

NEUROPATHOPHYSIOLOGY

It is generally accepted that the features of catatonia arise from disruption of the function of distributed cortical–cortical (frontoparietal and frontolimbic) networks and the cortical–subcortical and cerebellar–subcortical circuits that regulate cortical functioning (see Fig. 2.15–1). This disruption can be caused by psychological (functional) factors, neurologic lesions (e.g., ablations in motor systems or motor–perceptual integration systems, or excitatory lesions in the thalamus), neurochemical imbalances (e.g., reduced dopamine or GABA-A activity or increased GABA-B activity due to drugs or disease), metabolic derangements, epilepsy, and other causes.

Disruptions in the motor circuitry may be involved in rigidity, anterior cingulate–medial orbitofrontal circuitry in akinetic mutism, and dorso- and ventromedial prefrontal cortex in perseverative-compulsive behaviors in catatonia. Such dysfunctions may be due to reduced $GABA_A$ inhibition of $GABA_B$ interneurons in the substantia nigra and ventral tegmental area. This reduced GABAergic activity would induce a state of hypodopaminergia in the dorsal and ventral striatum and paralimbic cortex. Another network involves upregulation of *N*-methyl-D-aspartate (NMDA, a glutamate receptor) activity in the dorsal striatum secondary to reduced $GABA_A$ inhibition of frontal corticostriatal tracts (Fig. 2.15–2). Activation of $GABA_A$ through the use of agonists such as lorazepam would cause disinhibition of dopamine activity in the striatum and paralimbic cortex, restoring normal regulation of the functions of these systems. Likewise, glutamate antagonists such as amantadine have been effective in some lorazepam-refractory cases. Serotonin disequilibrium with upregulated serotonin 1A (5-HT1A) and downregulated serotonin 2A (5-HT2A) receptors have also been implicated in catatonia. In NMS and akinetic Parkinsonism, dysfunction in the system is due to “bottom-up”

Telegram: @medical_k

www.konkur.in

dysregulation of striatal D2 receptor activity by blockade in NMS, usually by neuroleptics with high affinity for this receptor, or by loss of substantia nigra dopaminergic inputs to the striatum in Parkinson disease.

A “gridlock analogy” may be helpful in understanding the pathophysiology of catatonia. Cortical–subcortical (frontal cortex to striatum to globus pallidus to thalamus and back to cortex) circuits forming the direct and indirect pathways serve to regulate cortical function, essentially modulating the flow of information in the system, disinhibiting desired functions (direct pathway) and inhibiting undesired function (indirect pathway), much the same way a traffic light system regulates the flow of traffic through a city street grid. Continuing with this analogy, if all the traffic lights are green, then all traffic is going at the same time resulting in gridlock. Proper timing and balance of green lights (disinhibition) and red lights (inhibition) are necessary for normal traffic flow. Restoring inhibition by giving GABA agonists in catatonia can thus free up the gridlock from a relative deficit of inhibitory modulation.

Neuroimaging Findings in Catatonia

Computed tomography (CT) studies show cortical enlargement (in catatonic schizophrenia) and cerebellar atrophy in catatonic patients relative to controls. Cerebral blood flow studies have shown imbalanced perfusion with hyperperfusion of the left basal ganglia and hypoperfusion in the left medial temporal region and right parietal cortex, which may normalize following ECT. Functional magnetic resonance imaging (fMRI) has shown reduced right motor cortex activation related to motor signs and reduced orbitofrontal cortical activity related to behavioral and affective symptoms. Single-photon emission computerized tomography (SPECT) studies have shown lower GABA-A binding and imbalances in the left sensorimotor cortex and right lateral orbitofrontal, and right posterior parietal cortex in patients with catatonia.

What catatonia can tell us about "top-down modulation": A neuropsychiatric hypothesis. *Behav Brain Sci*. 2002;25(5):555–604, with permission of Cambridge University Press. doi:10.1017/S0140525X02000109.)

MANAGEMENT AND TREATMENT

Catatonia can be a life-threatening illness with significant morbidity and mortality. Thus, the clinician would be wise to "treat first, ask questions later" with an emphasis on supportive interventions. The presence of dysautonomia denotes "malignant catatonia," with a 75% to 100% mortality rate. Now with ECT and benzodiazepines, the mortality rate has decreased to 10%. If an etiology is found, then treatment for the underlying condition follows the initial interventions for catatonic symptoms. If dopamine antagonists (i.e., antipsychotics, metoclopramide) or dopamine-depleting agents (i.e., tetrabenazine) are suspected, they should be discontinued. If symptoms are suspected to be from the withdrawal of dopamine agonists or GABAergic agents, they should be resumed.

Telegram: @medical_k

www.konkur.in

Supportive interventions should be provided for consequences of catatonia: hyperthermia, dehydration, malnourishment, bed sores, flexion contractures, rhabdomyolysis (acidosis, renal failure), deep venous thrombi, pulmonary emboli, urinary retention, infection, and aspiration pneumonia. Management may involve attentive nursing care, intravenous (IV) fluids, anticoagulation, urinary catheterization, nasogastric tube/percutaneous endoscopic gastrostomy (PEG) tube feeds, oral care, suction, cooling blanket, and autonomic control.

Lorazepam is the first-line treatment regardless of etiology and carries an efficacy of 70% to 80% for a reduction in symptoms. IV lorazepam is preferred due to its quick onset of action and ease of administration. Intramuscular (IM) and sublingual administration may be used if IV access is not available since patients may not be able to swallow the oral formulation. Clinicians should be aware of IM administration potentially causing pain and increased fear in patients with catatonia. An initial lorazepam dose of 2 mg (lorazepam challenge) is used for both diagnostic and treatment purposes. Lower doses of lorazepam may be used in pediatric and frail older adult patients, but 2 mg is recommended for most adults to avoid an equivocal response. A robust “Lazarus” response may be seen within 30 minutes of administration, though some patients may require up to 120 minutes to see effects. A positive response (increased interaction, reduction of catatonic features) is confirmatory of catatonia, whereas a negative response (sedation) to the initial dose does not rule out catatonia. If the response is equivocal, that is, there is no change, the patient is neither sedated nor more interactive, and clinical suspicion remains high, another dose of lorazepam should be given. In healthy individuals, 2 mg of lorazepam should be quite sedating; no response may be a significant observation. Multiple doses may be required for a response. Once a positive response to lorazepam has been established, lorazepam should be scheduled (i.e., 2 mg q6h) at least for the first 24 to 48 hours. Some patients need a lorazepam drip (1 to 2 mg q4h), titrated to a total daily dose that reduces symptoms without excessive sedation. Some patients may require up to a total daily dose of 30 mg or more. It is important for nursing staff to administer medications even when the patient appears to be sleeping because the “sleep” may represent stupor and indicate a recurrence of symptoms from lorazepam wearing off. Once there is a significant improvement in symptoms, a slow taper of benzodiazepines may be considered (10% to 25% decrease in a dose per

Telegram: @medical_k

www.konkur.in

day). Lorazepam treatment should be considered a temporary bridge to definitive ECT in many cases.

For all patients with catatonia, ECT should be considered and arranged if there is high clinical suspicion and/or if there is a positive response to lorazepam. This foresight prevents delays in treatment if the patient does not adequately respond to lorazepam or progresses into malignant catatonia. ECT is the gold standard treatment with a 90% efficacy in catatonia. There are no absolute contraindications for ECT, and it is well tolerated in even medically ill patients. However, patients with recent myocardial infarction, stroke, and other cardiovascular conditions are at increased risk of complications from ECT. Appropriate consultations (i.e., cardiologist) prior to ECT can mitigate risks. Altogether, ECT is the most effective treatment for catatonia, and risks should be weighed against potential benefits. Most patients improve within the first two to three treatments. More treatments are often recommended to prevent a recurrence, with some needing monthly maintenance ECT to prevent relapse into catatonia. The requirements for informed consent for ECT vary in each state. In some states, patients must voluntarily consent to ECT, and the use of surrogate decision-makers is not permitted, which limits its use in nonresponsive catatonic patients. In such situations, if the patient becomes alert with lorazepam, discussion of ECT during these periods may allow for it as an option.

Alternative treatments for catatonia that have shown efficacy include hypnotics such as zolpidem 5 to 10 mg, antiepileptics that increase GABA (topiramate, valproate, carbamazepine, zonisamide), dopamine agonists (bromocriptine), and NMDAR antagonists (amantadine, memantine). Amantadine (100 to 600 mg daily) and memantine (10 to 20 mg daily) are used as adjunctive treatments to lorazepam rather than monotherapy. Some case reports have described the success of targeting the dorsolateral prefrontal cortex (DLPFC) using transcranial magnetic stimulation (TMS) and transcranial direct current stimulation (TDCS), though this effect appears to be inconsistent. Other treatments that have had mixed success include muscle relaxants, calcium channel blockers, anticholinergics, lithium, thyroid meds, stimulants, and corticosteroids. Antipsychotics were frequently used to treat catatonia in the past, but in many cases, this worsened symptoms and increased mortality. Therefore, for the treatment of underlying psychosis, the use of antipsychotics should be accompanied by lorazepam, and second-generation antipsychotics,

Telegram: @medical_k

www.konkur.in

especially agents with partial D2 agonist activity (i.e., aripiprazole), are preferred.

Workup of Underlying Causes of Catatonia

The initial evaluation and treatment should occur at the same time or prior to the workup of underlying medical or psychiatric causes. Catatonia is not associated with the specific laboratory, imaging, or EEG findings. Initial labs, useful for looking for underlying causes or monitoring for complications of catatonia, can include complete blood count (CBC) with differential, complete metabolic panel (CMP), serum iron, serum creatine kinase (CK) (Table 2.15–5 for a list of workup considerations). Serum CK is especially elevated in malignant catatonia and NMS and can increase the risk of renal failure. Serum CK should be tracked to ensure a downtrend. Neuroimaging, such as MRI or computed tomography (CT) brain can be obtained to detect lesions. Electroencephalography (EEG) showing diffuse background slowing may indicate delirium. If there are signs of encephalitis, a lumbar puncture is indicated. The cerebrospinal fluid (CSF) may be sent for an autoimmune encephalitis panel. Other workup is guided by clinical suspicions of underlying conditions. If testing results are unremarkable, the patient is likely to have an underlying psychiatric cause of symptoms.

Catatonia may masquerade as DOC as there is considerable overlap in symptoms (mutism, staring, etc.). Thus, the diagnosis of catatonia may be missed in settings where the focus is on DOC (minimally responsive, comatose). Whyte et al. published a placebo-controlled, double-blind, single-dose, crossover study with 84 patients who had DOC based on observations that some vegetative and minimally conscious patients paradoxically experienced temporary recovery of consciousness when given zolpidem. Their objective was to determine the frequency and predictability of this response. While 4.8% of the participants responded to zolpidem, the responders could not be distinguished from the nonresponders. Catatonia was not evaluated in these patients. Based on the response to zolpidem, some patients with presumed DOC may actually have catatonia. In a pilot study, DOC patients in a neurorehabilitation hospital were assessed with the BFCRS and treated with zolpidem or other GABA-A agonist (Rodgers and Arciniegas, 2015). Patients who responded were noted to exhibit posturing/catalepsy, grimacing, rigidity, and dysautonomia. Nonresponders did not exhibit

Telegram: @medical_k

www.konkur.in

these signs but did exhibit other catatonic features. Subcortical networks may have been too severely damaged (e.g., thalamic stroke) to allow for a therapeutic target in nonresponders.

Table 2.15–5.
Workup Considerations for Catatonia

Test	Comments
CBC with differential	Look for leukocytosis
CMP	Look for electrolyte abnormalities, changes in nitrogen balance
Serum CK	Elevated in malignant catatonia and NMS
Serum iron	May be low in NMS and catatonia
MRI brain	Look for acute and chronic lesions, usually correlated with a focal deficit
EEG	May be normal in psychiatric catatonia but abnormal in other causes (i.e., diffuse slowing in encephalitis, nonconvulsive status epilepticus)
CSF	Indicated if there are signs of encephalitis; CSF may be tested for autoimmune encephalitis

CBC, complete blood count; CK, creatine kinase; CMP, complete metabolic panel; CSF, cerebrospinal fluid; NMS, neuroleptic malignant syndrome.

SUMMARY AND FUTURE DIRECTIONS

Catatonia is a common clinical syndrome diagnosed on the basis of observed and elicited motoric and behavioral signs. There is no established cardinal feature, but dysfunction of executive volition in motoric, behavioral, and affective domains is a central theme. Catatonic features can result from any disruption in the function of cortical–subcortical (basal ganglia–thalamocortical; direct and indirect pathway) circuits regulating cortical–cortical networks and lead to neurotransmitter abnormalities: reduced dopaminergic and GABAergic activity and upregulation of NMDA activity. Etiologies are widespread and include acute and chronic medical conditions, psychiatric conditions, medications,

Telegram: @medical_k

www.konkur.in

substance use, and genetic predisposition. Benzodiazepines and ECT are the mainstays of treatment. There is a considerable overlap of features between catatonia and DOC, which is a diagnostic dilemma. However, the presence of catatonic features in DOC may predict response to GABA agonists such as zolpidem and benzodiazepines.

Psychotherapeutic Interventions for Catatonia

Our understanding of catatonia has largely focused on clinician observations rather than the subjective experience of the patient. Limited case literature examining the psychological state of catatonia describes themes of death, fear, and overwhelming defeat. Northoff's Catatonia Rating Scale includes affective symptoms, including emotional lability, anxiety, ambivalence, and other symptoms. Fink and Shorter posited that persisting fear may play a role in sustaining catatonia, where defensive mechanisms of withdrawal and denial are activated (Fink and Shorter, 2017). Like any psychiatric condition, there is not a clear boundary between the biologic and psychological causes of catatonia. In patients with chronic relapsing and remitting catatonia, long-term maintenance treatment with ECT and benzodiazepines is often needed. However, psychotherapeutic interventions to help the person manage stress, tolerate anxiety, manage ambivalence, and regain agency may be part of the treatment (Heckers and Walther, 2021). As far as the authors are aware, there is no literature on psychotherapeutic interventions that could improve or prevent relapse into a catatonic state. Various psychotherapies such as cognitive behavioral therapy, dialectical behavioral therapy, and psychodynamic therapy, all have evidence for enhancing coping strategies and increasing insight, which could theoretically improve the quality of life and potentially reduce the risk of a relapse into catatonia. Further research may elucidate methods for assessment of the subjective experience, which may narrow down the etiology (psychiatric vs. medical).

3 Contributions of the Psychological Sciences

3.1 Contributions of the Psychological Sciences: Sensation, Perception, and Cognition

Aldrich Chan, Psy.D., Louis J. Cozolino, Ph.D., and Daniel J. Siegel, M.D.

The brain is a social organ of adaptation, built and maintained through the interaction of social, psychological, and biologic forces. Because of the vast complexity of this synergistic process, the study of sensation, perception, and cognition is necessarily broad and far-reaching. The rapid increase in knowledge of neuroscience and the development of new hypothetical models through which one can understand the brain's functioning make this an exciting time in the cognitive sciences.

Mental processes such as thinking, feeling, and remembering are not synonymous with brain activity, but they may be dependent upon them. At a minimum, the subjective, inner felt experience of these fundamental mental processes, the feeling of being alive and awake, cannot be reduced to neural firing, even if subjective experience arises from that brain activity. Further, the mind may be more than just "an output" of what the brain does, with the possibility that it is an emergent, self-organizing process that is both fully embodied and embedded in one's relationships.

Telegram: @medical_k

www.konkur.in

In this way, the system of mind may be characterized by patterns of energy with a symbolic value called “information.” Energy and information flow happens both within humans and between humans. Seen this way, the mind is an emergent aspect of a complex system arising from energy and information flow, and as a self-organizing emergent process, it may regulate that flow. This regulation is reflected in mental processes, beginning with sensation and perception, to cognition, then into the initiation of behavior. Nevertheless, science is clear: Mental processes are profoundly shaped by neural activity, even if they are not limited to what goes on in the head. For this reason, understanding neural processing is an important part of comprehending information processing, one of many important aspects of the mind.

The terms s*ensation, perception,* and *cognition* are used to describe the three broadening tiers of human information processing. Think of s*ensation* as the immediate result of the stimulation of sensory neurons and *perception* as involving the organization and conscious awareness of these sensations by distinct regions of the brain. *Cognition* refers to the set of interwoven processes, including memory, language, and problem-solving, which both comprise and organize our conscious processing. Although distinguishing among sensation, perception, and cognition has a long academic history, the ability to separate them anatomically and functionally in the brain grows increasingly difficult as more is learned about their interdependence in the dynamic functioning nervous system.

COGNITIVE SCIENCE

The fields relevant to this overview are part of the interdisciplinary studies of cognitive science, which include cognitive and developmental psychology, psycholinguistics, computational science, and the emerging field of interpersonal neurobiology. Biologic, psychodynamic, and social psychiatry find a common home within cognitive science whereby the usual divisions of nature versus nurture and of biology versus psychology disappear on examination of brain development and the origins of mental processes.

In recent years, discoveries in the neurosciences have revealed a wide range of findings relevant to psychiatry. One such discovery showed that the brain’s structure and function are a result of the transaction among genetic, physiologic, and experiential influences. In particular, brain

Telegram: @medical_k

www.konkur.in

development requires specific forms of experience to foster the growth of neural circuits involved in a wide array of mental processes, including attention, memory, emotion, attachment, and self-reflection. Whereas genes function as a template of information and a mediator of transcription of the proteins that determine the neural structure, experience directly shapes the selection and timing of how gene activity is translated into the structure of the brain; it is now known that experiences influence the epigenetic regulators that modulate which, when, and how genes are expressed in response to experience and thus shape the unfolding of genetically programmed development of the central nervous system (CNS).

The human brain, especially the cerebral cortex, is undeveloped at birth. This functional immaturity requires the use of the caregiver's brain to help the child's brain grow and organize to mature functioning—findings from developmental neuroscience point to the centrality of interpersonal relationships in the development of the brain. The cooperative communication of infant–caregiver attachments is thought to shape neural infrastructure, not only for emotional development but also for abstract reasoning and cognitive abilities. The patterns of interaction between child and caregiver have a direct impact on the development of the child's brain and the functioning of the mind—the emergence of energy and information flow within and between. Consequently, cognitive processes and the internal flow of energy and information are an expression of the genetic, physiologic, social, and experiential factors that shape the development and maintenance of mental function.

Hot and Cold Cognition

Traditionally, cognition was studied by experimental psychologists in university laboratories, whereas emotion was explored clinically by psychoanalysts in consulting rooms. Striving to avoid the subjective and imprecise nature of emotions, cognitive psychologists devised flowcharts and algorithms similar to those used to describe computer programs. Input was calibrated, output was measured, and theories were generated concerning what might be happening within the "black box" of the brain. The increasing complexity of these models did not improve their explanatory power, and questions concerning motivation and emotion invariably arose.

Telegram: @medical_k

www.konkur.in

As knowledge of brain functioning increased, it has become more and more evident that neural networks involved in perception and cognition are inextricably interwoven with other networks responsible for processing somatic states, survival value, emotion, meaning, and motivation. The myth of *cold cognition,* or cognitive processes devoid of affective and somatic influence, is gradually fading. Flowcharts depicting linear input–output processes are being replaced with more sophisticated models reflecting the reality of the complex neural systems being discovered. When this change is added to the notion that mental life is also shaped by the context, especially the social context, then it can be seen that the mind emerges from factors within the brain, the body, and the larger interactive environment. This is the "mind in context" that needs to be considered to understand all mental processes.

Some cognition is "hot," such as recalling traumatic memories or spotting someone that is sexually attractive, and some cognition may be "cool," such as adding rows of figures or stacking dishes. These same cool tasks, however, if performed before an Internal Revenue Service auditor or in front of a strict teacher, may become warm or even hot. The fundamental principle, therefore, is that sensation, perception, and cognition all occur within the context of feedforward and feedback neural influences interwoven with and guided by complex contextual and emotional determinants.

Emotion

What is an emotion? The answer to this question is as complex as the mind itself. Although the lack of clear definitions and good animal models have hindered empirical research, it is clear that emotions play a central role in many cognitive processes. In fact, a broad view suggests that an emotion is a profoundly integrative process. Emotions connect the body to the brain, bring continuity to states of mind across time, and link one person to another within the "emotional connections" that create the fabric of human social lives.

One view considers emotion as a primary value system of the brain, engaging attentional resources, appraising the significance of an event, and allowing activations to be selectively elaborated and reinforced as they are encoded and stored, such that emotionally charged experiences may be more readily recalled later on than uneventful ones. According to this view, the most fundamental aspect of emotion is the arousal–

Telegram: @medical_k

www.konkur.in

appraisal system in which the brain responds to a given stimulus with the signal of “this is important—take note and pay attention now!” Emotion thus gives value to a representation by arousing attentional mechanisms and focusing a spotlight of attention on the stimulus. The second stage would then appraise the meaning of such emotional arousal by assessing its hedonic tone: “Is this good or bad? Should this be approached or avoided?” Emotion thus directs the flow of energy—the activations within specific circuits of the brain—as the arousal–appraisal system focuses cognitive processes on elements of the internal and external environments. The third level of emotional processing is the elaboration of this appraisal into a more specific form called a *categorical emotion,* which includes joy, interest, surprise, fear, anger, sadness, or shame. These categorical emotions have distinct psychophysiologic manifestations and are found across cultures.

The research of Jaak Panksepp revealed seven distinct primary affective systems that converge at a nucleus nested in the midbrain called the periaqueductal gray (PAG). These primary systems govern emotions that induce seeking, lust, care, play, fear, panic, and rage. Higher-order cognitive systems order themselves according to the systems that may be dominant at any time. Feedback and feedforward loops in response to these affective systems may subsequently modify the expression of select systems. This is in contrast to LeDoux and Brown’s perspective, who argue that emotions are, in fact, a consequence of higher-order cognition. This theory relegates subcortical networks to nonconscious inputs that may influence emotional experiences but are not central to their conscious expression. Their proposal is still considered controversial given the current consensus in overall emotional research.

Another examination of emotion investigates the way in which changes in the body’s state are represented in the brain in the form of what Antonio Damasio called a *somatic marker.* According to this perspective, the bodily responses to a situation or a choice that needs to be made lets the brain know how the individual feels about an experience. Such a somatic marker can then be used as a gut reaction to an experience, providing additional input into cognitive processing. A part of the brain called the *ventromedial prefrontal cortex* is implicated as the site of somatic marker processing, or what is called *intuition.* Allan Schore noted the importance of early experiences with caregivers in the maturation of this region and its role during early development in coordinating self-regulatory functions

Telegram: @medical_k

www.konkur.in

with basic emotional reactions and social functioning. A closely related region, the anterior insular cortex, mediates the interoception that allows internal somatic states to be represented in the higher cortical areas and the mind to experience awareness of the interior of the body. Being open to monitoring the body's signals permits the modulation of the somatic elements of emotions and allows for the development of emotional regulation. Disorders in self-organization and social functioning may be better understood by examining the central role of emotion and, perhaps, the orbitofrontal and insular cortex and related regions in the development and maintenance of dysfunctional mental states.

Studies also suggest that the orbital and medial prefrontal regions are responsible for subjective experience and self-awareness, enabling the mind to reflect on the self in the past, present, and the potential future, and even to consider the internal states of others. Inborn and experiential factors may play important roles in allowing this region to develop the capacity to integrate a wide range of important functions of the mind, including the appraisal of meaning, emotional regulation, social cognition, and autobiographical consciousness.

NEURAL NETWORK GROWTH AND INTEGRATION

The growth and selective connectivity of neurons is the basic mechanism of all learning and adaptation. Learning can be reflected in neural changes in a number of ways: (1) the growth of new neurons, (2) the expansion of existing neurons, (3) the changes in the connectivity among existing neurons, and (4) alterations in epigenetic regulation of specific regions of the genome. All of these changes are expressions of plasticity or the ability of the nervous system to change.

There is now sufficient evidence demonstrating neuronal growth and change in reaction to new experiences and learning. Existing neurons grow through the expansion and branching of the dendrites that they project to other neurons. Neurons interconnect to form neural networks, which, in turn, integrate with one another to perform increasingly complex tasks. For example, networks that participate in language, emotion, and memory interact and integrate, allowing for an emotionally meaningful story to be recalled and told with the proper affect, correct details, and appropriate words.

Telegram: @medical_k

www.konkur.in

Association areas within the brain serve the role of bridging, coordinating, and directing the multiple neural circuits to which they are connected in what is now called "*the connectome.*" Although the mechanisms of this integration are not yet known, they are likely to include some combination of (1) biochemical processing within neurons, (2) synaptic connections among neurons, (3) relationships among local neuronal circuits, and (4) interactions among functional brain systems. Changes in the synchrony of activation of multiple neural networks may also play a role in the coordination of their activity in a process that has been named by Kringelbach and colleagues as "connectome harmonics."

If everything humans experience internally is represented within neural networks, then psychopathology of all kinds, from the mildest neurotic symptoms to the most severe psychosis, must be represented within and among neural networks. The social environment, too, plays a crucial role in well-being and can itself support healthy or unhealthy states. Healthy functioning requires the potential for proper development and functioning of neural networks that are responsible for organizing conscious awareness, behavior, emotion, and sensation. Severe trauma early in life, in situations of abuse or neglect, can alter the healthy development of the brain's integrative potential. Innate neurologic conditions unrelated to an experiential cause may also result in impediments to the connectome functioning as an integrative whole. With integration, flexibility and harmony arise, and health may ensue. Impaired integration may result in chaos and/or rigidity when the differentiation and/or linkage of areas are impeded.

Symptoms of the various syndromes seen through this lens may be envisioned as the chaos and rigidity of impaired integration within the brain. Psychopathology, then, can be conceptualized as an expression of suboptimal integration and coordination among neural networks—whatever the etiology. Given that experience shapes the brain's development, as do nonexperiential factors such as genetics, infection, inflammation, and random events, the finding that individuals with various forms of psychiatric disorders have suboptimal integration in the brain is supportive of this proposal. Patterns of dysregulation of brain activation in specific disorders also support the theory of a brain-based explanation for the symptoms of psychopathology.

In general, psychological integration suggests that the cognitive functions of the executive brain have a high degree of access to

Telegram: @medical_k

www.konkur.in

information across networks of sensation, behavior, and emotion.

Integration requires both differentiation of elements of a system and their linkage. And integration appears to be essential for optimal regulation. Anything that impedes either differentiation or linkage can disrupt integration at the moment as a function, or over the long run, as a structural impediment leading to impaired self-regulation. Functional dissociation among these processes can occur when biochemical changes caused by high levels of stress inhibit or disrupt the brain's integrative abilities. With brain growth influenced by a range of processes, structural impairments to integration may ensue. Physical trauma, disease processes, or genetic predispositions that disrupt the development and functioning of integrative neural networks can all result in neural dysregulation and psychiatric symptomatology.

In applying this integration and brain-based model to treatment, psychotherapy, psychopharmacology, and psychosurgery can be viewed as ways of creating or restoring integration and the resultant coordination among various neural networks. For example, research has demonstrated that successful psychotherapy correlates with changes in activation in areas of the brain hypothesized to be involved in psychiatric disorders, such as obsessive-compulsive disorder (OCD) and depression. The return to normal levels of activation results in reestablishing positive reciprocal control among relevant neural structures and networks and a reduction of symptomology.

MIND AND BRAIN

What is this activity of the brain, and how does it give rise to such mental processes as perception and cognition? How do the human experiences of perception, thought, emotion, attention, self-reflection, and memory emerge from neural processes?

A generally accepted view of the conscious mind is that it emanates from cortical networks; yet, there are several clinical cases of individuals who have suffered the destruction of a variety of cortical regions who retain consciousness. Moreover, a minor lesion to subcortical areas such as the PAG can result in the complete loss of intentionality, a significant attribute often associated with conscious mental processing. Cognition, emotion, and even personality have further been demonstrated to be influenced by alterations in gut microbiota. These sorts of findings result in

Telegram: @medical_k

www.konkur.in

the necessity to revise theories that no longer suit the new discoveries. Brain-based perspectives may thus be limited, further necessitating the involvement of evidence supporting the importance of social relationships. It is for these reasons that the prevailing definition of the mind as purely neuronal firing is insufficient. A more flexible definition that incorporates these sorts of findings is the mind is an embodied and relational process that regulates the flow of energy and information. In other words, envisioning human experience as an interaction of mind, brain, and relationships allows mental health practitioners to free themselves from the overly simplistic view that the mind is "just the activity of the brain." Conceptualizing sensation, perception, and cognition as arising from a synergy of mind, brain, and relationships, provides a perspective that is broad enough to integrate findings across various fields of study.

ENERGY AND INFORMATION

The brain is composed of tens of billions of neurons and perhaps ten times that number of supportive cells called glia. When regions such as the cortex (which may have around 20 billion neurons) and the cerebellum (which may have 100 billion) are combined with other areas, an estimate of over 120 billion neurons is derived with the distribution of glia varying in different areas. An average neuron is connected to approximately 10,000 other neurons at synaptic junctions. With hundreds of trillions of connections within and among thousands of web-like neural networks, there are countless combinations of possible activation profiles. The term *neural net profile* is used to describe a certain pattern of activation of the complex layers of neural circuits, which is the fundamental way in which mental processes are created. These activations can lead to further neural processes in a cascade of dynamic interactions that produce a range of internal events and external behaviors.

The essential components of the mind come directly from how these neural events shape the flow of energy and information. How one subjectively feels the texture of this flow from the shifts of energy and information within the matter of the brain and other regions of the body is something no individual or theory has yet to be able to fully explain. Emergence is a property of complex systems, a way in which the components interacting give rise to something more than the components themselves. It may simply be that an irreducible aspect of embodied

Telegram: @medical_k

www.konkur.in

energy flow, the emergent aspect of that flow, is a subjective experience. The consciousness of that subjective experience and information processing may be emergent properties of energy flow. And one of the emergent aspects of a complex system is self-organization. We can propose that one of the key facets of the mind is a self-organizing emergent process of embodied and relational energy flow; this may be how the mind functions as a regulatory process that influences and is influenced by both embodied and relational energy and information flow.

Table 3.1–1.
Basic Ideas of the Mind

The mind is a processor and regulator of energy and information
Energy is contained within and among the activations of neural circuits as well as in the communication between people
Information is contained within and among the patterns of activation, termed a *neural net profile* or *mental representation,* and information is embedded in energy patterns shared as communication between people
These representations are energy patterns that serve as symbols that cause further effects in the mind, leading to the processing of information both within the nervous system and in relationships

The mind is a processor of patterns in the flow of energy and information within the brain, the body as a whole, and our relationships with our surroundings—people and with nature (Table 3.1–1). Within the brain, activations of individual neurons, as well as groups, circuits, or networks of neurons all, involve the flow of energy through this complex system. On one level, the system includes the brain and its body. On another level, this system may involve communications with one another. Within the brain, this energy reflects the flow of ions across membranes, the consumption of oxygen and nutrients by neural cells, and the active transport of molecules into and out of nervous tissue.

Information is created within the brain by a process of representation. The essential feature of information processing in the brain is that the patterns of activation of neural circuits (the neural net profile) contain information. Recent research from Seth and Friston characterizes the brain as Bayesian. By this, it is meant that there are predictive neural

Telegram: @medical_k

www.konkur.in

mechanisms influencing how sensory data is being represented. Feedback from alternate circuits even occurs at the earliest stages of visual perception. These mental representations, in turn, produce further neural events. The location and pattern of neural activations determine the nature of what the neural net profile represents. For example, activity in the optic nerve in response to light leads to a cascade of neural responses within the visual cortex, generating a visual sensation. Future activation of those layers in the visual cortex in that general pattern is the recollection of the visual image. Pattern and localization determine the kind of representation and the information that it specifically contains. For example, when an individual sees the Eiffel Tower, the visual system responds with the activation of a neural net profile. When the Eiffel Tower is recalled at a later time, the visual cortex activates a similar neural net pattern, and the Eiffel Tower is visualized. The activation of a particular pattern of neural firing thus contains representations of information about something, in this case, the Eiffel Tower. Examples of representations include perceptual, emotional, sensory, and linguistic forms, as well as more abstract concepts and categories. Extant literature introduces the notion of the brain as an active agent in processing information rather than a passive recipient. Indeed, Raichle notes that 60% to 90% of data processed in the brain occurs outside of external events.

FIGURE 3.1–1. Information-processing models.

INFORMATION PROCESSING

Several elements of the brain's function as an information processor can be described (Fig. 3.1–1): At the most basic level (Fig. 3.1–1A), energy leads to neural responses. This energy can be in the form of light stimulating the rods and cones of the retina or sound waves vibrating the

Telegram: @medical_k

www.konkur.in

tympanic membrane. It may also take an internal form in which the flow of energy within neural activations produces subsequent neural responses.

A second level of conceptualizing information processing (Fig. 3.1–1B) lies in the idea that an input (internal or external) leads to a representational response (a neural net profile of activation), which, in turn, produces a downstream effect or output. This output can be internal, such as the generation of other representations, or external, such as in the form of observable behavior. Within cognitive psychology, these information-processing events can be analyzed in terms of contrasting, comparing, generalizing, chunking, clustering, differentiating, and extracting processes, all of which lead to increasingly complex mental representations.

A third level of understanding information processing in the mind (Fig. 3.1–1C) is the conceptualization of sensation, perception, attention, and memory. According to this view, external energy is sensed by the peripheral nervous system and is registered as a sensation within the brain. The selective processing of aspects of these sensations, called filtering, leads to the production of perception. These perceptions are subject to further filtering during which only a select few are placed within working memory; this is sometimes called the “chalkboard of the mind.” It is within working memory that representations can be consciously manipulated, contrasted, clustered, and reassembled. Thus, consciousness may be intimately related to this aspect of mental functioning.

Sensation refers to the initial stages of the basic information-processing model (Fig. 3.1–1). In traditional experimental paradigms, sensory memory is conceptualized as lasting for approximately 0.25 seconds. Items in sensory memory are then filtered into working or short-term memory, where they last for approximately 0.5 minutes. When humans consciously attempt to learn new information, working memory is able to handle approximately seven items unless further processing creates links to other items within longer-term memory. *Rehearsal* allows these representations to remain in working memory for longer periods of time. Cognitive processes that can group bits of information into large chunks (chunking) can increase the capacity of working memory by making each unit more information rich. Representations are then processed and placed within long-term memory, where they can be retrieved for future use.

Telegram: @medical_k

www.konkur.in

ATTENTION

Attention is the process that controls the focus and flow of information processing. Three components of attention (selectivity, capacity, and sustained concentration) have traditionally been used to describe cognitive deficits seen in psychiatric disorders, such as schizophrenia and attention-deficit/hyperactivity disorder (ADHD). All aspects of attention in clinical or nonclinical populations are influenced by the emotional or motivational value of the stimulus.

Early conceptualizations of attention were based on Donald Broadbent's idea of a filter that selects a limited number of incoming stimuli to be further processed. The limited capacity of attention was thus seen as being attributable to the inability to process the overwhelming number of incoming stimuli. An attention "bottleneck" was described as occurring early in the sensory process (automatic) or late in the perceptual processing stage (identification and classification).

Selective Attention

Attention focuses a metaphorical spotlight on external stimuli or internal mental representations. In Broadbent's conceptualization, selectivity has three dimensions: (1) filtering—focusing on specific attributes (e.g., large squares vs. small squares); (2) categorizing—recognizing information based on stimulus class (e.g., attending to letters in whatever script they are written); and (3) pigeonholing—reducing perceptual information needed to place a stimulus into a specified category (e.g., using only long hair to classify individuals as female). Each of these aspects of attention acts on incoming stimuli to make a determination of fit for the sought-after characteristic.

Attention Capacity

The concept of processing capacity involves the idea that a given task makes a demand on a limited pool of resources: A task with a high-processing load draws more resources from the finite pool than does a task with a low-processing load and thus will inhibit the accessibility of resources for other simultaneous functions drawing from the same pool. Focal attention requires cognitive effort and thus has a high-processing load demand. Cognitive models describing several resource pools

Telegram: @medical_k

www.konkur.in

suggest an executive process that distributes resources to various cognitive functions.

Optimal performance is attained when there are moderate levels of arousal because this allows for the establishment of task goals, feedback, and appropriate resource allocation. Low levels of arousal impair those processes and lead to inadequate resource allocation, whereas high levels of arousal may be detrimental to the performance because of poor discrimination of stimuli and diminished efficiency of allocation, resulting in poor attention functioning.

Sustained Attention

The ability to sustain attention is called *vigilance* and can be tested with task demands for alertness and concentration over a period of a few minutes to an hour. The tests usually involve detection requirements for target stimuli that infrequently occur at random intervals. An example of such a test is the Continuous Performance Test. Defining aspects of the tests are derived from signal detection theory and include the factors of *sensitivity* and *response criterion.* Sensitivity is the distinguishing of target stimuli from nontarget stimuli; the response criterion is the amount of perceptual evidence required to support the decision regarding a target item versus a nontarget item.

SENSATION AND PERCEPTION

Forms of representations, including sensory and perceptual representations, derive from input from the external world via the peripheral sensory nervous system. The initial stage of encoding a visual representation is called an iconic image and is held within sensory memory for a brief period. Features of the initial stimulus, such as its size, direction, and color, are held within this sensory representation. This is termed bottom-up processing and is as direct as the nervous system allows. As the initial sensory activations are processed, they become influenced by higher-order, prior-experience–shaped influences called top-down processes and are organized as perceptual representations. In other words, learning from the past embedded in synaptic neural patterns of memory shapes perceptual streams of representations in the moment. This can be seen as an important distinction between sensation and perception.

Telegram: @medical_k

www.konkur.in

Attentional processes, at the level of sensory memory, act on the initial image with higher cognitive functions, such as classifications, memory, and chunking. In their essence, these top-down processes compare, contrast, and transform the initial representation from sensation to create new perceptual images within working memory. These processes are often automatic, rapid, and outside of awareness.

Perception is thus created by the top-down transformations of sensory images but does not necessarily involve the experience of consciousness. This has important clinical implications in that patients may be influenced by events and stimuli that they cannot consciously recall. Take, for example, the experience of a young girl with anorexia or body dysmorphic disorder. When she looks at herself in the mirror, she becomes consciously aware of the perception of her reflection in approximately half a second (500 ms). In contrast, the sensation of her visual reflection has already reached her eyes almost instantaneously and has resulted in nonconscious neural activation in only 50 ms. As neural networks are being instantiated within her visual cortex, activation in other brain regions, such as the amygdala, is also occurring, streaming top-down emotional and appraisal information back to the visual cortex.

In the 450 ms between initial sensory activation and conscious perceptual awareness, the visual experience of her reflection is constructed through a combination of bottom-up sensations and top-down emotion, learning history, and other visual memories to which it is compared and contrasted. What she focuses on, how she feels about it, and what it means to her—in essence, how she is seeing what she is seeing—is a blend of bottom-up and top-down constructed in automatic, nonconscious processes. At 500 ms, she experiences her brain's construction of her body, this perceptual image, as an external reality. In other words, a great deal happens on the way from sensation to perception.

MEMORY SYSTEMS

The neural networks of the brain are capable of responding to experience through the activation of neural net profiles—particular patterns of distributed neural activation. Donald Hebb described a basic principle of memory, paraphrased by Carla Shatz, that has been repeatedly supported by research: "Neurons that fire together, wire together." Neurons that are

Telegram: @medical_k

www.konkur.in

activated in a particular pattern at one time tend to fire together in a similar pattern in the future—this long-term potentiation (LTP) is the essence of memory.

Table 3.1–2.
Memory Systems

Implicit
A behavioral, emotional, and perceptual form of memory devoid of the subjective internal sense of something originating in the past. Can include schema or mental models that are summations of representations from numerous experiences
Also known as *early, procedural,* or *nondeclarative memory.* Cannot be directly expressed in words
Present from birth. Does not involve the hippocampus or require focal, conscious attention. Probably involves various circuits, including those of the basal ganglia, limbic system (amygdala, anterior cingulate, and orbitofrontal cortex), and perceptual cortices
Explicit
A form of memory requiring conscious awareness for encoding and involving the subjective sense of recollection and, if autobiographical, of self and past
Also known as *late, episodic* or *semantic,* or *declarative memory.* Can be directly expressed in words
The autobiographical component of explicit memory does not fully develop until past the first 2 years of life, as the hippocampus and orbitofrontal cortex, on which it depends, are maturing.

The brain has various circuits responsible for different systems of memory (Table 3.1–2): The form of memory most commonly thought of as *memory* is termed *explicit* or *declarative memory.* This form involves the conscious sensation of something coming from the past, a feeling of remembering, focal attention (attention with awareness), recall of autobiographical or factual knowledge, and hippocampal activation. In these circuits, items focally attended to are placed in working memory, processed further, and then placed in long-term memory. After a period of weeks or months, items are thought to undergo a process called *cortical*

Telegram: @medical_k

www.konkur.in

consolidation that places them in permanent memory, where their retrieval no longer requires the hippocampus.

Explicit autobiographical memory becomes reliably available after 3 years of life once the hippocampus and cerebral cortex have sufficiently matured. Before this, a form of memory that does not require conscious awareness and focal attention for encoding, called *implicit* or *nondeclarative memory,* is already in place and remains active throughout the life span. This form of memory involves a wide range of neural regions, including behavioral, emotional, and perceptual systems. When these circuits are activated in the retrieval of pure implicit memory, they do not include the conscious sensation of something being recalled. For example, when riding a bicycle, a person may not recall having learned to ride and may not even feel that anything is being recalled. Similarly, a person with a fear of dogs may be unable to explicitly recall any event that may explain such an emotional response.

The existence of intact implicit recollection in the absence of explicit memory is found in various conditions, including being under surgical anesthesia or having neurologic conditions such as Korsakoff syndrome and bilateral hippocampal strokes. Dissociation of memory systems may also occur in response to trauma. For example, patients with posttraumatic stress disorder (PTSD) may not explicitly recall a traumatic event, yet they may implicitly avoid stimuli similar to the initial trauma. They may also evidence implicit symptoms such as a startle response, anxiety, and intrusive perceptual images for that event in the absence of an explicit autobiographical memory. These latter symptoms are thought to reflect the intrusion into conscious awareness of implicit memory in the absence of the subjective sensation that something is being recalled.

CONSCIOUSNESS

The vast majority of mental processes are outside of awareness as energy and information flow without consciousness. A simple way of defining conscious awareness is the subjective sense of knowing. When someone is aware, there is a knowing. And the object that one is aware of is the known, such as visual input, a memory, or a thought. In general, many authors' views converge on the idea that there exist two fundamental forms of consciousness, enabling a knowing of two forms of what can be known in consciousness: A *here-and-now* and a *past–*

Telegram: @medical_k

www.konkur.in

present–future process of awareness. These two forms of consciousness are likely mediated via the integration of different neural circuits in the brain, and the experience of the known is distinct, one in the moment, the other focusing on events across time.

Two hypotheses focus on the way in which representational processes are linked or are bound together during the flow of informational transformations within the mind: Crick and Koch suggest that a 40-cycle-per-second sweeping process extends from the thalamus to the neocortex. This sweep may serve to bind representational processes together in the internal experience of consciousness. Processes that are active at the time of the sweep then become linked within consciousness. In more recent research, they have suggested the claustrum as a convergence zone that may be involved with unifying consciousness into a singular experience. A second view implicates the lateral prefrontal cortex and its role in working memory—working memory serves as the chalkboard of the mind, and representational processes that become integrated to a certain degree and linked to the activity in this region fall under the attentional spotlight of conscious awareness called *focal attention*.

Theories of consciousness continue to be unresolved and are by far one of the most controversial subjects of debate. Luckily, discord within the community has spawned creative theories which may provide the proper input towards some form of resolution. Northoff proposes that consciousness is a product of relational connections, specifically between the spatiotemporal alignment of the brain with the world. His theory was influenced by research into mental illnesses, such as schizophrenia, whereby disturbances in consciousness are evident. Gerald Edelman asserts that consciousness is epiphenomenal, arising through natural selection via complex neural processes such as reentrant signaling in interaction with the environment. Dynamic recursive activity among distributed neuronal ensembles induces the layering of multiple sensory-motor maps, which, when integrated with memory and prospective systems, may eventually result in experiential continuity.

Beyond materialist and physicalist views of consciousness, there are two theories that have emerged. Tononi, a previous student of Edelman's and whom Koch supports, views consciousness as integrated information. His theory translates phenomenologic tenets into quantifiable units. Thus far, his theory has been used to quantify potential consciousness in coma

Telegram: @medical_k

www.konkur.in

patients. Hoffman asserts that perception favors fitness over truth; in other words, we do not see reality as it is, rather we see it as it best fits our survival. This conclusion was reached through computer-simulated games that mimic the process of evolution. Digital units which operated in accordance with the truth of what composed their reality perished, in contrast to those which operated according to natural selection. His conclusion, supported by mathematical formulae, is that conscious agents, not matter, are the fundamental elements of the world. Thus, to him, even brain processing is akin to holding a magnifying glass to view pixels of a computer screen rather than understanding the coding that gives rise to its presentation.

Disturbances of Consciousness

Consciousness provides a sense of continuity—yet many psychiatric patients experience a profound sense of discontinuity and confusion that may be related to a dysfunction in the sense-making, continuity-creating process of consciousness. Some psychiatric symptoms, including derealization and depersonalization, intrusive memories and flashback phenomena (as in PTSD), and hallucinations (as in psychotic states), may be conceptualized in terms of dysfunctions in conscious functioning.

Misidentification syndromes are other manifestations of disturbances of subjective, conscious experience. In prosopagnosia, for example, patients are unable to consciously access memories regarding persons familiar to them. Patients suffering from Capgras syndrome, on the other hand, are able to recognize a familiar person's face but cannot experience the feelings of recognition and emotional arousal associated with that person. This lack of emotional recognition then results in their conviction that their loved ones have been replaced by imposters. "Being certain," as in the process of recognition, is one aspect of consciousness that is a cognitive process. Theoretically, then, the pathologic uncertainty of patients with OCD can be viewed as a disturbance in that aspect of conscious functioning.

Another example of disturbance of conscious functioning is found in cortically blind patients, who state that they cannot see visual stimuli but behaviorally respond as if they were fully sighted. Cortically blind patients describe being unaware of visual perception yet are able to make eye and hand movements that reflect the processing of information about stimulus location, shape, orientation, and direction of motion. In information-

Telegram: @medical_k

www.konkur.in

processing terms, behavioral tests reveal that these blind-sighted patients do sense and perceive visual stimuli but do not have conscious awareness of this perceptual process. Cortical blindness, then, is an example of the dissociation of the usually associated processes of perception and consciousness or awareness of phenomena.

Mental Models and Schemata

Studies of perception and memory support the view that the mind has organizational structures that influence the interpretation of sensory data, shape the encoding of information into long-term memory, bias the retrieval of items stored in memory, and help to determine the behavioral responses. These organizing cognitive functions are called *mental models* or *schemata.*

Mental models are highly organized, implicit, top-down processes derived from past experiences that guide the interpretation of present stimuli and influence the direction of behavior. The adaptational value of a given mental model depends on an accurate reading of the survival demands of the situation. The downside of these models is seen when their unconscious and automatic activation occurs in situations in which they are inappropriate, such as in PTSD, or when they no longer sufficiently meet the demands of a given situation.

Aaron Beck's theory of depression is based on the idea that mental models or schemata can guide depressive thinking as they trigger and enhance depressed moods. John Bowlby and Mary Ainsworth used the concept of internal working models to describe the development of early forms of schemata for relationships: Difficulties in intimate relationships and related behavioral dysregulation can be seen as derivatives of models of inadequate early attachment and the presence of multiple, conflictual models. The *inner objects* of psychodynamic theory are also examples of such mental models. Some psychiatric signs and symptoms can be seen as derivatives of conflicted schemata and situations. Classic descriptions of interpersonal patterns in some patients with personality disorders, such as idealization and devaluation, can be seen as maladaptive schema functions.

Thought and Language

Although there is no universally accepted definition of *thought,* thinking most generally involves the mental representation of some aspect of the

Telegram: @medical_k

www.konkur.in

world or of the self and the manipulation of those representations. Thinking depends on explicit and implicit memory of prior experiences and is influenced by a person's emotional state, mental models, and other unconscious determinants. The basic components of thinking include categorization, judgment, decision making, and problem-solving. Cognitive processes, such as thoughts, are often directly known only through their experience in consciousness and translation into language. As a result, there is always a question of whether thought and language can be fully separated.

Cognitive science has traditionally viewed language as a dominant influence on subjective experience. Language shapes the ways in which the world is perceived, the manner in which desires are communicated and satiated, and the way in which society responds. For example, the language used to describe and define psychiatric disorders can shape how mental health professionals perceive what a patient may be experiencing as top-down filters shape and constrain the sensory input from the patient's presentation and mold a clinician's assessment and treatment planning.

Rational thought contributes to the ability to judge the probability of uncertain events and to choose among various options. These processes contribute to problem-solving in which data are assessed, classified, transformed, and compared on the basis of logical rules to produce a choice that solves a problem; failures in these steps can result in limitations and distortions in normal thought processes.

Modes of Processing and Laterality

The mind is capable of distinct modes of processing mental representations: A serial mode uses sequential processing in a linear fashion but is thought to be slow and energy-consuming because only a few items can be processed at a time; focal, conscious attention is believed to occur in this serial fashion. A parallel mode involves the simultaneous manipulation of large numbers of representations in a nonlinear fashion and occurs in a rapid, low–energy-consuming process; pattern recognition is one example of parallel processing that can deal with a wide array of stimuli at the same time.

Another distinction in contrasting modes of processing has been identified in the type of mental processes primarily attributed to the right and left cerebral hemispheres. Studies in which patients whose corpus

Telegram: @medical_k

www.konkur.in

callosum have been surgically severed, who have had unilateral neurologic lesions, or who have undergone brain-imaging protocols have revealed a remarkable consistency in trends of left- versus right-hemisphere functioning. Some general principles from these studies suggest that whereas many processes involve both hemispheres, there are also distinct patterns primarily originating from one side of the brain or the other.

The forthcoming generalizations relate to right-handed individuals and to most left-handed people: In the right hemisphere, there are fast-acting, parallel, holistic processes, including perception and communication of nonverbal signals. The right side specializes in representations with a wide spectrum of values, such as images and sensations, and in the nonverbal meaning of words, sometimes referred to as analogic representations. The right hemisphere is thought to work as a pattern recognition center, capable of assessing the Gestalt context of a scene and providing a synthetic interpretation. In the left hemisphere, there are primarily more slowly acting, linear, time-dependent, serial processes. Left-hemispheric processes manipulate the verbal meaning of words in a logical, analytical mode of processing, focusing on the digital or clearly demarcated meaning of terms categorically organized, such as up or down, right or wrong, left or right. A generalization from a number of studies is that the right hemisphere tends to note the patterns in the world and creates contextual meaning, whereas the left hemisphere notes the details of what it perceives and attempts to organize and make sense of the world, creating a cause–effect explanation of experience.

The processing of emotion appears to be biased toward the right hemisphere. Facial recognition of the affective expression of others also appears to be a specialty of the right hemisphere. Notably, the right hemisphere appears to have a more integrated representation of the body's internal status, or interoception, information that may be essential for individuals to know how they feel. The hemispheres also seem to demonstrate biases with regard to emotional tone, with the left having a positive affect bias and approach state, whereas the right has a negative bias and a withdrawal state. Integration and balance of hemispheric influences appear to be necessary for adequate affect regulation and mental health.

Jerome Bruner described the distinction between an earlier mode of thought, which he referred to as *narrative cognition,* versus a later mode,

Telegram: @medical_k

www.konkur.in

called scientific, logical, or paradigmatic cognition. Narrative thinking is a context-dependent form of processing that incorporates the internal experiences of the teller with the perceived expectations of the listener in the production of a story. Stories also involve the subjective experiences of the characters involved in the unfolding sequence of events. Children develop narrative thinking by 2 years of age, and the coconstruction of stories between parent and child is a primary mode of communication across cultures. Drawing on context, emotions, and linear explanations, such narratives help make sense of experiences in ways that involve both the right and left hemispheres of each person.

Logicoscientific paradigmatic processing is said to occur in a context-independent manner that focuses on abstract concepts and their logical, cause-and-effect relationships and thus may rely primarily on left hemisphere dominant processing. The unfolding of each of these distinct processes coincides with the specialized processing of the right and left hemispheres and the sequential process of developmental maturation. See McGilchrist (2009) for an expansive and fascinating exploration of the origins and impact of cerebral lateral specialization.

Metacognition and Self-Reflective Capacity

Metacognition concerns conscious processes that act on cognitive processes—thinking about thinking. Awareness of cognition appears to develop by approximately 6 years of age and takes various forms, including the appearance–reality distinction (things may not be as they appear). This is well documented since Piaget's formulations on the conservation of liquid task. Two components of this awareness are representational diversity (the same object may appear to be different to different people) and representational change (thoughts today are different from those of yesterday and may be different again tomorrow). This form of knowledge about the person-specific meaning of cognitive representation requires some sense of the person's awareness of the separateness of minds, a theoretical domain in developmental cognitive psychology called the *theory of mind.*

The regulation of cognition, also called *metacognitive monitoring,* includes such processes as planning activities, monitoring activities, and checking outcomes. Metacognitive monitoring may involve the assessment of thinking sequences for fallacious logic, factual errors, and contradictions in the content of speech. Peter Fonagy and colleagues

Telegram: @medical_k

www.konkur.in

explored the development of the reflective function or experiencing an internal observer of mental life. Parents teach children how to be self-reflective by including their own internal state in interactions with them and by encouraging children to share their own. Children who have been taught to tell stories that include mental states usually demonstrate a greater frequency of secure attachment. Being able to understand and consider the mental states of self and others has also been shown to decrease dependency on defensive strategies.

Research suggests that what is created in parent–child narratives about experience is not just a story; embedded within the storytelling is the selection of information to be included, how it is to be processed and understood, and whether it is egocentric or has multiple subjective centers. Children who can appreciate more than one perspective in a story may develop greater empathic capacity.

Social Cognition

Bridging the fields of social psychology and cognitive psychology, the study of social cognition focuses on the mental processes involved in social interactions. Its domains include the study of empathy, interpersonal communication (verbal and nonverbal), person perception, relationship scripts, and group processes. Other related areas include studies of attribution bias, memory for social interactions, stereotyping, mental control of social cognitive processes, and cognitive origins of a sense of self. Social cognition can be seen as a domain of social psychology that uses information processing theory to assess the components of attention, perception, encoding, memory, retrieval, and schemata. A dominant theme in social cognition research has been that top-down, theory-driven processing influences interpretations of and behaviors in social situations. Developmental psychologists have focused on the origins of social cognition and its deviation to reveal, for example, that children with autism spectrum disorder (ASD) have significant deficits in empathic capacity and in the ability to interpret social cues. Social cognitive deficits are also present in other psychiatric disorders, such as bipolar disorder, PTSD, and social anxiety.

There are two theories proposed to explain how we are capable of understanding another person's point of view: "Theory-theory" and "Simulation Theory." Theory-theory posits that we develop internal social models based on an individual and use them to predict their behavior.

Telegram: @medical_k

www.konkur.in

Simulation theory suggests the idea that we put ourselves in the other person's position in the process of empathy. Simulation theory has gained favor as a result of recent research on mirror neurons, which are hypothesized to be involved in an intricate process creating resonance, sympathy, and "mirrored states" in the perceiver. Mirror neurons activated during the perception of another's intentional acts stimulate neural networks that organize the same motor actions. This work has led to several hypotheses involving a process by which these cortical maps of behaviors are communicated to the limbic areas and down into the body itself. The resulting emotional and bodily states are then registered in the middle areas of the prefrontal cortex involved in self-experience. The "resonance" of the perceiver's limbic and somatic states with that of the person being observed then serves as an unconscious template through which the prefrontal region assesses how the self is "feeling." Thus, based on simulation theory, what one experiences as self-states is highly influenced by the experiences of those around them.

These networks are hypothesized to be the substrate of sensing another person's mind—those intentions and emotions experienced by another are now felt within the observer. Maps of others' minds are thought to be created in the medial prefrontal cortex and related areas allowing for the empathic understanding of another person's experience in what can simply be called mindsight or mentalization. One hypothesis regarding the social cognition deficits in autistic individuals suggests that there may be difficulties in the activation of mirror neuron-related areas, either from impairment in input or functioning to these social circuits of the brain. Further research is needed to validate this preliminary view, but it serves to highlight how impairments in neural mechanisms underlying empathy and the ability to map out another person's mind may be at work in a range of disorders.

Discourse and Narrative

Discourse is communication from one person to another; it is thought to involve a sense of intention or plan. Normal discourse follows a set of rules that ensures the coherence and effectiveness of communication as what is intended to be communicated by the sender is understood by the listener or receiver. Some researchers support the idea that discourse is a cognitive function that follows the basic principles of information processing, including a schema for effective communication that takes

Telegram: @medical_k

www.konkur.in

into account the listener's perspective. Incoherent discourse can be noted by analyzing violations of the primary maxims of discourse in a process called *discourse analysis,* which examines the ways in which discourse deviates from an assumed discourse plan.

The exact method to quantify abnormalities in discourse is controversial, but clinical impressions of incoherence are important for assessing deficits in thought and social communication. The deficits may result from learned behavior, inherent cognitive abnormalities in thought or language, or deviations in social cognitive functioning, and they are clinically evident in psychosis, specifically in schizophrenia, and in individuals with unresolved trauma.

Narrative is a broad domain of research ranging from the literary study of fiction to investigations of the origin of autobiographical accounts in developmental psychology. From a cognitive point of view, narrative is important in understanding the relationships among language, memory, consciousness, mental models, self-schemata, and social cognition. *Narrative* can be generally defined as the way in which a person creates a verbal account of a sequence of events in the world and an internal experience of the characters of the story.

Studies of early monologues find that young children interpret and assign meaning to events in their world from an early age and that narrative helps to record and make sense of the past, interpret the present, and anticipate the future. The brain has been called an "anticipation machine," and mental models, prospective memory, and narrative are all ways in which networks of top-down processing prepare for possible futures. The enactment of narrative themes guides the way in which individuals live out their lives.

Cognitive Development

Developmental theories and research can be divided into several views: Stage theories (Jean Piaget, neo-Piagetian approaches, and the sociocultural school of Alexander Luria and Lev Vygotsky) describe discontinuous periods of development, with periods of stability and consolidation alternating with periods of instability and transition. Information-processing models postulate a nonstage theory, in which the emergence of cognitive capacity is a continuous process rather than a set of invariant sequences. Both stage and nonstage views embrace the idea

Telegram: @medical_k

www.konkur.in

that hierarchical integration and ongoing differentiation are fundamental aspects of cognitive development.

A distinguishing feature of each of these theories is the relative weight given to the role of innate, biologic factors on the one hand and culturally determined social learning experiences on the other. In other words, do cognitive capacities emerge from a genetically determined plan, as in the Piagetian view, or do they develop in response to experience, as in the sociocultural view? More recent conceptualizations have drawn on the functioning of complex systems, supporting the idea of a transaction between innate factors and environmental experiences in the emergence of ever-more-complex capacities.

Psychiatric disturbances in cognition may reflect arrested patterns of typical cognition (mental retardation), atypical developmental pathways (ASD), and specific cognitive impairments (schizophrenia) that may have been present early on or that only became evident after life requirements such as school, became demanding. Investigations into the developmental features of these disorders are a major focus of the field of developmental psychopathology.

Self-Organizational Processes

An understanding of the development and subjective experience of cognitive processes has been greatly informed by insights from the fields of evolutionary neurobiology and the nonlinear dynamics of complex systems, otherwise known as *chaos theory.* With billions of neurons and trillions of synaptic connections, the brain is capable of organizing an incomprehensible number of activation patterns. In selectionist theory, the billions of neurons become organized into networks with similar functions that can be selected and reinforced by interaction with the environment in an experience-dependent fashion. In addition, the brain has value systems that selectively reinforce the activity of neuronal groups that enhance survival. In this way, the brain's neuronal groups compete and differentiate within the brain in an ever-evolving adaptational system.

Chaos theory suggests that complex systems adhere to a specific set of principles. Three of these principles, nonlinearity, self-organizational processes, and movement toward complexity, are especially relevant to psychiatry. Nonlinear refers to the finding that small changes in input (or initial conditions) can lead to large and difficult to predict changes in output. Complex systems function on the rules of probability, which predict

Telegram: @medical_k

www.konkur.in

that certain combinations of activity within the system are more likely than others and that these combinations will tend to move the system toward self-organization. This probability also predicts that the system moves toward increasingly complex states of functioning. A complex system is a collection of elements that have the three characteristics of being open to influences from outside of the system itself, being capable of chaotic or essentially random behavior, and being nonlinear.

Complexity theory may offer a foundation for proposing a useful working definition of mental health applicable to individuals, families, and larger social systems. In complex systems, self-organizational processes that move the system's states toward maximal complexity are mathematically shown to be the most flexible, adaptive, coherent, energized, and stable. The movement toward complexity lies between the extremes of sameness, with rigidity and order on the one side, and change, with randomness and chaos on the other. Complexity is achieved when the components of the system achieve a balance between the two fundamental processes of differentiation (specialization in function) and linkage (connected together as a functional whole). Please note that in some neuroscience studies, the term "integration" is used to indicate linkage, and the term "segregation" is used to indicate differentiation. Here we are using the same notions but with the overall blending of the linkage of differentiated components to be designated with the term integration. When a system links differentiated parts, it becomes integrated and achieves a state of complexity and harmoniousness, advancing adaptive functioning bordered on either side by chaos and rigidity.

Examination of psychiatric syndromes reveals examples of deviations from this integrated complex state in which an individual exhibits states and traits of chaos and/or rigidity. For a given individual, such a balance can be achieved when the genetically and experientially influenced growth of neural circuits combines the differentiation of specialized regions with linkage via neural fibers connecting widely distributed areas into a functional, integrated whole. According to this view from the interdisciplinary field of "interpersonal neurobiology," disorder can be seen as occurring when a system's integration is impaired, and its flow toward complexity is impeded as revealed in its movement toward either rigidity or chaos.

Trauma may impair integration by blocking neural linkages within an individual, as seen in the negative effects on the integrative regions of the

Telegram: @medical_k

www.konkur.in

corpus callosum, prefrontal cortex, and hippocampus in abused and neglected individuals. A dysfunctional family system would be thought to occur when the individuals are excessively differentiated (without emotional connections) or linked (enmeshing that inhibits individuality from being expressed). Such stressed systems are limited in their movement toward complexity and, hence, in their stability, flexibility, and adaptability. Such impediments to integration make a system prone to chaos and rigidity.

Psychiatric disturbances may be conceptualized as disturbances in self-organizational processes. Both inherited and experiential internal determinants, as well as ongoing external, environmental, and social influences that place constraints on the system, can directly affect the development and effective use of integrative self-regulatory mechanisms. Integration is the underlying mechanism of optimal self-regulation. And interpersonal integration likely supports the growth of integrative regions of the brain. Clinical interventions may thus function at the level of external constraints (psychotherapy with integrative communication within a relationship) or internal constraints (pharmacologic treatments) that alter the ways in which the individual's mind is able to achieve integration and healthy forms of self-organization. Optimal self-organization is created with integration, the linkage of differentiated parts of a system. By seeing the mind as something beyond "brain activity" and "subjective experience" alone, a definition of one aspect of mind as "the embodied and relational, self-organizing emergent process that regulates the flow of energy and information" makes it possible to understand the interconnected nature of the broad range of disorders and interventions as related to the fundamental process of integration. Viewing psychiatric disturbances in this way also allows for a synthesis of the views of psychodynamic, biologic, and social psychiatry.

States of Mind

The state of activation of the various parts of the system can cluster into repeated patterns called *states.* In the brain, a *state of mind* or *mental state* describes the way in which various neuronal groups may become activated at a given time. Repeated patterns of neuronal group activation —a neural net profile—can become reinforced if they occur frequently or if the value system of the brain ingrains their profile. These ingrained patterns of activation are called *attractor states*; those states that are least

Telegram: @medical_k

www.konkur.in

likely to occur are called *repellor states.* These mental states are determined by the constraints on the system, and modification of constraints allows the nature of attractor and repellor states to be altered. Constraints on the system are both external and internal: Features of the external environment, such as the way in which other people behave and relate to an individual, can directly affect which mental state is more likely to be activated within the person. Internal constraints include the synaptic strengths of association, as determined by constitutional features and genetics, and those learned from experience, as encoded within memory processes.

Repeatedly reinforced patterns of neuronal group firing link the cognitive processes of attention, perceptual bias, memory, mental models, behavioral response patterns, emotional tone, and regulation. These states of mind result in the patterns of cognitive, emotional, and behavioral symptoms seen in both mental health and various psychiatric disorders; in a depressed state of mind, for example, one may pay conscious attention to negative aspects of experience, interpret incoming stimuli in a pessimistic manner, have greater access to depressing past experiences, activate mental models of the self as bad or guilty, have behavioral patterns of withdrawal, and have a depressed mood with difficulty regulating intense affect.

Healthy mental functioning may depend on a flow of state of mind through time, which can then allow for flexible adaptation to an ever-changing environment. This relates back to chaos theory, which suggests that nonlinear complex systems must move continually toward maximizing complexity by balancing predictability and novelty. This is how mental health can be seen to emerge from integration, both within the individual and between the individual and the environment, especially the social world.

SENSATION, PERCEPTION, AND COGNITION IN PSYCHIATRIC DISORDERS

Since the time of Emil Kraepelin and Eugen Bleuler, psychiatrists have known that certain disorders include profound disturbances in cognitive functioning. Since the 1950s, researchers have attempted to determine the exact nature of such deficits. With advances in computer technology and an increasing technical ability to analyze stimulus presentation and

Telegram: @medical_k

www.konkur.in

response times on the order of tens of milliseconds, cognitive psychologists have been able to devise research paradigms capable of testing increasingly subtle aspects of cognitive processing.

Processing research has focused on all three domains of sensation, perception, and cognition. Sensory-processing studies, using simple stimuli, focus on poststimulus events for as long as 1 second; perceptual studies, using slightly more complex stimuli, examine processing after a period of as long as approximately 5 seconds. Cognitive processing experiments can examine the early aspects of processing (e.g., phenomena occurring within the first 30 seconds), as well as long-term processes that occur over hours, days, or even years. Recent attempts have been made to correlate complex cognitive findings with clinical presentations.

A general problem with correlating cognitive processes with clinical populations lies in the symptomatic heterogeneity of patients falling within the same diagnosis. A related problem is a distinction between general and specific deficits: Do psychiatrically ill patients perform less well on a given task because they are ill or because of a deficit specific to the disorder? For example, psychomotor slowing, as measured by reaction time and response rate, is seen in schizophrenia, depression, and other psychiatric and neurobehavioral disorders. The side effects of medications can also influence processing and response speed. Researchers rely on the creative design of experimental tasks to help distinguish between general and specific deficits. A comparison of target-patient populations with matched healthy persons and other psychiatric patients can help to determine disorder-specific cognitive dysfunction. New research surrounding deficiencies of a protein called SV2A has revealed a linkage of this state to deficiencies in cognitive tasks in patients with schizophrenia. Medications address positive symptoms with clinical efficacy, but cognitive impairments and negative symptoms are still ineffectively addressed to date.

Another general issue is that of state markers versus trait markers; a patient with schizophrenia, for example, may have a cognitive deficit only when actively psychotic (state) or all the time (trait). These results have been found in certain cognitive tests of attention that correlate with improvement on medications. Some atypical results are also found in the nonill first-degree relatives of patients with schizophrenia. Is the marker of genetic vulnerability a coincidental finding or part of the core deficit in

Telegram: @medical_k

www.konkur.in

schizophrenia? An exploration of the implications of these cognitive differences for the daily life of the patient is an important application of the research findings to clinical psychiatry.

Schizophrenia

Three general hypotheses inform our understanding of the biologic foundations of schizophrenia: NMDA-Glutamate hyperactivity, hyperactivity in the mesolimbic system, and hypoactivity in the mesocortical system. Positive symptoms are attributed to mesolimbic activity and negative symptoms to mesocortical activity (along with nucleus accumbens/reward circuitry). Schizophrenia is often associated with positive and negative symptoms, yet cognitive and affective symptoms are just as significant, especially in relation to problems adjusting to real-world demands. In general, cognitive symptoms have been correlated with inefficiencies in the dorsolateral prefrontal cortex, whereas affective symptoms relate to the ventromedial prefrontal cortex, with aggressive symptoms corresponding to the orbitofrontal cortex and amygdala.

Even before higher-order cognitive processes, individuals afflicted with schizophrenia suffer from issues with sensorimotor gating. Studies have repeatedly found that schizophrenic patients have differences in their capacity to tune out irrelevant data. This is usually an automatic process that occurs in healthy individuals. Attention may become compromised when these implicit processes are malfunctioning. They also show a markedly diminished capacity to habituate, for example, demonstrating a persistent acoustic startle reflex with repetitive tones. In general, deficits in habituation and sensorimotor gating support the idea that schizophrenic patients have a diminished capacity to regulate the flow of rapidly presented information; they experience being inundated by stimuli that are regularly filtered out in the brain of a nonclinical person. Deficits in processing may also occur with internally generated stimuli, producing an overwhelming and confusing experience of the internal and external world.

Three of the most prominent cognitive problems include executive dysfunction, social cognition, and attention. Executive dysfunction is typically registered in assessments evaluating cognitive flexibility, conceptualization, complex problem solving, and verbal fluency. Problems in these domains highly correlate to reduced adaptive potential in daily

Telegram: @medical_k

www.konkur.in

functioning. For example: to successfully maintain and/or ascend in the domain of occupation, processes involved with strategizing and decision-making are critical. Fostering relationships are just as important, and in order to do so, individuals must have an accurate perception of others and the meaning of their interactions. In this regard, individuals who suffer from schizophrenia have been shown to exhibit hyperactive amygdala activation when viewing neutral faces and hypoactivity when viewing fearful and emotionally charged facial expressions. This may result in social misperceptions such as perceiving a threat in a neutral environment or neutrality in a potentially threatening environment.

Selective attention is a necessary component to learning and responding appropriately to any given context. Patients diagnosed with schizophrenia have an impairment in their ability to avoid distracting stimuli (to filter) and to pigeonhole. Recent conceptualizations have also examined a generalized impairment in the information-processing capacity in schizophrenia. The capacity model examines the way in which a pool of attention is allocated across mental activities. Two components of this model are the *quantity of resources available* (capacity) and *executive allocation policy.* Schizophrenic patients may also suffer from an impaired response selection process and thus demonstrate atypical responses on tasks.

Sustained attention, or *vigilance,* is required to process stimuli of long duration. The most common research paradigm used to examine sustained attention is the *Continuous Performance Test.* This test consists in rapidly presenting a set of letters with varied spacing and timing of target and nontarget stimuli. The analysis of response features is important in the interpretation of results and has led to the finding that patients with schizophrenia have a deficit in their ability to distinguish target stimuli from nontarget stimuli, especially when the stimuli are presented as brief signals at a rapid pace. When compared to nonclinical controls, positron emission tomography (PET) in patients performing a Continuous Performance Test revealed lower metabolic activity in the prefrontal cortex bilaterally but normal or elevated activation in the occipital region. This finding is consistent in supporting the idea of impaired executive functioning in schizophrenia.

Attention-Deficit/Hyperactivity Disorder

Telegram: @medical_k

www.konkur.in

Peterson and Posner identified three neural systems critical for attention: These are alerting, orienting, and dual executive networks. Attention is initiated with alertness, which elicits the reticular activating system in the brain stem maintained by adrenergic projections from locus coeruleus in the pons of the brain stem to the forebrain. What follows is the necessity to orient towards a stimulus, which induces activity in two networks, the dorsal and ventral. The dorsal network includes the parietal and frontal eye fields and is involved with synchronizing visuospatial orienting activity. The ventral network houses the temporoparietal junction and ventral frontal cortex, which selects which competing input should be given priority. Given the range of potential surprises, these networks allow us to focus on anomalous activity that may be a threat or of potential benefit to our survival. The dual executive network includes the DLPFC-parietal network involved with task initiation, switching, and adjustments and the ACC-anterior insula network, which assists with sustaining attention. Individuals with ADHD tend to demonstrate deficits in the alerting and executive attention networks.

Data from numerous studies show that patients with ADHD have dysfunctions on a variety of tasks, including those that involve monitoring, perception, memory, and motor control. Intact performance has been found on a number of memory tasks requiring verbal processes (digit span, word tests, and story recall) and nonverbal processes (recall, visual arrays, and block series).

In general, patients with ADHD evidence behavior that is consistent with patients suffering from frontal lobe damage, specifically with regard to deficits in the control of motor responses, in the execution of fine-motor movements, and in the inhibition of ongoing response patterns. Although memory tasks and basic aspects of information processing remain intact, these patients have impaired performance across several modalities (auditory, visual, motor, and perceptual–motor), suggesting some global deficit. These patients also appear to be unusually susceptible to boredom when the required tasks are long and repetitive.

One view examines two proposed systems, an underactive behavioral inhibition system, and an impaired behavioral reward system, to explain the behavioral challenges of ADHD. A related view is that the rule-governed behavioral system is not intact, as evidenced by the fact that patients with ADHD appear to do especially poorly with delayed or nonexistent rewards, including those tasks that require sustained

Telegram: @medical_k

www.konkur.in

attention, accuracy, or task-directed activity governed by another person's direction or rules. Under these conditions, the patient's poor regulation and inability to meet functional demands are revealed. A related issue is a diminished motivational drive and, possibly, a diminished arousal regulation system.

Another perspective supported by research data is that ADHD patients have metacognitive differences. According to this view, the metacognitive processes that help to plan, monitor, and regulate performance are impaired, and the patient's ability to assess the task and determine strategies is deficient. This is an example of a top-down aspect of attention because there is impairment of the higher cognitive processes that regulate information flow. Bottom-up deficiencies, on the other hand, would involve impairment in basic aspects of attentional focus due to abnormalities in arousal, capacity, and selectivity.

The finding that numerous factors can influence the appearance of deficits led Virginia Douglas to hypothesize that ADHD is a self-regulatory disorder with pervasive effects. According to Douglas, the impairments affect each of four domains—attention, inhibition, reinforcement, and arousal—and result in deficits in several aspects of self-regulation: (1) the organization of information processing, including the making of plans, metacognition, executive functions, the adoption of appropriate cognitive sets for a given task, the regulation of arousal levels and alertness, and self-monitoring and self-correction; (2) the mobilization, deployment, and maintenance of adequate attention; and (3) the inhibition of inappropriate responses to extraneous stimuli and reinforcers. These deficits in self-regulation imply that increased processing demands result in the diffusion of attention and the impairment of the in-depth, coherent acquisition of knowledge and understanding.

The diversity of research findings and theoretical explanations is paralleled by the clinical finding that children who are severely impaired in the classroom may have no attention problems in the confined, one-on-one setting of the psychiatrist's or psychoeducational examiner's office. Such children may also be able to attend for indefinite periods to video games and yet be unable to follow complex conceptual information. This is an important reminder that cognitive dysfunction in psychopathologic conditions may be task, context, or relationship specific, depending on the nature of the cognitive impairment. The patient's clinical history and

Telegram: @medical_k

www.konkur.in

evaluation must therefore consider potentially hidden domains of atypical cognition.

Autistic Spectrum Disorder

Although early descriptions of autism delineated deficits in social functioning, later studies found cognitive dysfunctions involving abstraction, sequencing, language, and comprehension. Researchers are now focusing on the nature of the core deficit in the disorder, and how the cognitive domains relate to the social-affective deficits is of particular interest. However, there may be many “autisms,” and finding a single process may prove unhelpful. In general, three broad areas appear to be atypical for those on the autism spectrum: sensory integration, emotion regulation, and social cognition.

A majority of patients with ASD are assessed as having mental or cognitive deficiencies, although cognitive impairments are especially difficult to assess if language functioning is severely limited. Mental retardation involves global, cognitive, and language impairments that may make it difficult to distinguish autistic disorder features. Studies of high-functioning patients with autistic disorder have permitted a deeper exploration of a variety of cognitive deficits. An array of dysfunctional areas, including numerous language problems, excessive or impaired responsiveness to stimuli of various modalities, different encoding of auditory stimuli, and impairment in the ability to extract important features from incoming information, have all been found; in contrast, some patients with autistic disorder have relatively intact visuospatial and Gestalt functions, musical abilities, and rote memory. Performances on standardized tests reveal relatively good results in object assembly and block design but poor results in comprehension. Language deficits vary and include syntactic, phonologic, prosodic, and pragmatic domains, also suggesting right-hemisphere involvement. The wide array of dysfunctions in autistic disorder may be due to the existence of a variety of subtypes with dysfunction in different loci in the brain. One general finding is that of a larger brain in individuals with autism, with some suggestions that differentiation has become impeded, thus impairing the capacity for integration and the achievement of complex states of cognition and behavioral social interactions.

Other studies have focused on the social cognition of patients with ASD; they have examined the nature of the patient’s emotional behavior

Telegram: @medical_k

www.konkur.in

and level of understanding in order to assess the earliest manifestations of an atypical emotional connection between autistic children and their parents. Recent work in neurobiology suggests a role of the orbitofrontal cortex and the cerebellum in mediating some of these deficits. Two findings support these initial impressions: (1) Autistic children are much less likely than nonautistic children to imitate adult vocalizations and gestures, and (2) they show much less sophisticated representational play with objects than do nonautistic children. These findings have led to the suggestion that a core deficit in ASD exists in the representation of representations (meta-representations), leading to deficits in symbolic play and to the inability to understand the mental states of others. The inability to transfer cognitive representations into language symbols may be a related meta-representational deficit.

A series of studies explored the relation of these possible cognitive impairments to socioemotional behavior. In contrast to clinical lore, children with ASD were found to look at their parents; they had eye contact with their parents when social interactions were parentally elicited, and they revealed a typical distribution of behavioral patterns of attachment, even if the behaviors were not typical themselves. These studies did find a marked lack of social referencing (looking to parents for emotional cues in ambiguous situations) and protodeclarative gestures (pointing to objects and showing objects to familiar adults); three hypotheses have been proposed to explain these findings: (1) Autistic children may not have the capacity to have a representation of another person as having ideas, perspectives, or emotions that can be shared. This proposal is consistent with a “theory-of-mind” hypothesis, in which a core deficit in autism is believed to be the inability to have a sense of another’s mind; (2) autistic patients may have an impaired ability to perceive or to comprehend the emotional (usually facial) signals of others; and (3) the core deficit may involve a lack of interest in others or an aversion to responding to others. Studies have found that although children with autistic disorder do express emotions, they have less positive affect during periods of joint attention with another person. Furthermore, they reveal impairments in their responsivity to the display of strong emotion by another, whether it is of distress or of pleasure.

Telegram: @medical_k

www.konkur.in

FIGURE 3.1–2. Sigman's model for the development of socioemotional understanding. (Courtesy of M. Sigman.)

Tests of high-functioning autistic patients reveal poor performance on emotion-recognition tasks, little comprehension of and empathy with depictions of social situations, and difficulty in talking about socially derived emotions, such as pride and embarrassment. Autistic patients with relatively high intelligence use adaptive cognitive strategies to interpret social stimuli to compensate for impaired emotion-processing abilities. The development of social cognition and socioemotional understanding requires complex interactions among the cognitive, perceptual, and emotional processes.

A series of interactive elements essential to the development of social understanding has been proposed (Fig. 3.1–2) to describe the basic precursors of emotional responsiveness: The ability to attend to, encode and interpret verbal and nonverbal social stimuli, the awareness of one's own and others' emotional responses, and the ability to contrast oneself with others. Out of that matrix develops the ability to understand others' views, desires, and beliefs. Accordingly, a deficit in any one of those basic elements may explain the characteristic deficits observed in the social cognition of persons with ASD. As discussed in the section on Social Cognition, one hypothesis in need of further validation is whether an atypical functioning of mirror neurons and related circuits plays a role in the social deficits of autistic individuals.

Mood Disorders

In contrast to schizophrenia, ADHD, and autistic disorder, mood disorders do not appear to have core cognitive deficits that are diagnosis specific. Instead, cognitive abnormalities appear to be related to the degree of psychopathology and the severity of the mood disturbance. In other words, they are state-dependent. Most studies have examined patients with depression, whereas only a few studies have assessed cognitive

Telegram: @medical_k

www.konkur.in

functioning in patients with bipolar I disorder during a manic state. In depressed patients, the severity of the depression has ranged from mild depression in students to severe illness in hospitalized patients with major depressive disorders. The studies have primarily examined attention and memory for neutral and emotionally toned stimuli; for the majority of these studies, the concept of self-organizational processes and state regulation has not been the primary focus of attention. These recent conceptualizations of the brain's functioning as a nonlinear complex system capable of self-organization, however, may aid in the future investigation of the primary dysregulatory aspects of mood disorders.

Depressive Disorders. Depressed patients often complain of difficulties with concentrating, learning, and remembering. Studies have documented that such patients perform poorly on tasks that require sustained attention or effortful and elaborate rehearsal, and thus, controlled limited-capacity processes appear to be impaired in major depressive disorder. This limitation of access to capacity-demanding resources appears to be directly related to the severity of the depression and normalizes with remission from a depressive episode.

Depressed patients have also been found to require increased supportive data from the presented stimuli before responding in a test situation. Whether this pause before responding is a psychological response to being depressed, an emotional "need to be certain," or a specific feature of the depression itself is yet to be determined. The reluctance to respond must be considered in interpreting research data and clinical interview findings.

The attention and memory findings have suggested several theoretical frameworks that are clinically useful: A schema theory of depression outlines a positive feedback loop in which negative self-schemata prime persons to have negative thoughts, to recall negative events in their lives, and to interpret present events with a negative bias. Whether as a cause or as a maintaining influence, these depressogenic schemata are thought to create a series of cognitive functions that produce and maintain a depressed mood.

A network theory of memory and emotion, supported by research on depressed and nondepressed persons, posits that mood leads to a spreading activation of items in memory that are congruent with the mood. Thus, emotion directly influences retrieval by the process of state-

Telegram: @medical_k

www.konkur.in

dependent learning and memory. Furthermore, while depressed, patients are likely to encode items in a form that makes them readily accessible when retrieved in a depressed state. Depressed mood, then, becomes an internal context cue that accesses depression-related memories.

The network and schemata theories of depression provide a framework for understanding how emotions and moods influence cognitive processing. Emotions in health and illness can shape the mental state instantiated at a given time by triggering the activation of previously formed depressive schemata. The activated schemata, in turn, can produce retrieval biasing and behavioral responses fundamental to a mental state, which can then further elicit a negative emotional response; this self-reinforcing loop is established and supports the continuation of both depressed cognition and mood.

Some patients may be especially prone to marked cognitive alterations based on rapid shifts in mood, and these shifts may be a learned or constitutional feature of the individual. From the nonlinear dynamics view, rapid shifts in mental state can be conceptualized as sudden and intense changes in the constraints on the system, which determine the flow of states of mind across time. The depressed state may become deeply ingrained as an attractor state that is difficult to alter. Pharmacologic interventions may aid in directly altering the synaptic constraints that maintain such a state, thereby promoting neural plasticity. Psychotherapeutic interventions, such as cognitive-behavioral, interpersonal, and mindfulness-based therapies, can all be theorized to produce changes in the internal processing of constraints, as well as in the ways in which external constraints from the social world interact to shape the overall shifts and stability of mood.

Bipolar I Disorder. Patients with manic episodes present with a spectrum of state-related cognitive dysfunctions tied to the severity of their episode. Manic disturbances have been described clinically as rapidly paced thinking and speech, quick associations to self-generated or other-generated stimuli, grandiosity, and increased distractibility.

Studies have suggested a high rate of combinatory thinking and the inclusion of loosely associated but related intrusions. The clinical impression of humor (even in the face of underlying dysphoria) in some patients is corroborated by playful, extravagant, or flippant elaborations, as well as intrusions in speech, and seems to indicate primarily state-

Telegram: @medical_k

www.konkur.in

dependent symptoms that improve on recovery. Forced-choice, span-of-apprehension, and backward masking tasks all reveal impairments similar to those seen in actively psychotic patients with schizophrenia and yet are unlike those seen in schizophrenic patients who have persistent deficits in the remitted state. Bipolar disorders, then, can also be viewed as disorders of self-organization in which the system fluctuates between the extremes of highly activated manic states and highly deactivated depressed states of mind. Structural brain imaging of patients with both disorders has revealed impairments to integration in the form of impediments to linkage.

Two networks are involved in the pathology of bipolar disorder, one involving the patient's homeostatic network, which includes internally directed amygdala-based feeling states, and the second network involving the external regulatory network assisting with cognitive emotion regulation while suppressing maladaptive affect. Compared to healthy individuals, where these two networks would normally regulate the emotional responses collaboratively, in those diagnosed with bipolar disorder, these networks fail at regulating emotional responses with the complexity and flexibility of healthy individuals. Research-based on a better understanding of neural origins of complex emotional symptoms of bipolar disorder is still needed to better understand the overall link between physical symptoms and emotional responsiveness.

Anxiety Disorders

Cognitive studies of patients with anxiety disorders have focused primarily on attention or memory. Various research paradigms have been applied to assess attention bias and memory retrieval for neutral and emotionally activating stimuli. Studies find that anxious patients have an increased tendency to attend to fear- and threat-related words. One research approach includes a dichotic listening task in which an anxious patient is more easily distracted than are controls by fear-related stimuli in the nonattended channel. This finding suggests that anxious patients have automatic, parallel attention processes that are primed to detect certain types of stimuli.

Another approach uses the Stroop paradigm, in which words are presented in different-colored inks, and the person must look at the word and state the color of the ink. Anxious patients have a significant delay in their response times for fear-related words, a finding that suggests that

Telegram: @medical_k

www.konkur.in

increased attention capacity or cognitive processing is necessary when those “fear” words are perceived, and the color of the ink must subsequently be determined.

One theory that explains these aforementioned findings posits the idea of a “fear network” that encodes fear-related information in a memory structure that is readily accessible and able to influence cognitive, motor, and psychophysiologic responses. The theoretical fear networks, which may be similar to mental models, are thought to contain three related forms of information: (1) fear-eliciting stimulus cues, (2) specific response patterns, and (3) the meaning of the cues for that particular person. According to this theory, patients with anxiety disorders are believed to have fear networks that are especially coherent and stable, easily activated, and require few environmental cues.

Posttraumatic Stress Disorder

Patients with PTSD have been found to have attentional biases toward threat-related stimuli specific to the experienced traumatic event. Cognitive aspects of the disorder are characterized by intrusive processes (memories, images, emotions, and thoughts) and avoidance elements (numbing, amnesia, and withdrawal), which are driven by increased arousal. These patients are thought to have a unique configuration of fear networks containing stimulus cues (environmental stimuli), response components (cognitive, motoric, and psychophysiologic), and meaning elements (the moral implications of the trauma, survivor guilt, and the meaning of intentional trauma vs. accidental trauma).

Some theories argue that states of excessive arousal during trauma impair attention capacity and memory encoding during that event. Emotional processing during and after a traumatic experience may also be hampered by the heightened state of psychophysiologic arousal and altered memory storage. In fact, the part of the brain necessary for explicit memory processing, the hippocampus, has been shown to be smaller in individuals experiencing chronic PTSD. Patients who have used dissociative mechanisms during and after a traumatic experience appear to be at far greater risk for developing PTSD.

One line of research that has expanded upon PTSD has been the examination of neural networks such as The Default Mode Network (DMN), the Salience Network (SN), and the Central Executive Network (CEN). The DMN, a network related to internal cognition such as mental

Telegram: @medical_k

www.konkur.in

time travel, the experience of self and others, has been found to be one of the first networks to be disrupted upon the experience of a traumatic event. Studies have found that the extent of these disruptions may be predictive of the consequent diagnosis and severity of PTSD. With the diagnosis of PTSD, the flexibility with which these networks operate in a nonclinical population has been found to be disrupted. During resting state, there has been evidence of intrusions from the SN, which typically allows one to toggle between the DMN and the CEN. The CEN is operative when an individual is engaged in a goal-directed task. In a healthy population, the DMN and CEN are mutually inhibitory. In PTSD, the CEN exhibits intrusions from the DMN. Put simply, intrinsic reflection may be characterized by a lack of safety resulting in hypervigilance, whereas internal cognition intrudes upon goal-directed tasks. Some of the underlying cognitive deficits found in PTSD are likely attributable to these dynamic challenges.

PTSD may have some aspects that are adaptive: Attention biases primed to detect fear-related stimuli may permit the early detection of threatening situations that, if not avoided, would produce incapacitating psychophysiologic arousal. Automatic, nonconscious behavioral avoidance response patterns embedded in the proposed fear networks or mental models allow these patients to minimize excessive arousal by avoiding trauma-related situations.

The psychopathologic aspects of PTSD can be cognitively exemplified as follows: A combat veteran with chronic PTSD may have no direct recall (impaired explicit memory) of a helicopter crash in which his best friend, who was seated next to him, was killed. Years later, continued avoidance of airports, amnesia for combat, general apathy, and social withdrawal (avoidance elements), combined with an exaggerated startle response, panic attacks, intrusive images, and nightmares (intrusive components), all suggest intact implicit memory of the combat trauma; the veteran has become emotionally, behaviorally, and cognitively impaired.

Speechless Terror. Scott L. Rauch and colleagues explored the neurobiology of intense fear using patients with PTSD. They took eight patients with PTSD and exposed them to two audiotapes. One tape was emotionally neutral, and the other was a script of a traumatic experience. While patients listened to these tapes, measures of their heart rate and regional cerebral blood flow (rCBF) were measured via PET scans.

Telegram: @medical_k

www.konkur.in

Studies found that, during the play of traumatic audiotapes, rCBF was greater in right-sided structures, including the amygdala, posterior medial, orbitofrontal, insular, anterior, and medial temporal lobes, and anterior cingulate cortex. These are the areas thought to be involved with intense emotion. Such findings are consistent with the view of unresolved PTSD as a state of impaired integration prone to the chaotic (intrusive) and rigid (avoidant) symptoms. In developmental trauma, too, those who have experienced abuse or neglect have been found to have structural differences in the brain's integrative regions, including the hippocampus, prefrontal cortex, and corpus callosum, as described below. Psychotherapeutic intervention in posttraumatic patients may yield significant healing by way of promoting the growth of integrative functioning, which future research may reveal as including the growth of integrative structures in the brain of those who resolve their previously unresolved states.

An extremely interesting and potentially important clinical finding was the decrease of rCBF in the Broca area (left inferior frontal and middle temporal cortex) in states of high arousal. These findings suggest an active inhibition of expressive language during trauma and high levels of stress. Based on these results, speechless terror, often reported by victims of trauma, may have neurobiologic correlates consistent with what is known about brain-behavior relationships. This inhibitory effect on the Broca area also impairs the encoding of conscious memory for traumatic events at the time that they occur. It then naturally interferes with the development of narratives that later serve to process the experience and lead to neural network integration and psychological healing. Activating the Broca area and left cortical networks may thus be essential in psychotherapy with patients experiencing PTSD and other anxiety-based disorders.

Approaches to the treatment of patients with PTSD need careful evaluation but generally include the view that the impaired emotional processing of the traumatic event requires the active recollection, in explicit terms, of the details of the experience. The process of effectively treating unresolved trauma usually involves the active cognitive processing of specific memories, including emotional responses, derived belief systems, and psychophysiologic arousal at the time of the traumatic event and during recall.

Telegram: @medical_k

www.konkur.in

The provision of new cognitive information in the course of psychotherapy, as well as the relative safety of the therapist's office, can, in theory, widen the "windows of tolerance" for certain emotions and memories to be held flexibly in consciousness and to alter the configuration of the fear networks and allow previously inaccessible information to be explicitly processed and made available to consciousness for incorporation into memory and an ongoing autobiographical narrative. Specific techniques, such as those that facilitate cognitive processing of previously dissociated or, in other ways, isolated cognitions—such as beliefs, images, and sensations—may be useful in alleviating the symptoms and dysfunction after acute or chronic trauma. Such therapy and changes in mental processing may reduce the avoidant and intrusive components of the clinical syndrome of PTSD, and they also may improve social, emotional, and cognitive functioning.

The evaluation and treatment of PTSD patients can be greatly enhanced by an understanding of the relevant cognitive processes and a careful application of the assessment to presenting symptoms. Several related areas that have interested clinicians for decades, and which have become a source of great societal concern and controversy, include the delayed recall of repressed memories of traumatic events and the suggestibility of patients influenced by clinicians, society, or friends to believe that they are the victims of childhood trauma.

Delayed Recall. Many scientists and clinicians believe in the cognitive capacity of patients to be unaware, for years or even decades, of severely traumatic experiences that took place in their childhoods. Other researchers disagree and emphasize the paucity of studies of corroborated cases of childhood trauma that have been followed prospectively into adulthood and have documented impaired access of consciousness to events presumably stored in memory. Two distinct mechanisms that may explain delayed recall of childhood trauma are *repressed* memories and *dissociated* memories.

A repressed memory can be thought of as originating from the active, intentional suppression of memory from consciousness. The mechanisms that underlie this process may then become automatic, and the contents of memory may become inhibited from retrieval into consciousness. This blockage may exist to avoid flooding the person's awareness with information that is associated with excessive anxiety or fear that would

Telegram: @medical_k

www.konkur.in

impair effective functioning. This is an example of knowledge isolation in which information may be layered in the nervous system, and certain aspects may be kept from conscious awareness.

In contrast, a traumatic event may be so overwhelming that adaptive processing may be impaired. If focal attention is divided or if the hippocampus is shut down temporarily with high cortisol secretion, the nonfocally attended (traumatic) material will only be processed implicitly. Thus, to adapt to a traumatic event, some persons may have the capacity to focus their attention on a nonthreatening aspect of the environment or on their imagination during the trauma; this may be an underlying mechanism in a process called *dissociation.* Traumatic memory that has only been implicitly encoded affects behavior and emotions and possibly contains intrusive images and bodily sensations that are devoid of a sense of past, of self, or of something being recalled. This may partly explain such symptoms of PTSD as amnesia (blocked conscious access to a memory or its origin), avoidance behaviors, hyperarousal, intrusive images, and flashbacks.

A person may use both mechanisms of repression or dissociation for different aspects of a traumatic event, and recollection of the traumatic memory may take different forms. Repressed memories may have been processed to some degree in narrative form, whereas dissociated memories probably lack integrative processing. This latter form may thus be experienced as nonpast and nonself, making the intrusive retrieval of dissociated memories a confusing and frightening experience. This is implicit memory retrieval of traumatic events.

Studies of the development of memory in children suggest that the shared construction of narratives about experienced events is often crucial in making the events accessible to long-term retrieval. The establishment of a personal memory system appears to be a function of such “memory talk,” in which parents discuss with children the contents of their memory. In children who have been forced to keep traumatic events a secret, as may occur with childhood abuse, the important developmental process of narration may be blocked. This may be an additional cognitive mechanism underlying the inaccessibility of some forms of childhood trauma to consciousness in adult patients.

Suggestibility. Numerous studies have demonstrated that human thought and memory are easily influenced by suggestion from others.

Telegram: @medical_k

www.konkur.in

Suggestibility is adaptive for a social being who relies on the experiences of others for knowledge of the world. Therefore, listening to the stories of others, reading a textbook, and being coached in athletics all require the receiver to accept data from the sender. Critical analysis of the data received is also an important component of learning; however, the metacognitive function of assessing the accuracy or usefulness of newly acquired information may be suspended under certain conditions, including hypnosis, drug-altered states, and conditions of severe threat.

Studies of human suggestibility indicate that postevent questioning can bias the metamemory processes that help to determine the source and accuracy of a retrieved memory. The verbal and nonverbal cues given by the interviewer may influence a person to believe that actual aspects of an event never took place. A person can also be convinced of the accuracy of an event despite its lack of correspondence with actual experience. Factors that may influence the biasing of interviewees include a belief in the trustworthiness and authority of the interviewer, not being aware that “I don’t know” is a permissible response, repetition of a question that has already been answered, and the interviewer’s beliefs as communicated through emotional tone and nonverbal gestures.

It is crucial for clinicians to be aware of human suggestibility to avoid iatrogenic distortions. Similarly, it is important for persons who experienced severe trauma early in life to receive informed and empathic evaluations and treatment. There is a delicate balance between supportive neutrality and active advocacy in assessment and intervention; awareness of these fundamental cognitive processes may help to guide the clinician toward achieving this goal.

Complex PTSD. Complex PTSD results from prolonged and inescapable stress and trauma during early childhood. It is complex because of its extensive impact on all areas of development and functioning. Trauma-shaped personality traits and coping strategies tend to increase the individual’s vulnerability to future trauma through engagement in abusive relationships, cognitive distortions, poor judgment, and a lack of self-protection. Long-term PTSD has been shown to correlate with the presence of *neurologic soft signs,* suggesting either a vulnerability to the development of PTSD or the long-term impact of the physiologic dysregulation caused by PTSD.

Telegram: @medical_k

www.konkur.in

Research on individuals with documented early developmental trauma in the form of severe neglect or abuse (emotional, physical, sexual) has revealed that the regions of the brain that are impaired in their growth are those that link widely separated areas to each other. These integrative regions are affected differentially depending on the timing of the trauma and include the hippocampus, which links various forms of memory into explicit factual and autobiographical memory, the corpus callosum linking left and right sides of the brain, and the prefrontal cortex, which links the cortex, limbic region, brainstem, bodily signals, and the social input from other brains into a coherent whole. In many ways, developmental trauma can be thought of as a severe example of impaired interpersonal integration. With neglect, there is an impairment to linkage; with abuse, there is an impairment in honoring differential needs of child and adult.

This clinical finding of developmental trauma leading to impaired neural integration supports the following possibility: Interpersonal integration (honoring differences and promoting compassionate linkages with other people) stimulates the growth of neural integration (the linkage of differentiated regions of the brain to each other). If this proposal is true, it may mean that integrative psychotherapy techniques may promote a healing process in those with complex PTSD that helps stimulate the activation and growth of neural integration. Future research will need to validate this hypothesis of a potential core mechanism in how therapeutic relationships work to improve the lives of those who have experienced severe forms of trauma early in development.

Why would developmental experiences that overwhelm an individual's ability to cope have such a profound impact on their growth? When confronted with a threat under usual adult circumstances, the processes related to arousal and the fight-or-flight-or-freeze-or-faint reactivity states become activated; the threat is dealt with and soon passes. For obvious reasons, children are not well equipped to cope with a threat in this way. Because their survival is linked to dependency, fighting and fleeing with an attachment figure may actually decrease their chances for survival. When a child first cries for help, but no help arrives, or when trauma is being inflicted by a caretaker, the child may shift from hyperarousal to dissociation. Traumatized children who are agitated may be misdiagnosed as having an attention-deficit disorder, and the numbing response in infants can be misinterpreted as a lack of sensitivity to pain.

Telegram: @medical_k

www.konkur.in

Dissociation allows the traumatized individual to escape the trauma via a number of biologic and psychological processes. Increased levels of endogenous opioids, for example, create a sense of well-being, pain reduction, and a decrease in explicit processing of the overwhelming traumatic situation. Psychological processes such as derealization and depersonalization allow the victim to avoid the reality of his or her situation or to watch it as an observer. These processes provide the experience of leaving the body within awareness, traveling to other worlds, or immersing oneself in other objects in the environment. Hyperarousal and dissociation in childhood create an inner biopsychological environment primed to establish inflexible boundaries between different emotional states and experiences for a lifetime. If it is too painful to experience the world from inside one's body, self-identity can become organized outside of the physical self.

Early traumatic experiences shape neurophysiology and neuroanatomical networking, thus impacting experience and adaptation throughout development. The tendency to dissociate and disconnect various tracks of processing creates a bias toward unintegrated information processing across conscious awareness, sensation, affect, and behavior. General dissociative defenses result in an aberrant organization of networks of memory, fear, and the social brain and contribute to deficits of affect regulation, attachment, and executive functioning. One way of understanding such fragmentation of mental processes is in the simultaneous activation of two mutually incompatible motivational drives, mediated by two differentiated circuitries. One is the mammalian limbically mediated drive to move toward the caregiver when the infant or child is in a state of distress. The other is the brainstem-mediated drive to move away from the source of terror.

If the attachment figure is the source of terror, then the two circuits driving the body to simultaneously move both toward and away from the same individual create a biologic and psychological dilemma. This has been called "fear without solution" and is a biologic paradox thought to be the mediating mechanism of disorganized attachment common in developmental trauma and often associated with clinical degrees of dissociation. Without a solution, the organized strategy to cope with stress is overwhelmed, and the mind of the child cannot achieve integration as the differentiated circuitries are unable to become linked in a coherent way to deal with the abuse or neglect. Disorganized attachment

Telegram: @medical_k

www.konkur.in

experiences may be one common developmental origin of clinical dissociation and complex PTSD.

The lack of coherent integration of the interdependent systems within an individual, which may be due to extreme early stress, results in many disorders: Compulsive disorders related to eating or gambling, for example, and somatization disorders in which emotions are converted into physical symptoms can all be understood in this way. Some forms of borderline personality disorder and conversion disorder may also reflect complex adaptation to early trauma, as does dissociative identity disorder.

Cognition in Racial Prejudice

The modern notion of the brain as a human-computer is both alluring and misleading. Unlike computers, human brains have been programmed over millions of years to process the environment in ways that enhance human survival. Adaptations that enhance survival trump accuracy nearly every time. In Ortega y Gasset's words, "*We do not live to think; we think in order that we may succeed in surviving.*" Because of this evolutionary strategy, cognition is as much distortion as it is representation. One of the consequences of this distortion is racial prejudice.

The ubiquity of implicit bias, prejudice, and racism seems to suggest that humans are hardwired to dislike, distrust, and even hate those who are different. The fact that conflicts and slaughter based on race, tribal affiliations, and religion continue unabated in the "modern" world only seems to strengthen the argument for prejudice as a basic component of human nature. Standing in stark contrast to this view are countless examples of harmony, cooperation, and acts of altruism that seem to contradict racism as a basic human truth.

When we imagine the lives of man's tribal ancestors, it is easy to see the survival benefit of developing a reflexive system for the classification of unfamiliar others that trigger fear circuitry and a fight–flight response. It would then follow that these primitive reactions would lead one to distortions of sensory perceptions and social judgments that parallel those seen in social phobia. These distorted attitudes and perceptions would then become woven into the culture, guiding everything from interpersonal behavior to public policy to international relations. Therefore, the most relevant questions facing psychiatrists in this area of study are how do human brains process social information, and how can one counteract those perceptions that are incorrect and harmful to others?

Telegram: @medical_k

www.konkur.in

In an attempt to identify the neural substrate of prejudice, a number of studies have examined brain activation during exposure to pictures of same/other group faces. It turns out that the old statement “they all look alike,” where “they” are another racial group, may reflect an underlying truth of cognitive processing. Across studies, subjects demonstrate a clear advantage in recognizing faces and distinguishing among faces for same-race faces. Neural processing for the recognition of other-race faces results in longer periods in frontal activation, suggesting that they are processed less automatically and with greater effort.

Supporting this idea is the fact that interracial interactions have been those that show impaired executive functions when confronted with people of other races. It is possible that the extra frontal lobe activation required for facial processing may divert energies and attention away from other frontal functions. Consistent with these findings are those that show that stereotypes are automatically activated and require conscious inhibition to produce low-prejudice responses. The overall result of these processing differences may lead one to think about individuals of other races in less complicated and more stereotyped ways.

Assuming that fear is at the heart of prejudice, a second line of research directly explored amygdala activation in same versus other race encounters. It was found that when Caucasians and African Americans are shown pictures of other-race faces, they exhibit more amygdala activation and an enhanced startle response compared to same-race faces. Although it takes approximately 500 ms for a visual stimulus to reach conscious awareness, information about race is encoded during the earliest stages of visual processing, well before conscious perceptions of who is being seen. The rapidity of this “race response” results in the automatic and instantaneous frontloading of all past biases into the experience of each new person.

This activation of a rapid and unconscious fear response influences the conscious experience in many ways. A finding that directly parallels the experience of social phobics. For example, individuals from other groups are more readily associated with aversive stimuli. This is the likely reason why African Americans are more readily misperceived as carrying weapons, and black faces are more likely to be perceived as angry by white subjects. Interestingly, both African Americans and Caucasians have greater amygdala activation to African-American faces, which may be due to the consistent pairing of African-American faces with criminal

Telegram: @medical_k

www.konkur.in

behavior in the media. This conditioning may not have as extreme of an impact on African-American viewers because of their greater exposure to other African-American faces. African Americans are also better at recognizing Caucasian faces than vice versa for this same reason. Thus, while one's responses to people of other races are guided by bottom-up amygdala activation, they are also modulated by a variety of top-down cognitive and social factors.

Greater liberalism has been associated with greater gray matter volume in the anterior cingulate, while greater conservatism is associated with increased volume in the right amygdala. Conservatives demonstrate more amygdala activation and persistent cognitive styles compared to liberals, who demonstrate more sensitivity for cues to alternate responses. Along with these differences in cognitive style, greater liberalism was associated with stronger conflict-related anterior cingulate activity reflecting their continued engagement with the complexity of the problems posed to them.

To explore the issue of whether prejudice is learned or innate, faces of well-known and well-liked African Americans were shown to Caucasian subjects who demonstrated an absence of amygdala activation. These findings strongly suggest that exposure and positive experiences can counteract the effects of general cultural prejudice. Even simple exposure to other-race faces increases liking for strangers of that race, and an experience of empathy for one member generalizes to other members of that group. It is also known that through exposure and paying conscious attention to facial details, Caucasian adults can be successfully trained to distinguish among African-American faces and that this learning process results in a decrease of implicit racial bias.

Once stereotypical attitudes and beliefs are inculcated, change requires "intention, attention, and time." Because most children are exposed to some degree of racial prejudice, open discussion and increased interracial exposure work against prejudice, turning into conscious beliefs and negative behaviors. Increased focus and awareness of the handicapped have also been found to decrease discrimination in the same way. It is known from studies of anxiety and fear that conscious labeling activates cortical neural networks, which can regulate and inhibit emotional activity.

People from other cultures, with different degrees of exposure, proximity, and prejudice need to be studied with the same depth that one has studied their own society before one can arrive at any conclusions

Telegram: @medical_k

www.konkur.in

about the origins of racial prejudice in the human brain. With the science of genetics revealing that the notion of race is more of a cultural than a biologic construct, future study of how human brains react to one another can only help shed light not just on the nature and etiology of the neuroscience of prejudice but on how everyone who lives on this increasingly crowded planet may learn to overcome their differences and discover the true wealth of human diversity.

Cognition in Social Phobia

It is clear that those that struggle with social phobia do not perceive the same interpersonal landscape as others. Social phobia disrupts and distorts the ability to gather and process social information with attentional and memory processes biased toward detecting, orienting toward, exaggerating, and remembering negative responses by others. Once focused on negative input, they fixate on it and find it difficult to disengage, even when it is irrelevant or harmful to their well-being.

Social phobia is most likely the result of an imbalance of the alarm and feedback systems that regulate the balance of approach and avoidance in social situations. At the same time, social phobics show a decreased activation in left-hemisphere regions involved in other aspects of facial evaluation and reality testing. In essence, their brains react to others as if they are in extreme danger no matter what the situation. Fear of direct eye gaze is an evolutionary conserved submissive behavior that is woven into all human cultures but exaggerated in those with social phobia. Social phobics employ visual gaze avoidance and elaborate processing strategies to modulate the fear evoked by being seen.

Children with social phobia experience greater anxiety while looking at faces, and as adults, their memory for faces, especially those with negative expressions, is far better than average. It makes sense, then, that social phobics avoid looking directly at faces, especially eyes, preferring to focus on other aspects of those with whom they interact. Turning away from others has a number of negative consequences. First, it keeps them from viewing potentially positive expressions. Second, it keeps these children from learning to process facial expressions in a more sophisticated manner, especially during development. Finally, turning away from others correlates with using their negative self-image when developing a theory of what is on another's mind. This may be why social

Telegram: @medical_k

www.konkur.in

phobics have been found to come to conclusions faster in social situations; recycling old information is faster than acquiring new data.

In social phobia, the amygdala shows decreased coupling with the frontal lobes and higher sustained activation in face processing networks. The combination of increased orientation to and fixation on social evaluation makes the experience of the social phobic, one of constantly being on trial: Every interaction is experienced as a negative evaluation of their worth. Thus, the memories and emotional impact of negative interpersonal responses cut deeper and last longer.

The most consistent findings have tied social phobia to hyperactivation of the amygdala. Subjects with social phobia show increased metabolism in the amygdala, fusiform gyrus, insula, anterior cingulate, and the prefrontal cortex when subject to direct eye gaze. Simultaneously, they demonstrate decreased cortical activation that could inhibit and regulate their subcortically generated fear.

Decoupling of cortical and subcortical processing is likely a major contributor to the disruption of current social information processing and the tendency to become overly reliant on past experience and negative internal self-images in interpreting the present. One group of researchers found that a combination of right prefrontal and left parietal activation was specific to social phobia. This led them to hypothesize that social phobia is related to a unique interaction between the processing of autobiographical memory and social presentation. Perhaps such neural wiring makes it difficult or impossible to overcome self-consciousness and the expectation of negative evaluation about the self.

More recent research has revealed a deactivation of the precuneus and posterior cingulate in these individuals suggestive of inhibition of the default mode processing that is used to process information about oneself and others. Mindfulness- and cognitive-based interventions have proven helpful with social phobia because they simultaneously result in decreased amygdala activation and increased activation in brain regions involved in the deployment of attention.

While individuals who suffer from social phobia share the neurochemical profiles of other anxiety disorders (heightened adrenergic activity combined with decreased GABA activity), they appear to also have evidence of dysfunction in serotonin and dopamine systems. Hypersensitivity to negative social stimuli appears to be linked to variation in serotonin receptor pathways. Lower dopamine (D2) binding has been

Telegram: @medical_k

www.konkur.in

found in the striatum of social phobics, which in animals correlates with a lack of exploration and lower social status. Remember, dopamine is an important neurochemical in the social reward system related to approaching others, sustaining attachment, and a sense of well-being. As with so many other findings, it is not known if biologic differences are a cause or effect of social phobia.

Social phobia could reflect an innate inability to compete socially or an experience-dependent shutdown of activity in the face of anxiety and shame. When parents dominate children through physical or psychological punishment, some young brains may be shaped to be of persistently lower social rank. On the other hand, social phobia may be an evolutionary continuation of the behavior of lower-ranking individuals in mammal and primate groups who “know their place” and stay in it.

The finding that social rejection is mediated in the same part of the brain as physical pain—the dorsal anterior cingulate cortex—suggests that the fear of social engagement is tantamount to a fear of being injured. Some studies suggest that the experimental use of pain-relieving medications even temporarily reduces social phobia, pointing to this common pathway of somatic and social pain.

FUTURE DIRECTIONS

Clinicians must keep in mind that every client strives to make sense of the world, albeit through information-processing apparatus that are negatively impacted by the acute and chronic aspects of their disorder. Cognitive science offers an array of conceptualizations for understanding the ways in which the mind functions in health and disease. One broad approach to the mind is the approach we’ve been taking here called interpersonal neurobiology—a framework that synthesizes a wide array of research into one perspective. This broad, interdisciplinary field provides numerous research paradigms that are helpful in further elucidating the nature of psychopathology, from the techniques of the neurosciences to the biologic applications of chaos theory. It also provides ways of thinking that can be helpful in the consulting room in understanding the cognitive, emotional, and social impact of the ways in which the brains of maladaptive information processing. The cognitive understanding of emotions and consciousness may also expand psychiatry’s framework for understanding the subjective human experience. Clinical tools, from

Telegram: @medical_k

www.konkur.in

medications to in-depth psychotherapy, may also find wider and more finely tuned applications as the processes of self-organization and psychological change are better understood.

Psychiatry, in turn, also has much to offer the field of cognitive science. The long history of descriptive psychopathology and the attempt to synthesize views of the mind and the brain can provide nonclinical cognitive scientists with unique data and relevant questions. This may be especially true in the understanding of the social nature of the brain and mind and the impact of both positive and negative relationships on mental health and illness. Psychiatry is invited to join in the search for understanding the cognitive processes of the human mind.

These findings support the view that the mind is more than simply a synonym for brain activity. Our mental lives are fully embodied, and they are fully relational. While the brain in our heads is a core locale for how energy and information both flow and are regulated in our lives, the wholeness of the body proper and the relational systems—families, communities, cultures, and the natural world—in which we live each play a central role in our mental lives. Energy and information flow are not limited by skull or skin. Mind is not just inside the skull, nor limited to only inside the skin-encased body. We are, in our mental health and dysfunction, fully embodied and fully relational beings. When that flow is disrupted in achieving optimal self-organization by a blockage in its differentiation or linkage, the foundations of integration, then the chaos and rigidity of unhealthy conditions arise. And when differentiation and linkage, in the body and in our relational lives, can be cultivated, then we flourish and thrive individually and collectively, here on our shared home, this precious planet we've named Earth.

3.2 Piaget and Cognitive Development: History, Theory, Extensions, and Modifications

Harrell Woodson, Ph.D.

Jean Piaget (1896 to 1980) was, at various points in his career, considered to be a natural scientist, psychologist, sociologist, and historian of the philosophy of science. His major enterprise was what he termed "genetic epistemology," the study of the development of logic, reasoning, and higher-level thinking. He had points of contact with European psychiatry and even based his own research method in part upon the psychiatric interview. However, he avoided the emphasis on individual differences or interventional psychology, as practiced by clinical diagnosticians and therapists, and focused instead on the most universal and general characteristics of children's cognitive development. His influence on education was considerable, not through a specific teaching method, but through his view of the child as an active constructor of his or her own knowledge rather than a passive recipient of information.

Piaget was born in 1896 in Neuchâtel, Switzerland. Growing up, he was influenced by social groups and unique opportunities that supported his interest in natural science, including the Swiss YMCA, the local Friends of Nature, and the director of the natural history museum, who allowed him to work with the specimens of mollusks, the topic of his 1918 doctoral thesis. For a year, he then worked in Zurich, combining laboratory research with clinical psychiatric interviewing supervised by Bleuler. He then moved to Paris to study at the Sorbonne and was recruited by Theodore Simon to work in Alfred Binet's school-based laboratory, standardizing a reasoning test developed by Cyril Burt. In 1921 he began a long association with the Jean Jacques Rousseau Institute, with parallel appointments at varying times at the Universities of Geneva, Lausanne, and the Sorbonne. In 1955, with support from the Rockefeller Foundation, he founded the Center for Genetic Epistemology, where he continued his

Telegram: @medical_k

www.konkur.in

research and teaching with European and international colleagues, including prominent American psychologists.

Bennour and Voneche note several of the major intellectual and personal influences on Piaget. His interest in evolution stemmed from exposure to Henri Bergson's work, whereas his interest in psychiatry, psychology, and psychoanalysis stemmed from multiple sources. As mentioned above, Bleuler supervised him in clinical interviewing; Jung and others gave psychoanalytic lectures that he attended, and Simon mentored him in standardized psychometric assessment and influenced his view of cognition as adaptation rooted in biology. Janet was a strong influence on Piaget's thought in terms of his emphasis on psychology as a science of action and representation, with affect as a driver of both action and thought.

Piaget's contacts with American psychology and social science are fascinating, considering the prominence of experimental methodology and of behaviorism in the United States. In 1936, he was awarded an honorary doctorate from Harvard, but Hsueh has documented that the impetus for this came from the business school and sociology faculty rather than from the psychology faculty. Social scientists outside of psychology were impressed with Piaget's method of close observation and detailed "clinical" note-taking and his emphasis on cooperation in problem-solving. In 1969, however, Piaget became the first European to receive the American Psychological Association's Distinguished Scientific Contribution Award. The award noted his creation of an empirical science of epistemology, a field previously restricted to philosophy, as well as both his observations and his controlled data on human cognition, which by then was a major influence on all scientists concerned with cognitive development.

PIAGET'S CLINICAL METHOD

Susan Mayer has shown that Piaget's "Clinical Method," which had brought him to the attention of Harvard social scientists relatively early in his career, was a synthesis of three sources: naturalistic observation, psychometric evaluation, and psychiatric interviewing. Naturalistic observation was practiced by Piaget even as a youth with his biologic studies. He continued this approach when he began to be trained in the psychological testing of children. Under Simon, Piaget learned the

Telegram: @medical_k

www.konkur.in

psychometric approach, which requires a standardized presentation of specific probes, tasks, and questions. Strictly speaking, psychometric assessment depends on quantitative comparisons of a given child with an adequate normative sample and on intrasubject comparisons across tasks. It requires little interest in the reasons why children make cognitive errors.

Piaget, however, brought to bear his earlier learning of psychiatric interviewing to follow up on erroneous child responses to psychometric items. This served the purpose of identifying forms of thinking that lay between clearly faulty (immature) and fully logical responses. Careful attention to children's language, explanations, and the social functions of their utterances was a further contribution of naturalistic observation to the overall clinical method.

Later in his career, as the clinical method was criticized, Piaget and Inhelder added more experimentally controlled methods to their studies of logical reasoning. However, they did not abandon the observational, psychometric, and individualized probing aspects of the clinical method.

GENETIC EPISTEMOLOGY

Piaget's overarching task was the understanding of how one comes to know things. He took a developmental approach to this question, inquiring how knowledge becomes more adequate over time. He designated himself a genetic epistemologist—one who studies the development of knowledge from infancy to adolescence. By "genetic," he did not mean an approach based on genes but rather an approach based on development over time. It remains important to distinguish Piaget's approach from that of nativism, on the one hand, and empiricism, on the other. Nativism is a theory proposing that at least certain kinds of knowledge are innate or given. In philosophy, Kant took a nativist position regarding the categories of space, time, and causality, arguing that these categories on the data of sensory perception be imposed. In psychology, Gesell theory was essentially based on a nativist position. According to this perspective, certain types of thinking and behavior are expected at certain ages as development unfolds in a predetermined manner.

Empiricism, at the opposite end of the spectrum, proposes that all knowledge is accumulated from the data of sensory perception. In psychology, empiricism is equated with behaviorism and learning theory.

Telegram: @medical_k

www.konkur.in

Little attention is paid to predetermined (innate) factors, and the emphasis is on common processes of learning, such as classical and operant conditioning, that lead to accumulated knowledge.

Piaget's approach was, in his words, "constructivist structuralism," according to which mental structures are built through the interaction of the child and the world. Mental structures originate through the actions of the child on objects as the child strives to adapt to the environment. In the educational realm, this implies that guided discovery is preferable to memorization. Only through action and interaction can the child develop a comprehensive and stable structure that enables understanding. What Piaget deemed innate was only an intelligent functioning that makes possible the construction of progressively more adequate structures of knowledge. This improvement of structures is based on abstractions from actions performed over time, and qualitative improvements mark progressive stages of development. The action takes precedence over language in Piaget model. Abstractions from repeated actions lead to the construction of robust and adequate structures. For example, the concept of space is a fundamental mental structure developed in the earliest period of children's lives. In earliest infancy, the child is aware not of one homogeneous space but of several heterogeneous spaces, and each is centered on a certain part of the child's body (e.g., visual space and tactile space). As the child acts on objects that may traverse these various spaces (e.g., a rattle occupying visual, tactile, and auditory spaces), he or she comes to coordinate these individual spaces. Eventually, actions representing displacements in space are organized mentally into the general concept of space. That concept is a structure.

PIAGET THEORY

Piaget provided a succinct summary of his work in a chapter prepared for the 1970 edition of *Carmichael's Manual of Child Psychology.* The interested reader is referred to that source, which was reprinted in the 1983 edition of the *Handbook of Child Psychology.* The summary is based on this and other primary and secondary sources. Piaget theory is broad and comprehensive with regard to cognitive development. It is analogous in this sense to Sigmund Freud or Erik Erikson theories of emotional or personality development. Like those comprehensive theories, it now seems to belong to an earlier era as numerous specific predictions have

Telegram: @medical_k

www.konkur.in

been modified or falsified, and a great deal of more detailed research has accumulated regarding children's cognitive capacities and processes. This topic will be discussed again after presenting the overarching theory.

Equilibration

For Piaget, the general criterion for intelligent functioning is *equilibration,* briefly defined as "compensation for an external disturbance." Hans Furth described equilibration as "the factor that internally structures the developing intelligence. It provides the self-regulation by which intelligence develops in adapting to external and internal changes." At every level of development, the equilibration mechanism operates to further adaptation, but as development proceeds toward the highest level of cognitive functioning, equilibration becomes progressively more adequate in enabling the organism to adapt to a wider range of internal and external disturbances. Piaget's notion of intelligence as adaptation is, therefore, essentially bound to an equilibration model of intelligent functioning. Equilibration can be thought of as a dynamic exchange as the organism strives to "take in" new and challenging information and "adjust" to this new input.

Equilibration is the final of four necessary components that lead to cognitive development. Piaget recognized the importance of biologic maturation, and more specifically the maturation of the CNS, as essential for cognitive development. He also incorporated learning experiences, including learning based on conditioning, as a necessary component. The third essential component in his theory is social interaction. Not surprisingly, this component appears to be particularly essential for social intelligence. Thus, for Piaget, biologic maturation, learning, and social interaction flow together to facilitate development and crystallize in the process of equilibration as the developing child reacts to cognitive challenges generated by new input.

Assimilation and Accommodation

The biologic foundation of Piaget's developmental theory is clearly evident in his discussion of assimilation and accommodation; these processes are considered functional invariants of all intelligent behavior. At every level of intellectual development, from infancy to adulthood, the processes operate in adaptation.

Telegram: @medical_k

www.konkur.in

The assimilation–accommodation account of development stresses the interaction between organism and environment. A certain readiness within the organism is necessary for change or development to occur. In Piaget's view, associationism (empiricism) in psychology commits the fallacy of crediting only one-half of those conditions necessary for learning with all of the explanatory power. A full account of human development must include not only the influence of stimuli on respondents (S → R) but also the influence of the responding organism on incoming stimuli (S ← R). Such an account is provided by Piaget's assimilation–accommodation viewpoint": from a biologic point of view, assimilation is the integration of external elements into evolving or completed structures of an organism. In its usual connotation, the assimilation of food consists of a chemical transformation that incorporates it into the substance of the organism."

Furth referred to assimilation as "an inward-directed tendency of a structure to draw environmental events toward itself." Assimilation is the conservative side of intellectual development, ensuring continuity and coherence by incorporating new aliments (stimuli) into existing mental structures. However, assimilation alone cannot account for growth or change within those structures.

Accommodation occurs during the developmental periods when new data cannot be wholly assimilated into the child's existing mental structures, and yet the data are not so foreign to those structures that they can be ignored. Furth referred to accommodation as "an organism-outward tendency of the inner structure to adapt itself to a particular environmental event." This line of thought reveals the sense in which Piaget defined *intelligence* in terms of equilibration. His equilibration is not a static, balanced system but instead is a dynamic, or mobile, equilibration between assimilation and accommodation as the child responds to the environment.

Structuralism

The term Piaget used for a cognitive structure is *scheme* (*schema*): "A scheme is the structure or organization of actions as they are transferred or generalized by repetition in similar or analogous circumstances." Schemata exist in the infant as perceptual-motor behavior patterns (e.g., the grasping reflex). They also exist in mature intelligence, although, as Furth pointed out, a *schema* is more commonly used to refer to an early

Telegram: @medical_k

www.konkur.in

mental structure, whereas general schemata resulting from the use of higher intelligence are referred to as *operations.*

The abstraction process that leads to the formation of cognitive structures is called *reflective* or *formal abstraction.* It is an abstraction from *actions,* according to which the similarities inherent in various behavioral acts are dissociated from their particularized contexts (e.g., the earlier example of the rattle in space). These can be contrasted with *simple abstractions,* which are more familiar to psychologists and psychiatrists. Simple abstractions are similarities between or among several things. For instance, when learning colors, the child will note that "green" refers to numerous objects, all of which have the same color; when learning shapes, the child will become able to discriminate circles from squares. Although such abstractions are obviously critical for learning, they do not occur at the same depth of cognitive development as reflective abstractions. The latter contributes not to the content of knowledge but to its progressively more adequate structure.

Theory of Stages

An integral part of Piaget theory of genetic epistemology is a psychology of cognition that seeks to describe how knowledge develops and changes. The genetic framework for that and the process of intellectual adaptation during the major early periods of life is provided in Piaget theory of the stages of cognitive development.

The stages of cognitive development that Piaget and his associates delineated empirically are not defined merely by the dominance of some aspect that remains present but less dominant throughout development.

Piaget was not entirely consistent concerning his stages of cognitive development, but the primary source of confusion in his later writings is whether the so-called preoperational period is to be considered apart from the period of concrete operations in which it culminates. John Flavell's 1963 study and Piaget's 1983 summary defined three major periods and one subperiod of intellectual development (Table 3.2–1). These periods contain subdivisions called *stages.* The major developmental periods are as follows:

1. The sensorimotor period extends from birth until approximately 1.5 years of age. The period is divided into six stages, which are described

Telegram: @medical_k

www.konkur.in

in general in the following discussion with reference to the development of the concept of the permanent object.

2. A period of preparation for and acquisition of concrete operations. This period extends from the appearance (at approximately 2 years of age) of the symbolic (semiotic) function to the beginning (at approximately 7 years of age) of higher mental operations applied to concrete objects.
3. The period of formal operations begins at approximately 11 years of age. During this period, full adult intelligence develops as the operations are extended to apply to propositional or hypothetical thinking.

Sensorimotor Period. The *sensorimotor period* of intelligence is so named because the child's construction of mental schemata is in no way aided by representations, symbols, or thoughts. Rather, schemata depend totally on perceptions and bodily movements.

Stage 1 of sensorimotor development is marked by a relatively few organized reflexes that stand out from the spontaneous general activity of the neonate, such as the sucking reflex and the palmar reflex. These primitive reflexes demonstrate three types of assimilation: (1) reproductive (repeating the actions), (2) generalizing (repeating the actions on new objects), and (3) recognitory (performing different varieties of actions on different objects).

Table 3.2–1.
Stages of Intellectual Development Postulated by Piaget

Age (Years)	Period	Cognitive Developmental Characteristics
0–1.5 (to 2)	Sensorimotor	Divided into six stages, characterized by: 1. Inborn motor and sensory reflexes 2. Primary circular reaction 3. Secondary circular reaction 4. Use of familiar means to obtain ends 5. Tertiary circular reaction and discovery through active experimentation 6. Insight and object permanence
2–7	Preoperations subperiod[a]	Deferred imitation, symbolic play, graphic imagery (drawing), mental imagery, and language
7–11	Concrete operations	Conservation of quantity, weight, volume, length, and time based on reversibility by inversion or reciprocity; operations; class inclusion; and seriation
11 through the end of adolescence	Formal operations	Combinatorial system, whereby variables are isolated and all possible combinations are examined; hypothetical-deductive thinking

[a]This subperiod is considered by some authors to be a separate developmental period.

Telegram: @medical_k

www.konkur.in

Stage 2 contains the first habits and the primary circular reactions. The first habits develop out of the original schemata as they are applied to objects in the environment or parts of the infant's body without any differentiation between means and ends. In a primitive state of consciousness, the infant is aware only of action sequences and is not even aware of the self. Primary circular reactions occur when, by chance, the infant experiences a new consequence of a motor act and tries to repeat the act.

In stage 3, an initial distinction between means and ends becomes apparent, but in a primitive sense. The infant repeats a particular action pattern that achieves one end for the purpose of achieving other (unrelated) ends. For example, a baby who succeeds in shaking a rattle by pulling a string may repeatedly pull the string in an attempt to bring about other sounds or results.

In stages 4 and 5, infants use a variety of means to obtain particular goals. The distinction between stages 4 and 5 lies in the relative creativity or newness of the means. Stage 4 is marked by the use of familiar means. Stage 5 is marked by a search for new means based on further differentiation of already known schemata and by tertiary circular reactions. The latter differs from secondary circular actions in that the child no longer produces schemata that were effective in one situation to produce magically efficacious results in every situation. Instead, the child explores the environment utilizing various means to achieve an outcome. Discovery is a hallmark of stage 5. For example, a child may use a stick to move an object that is not within reach.

Stage 6 is transitional, leading into the preoperational subperiod. In stage 6, the child becomes capable of inventing new means, not by direct actions on objects but by mental combination. Whereas discovery marked stage 5, insight is a characteristic of stage 6. For example, a child who has seen the father bang on a drawer to loosen it may bang on a toy box to make it easier to open.

During the sensorimotor period, a number of significant concepts are developed, including the child's concepts of space, time, and causality. These categorical concepts develop in a process parallel to the sequence of the six stages outlined in the previous discussion. Most important, during the sensorimotor phase, the child develops the schema of object permanence, the first major victory of conservation and the foundation of all future knowledge.

Telegram: @medical_k

www.konkur.in

SCHEMA OF OBJECT PERMANENCE. The knowledge that objects in the external world have an existence independent of the child's actions on them or interactions with them is a major accomplishment of the sensorimotor period. Piaget described his observations of infants' reactions to the disappearance of interesting objects as the foundation for his theory of the development of object permanence. In stages 1 and 2, for example, a child simply continues to look at the place where the object was last seen. In stage 3, if an object such as a spoon drops to the floor, the infant will look for it (e.g., by leaning over and looking at the floor). In stage 4, if an object is repeatedly hidden at point A (visible to the child) and then hidden at point B (also visible to the child), the child searches for it at A, not B. In stages 5 and 6, the infant can follow multiple displacements of the object through points in space, even if the object is hidden within another object.

Preoperational Subperiod and Semiotic Function. The advent of the preoperational subperiod is marked by the appearance of what Piaget called the *semiotic function.* This new ability was defined by Piaget and Inhelder as follows: "It consists in the ability to represent something (a signified object, event, conceptual scheme, etc.) by means of a signifier which is differentiated and which serves only a representative purpose: language, mental image, symbolic gesture and so on."

During the sensorimotor period, a thing could be represented in a limited sense by a part of itself (e.g., the mother's voice might represent the presence of the mother in the room). However, such signifiers are part of what they signify. Symbols and signs are signifiers that are differentiated from what they signify. A drawing of a person, for example, is not part of the person. A word is different from the object to which it refers. These become available to the child only with the appearance of the semiotic function, which makes representational thought possible.

CHARACTERISTIC BEHAVIOR PATTERNS. The semiotic function is heralded by five characteristic behavior patterns in evidence during the second year of life: (1) deferred imitation (imitation that starts after the disappearance of the model); (2) symbolic play, or the game of pretending; (3) drawing, or the use of graphic imagery; (4) the presence of a mental image, which appears as an internalized imitation and not as a function of perception; and (5) the verbal evocation of events not occurring at the time. For

Telegram: @medical_k

www.konkur.in

Piaget, the semiotic function, which so enlarges children's worlds—liberating them from the bonds of immediate space and time and enabling them to begin to manipulate symbols and to think rather than just to act on immediately present objects—is rooted in imitation.

Imitation. One can follow the development of imitation through the same six sensorimotor stages delineated for the concept of object permanence. Piaget did this in his volume *Play, Dreams, and Imitation in Childhood.* A radically new form of imitation occurs during the second year of life: deferred imitation. For example, a child may put on their father's hat and walk as their father does, even hours after their father has gone off to work.

For Piaget, intelligence is an equilibration process in which assimilation and accommodation are in balance. However, in imitation, accommodation outweighs assimilation. According to Piaget, imitation is behavior in which "the subject's schemes of action are modified by the external world without his utilizing this external world." In imitation, the child's cognitive structures undergo temporary change without simultaneously incorporating new aliment.

Symbolic Play. A second new behavior pattern that now appears is symbolic play. In imitation, the imbalance between assimilation and accommodation is weighted in favor of accommodation; however, the opposite is true in symbolic play, which is a lessening of the demand of the adaptive process.

Symbols are used in play only after the sensorimotor period, in the type of play characterized by games of pretending. For example, a little girl may pretend that she is asleep, that a box is her pet cat, or that she is in a church. In each instance, symbols are generated "to express everything in the child's life experience that cannot be formulated and assimilated by means of language alone."

According to Piaget, these symbols are created by the same process of imitation that gives rise to deferred imitation at this time (a process in which accommodation outweighs assimilation). Instead of being used accurately (realistically), however, they are used in a process in which liberating assimilation outweighs accommodation.

Drawing. A third behavior pattern associated with the rise of the semiotic function is drawing or the use of graphic imagery. Piaget sees

Telegram: @medical_k

www.konkur.in

elements of play and imitation in this activity. In developmental terms, he considers drawing “halfway between symbolic play and the mental image,” appearing at approximately 2 or 2.5 years of age. The child enjoys producing drawings for their own sake (assimilation). However, the graphic play also has accommodative elements, especially as the child grows older and attempts to draw not just formless scribble but something.

Mental Image. Closely related to drawing is the presence of a mental image. Piaget tied the genesis of mental imagery to accommodation and imitation. He explicitly denied that mental images could be the product of perception; they are a construction, something the child creates. The mental image is not directly given by perceptual input; it is constructed by the process of accommodation.

Verbal Evocation of Events. The fifth behavior pattern associated with the rise of the semiotic function concerns language, the verbal evocation of events that are not present. Piaget gave the example of a little girl saying, “Anpa, bye-bye.” (Grandpa went away) while pointing to the path he had taken when he left. The parallel with deferred imitation is clear, but the new representational ability is supported by the social system of language.

Concrete Operations. A crucial difference between preoperational and concrete-operational thought is the presence within operative thinking of concepts of conservation. When concrete operations have been organized into a system, the child can conserve, that is, “discover what values do remain invariant … in the course of any given kind of change or transformation.” The progressive and continual structure building that occurs in the concrete-operational period is evident in the increase, with development and age, in the scope of such concepts, such as conservation of quantity, substance, and number. In other words, conservation indicates a stable cognitive structure.

CONSERVATION OF QUANTITY. If a liquid is poured from a short, wide glass into a tall, narrow one, the child in the preoperational stage thinks that the amount of liquid has changed. At the level of concrete operations, however, children are no longer overwhelmed by the perceptual discrepancy between the two configurations. They begin to reason about

Telegram: @medical_k

www.konkur.in

the transformation, and their correct judgments regarding the conservation of quantity of liquid are accompanied by explanations grounded in logical properties. It is assumed that children are not aware of the logic they use. When problems of conservation begin to be solved, the child passes from the preoperational subperiod into the period of concrete operations.

CONSERVATION OF WEIGHT AND VOLUME. At approximately 7 or 8 years of age, the child can solve the conservation-of-quantity problem and can perform similar judgments of conservation when, for example, a lump of clay is transformed in shape. Between 9 and 10 years of age, the child discovers that the weight of a given object is also conserved, even when its shape is transformed. However, not until approximately 11 or 12 years of age do children have a logical comprehension that the volume displaced by a given object is conserved even after a transformation of the object's shape. Conservation entails the logical certainty that one characteristic of an object remains invariant while the object itself undergoes some type of perceived transformation.

CARDINAL NUMBERS. The concept of cardinal numbers also develops from an initially nonconserving to a conserving stage. For example, consider children in the preoperational subperiod presented with two horizontal rows of colored dots in one-to-one correspondence (i.e., imaginary vertical lines could be constructed between each red dot and its corresponding blue dot). When the experimenter destroys this optical correspondence by spreading out one of the rows of dots, the child in the preoperational period thinks that the larger row contains more dots. Only after the conservation of cardinal numbers has been established as a logical necessity does the child maintain the numerical equivalence of the spread-out row to the other row. Clearly, preoperational concepts of numbers provide inadequate bases for arithmetic skills. It is possible that a lag in the development of number conservation could underlie certain types of arithmetic-related learning disabilities.

Operations. Notions of conservation are the mark of well-established concrete-operational thinking; thus, one must understand the meaning of operation in Piaget's thought. Operations themselves constitute essential thinking. For Piaget, an operation is an action that is (1) interiorized, (2) reversible, and (3) part of an organized system of such actions.

Telegram: @medical_k

www.konkur.in

The operations that form this system are interiorized actions. In the sensorimotor period, external behavior patterns give rise through a process of abstraction to the construction of sensorimotor schemata. In a similar fashion, internal thinking patterns later give rise to operations. According to Furth, the possibly generalized aspects of actions, “those which can be found in any coordination of action,” enter into the construction of operations. Saying that the crucial aspect of actions in this regard is their ability to be generalized explains the importance of interiorization in the construction of operations. *Interiorization* refers to “the increasing dissociation of general form from particular content.” In other words, the notions of generalization and interiorization merely point out the process of abstraction that is occurring. For example, a child adds two apples and three apples to obtain five apples. In another instance, a child adds seven blocks and one block to obtain eight blocks. In a third instance, a child combines the category of fathers with that of mothers to obtain the category of parents. The operation abstracted from these three mental actions is an aggregation or combining, without reference to the particular content of numbers, objects, or categories.

Not only must an operation be interiorized action, but it must also be reversible. The action of combining (addition) is not an operation until its relationship to the action of separating (subtraction) is comprehended. To understand reversibility is to understand the third criterion of an operation, its inclusion in a system.

The reversibility essential to operatory thought may be inversion or reciprocity. In reversibility by inversion, an action +A is reversed by −A. For example, in the conservation-of-quantity example, pouring liquid into container 2 (+A) may be mentally reversed, that is, by mentally pouring it back into container 1 (−A). In reversibility by reciprocity, a relation $A < B$ is reversed by a relation $B < A$. Referring again to the conservation-of-quantity example, let A stand for container 1 and B stand for container 2. The rising height of liquid in container 2 ($A < B$) is offset by its narrower width ($B < A$).

Corresponding to these two types of reversibility are the two major categories of concrete operations: those pertaining to classes and those pertaining to relations. In the system of operations performed on classes, reversibility is by inversion; in those performed on relations, it is by reciprocity. For example, subtraction and addition relate to inversion; comparing sticks of different sizes relates to reciprocity.

Telegram: @medical_k

www.konkur.in

CLASS INCLUSION. The concrete operation demonstrating an understanding of classes is the class inclusion task. In this task, a child is shown, for example, an array of pets (superordinate class) consisting of dogs and cats (subordinate classes). After counting the number of dogs, cats, and pets, the child is asked whether there are more dogs or more pets. Children in the preoperational subperiod cannot keep in mind the superordinate class while perceiving only the subordinate classes. Thus, they fail the task frequently over a series of such arrays. The concrete operation of class inclusion underlies one's ability to think categorically.

RELATIONS. The concrete operation that demonstrates an understanding of relations is seriation. Children are asked, for example, to arrange a set of rods in order of increasing size. Children in the preoperational subperiod may subgroup the rods but have difficulty completing an entire array along the required dimension. They may understand the concept of smaller versus larger but have difficulty comprehending the gradual nature of change. The concrete operation of seriation underlies one's ability to think dimensionally.

Formal Operations. In the third and final stage in Piaget's conception of intellectual development in the child, the logical structures of concrete operations are superseded by structures referred to as formal operations. The relationship between the real and the possible that characterizes adolescent thinking represents a reversal of that relationship in the thinking of the concrete-operational child. Inhelder and Piaget noted that the real has priority for the younger child, and that possibility is conceived of merely as a prolongation or extension of real operations, "as, for example, when, after having ordered several objects in a series, the subject knows that he could do the same with others." For the adolescent, however, the possible has priority, and the real is seen as a particular instance of it. "Henceforth, they conceive of the given facts as that sector of a set of possible transformations that has actually come about." This immediately presupposes that the adolescent can take a given empirical event (such as "the long, thin rod bends") and categorize it within a system of possible combinations of events (e.g., long rods or short rods, thin rods or thick rods, bending or not bending). Three characteristics follow from this fundamental reorientation in thought: (1) adolescent thought is hypothetical-deductive; (2) it deals in propositions rather than in

Telegram: @medical_k

www.konkur.in

concrete events; and (3) it can isolate variables and examine all possible combinations of variables.

HYPOTHETICAL-DEDUCTIVE THOUGHT. As a hypothetical-deductive form of thought, formal operational intelligence proceeds from the possible to the real. In this sense, it mirrors scientific reasoning. The implications of a propositional statement are drawn and then tested against reality. Rather than building up a proposition by induction from disparate concrete examples to a loose generalization, formal intelligence operates systematically from a general statement to a specific instance by means of testable hypotheses.

PROPOSITIONAL THOUGHT. That formal operations deal in propositions rather than in concrete events implies increased freedom from immediate content. At one level, this freedom implies the ability to manipulate abstractions that have been tied to concrete examples or events. The adolescent, for example, can perform a transitive inference (A < B, B < C; therefore, A < C) without any empirical demonstration of referents for the terms A and B. At another level, this freedom implies that having performed a concrete operation, the adolescent can abstract the results of that operation and can perform further operations on them. For example, an adolescent can perform the concrete operation of combining two liquids to observe the color of the resultant mix and then take the result of this operation and systematically relate it to the results of all other combinations of available liquids.

ISOLATING VARIABLES AND EXAMINING COMBINATIONS. Instead of dealing with disparate concrete experiments, hypothetical-deductive adolescents can organize their investigations into a coherent pattern from the outset and then perform all relevant combinations of variables to test their hypotheses, thus isolating causal factors. Piaget's theory of formal operational cognition focused on scientific thinking. For example, the weight, speed, shape, and size of an object may all be seen to contribute to the size of a hole the object makes when it hits the ground.

A complete combinatorial system appears only during the period of formal operations. Instead of focusing on empirical givens, as a child in the concrete-operational stage does, the adolescent using formal operational thinking, constructs a hypothetical system comprising the

Telegram: @medical_k

www.konkur.in

empirical givens. Whereas the younger child could classify events according to various categories, such as length, width, and weight, the adolescent uses that classification as a basis for abstracting all possible combinations of variables. Having done this, the adolescent can then test hypotheses derived from the combinatorial system. The result of this new ability is the capacity to test the causal significance of each individual factor in succession by holding all other factors constant.

Piaget interpreted the rise of formal operational thought in the context of his equilibrium model of cognitive development. Thus, he considered neurologic maturation and experience of the object and interpersonal world as necessary but not enough to explain this qualitative improvement in thinking. The equilibration explanation is as follows: During the stage of concrete operations, several qualitatively heterogeneous factors are constructed by the child, resulting in the achievement of conservation of the factor in question even in the face of perceptual transformations. Such factors include quantity, weight, volume, time, and length. Eventually, the child discovers that, in many concrete instances, the operation of these factors is interrelated. Thus, although the factors have been constructed mentally in relative isolation from one another, their presence in real objects is mixed. Through experience with impersonal and interpersonal objects, the child's concrete operational understanding of these factors is shown to be insufficient, and a more comprehensive, more intelligent understanding is stimulated.

Egocentrism

Each major period of cognitive development is characterized by a qualitative shift toward more-comprehensive and more-adaptive cognitive structures. In this sense, the adolescent is more intelligent than the infant. However, each transition to a higher level of cognitive organization is initially accompanied by a lack of full differentiation between self and object. The most relevant of these episodes for psychiatry occurs with the shift to formal operational reasoning in adolescence. The adolescent has the capacity to engage in hypothetical thinking and to understand others' points of view. However, this is initially accompanied by characteristic patterns of thought in which others are unrealistically presumed to be focusing on the adolescent. This may lead to increased social anxiety, narcissistic reactions, or hypersensitivity. The capacity for formal operations also implies that real, individual people, including parents and

Telegram: @medical_k

www.konkur.in

teachers, are one instance of what ideal people could potentially be like. This may underlie some features of adolescent rebellion and idealism.

INTELLIGENCE: PIAGETIAN MODEL AND ITS ALTERNATIVES

The Piagetian view of intelligence can be further understood by contrasting it with other contemporary models of intelligence. In the European and American traditions of clinical and educational psychology, intelligence had a pragmatic meaning. Alfred Binet's work in Paris was intended to determine which children were delayed in learning and, thus, in need of special educational assistance. With Théodore Simon, he developed the first *intelligence test* by choosing a variety of tasks and arranging them in order according to the age at which most children master them. This enabled the clinician to assess at what mental age the child was functioning. Further developments in this tradition involved dividing the mental age by the chronologic age to determine the child's intelligence quotient (IQ). This age-corrected notion of intelligence emphasized individual differences through comparisons of children with their peers instead of emphasizing the most general and progressively adaptive competencies of individuals during childhood and adolescence, as Piaget had done. Age-corrected intelligence came to be viewed as a trait, with some children ahead of or behind their age mates in what was believed to be a basic capacity for learning.

Psychologists who espouse a trait model of intelligence differ among themselves on such key issues as to what extent the trait is heritable and whether there is a single general trait or numerous specific traits (types) of intelligence. Nevertheless, all trait theorists differ from Piaget by focusing on individual differences rather than on the most general aspects of cognitive adaptation.

Piaget's view of intelligence also differs from Lev Vygotsky's social model. In the latter, intelligence is viewed chiefly as the outcome of a process through which children internalize the cultural tools and practices represented in their social context. The contrast between Piaget and Vygotsky may at least superficially appear to be one between a theorist who emphasizes the most general cognitive processes and a theorist who emphasizes the most culturally specific cognitive content. As noted earlier, Piaget did include social experience and interaction as a factor

Telegram: @medical_k

www.konkur.in

contributing to cognitive development, along with biologic maturation, learning, and equilibration. However, he did not emphasize the social and cultural context to the same extent as Vygotsky.

Finally, Piaget's construct of intelligence may be contrasted with the cognitive social learning construct of competencies. Although both constructs involve active, developing processes rather than fixed knowledge, the former pertains to the most general structures of logic derived from coordination of actions, and the latter refers to more-specific, concrete sets of skills, including social and problem-solving skills. Attempts to integrate Piagetian and cognitive social learning models may hold some promise for psychotherapeutic interventions. The latter model points to certain areas that are developmentally crucial for adjustment (goal setting, planning, problem-solving), whereas Piaget model emphasizes the importance of active engagement in the development of structures.

Extensions of Piaget Theory

Piaget theory focuses primarily on logical-deductive reasoning. Little attention is paid to social intelligence, emotional intelligence, or alternative types of intelligence, such as artistic or athletic intelligence. Others have used a Piagetian framework to investigate some, but not all, of these realms. These efforts are referred to as "extensions" of Piaget theory. The first and perhaps best-known attempt to extend Piaget theory in this way was made by Lawrence Kohlberg, who studied the moral reasoning of children.

Although Piaget wrote *The Moral Judgment of the Child,* he did not further develop this area in subsequent work. Kohlberg developed a stage model in which the child's stage of moral reasoning depended on his or her stage of (Piagetian) cognitive development. For instance, to demonstrate moral reasoning at the conventional level, the child must have already entered the concrete-operational stage of cognitive development. Likewise, principled moral reasoning demanded a foundation in formal operational thought.

Kohlberg described three major stages of moral reasoning, each divided into two substages. The three major stages included the morality of the preschool period (based on notions of avoiding punishment and striving for reward), conventional morality (based on notions of authority or mutual benefit), and principled morality (based on general internalized

Telegram: @medical_k

www.konkur.in

moral principles). As was the case for Piagetian stages, Kohlberg's stages were proposed as progressively more adequate and more highly structured. That is, a child would move only in a forward direction through the stages. However, it was not proposed that all or even most people would necessarily attain the highest level of moral reasoning. Kohlberg investigated the moral reasoning of individuals by presenting them with moral dilemmas and then observing their thinking as they attempted to resolve the dilemmas. The theory of development pertained to the form of their thinking and not to the content of their solution. The best known of the dilemmas involved a husband who needed to obtain a rare medication to save the life of his wife. The druggist who had the medication was charging an exorbitant price for it. The question is whether the husband would be justified in stealing it. In addressing this dilemma, the research participant might have recourse to such considerations as fear of punishment (preconventional), concerns for social order (conventional), or relative values of life and property (principled). Kohlberg was not concerned with the participant's final choice but only with the methods of reasoning used to reach that choice.

Kohlberg's extension of Piaget work was subject to several criticisms. The moral subject was criticized as detached from moral content. In fact, individual differences in the predominant forms of moral reasoning did not seem to correlate highly or consistently with individual differences in actual moral behavior. The research methodology's approach may have confounded the level of verbal skills, and hence general intelligence, with moral reasoning. Finally, because his theory was originally developed from research with an entirely male sample, Kohlberg was criticized by Carol Gilligan for having proposed a theory that was gender-biased. She argued that a woman's moral reasoning proceeds from a primary concern with relationships, whereas a man's moral reasoning proceeds from a primary concern with justice. However, subsequent empirical research has demonstrated that women score as high as, or higher than, men on measures of Kohlberg's stages of moral reasoning.

Following Kohlberg theory, attempts were made to relate Piaget model to social cognition. Initial efforts followed Kohlberg's lead. That is, stages of social cognition were proposed as being dependent on stages of intellectual development. Interpersonal perspective-taking was hypothesized as being dependent on perceptual and cognitive perspective-taking. However, it became clear that children's concepts

Telegram: @medical_k

www.konkur.in

about other people did not always follow such a layered structural design. James Youniss then developed a theory of children's concepts of other people that appropriated a different key element from Piaget's work. Rather than attempting to layer stages of social cognition on stages of intellectual development, Youniss proposed that social cognition has its own process of development but that these are based on abstractions from interpersonal interactions. Integrating Piagetian psychology with the interpersonal psychiatric theory of Harry Stack Sullivan, Youniss proposed two major categories of children's social cognition: schemas about peers and schemas about authority figures. Each of these develops as a function of repeated interactions with peers or elders. As can be seen in this example, the second type of extension of Piaget's work into the interpersonal domain abandoned the position that stages of social cognition depended on broad structures of intellectual development in favor of the position that the active abstracting processes discovered by Piaget were operative across both types of cognition.

The third type of extension is directed toward the child's acquisition of social knowledge. Again, the Piagetian roots of this extension are to be found in *The Moral Judgment of the Child.* The extension is stimulated by cross-fertilization between adherents of Piaget model and adherents of Vygotsky theory. As Duveen argued, in *The Moral Judgment of the Child,* Piaget depicted two methods by which the child acquires knowledge of social and cultural content. The first is through social transmission, based on learning from an authority figure. The second is through processes of argumentation and debate with peers. Piaget's first process is similar to Vygotsky's notion that the child internalizes from elders a system of symbols that represents a social or collective product. Perret–Clermont pointed out that Piaget emphasized the second process much more than the first over the course of his career and that there was a definite sense in which he viewed the first as potentially constricting. Indeed, it appeared to him to be based on authority but was lacking in the stimulation of new learning that characterized debate with peers and the social construction of knowledge.

To the extent that Piaget neglected or underemphasized the acquisition of knowledge through social transmission, his theory would be deficient in accounting for children's knowledge of social and cultural material that is passed on rather than actively constructed by the individual. Such materials would range from the obvious (socially and culturally acceptable

Telegram: @medical_k

www.konkur.in

behavior) to the subtle (mathematical inventions, such as the current number system). The implications for education are significant. Discovery methods of education, including experimentation and peer discussion, may be more appropriate when the goal is to assist children in formulating the most general principles of reasoning or to facilitate creative processes, but other methods, including lecture, reading, and modeling, may be more appropriate when the goal is to convey specific social content.

The Post-Piaget Era

Piaget has been criticized for failing to account for individual differences among children in their intellectual development and for failing to account for the effects of cultural settings on the cognitive content of children's intelligence. Educators and clinicians may find Piaget's work of invaluable interest for its broad depiction of developmental stages and processes and yet frustrating because of its failure to provide guidance for interventions that would facilitate learning or correct deficiencies in individual children.

Cross-cultural research has called into question the generality or universality of Piaget's proposed stages. Different tasks appear to be mastered at different ages across cultures. Even within Western culture, there is evidence that modifications in training paradigms or in the way in which cognitive structures are operationalized can lead to significantly different results than those obtained by Piaget regarding children's abilities at different ages. More specifically, the criticism has been made that Piaget relied too heavily on the child's verbalizations to document understanding of a cognitive task. In fact, mastery of concrete and formal operational schema was only acknowledged in Piagetian research if the child could explain verbally why the correct answer was logically necessary.

Moreover, the superiority of formal to concrete operational thinking appears to be culturally relative, as reviewed by Marie-Anne Suizzo. In some cultures, social intelligence, or what has been termed "emotional intelligence," is valued over technical, scholarly forms of cognition, or analogic reasoning is as valued as propositional reasoning.

Moreover, the notion of a developmental stage that may last for as long as 7 years or more, during which schemas of conservation are sequentially developed across areas as divergent as quantity and volume, may simply be too broad to represent a cohesive period. Empirical

www.konkur.in

psychologists have also questioned the notion of cognitive structures by noting the low magnitude of correlations that are purported to measure the same underlying intellectual structure. Of course, similar criticisms have been made of proposed traits and of purportedly related functions in other areas of psychology as diverse as personality theory and the neuropsychology of executive functions.

As noted earlier, the era of “big theories” in psychology and psychiatry appears to be over. Given the explosion of knowledge across such diverse areas as neuroscience, cognitive science, personality and social processes, and cultural and ethnic diversity, it is unlikely that a big theory can possibly hold in such a way as to account for such a complex arena as cognitive development. Gopnik referred to the post-Piaget era, pointing out that cognitive development appears to be specific to certain domains rather than integrated across vast stages. She advocated for developmental pluralism, with a continuing emphasis on testing the validity of each proposed theory. Two theories she discussed are “theory theory” and “script theory,” both of which seem to have relevance for psychotherapy.

“Theory theory” proposes that cognitive development proceeds by way of the same mechanisms that scientists use to test, modify, and confirm or disconfirm theories. Like Piaget model, this model emphasizes the active construction of intelligence on the part of the child or adolescent (or adult) and the role of evidence in leading to modifications. Theories provide predictions, descriptions, interpretations, and explanations of the ensuing evidence. Psychologists using “theory theory” have found that children’s theories about phenomena are domain-specific rather than general or stage-specific (which Piaget proposed) and that the capacities for induction and causal thinking are present earlier in life than Piaget proposed.

Script theory is a more empirical approach to the learning of complex ideas and skills than Piagetian theory. Scripts (or narratives) provide coherence and predictability that are not derived from abstractions of repeated actions but from repeated sequences of actions. Scripts are explanatory in a subjective sense in that they represent the child’s “story” about what happened in a given instance. A common example of a script is the sequence of events that one expects to occur on entering a restaurant: being greeted and seated, ordering courses in sequence, requesting the check, and making payment.

NEW CONCEPTS OF INTELLIGENCE: EMOTIONAL BASIS OF INTELLIGENCE

Human emotions have traditionally been viewed as somewhat separate from cognition and as a minor concern to overall development. However, the research reviewed by Suizzo has shown that children's performance on cognitive tasks improves with higher levels of social support and is affected by the dynamics of interpersonal relationships and by feelings of self-efficacy. New clinical observations and theoretical formulations by Stanley Greenspan and emerging findings from several recent studies suggest that emotions are central to cognition and that they may regulate and orchestrate cognitive capacities. They may also be critical to the development of cognitive capacities. It is suggested that infants' emotional exchanges with their caregivers, rather than their ability to complete cognitive tasks, should become the primary measure of developmental and intellectual competence.

Twelve-month-old Cara sat in her mother's lap at a table, eyes locked onto the psychologist, who tried to get her to follow the bean he placed under the cup and search for it. Cara knocked over the cup. Is this little girl, as her mother fears, cognitively delayed? Does a 1-year-old child who never babbles like other children her age and who violently flings food and toys away from her show signs of a significant intellectual deficit? After a battery of similarly frustrating tests, the evaluator concluded that cognitive delay was the likely diagnosis in Cara's case.

When an evaluator schooled in this new thinking assessed Cara, he focused on her spontaneous interactions with her caregiver. He looked at each of Cara's intentional behaviors as a sign of her emotional interests. For instance, he observed her delight in yanking her mother's nose. At the assessor's suggestion, the mother permitted the tugging on her nose to continue and playfully responded, "Toot, toot." Cara smiled and pulled again. The baby was rewarded with another "Toot, toot" and a big smile from her mother. Cara soon began to copy her mother's gestures and eagerly thrust her nose toward mom. When the mother squeezed Cara's nose, the 1-year-old girl chirped, "Mo, mo," which were her first words.

Cara showed that she could initiate social interactions and could comprehend their consequences. That demonstrated a degree of understanding that put Cara at least at the 12-month level of cognitive development. Further observation revealed an extremely energetic, active, highly physical toddler who liked to have her way and control her surroundings. With the consultant's help, Cara's mother later altered her parenting style. She learned to follow Cara's behavioral lead, then enthusiastically engaged her daughter in creative interactions while simultaneously setting firm limits. Cara's energy quickly became more focused; her babbling became richer. Before long, she was saying real words and actively cooperating with her parents.

For 50 years, developmental testers have expected babies to sit still in their mothers' laps, to pay attention, and to perform prescribed tasks while adults assess their basic intelligence. Traditional wisdom has long insisted that carefully scoring how well a tiny child fits pegs into boards, sorts

Telegram: @medical_k

www.konkur.in

cards by shape, or hunts beans under cups can reveal an accurate measure of intelligence and developmental competence. However, recent results from research and clinical practice by Stanley Greenspan and others suggest that this entire approach to assessing children's capacities rests on false premises and has inadvertently led to mistaken diagnoses that can stigmatize children throughout their school years.

If a series of such simple, pleasurable interactions with her mother could reveal and foster Cara's language development and organizational ability, then any conception of intellect that marked her as cognitively delayed because of an inability to search for a bean has serious flaws. Those flaws are based on a long-standing mistaken belief that the intellect is superior to and supervises the passions. Clearly, as Cara's linguistic debut demonstrates, analysis of a child's early relationships and sensory and emotional experiences is a vital key to an accurate assessment of intelligence and developmental competence.

Until now, no one has provided an explanation of how emotions give birth to intelligence. In fact, a baby's earliest feelings play a pivotal role in all later intellectual development. Unlikely as the connection between feeling states and intelligence may seem, emotions orchestrate a vast array of cognitive operations throughout an individual's life span. Indeed, they make possible all creative thought.

Results from four distinct lines of inquiry have recently shed new light on the importance of emotions for intelligence. In work with Arnold Sameroff, Greenspan found that children with four or more family emotional risk factors had 24 times the chance of scoring an IQ of less than 80 than children without those risks. Stephen Porges and Greenspan showed that measurements in 8-month-old infants of a part of the brain that regulates emotions correlate with these same children's IQ scores at 4 years of age.

Greenspan's work with a group of children with autistic disorder, who experience some of the most severe thinking and language problems imaginable, also confirmed the inextricable linkage between emotional and cognitive development. Therapeutic programs for these severely challenged children have traditionally concentrated on trying to stimulate their cognition and teach them language. However, a program based on emotional cueing (like the one that revealed Cara's true abilities) proved to be more effective for a number of these children in fostering empathy, warmth, and creative thinking.

www.konkur.in

One young patient, Ashley, neither spoke nor made any response or eye contact with those around her. The 2-year-old child spent hours staring into space, rubbing persistently at the same patch of rug. Her abnormal repetition was viewed by the clinician observing her as more than just a distressing symptom of her autism. That symptom revealed an underlying interest and motivation that could be harnessed and redirected toward interacting with others. To initiate her cognitive progress, the clinician first had to motivate her to communicate with the simplest of emotional gestures—a smile, smirk, or purposeful hand movements. He suggested that her mother place her hand next to Ashley on the favorite stretch of rug. When Ashley pushed it away, the mother gently put her hand back. Each time the child pushed, the mother's hand would return. A cat-and-mouse game ensued, and after three sessions of these rudimentary interactions, Ashley was looking, smiling, and anticipating.

From that beginning, through a comprehensive therapeutic program, grew a bridge to emotional relationships and eventual verbal exchanges. For example, as therapy progressed, the therapist helped Ashley use her imagination by repeatedly initiating pretend play. He recognized that each time Ashley repeatedly flung herself on her mother, the child was deriving sensory-based simple pleasure from her behavior. He instructed the mother to whinny like a horse each time Ashley lunged at her. Soon Ashley imitated her mother's sounds and then started initiating her own sounds and words. In that way, the therapist helped the mother stretch a pleasant sensation for Ashley into a richer, more complex interaction. Over time, mother and child pretended to be neighing horses, mooing cows, and barking dogs. Their social and emotional interchange grew increasingly complex, passing through the same series of developmental stages identified in children without difficulties. At 7 years of age, Ashley enjoyed warm friendships, argued as well with her lawyer father, and scored in the low-superior IQ range.

The fourth line of inquiry—microscopic clinical observations of children's thinking—further clarifies the relationships between emotion and reason by revealing two necessary elements of thinking. The first process—creating a new idea—stems from the ability to use one's emotional

Telegram: @medical_k

www.konkur.in

experience to assign meaning and significance to daily events or concepts. The second process—reflection and logical analysis—examines the newly created idea according to whatever principles of logic the person possesses and places it in a wider frame of reference.

To understand those processes in action, Greenspan and Curry put a simple question to two young boys seen in therapy not long ago. When asked by the clinician, “What do you think about people who act bossy to you?” Chris replied, “Well, teachers are bosses, babysitters are bosses, policemen are bosses.” That articulate 7-year-old child lacked the emotional pathways that permit creative and intuitive thought. He could provide a formal classification of different types of bosses but could not relate these categories to his own life. However, 7-year-old Josh had no such difficulties. In response to the same question about bosses, he announced, “Most of the time, I don’t like being bossed, especially when my parents try to tell me when I can watch TV and when I have to go to sleep. I’m big enough to decide for myself. Sometimes when I’m being bad, I guess I need bossing, though. Maybe bosses are okay some of the time, and some of the time they’re not.” Josh found his answer in his, apparently generally irritating, brushes with bosses. Rather than simply listing categories or incidents, he could abstract a principle from the emotional core of those incidents.

How exactly did Josh’s ability to think and abstract develop? A baby’s experience begins with sensations like touch and sound. Each sensation, however, also gives rise to an emotion. A toy may feel interesting or boring; a voice may feel soothing or jarring. Even young infants react to sensations emotionally. They prefer the sound or smell of their mother, for example, to any others and, by 4 months of age, can react to certain persons with fear. Furthermore, contrary to long-held assumptions, basic sensations, such as touch and sound, can be perceived differently by different people, giving rise to emotional differences.

Emotional meaning also adheres to early concepts like *big* and *little, more* and *less, near* and *far,* and *now* and *later. A lot* is a bit more than makes a child happy. *Near* is snuggled next to a child in bed. *Later* is a frustrating stretch of waiting. For a child without an intuitive sense of *few*

Telegram: @medical_k

www.konkur.in

and *many,* numbers have no meaning. Furthermore, a young child's experience of any sensation always occurs within the context of a relationship that gives it broader meaning. Playing with mother's hair, for example, may evoke smiles and hugs or an angry scolding.

Each sensory experience has this dual aspect and is labeled by its physical properties and its emotional qualities. This double coding helps the child to place the memory or experience in a catalog of experiences and to retrieve or reconstruct it when needed. As the child grows, emotional reactions come to operate as a sixth sense that allows the child to recognize and understand situations.

Emotion orchestrates complex judgments as well. One of modern psychology's main enigmas is how children learn to discriminate among situations ("When can I yell and kick?") and to generalize from one to another ("Should I behave at school like I do at home?"). Consider how a child makes a seemingly simple judgment about when to say "hello." He or she does not learn a set of cognitive rules, such as greeting only those who live on his or her street or only those who wave at him or her. Instead, the child abstracts an emotional pattern from numerous social encounters; there is a feeling of warmth and friendliness in situations that rate "hello." The child's interactions create an emotional signaling system that tells him or her when to say "hello" and that it is okay to punt the football but not to kick Sarah or Charlie in the shins.

Looking at Piaget theory from this perspective reveals the limitations of a cognitive theory that did not adequately deal with the central role of emotions. Piaget's experiments focused on how children comprehend the relationship between physical objects, developing the ability to classify them by such parameters as shape or size, but most children can classify their emotions and emotionally relevant relationships far earlier than they can classify physical objects. For example, they know members of their families from those who are not members, classifying the family as a unit. Some of Piaget's observations are limited because he depended so heavily on children's perceptual and motor performance to signal cognitive advances, even though motor skills often lag behind other skills.

More important, however, is Piaget's relative lack of focus on the role of emotions. He emphasized learning through doing but did not realize that the doing generates formative emotional reactions as well as perceptual, motor, and cognitive ones. Consider how a child learns what an apple is. You can have the child handle an apple and determine it is something red

Telegram: @medical_k

www.konkur.in

and round, bigger than a peanut, and smaller than a watermelon. Alternatively, the child can observe the aspects mentioned previously, experience more satisfaction in eating an apple when he or she is hungry than when he or she is full and know the pleasure of giving one to his or her favorite teacher.

The child can also imagine how the teacher feels when he or she gives the teacher the apple. The child may catalog how he or she feels when the child throws one at his or her younger brother and gets him on the shoulder, as well as the child's disgust when an apple rots or when the child discovers half of a worm inside. If you ask creative adults to write an essay on apples, they will probably bring a large amount of personal affective experience to their reflections.

Piaget did emphasize how children's thinking comes to incorporate multiple perspectives as they grow older. A classic Piagetian experiment shows how school-age children learn to solve a problem involving weights on a seesaw. By assessing the heaviness of the weights and noticing where they are placed, they can figure out how a seesaw works. But what was not appreciated by Piaget was that the children's postulated perspectives incorporated the additional perceptions afforded by affective experiences. To neglect this element is, therefore, to fail to appreciate the rich array of experiences that contribute to forming abstract concepts.

TOWARD A GENERAL DEVELOPMENTAL MODEL

The diagnosis and treatment of emotional and developmental disorders in infants and young children require that clinicians address all facets of the child's experience. One needs a model with which to look at how constitutional–maturational (regulatory), family, and interactive factors work together as the child progresses through each developmental phase, and each phase must be viewed from affective and cognitive perspectives.

A developmental, structuralist model formulated by Greenspan integrates cognitive and affective development and applies the types of structure Piaget described to a range of experiences. Most importantly, the model also considers individual differences in terms of biology and interaction. New findings suggest that early interaction can alter the structure and wiring of the CNS. The model can be visualized with the infant's constitutional–maturational patterns on one side and the infant's

Telegram: @medical_k

www.konkur.in

environment, including caregivers, family, community, and culture, on the other side. Both sets of factors operate through the infant–caregiver relationship, which can be pictured in the middle. Those factors and the infant–caregiver relationship, in turn, contribute to the organization of experience at each of six developmental levels (consistent with cognitive and affective milestones), which may be pictured just beneath the infant–caregiver relationship.

This clinical and research model enables the user to look at the mutual influence of highly specific, verifiable constitutional–maturational factors on interactive and family patterns and vice versa, in relationship to specific developmental processes (and to relate these processes to later developmental and psychopathologic disorders).

Developmental Levels

The model contains six developmental levels, which include the ability of the infant and the child to accomplish the following:

1. Attend to multisensory affective experience and, at the same time, organize a calm, regulated state, and experience pleasure.
2. Engage with and show affective preference and pleasure for a caregiver.
3. Initiate and respond to two-way presymbolic gestural communication.
4. Organize chains of two-way communication (opening and closing many circles of communication in a row), maintain communication across space, integrate affective polarities, and synthesize an emerging prerepresentational organization of self and others.
5. Represent (symbolize) affective experience (e.g., pretend play and functional use of language), which calls for higher-level auditory and verbal sequencing ability.
6. Create representational (symbolic) categories and gradually build conceptual bridges between these categories. This ability creates the foundation for such basic personality functions as reality testing, impulse control, self–other representational differentiation, affect labeling and discrimination, stable mood, and a sense of time and space that allows logical planning. This ability rests not only on complex auditory and verbal processing abilities but also on visual-spatial abstracting.

Telegram: @medical_k

www.konkur.in

At each level, one looks at the range of emotional themes organized (e.g., can the child play out [symbolize] only dependency themes and not aggressive ones? Is aggression behaved out and dealt with presymbolically?). One also looks at the stability of each level. Does minor stress lead a child to lose the ability to represent, interact, engage, or attend?

In their use in day-to-day clinical work, the six developmental levels can be collapsed into four essential processes that characterize development in infants and young children. These processes concern how an infant and the parents or caregivers negotiate the various phases of their early interactions, and they serve as a basis for diagnosis and treatment.

Telegram: @medical_k

www.konkur.in

A 12-month-old infant's mother worried that "he cries any time I try to leave him, even for a second. If I'm not standing right next to him when he is sitting on the floor, he cries, and I have to pick him up. He's a tyrant. He's waking up four times at night and is a fussy eater. He eats for short bursts (breastfeeding) and then stops eating. I'm feeding him all the time."

The mother was feeling cornered, controlled, manipulated, and bossed around. Her baby was like a "fearful dictator" (therapist's term). She said, "that's the perfect way to describe him." The father was impatient with the mother; he felt that she indulged the baby too much. He was getting "fed up" because she had no time for him.

The baby was interactive and sensitive to every emotional nuance. As he came into the room, he immediately caught the clinician's eye. They exchanged smiles and motor gestures. He interacted with his parents with smiles, coos, and motor movements. Father intruded somewhat. He would roughhouse until the baby would cry, put the baby down, and then roughhouse again. Mother, in contrast, was ever so gentle, but long silences passed between her vocalizations. During her long silences, the baby would rev up, get more irritable, and start whining. He whined with his mother and cried fearfully with his father. Even before he could finish his motor gestures or vocalizations, his mother moved in and picked him up, gave him a rattle, or spoke for him. In this way, she undermined his initiative. Even while whining, however, he was interactive and contingent.

On physical examination, this baby was sensitive to loud noises and light touch on the arms, legs, abdomen, and back. He had a mild degree of low motor tone and was posturally insecure. He was not yet ready to crawl.

His constitutional and maturational patterns did not compromise his mastering the first developmental challenge of shared attention and engagement. He was an attentive, engaged baby. However, in the second developmental stage, intentional communication and assertiveness, he was a passive reactor. He was not learning to initiate two-way communication, to be assertive, and to take charge of his interactions. His low motor tone was compromising his ability to control his motor movements. His sensory hyperreactivity was compromising his ability to regulate sensation. He was frequently overloaded by just the basic sensations of touch and sound, and he

Telegram: @medical_k

www.konkur.in

was not receiving support from his mother through the nurturing and rhythmic caretaking that would foster self-initiative.

This family required therapeutic work on several tasks simultaneously. The infant's special constitutional–maturational patterns were discussed. Hands-on practice helped the parents help their baby be attentive and calm. Those tasks included helping the mother be more patient, waiting for the baby to finish what he started, and supporting his initiative (e.g., putting something in front of him while he was on his tummy to motivate him to crawl and reach); getting the mother to put more affect into her voice and to increase the rhythm and speed of her vocalizations, and getting the father to be more gentle. The parents' feelings about the interactions were explored: the father's tough-guy background, the mother's fear of her own assertiveness, her fear of her baby being injured, and their own associated family patterns.

Gradually, the baby began to sleep through the night, and he became more assertive and less clinging and fearful. He also became happier. He was slow to reach his motor milestones, so an occupational therapist worked with him and gave the parents advice on motor development and normalizing his sensory over-reactivity. In 4 months, this infant was functioning in an age-appropriate manner with a tendency toward a cautious but happy and assertive approach to life's developmental challenges.

As developmental clinicians and researchers build on Piaget's findings and formulations, the developmental model serves as a basis for understanding social and emotional development and provides a framework for clinical and educational intervention.

Implications of Piaget's Work for Psychotherapy

Piaget was not an applied psychologist and did not develop the implications of his cognitive model for psychotherapeutic intervention. Nevertheless, his work formed one of the foundations of the *cognitive revolution* in psychology. One aspect of this revolution was an increasing emphasis on the cognitive components of the therapeutic endeavor. In contrast to classical psychodynamic therapy, which focuses primarily on drives and affects, and in contrast to behavior therapy, which focuses on

Telegram: @medical_k

www.konkur.in

overt actions, cognitive approaches to therapy focus on thoughts, including automatic assumptions, beliefs, plans, and intentions. By including “theory theory” and “script theory,” additional applications to psychotherapy can be seen.

Cognitive development theory has influenced psychotherapeutic approaches in multiple ways. Some therapists have taken developmental notions from Piaget’s work and developed intervention techniques. Others have developed cognitive models of treatment independent of Piaget but with heavy reliance on the role of cognition. Others have included Piaget’s concepts in a broader set of constructs to undergird new developmental approaches to psychotherapy.

First, some psychotherapists applied Piagetian notions directly to child interventions. Susan Harter, for example, discussed techniques for helping young children become aware of divergent or contradictory emotions and integrate these complex emotions within a more abstract or higher class of emotions. One of Harter techniques is to ask the young child to make a drawing that shows different and conflicting feelings in one person. This technique represents an application of the concrete operation of class inclusion to the realm of emotions. Harter’s work applied Piagetian findings to the common therapeutic problem of helping children to recognize, tolerate, and integrate mixed or ambivalent affects within stable object relations. As such, it drew on cognitive theory and psychodynamic theory. Similar techniques are important in working with children who have been exposed to trauma or to sexual abuse. It is an essential component of such work to assist them in labeling, differentiating, and accepting the full range of emotions stemming from these experiences.

Second, other psychotherapists developed treatment models that, although not directly dependent on Piagetian psychology, emphasized core ideas quite similar to those Piaget discovered in his naturalistic observations of cognitive development. These models are even more closely aligned with recent developments in “theory theory.” Aaron Beck, for example, developed an entire school of cognitive therapy that focuses on the role of cognitions in causing or maintaining psychopathology. Cognitive therapy has been shown to be an effective treatment for problems as diverse as depression, anxiety disorders, and substance abuse.

Telegram: @medical_k

www.konkur.in

A core idea in cognitive therapy is that the patient has developed certain core beliefs, aspects of the self-schema, and conditional probability beliefs because of developmental experiences, and these contribute to emotional or behavioral problems. For example, depressed persons may have the core belief that “I am unlovable.” Addicted persons may have the belief, “Unless I drink, I cannot feel happy.” In cognitive therapy, the person can be assisted in identifying the negative automatic thoughts and underlying dysfunctional attitudes or beliefs that contribute to emotional distress or addictive behavior. The key therapeutic process after identification of the maladaptive thoughts is to help the patient view these thoughts more objectively, not take them in an unquestioning manner as veridical. Here, cognitive therapy emphasizes evidence, consistent both with Piagetian theory and “theory theory.” The patient is assisted in seeking out evidence to test negative thinking; active involvement, rather than passive listening, is required.

What the cognitive therapist accomplishes through such techniques as Socratic questioning and asking if there are other ways to look at the same event is similar to what the talented teacher does in guiding children to a more adequate, more intelligent understanding of operational tasks. The notion of equilibration is relevant in both instances. By helping the individual see that previous cognitive structures are in some ways inadequate, the therapist or teacher disturbs the old cognitive structure, and the patient or student experiences a disruption that leads to the search for more-adequate structures. The compensation for external disturbance is what Piaget termed *equilibration.* New structures can only be constructed through a process of accommodation, enabling the subject to assimilate a wider array of data, a new perspective, or more complex information.

Because it requires *thinking about thinking,* cognitive therapy seems to require formal operational thinking, although this has not been empirically tested. At the least, it requires the ability to recognize and articulate affects, to recognize and label events that give rise to affects, and to translate into thought the mediating process that occurs rapidly between the event and the affect. Cognitive-behavioral models of psychotherapy include cognitive techniques and more-behavioral, interactive techniques, such as increasing pleasant activities and improving communication and problem-solving skills. It is possible that the less-cognitive, more-behavioral techniques, although requiring a lower level of cognitive

Telegram: @medical_k

www.konkur.in

development, can also lead to the garnering of evidence and modification of specific expectancies, attributions, and self-schemata.

Because “script theory” or narrative approaches to cognition in psychotherapy are empirically based, generated by repetitive experiences rather than by reflective abstraction, and domain-specific, they may have even more general application to psychotherapy than classic Piagetian theories or “theory theory.” For example, in dialectical behavior therapy, patients provide a “chain analysis” of events, feelings, thoughts, situational stimuli, and interpersonal factors that led up to negative or self-damaging behavior. This narrative provides guidance to the patient and the therapist about where and how to intervene to prevent subsequent similar behavior.

A third approach is to use Piagetian insights in psychotherapy by integrating Piaget’s findings into a broader model. Greenspan, for example, has articulated a developmentally based psychotherapy that takes account of earlier, presymbolic levels of functioning that precede the ability to recognize, label, and articulate affects and their mediating cognitions.

Developmentally Based Psychotherapy

Developmentally based psychotherapy, as developed by Greenspan, integrates cognitive, affective, drive, and relationship-based approaches with a new understanding of the stages of human development. Different therapies look at different aspects of the proverbial elephant, whether from a psychodynamic, object relation, self-psychology, behavioral, or cognitive-behavioral point of view. A comprehensive, cohesive developmental framework integrates elements from these approaches with a broader understanding of the developmental processes essential for emotional or mental health. It formulates a series of principles that an understanding of human development says are prerequisites for emotional growth.

Developmentally based psychotherapy constructs its therapeutic strategies from these principles of human development and growth. The clinician first determines the level of the patient’s ego or personality development and the presence or absence of deficits or constrictions. For example, can the person regulate activity and sensations, relate to others, read nonverbal affective symbols, represent experience, build bridges

Telegram: @medical_k

www.konkur.in

between representations, integrate emotional polarities and abstract feelings, as well as reflect on internal wishes and feelings?

After determining the developmental level, the clinician looks for constitutional and maturational contributions and difficulties with sensory processing, modulation, or motor planning. The clinician looks for interactive and family contributions. Each of these is explored in the present, the past, and the anticipated future. The patient's fantasies, sense of self and others, and conflicts are understood in the context of all of these influences. These are how patients make sense of their ego structure, physical makeup, family patterns, and interactions with others. Developmentally oriented therapists do not focus on just one set of variables, such as inner fantasies, family dynamics, biologic proclivities, or prior experience. Similarly, the formulated therapeutic strategy cannot deal only with one or two factors. It must deal with all critical factors that influence the developmental process. As collaborators in the construction of experience, therapists use their understanding of the patient's development to help the patient to construct interactions that provide growth and overcome difficulties.

Often, it is assumed that critical aspects of development occur through the maturation of the nervous system along with routine, expectable experiences. It is also assumed that, from these routine, expectable maturational sequences and experiences, certain psychological structures having to do with the ability to regulate, engage, interact, represent (symbolize) experience, and reflect and compare experiences are present in most people. With these capacities in place, it is believed that the therapeutic process can focus on conflicts and anxieties and selected maladaptive behaviors or thoughts. It has been observed, however, that only a small percentage of individuals have these core capacities. For most, such capacities must be learned as part of the therapeutic process.

The developmental perspective shows how one learns these capacities during development. It suggests strategies that can be used in the psychotherapeutic process so that adults and children who have not achieved these capacities can learn them. From a developmental point of view, the integral parts of the therapeutic process include learning how to regulate experience; engage more fully and deeply in relationships; read and respond to boundary-defining behaviors and affects; perceive, comprehend, and respond to complex self- and object-defining affects, behaviors, and interactive patterns; to represent experience; to

Telegram: @medical_k

www.konkur.in

differentiate represented experience; and to form higher-level differentiations, including the capacity to engage in the ever-changing opportunities, tasks, and challenges during the course of life (e.g., adulthood and aging) and, throughout, to observe and reflect on one's and others' experiences. Mastering these core developmental processes makes dealing with conflicts, anxieties, maladaptive behaviors, and thoughts possible.

ACKNOWLEDGMENTS

This chapter represents an update and revision of previous chapters in this series, most recently by Stanley I. Greenspan and John F. Curry from the last edition. We are indebted to Drs. Greenspan and Curry for their work and retain much of their prose in this current edition.

3.3 Learning Theory

Mark E. Bouton, Ph.D.

The principles of learning are always operating and influencing human activity. Because so much human behavior (including overt behavior, thought patterns, and emotion) is acquired through learning, learning principles are often deeply involved in the etiology and maintenance of psychiatric disorders. And because behavior change, the goal of all psychotherapy, is also strongly influenced by learning processes, learning principles can influence the effectiveness of a therapy. In fact, no therapy can be said to be immune to the effects of learning. Even the simple prescription of a medication can bring learning processes into play, because the patient will have opportunities to learn about the drug's effects and side effects, will need to learn to comply with the instructions and directions for taking it, and will need to learn to overcome any resistance to compliance. Learning theory is worth knowing, it has been said, because "much like the law of gravity, the laws of learning are always in effect."

HISTORICAL CONTEXT

The modern study of learning can be traced back to roughly the turn of the 20th century, when two great traditions in biology began to focus on behavior and learning. Working in the reflex tradition, the Russian physiologist Ivan Pavlov first saw the importance of what is now called *classical (or Pavlovian) conditioning*. In the famous description of his simplest experiment, Pavlov rang a bell and then gave a dog some food. After a few pairings of bell and food, the dog began to salivate to the bell and thus anticipated the presentation of food. Today, classical conditioning is seen as an important and ubiquitous behavioral phenomenon, as well as a powerful method for studying basic associative learning processes (see later discussion). In addition, from its earliest days, classical conditioning was also applied to psychiatric phenomena. For example, in

Telegram: @medical_k

www.konkur.in

the 1920s (before most of Pavlov's work was available in English), John B. Watson showed that human emotions are influenced by classical conditioning. Watson showed an infant boy a stimulus (which happened to be a laboratory rat) and then made a frightening noise. After a few pairings of the rat and the noise, the child became afraid whenever the rat was presented. This fear generalized to a rabbit, a dog, and a fur coat. Watson saw conditioning as a means by which human emotions could be elicited by an expanding range of cues.

Also working at the turn of the 20th century, but in the tradition of the early comparative psychologists (who were interested in studying the evolution of the mind by studying the behavior of animals), Edward Thorndike ran some of the earliest systematic experiments on *instrumental (or operant) conditioning*. In his studies, cats were placed in "puzzle boxes" and required to learn to move a latch to get out of the box and find reward. Although the method was originally seen as a way to study the cognitive abilities of animals, the instrumental conditioning experiment was soon seen as a tool for studying how the effects of a behavior can strengthen or weaken it. In the late 1930s, B.F. Skinner expanded Thorndike's method by enclosing rats in a box and allowing them to operate a lever attached to the wall to earn a food-pellet reward. In this case, the animal was free to perform the behavior repeatedly, whenever it wanted to. Nowadays, and in parallel with Pavlovian conditioning, operant learning is seen as (1) an important and ubiquitous behavioral phenomenon, (2) a method for rigorously studying learning and motivation processes (see below), and (3) a phenomenon with applicability to clinical issues.

The application of learning theory to clinical issues became especially central to the *behavior therapy* movement that began in the 1950s and 1960s (e.g., Wolpe, 1958). The specific application of operant conditioning principles became known as *applied behavioral analysis.* The fundamental idea was that psychiatric disorders could be understood and treated using scientifically established principles of learning. The relationship between lab-based research on learning and the practice of clinical psychologists was viewed as analogous to the relationship between lab-based medical research and the practice of physicians. Since the 1970s, the field of behavior therapy (now called *cognitive behavior therapy*) has accepted what seem to be a wider range of explanatory principles, often grounded in social psychology and at least nominally in

Telegram: @medical_k

www.konkur.in

an information-processing ("cognitive") perspective rather than an explicitly "behavioral" perspective. At the same time, the basic science of learning theory has also advanced and expanded in ways that have not always been appreciated by clinical scientists. Beginning in the late 1960s and continuing today, new findings led to conceptual changes in how learning processes were analyzed—with an increasing emphasis on cognitive processes and evolution. These developments further deepened the understanding of learning processes and widened the possible implications and applications to clinical problems and issues.

BASIC CONCEPTS AND CONSIDERATIONS

A great deal of modern research on learning still focuses on Pavlovian and operant learning. Pavlovian conditioning occurs when neutral stimuli are associated with a psychologically significant event. The main result is that the stimuli come to evoke a set of responses or emotions that may contribute to many clinical disorders, including (but not limited to) anxiety disorders and drug dependence. The events in Pavlov's experiment are often described using terms designed to make the experiment applicable to any situation. The food is the *unconditional stimulus*, or *US*, because it unconditionally elicits salivation before the experiment begins. The bell is known as the *conditional stimulus*, or *CS*, because it only elicits the salivary response conditional on the bell–food pairings. The new response to the bell is correspondingly called the *conditional response* (*CR*), while the natural response to the food itself is the *unconditional response* (*UR*). Of course, as will be illustrated below, modern laboratory studies of conditioning use a very wide range of CSs and USs and measure a wide range of conditioned responses.

Operant conditioning occurs when a behavior (instead of a stimulus) is associated with a psychologically significant event. In the laboratory, the most famous experimental arrangement is the one in which a rat presses a lever to earn food pellets. In this case, as opposed to Pavlov's, the behavior is said to be an *operant* because it operates on the environment. And the food pellet is a *reinforcer*, an event that increases the strength of the behavior it is made a consequence of. A major idea behind this method is that the rat's behavior is "voluntary," in the sense that the animal is not compelled to make the response (it can perform it whenever it "wants" to). In this sense, it is similar to the thousands of operant

Telegram: @medical_k

www.konkur.in

behaviors that humans choose to commit—freely—in any day. Of course, the even larger idea is that even though the rat's behavior appears as though it is voluntary, it is lawfully controlled by its consequences: If the experimenter were to stop delivering the food pellet, the rat would stop pressing the lever, and if the experimenter were to allow the lever press to produce larger pellets, or perhaps pellets at a higher probability or rate, then the rate of the behavior might increase. The point of operant conditioning experiments, then, is largely to understand the relation of behavior to its payoff.

Pavlovian and operant conditioning differ in several ways. One of the most fundamental differences is that the responses observed in Pavlov's experiment are *elicited* and thus controlled by presentation of an antecedent stimulus. In contrast, the "response" observed in Skinner's experiment is not elicited or compelled by an antecedent stimulus in any obvious way—it is instead controlled by its consequences. This distinction between *operants* and *respondents* is important in clinical settings. If a young patient is referred to the clinic for acting out in the classroom, an initial goal of the clinician will be to determine whether the behavior is a respondent or an operant, and then go about changing either its antecedents or its consequences, respectively, to reduce its probability of occurrence.

Despite the academic separation of operant and respondent conditioning, they have an important common function: Both learning processes are designed by evolution to allow organisms to adapt to the environment. The idea is illustrated by considering the *law of effect* (Fig. 3.3–1), which says that whether an operant behavior increases or decreases in strength depends on the effect it has on the environment. When the action leads to a positive outcome, the action is strengthened; conversely, when the action leads to a negative outcome, we have *punishment*, and the action is weakened. In a similar manner, when an action decreases the probability of a positive event, behavior also declines. (Such a procedure is now widely known as *time-out* from reinforcement.) When an action terminates or prevents the occurrence of a negative event, the behavior will strengthen. By thus enabling the organism to maximize its interaction with positive events and minimize its interaction with negative ones, operant conditioning allows the organism to optimize its interaction with the environment. Of course, events that were once positive in the human's earlier evolutionary history are so

Telegram: @medical_k

www.konkur.in

prevalent in modern society that they do not always seem adaptive today. Thus, reward learning also provides a framework for understanding the development of rather maladaptive behaviors like overeating (in which behavior is reinforced by food) and drug taking (in which behaviors are reinforced by the pharmacologic effects of drugs)—cases where reward principles lead to psychopathology.

FIGURE 3.3–1. The law of effect in instrumental/operant learning. Actions either produce or prevent good or bad events, and the strength of the action changes accordingly (indicated by *arrow*). "Reinforcement" refers to a strengthening of behavior. *Positive reinforcement* occurs when an action produces a positive event, while *negative reinforcement* occurs when an action prevents or eliminates a negative event.

A parallel to Figure 3.3–1 exists in Pavlovian conditioning, in which one can likewise think of whether the CS is associated with positive or negative events (Fig. 3.3–2). Although such learning can lead to a wide constellation or system of behaviors (as illustrated later), in a very general way, it also leads to behavioral tendencies of approach or withdrawal. Thus, when a CS signals a positive US, the CS will tend to evoke approach behaviors—called *sign tracking*. For example, an organism will approach a signal for food. Analogously, when a CS signals a negative US, it will evoke behaviors that tend to move the organism away from the CS. Conversely, CSs associated with a decrease in the probability of a good thing will elicit withdrawal behaviors, while CSs associated with the decrease in the probability of a bad thing can elicit approach. An example

Telegram: @medical_k

www.konkur.in

of the latter case might be a stimulus that signals safety, or the decrease in probability of an aversive event, which evokes approach in a frightened organism. In the end, these very basic behavioral effects of both operant (Fig. 3.3–1) and Pavlovian (Fig. 3.3–2) learning serve to maximize the organism's contact with good things and minimize the contact with bad things.

Perhaps because they have such similar functions, Pavlovian learning and operant learning are both influenced by similar variables. For example, in either case, behavior is especially strong if the magnitude of the US or reinforcer is large, or if the US or reinforcer occurs relatively close to the CS or operant response in time. And in either case, the learned behavior decreases if the US or reinforcer that was once paired with the CS or the response is eliminated from the situation. This phenomenon, called *extinction*, provides a means of eliminating unwanted behaviors or behavioral excesses that were learned through either form of conditioning and has led to a number of very effective cognitive behavioral therapies.

Pavlovian and operant conditioning are usually described separately, in part because the separation has helped to simplify their analysis in the laboratory. However, it is important to bear in mind that both processes are occurring all the time, and that both are also always occurring together. For example, at the same time the drug user is learning to associate various operant behaviors with the reinforcing effects of drugs, they are also learning to associate the drug with various stimuli, such as room cues or drug paraphernalia, that are also present. As another example, when a person with a weight problem learns behaviors that lead them to a fatty meal, they are also learning where that food is obtainable, and to connect the flavors of the food with their (too-desirable) caloric consequences. Behavior results because both the tendency to repeat behaviors is reinforced and because the Pavlovian signals for drugs or food can evoke approach. But there is more than this, as we will now see.

	Decrease in probability of event	*Withdraw from CS*	*Approach CS*

FIGURE 3.3–2. Sign tracking in Pavlovian learning. CSs either signal an increase or a decrease in the probability of good or bad events, and the CS generally engages approach or withdrawal behaviors accordingly.

PAVLOVIAN CONDITIONING

Effects of Conditioning on Behavior

As noted in an article by Bouton in 2001, where some of the following discussion was first presented, many laypeople have the mistaken impression that Pavlovian learning is a rigid affair in which a fixed stimulus comes to elicit a fixed response. In fact, conditioning is considerably more complex and dynamic than that. For example, signals for food may evoke a large set of responses that function to prepare the organism to digest food: They can elicit secretion of gastric acid, pancreatic enzymes, and insulin in addition to Pavlov's famous salivary response. The CS can also elicit approach behavior (as above), an increase in body temperature, and a state of arousal and excitement. When a signal for food is presented to a satiated animal or human, they may get up and eat more food. Some of these effects may be motivational; for example, an additional effect of presenting a CS for food is that it can invigorate ongoing operant behaviors that have been reinforced with food. CSs thus have powerful behavioral potential. Signals for food evoke a whole *behavior system* that is functionally organized to find, procure, and consume food.

As suggested earlier, Pavlovian conditioning is also involved in other aspects of eating. Through conditioning, humans and other animals may

Telegram: @medical_k

www.konkur.in

learn to like or dislike different foods. In animals like rats, flavors associated with nutrients (sugars, starches, calories, proteins, or fats) come to be preferred. Flavors associated with sweet tastes are also preferred, while flavors associated with bitter tastes are avoided (these tendencies may be seen as additional examples of the approach and withdrawal tendencies summarized in Figure 3.3–2). At least as important, flavors associated with illness become disliked, as illustrated by the person who gets sick drinking an alcoholic beverage and consequently learns to hate the flavor. The fact that flavor CSs can be associated with such a range of biologic consequences (USs) is important for omnivorous animals that need to learn about new foods. And it has some clinical implications. For example, chemotherapy can make cancer patients sick, and can therefore cause the conditioning of an aversion to a food that was eaten recently (or to the clinic itself). Other evidence suggests that animals may learn to dislike food that is associated with becoming sick with cancer itself. On the flip side, conditioning can enable external cues to trigger food consumption and craving, a potential influence on overeating and obesity.

Pavlovian conditioning, as noted in the previous section, also occurs when organisms ingest drugs. Whenever a drug is taken, in addition to reinforcing the behaviors that lead to its ingestion, the drug constitutes a US, and may be associated with potential CSs that are present at the time (rooms, odors, injection paraphernalia, etc.). CSs that are associated with drug USs can sometimes have an interesting property: They can elicit a conditioned response that seems opposite to the unconditional effect of the drug. For example, although morphine causes a rat to feel less pain, a CS associated with morphine elicits an opposite increase, not a decrease in pain sensitivity. Similarly, although alcohol can cause a drop in body temperature, a conditioned response to a CS associated with alcohol is typically an increase in body temperature. In these cases, the conditioned response is said to be *compensatory* because it counteracts the drug effect. Compensatory responses are another example of how classical (Pavlovian) conditioning helps organisms prepare for a biologically significant US.

Compensatory conditioned responses have implications for drug abuse. First, they can cause drug tolerance, in which repeated administration of a drug reduces its effectiveness. As a drug and a CS are repeatedly paired, the compensatory response to the CS becomes stronger and more

Telegram: @medical_k

www.konkur.in

effective at counteracting the effect of the drug. The drug therefore has less impact. One implication is that tolerance will be lost if the drug is taken without being signaled by the usual CS. Consistent with this idea, administering a drug in a new environment can cause a loss of drug tolerance and make drug overdose more likely. A second implication stems from the fact that compensatory responses may be unpleasant or aversive. A CS associated with an opiate may elicit several compensatory responses—it may cause the drug user to be more sensitive to pain, undergo a change in body temperature, and perhaps become hyperactive (the opposite of another unconditional opiate effect). The unpleasantness of these responses may motivate the user to take the drug again to get rid of them, an example of escape learning, or negative reinforcement (Fig. 3.3–1), and a classic example of how Pavlovian and operant learning processes might readily interact (see below). The idea is that the urge to take drugs may be strongest in the presence of CSs that have been associated with the drug. The hypothesis is consistent with self-reports of abusers who, after a period of abstinence, are tempted to take the drug again when they are re-exposed to drug-associated cues.

USs do not always cause the conditioning of compensatory responses, as is illustrated by the fact that Pavlov's CS for food caused the dog to salivate, rather than acquire a dry mouth. Moreover, not all drugs cause the conditioning of compensatory responses either; for example, when cocaine or amphetamine are associated with an environment, the environment tends to evoke a drug-like increase in activity rather than its opposite. Whether the CR appears similar or opposite to the unconditional effect of the drug (the UR) appears to depend on how the UR is actually mediated by the nervous system. Compensatory responses appear to develop as the CR when what we label as the "unconditional response" is actually independent of the brain or spinal cord. For example, although an injection of insulin will cause a drop in the level of blood glucose, it does so because of its direct effect on the body's cells, and not via a reaction by the nervous system. The "response" is actually a stimulus to the nervous system, which unconditionally responds by recruiting an increase in blood glucose. The CR that consequently develops to CSs associated with insulin can therefore be a compensatory increase in blood glucose. The CR, however, is the same as the brain's actual reaction—the UR, correctly identified.

Telegram: @medical_k

www.konkur.in

USs, however, may have multiple effects on the body, some of which may be mediated by the nervous system, and some of which may not be. For example, an injection of atropine causes both dilation of the pupils and a drying of the mouth. The first effect is mediated by the brain, but the second effect is not; atropine suppresses activity of the salivary glands, which presumably initiates a brain reaction that compensates. Consistent with the aforementioned, a CS associated with injection of atropine will elicit a conditioned dilation of the pupils as well as salivation, the latter being a compensatory response.

Pavlovian learning may potentially be involved in anxiety disorders. We now know that CSs associated with frightening USs can elicit a whole system of conditioned fear responses, broadly designed to help the organism cope. In animals, cues associated with frightening events (such as a brief footshock) elicit changes in respiration, heart rate, and blood pressure, and even a (compensatory) decrease in sensitivity to pain. Brief CSs that occur close to the US in time can also elicit adaptively timed protective reflexes. For example, the rabbit blinks to a brief signal that predicts a mild electric shock near the eye. The same CS, when lengthened in duration and paired with the same US, elicits mainly fear responses, and fear elicited by a CS may potentiate the conditioned eyeblink response elicited by another CS or a startle response to a sudden noise. Once again, CSs do not merely elicit a simple reflex, but evoke a complex and interactive set of responses.

Classical fear conditioning can contribute to phobias (where specific objects may be associated with a traumatic US), as well as other anxiety disorders such as panic disorder and post-traumatic stress disorder (PTSD). In panic disorder, people who have unexpected panic attacks can become anxious about having another one. In this case, the panic attack (the US or UR) may condition anxiety to the external situation in which it occurs (e.g., a crowded bus) and also internal ("interoceptive") CSs created by early symptoms of the attack (e.g., dizziness or a sudden pounding of the heart). These CSs may then come to evoke anxiety or panic responses. Panic disorder may begin because external cues associated with panic can arouse anxiety, which may then exacerbate the next unconditional panic attack and/or panic response elicited by an interoceptive CS. It is possible that the emotional reactions elicited by CSs may not require conscious awareness for their occurrence or

Telegram: @medical_k

www.konkur.in

development. Indeed, fear conditioning may be independent of conscious awareness.

As suggested earlier, in addition to eliciting conditioned responses, CSs also motivate ongoing instrumental or operant behavior, a phenomenon known as *Pavlovian-Instrumental transfer*. For example, presenting a CS that elicits anxiety can increase the vigor of operant behaviors that have been learned to avoid or escape the frightening US. Thus, an individual with an anxiety disorder will be more likely to express avoidance in the presence of anxiety or fear cues. Similar effects may occur with CSs that predict other USs (such as drugs or food)—as already mentioned, a drug-associated CS may motivate the drug abuser to take more drugs. The motivating effects of CSs may stem from the fact that CSs may be associated with both the sensory and emotional properties of USs. For example, the survivor of a traumatic train derailment might associate stimuli that occur immediately before derailment (such as the blue flash that occurs when the train separates from its overhead power supply) with both the emotional and the sensory aspects of the crash. Consequently, when the survivor later encounters another flashing blue light (e.g., the lights on a police car), the CS might evoke both emotional responses (mediated by association with the trauma's emotional qualities) and sensory associations (mediated by association with the trauma's sensory qualities). Both might play a role in the nightmares and "re-experiencing" phenomena that are characteristic of PTSD.

The Nature of the Learning Process

Research beginning in the late 1960s began to uncover some important details about the learning process behind Pavlovian conditioning. Several findings proved especially important. It was shown, for example, that conditioning is not an inevitable consequence of pairing a CS with a US. Such pairings will not cause conditioning if there is a second CS present that already predicts the US. This finding (known as *blocking*) suggests that a CS must provide new information about the US if learning is to occur. The importance of the CS's information value is also suggested by the fact that a CS will not be treated as a signal for the US if the US occurs equally often (or is equally probable) in the presence and the absence of the CS. Instead, the organism treats the CS as a signal for the US if the probability of the US is greater in the presence of the CS than in its absence. In addition, the organism will treat the CS as a signal for "no

Telegram: @medical_k

www.konkur.in

US" if the probability of the US is less in the presence of the CS than in its absence. In the latter case, the signal is called a *conditioned inhibitor* because it will inhibit performance elicited by other CSs. The conditioned inhibition phenomenon is clinically relevant because inhibitory CSs may hold pathologic CRs like fear or anxiety at bay. A loss of the inhibition would allow the anxiety response to emerge.

Correlated group	*Uncorrelated group*
AX – US	AX – US
AX – US	AX – no US
BX – no US	BX – US
BX – no US	BX – no US

FIGURE 3.3–3. Types of trials administered to different groups of subjects described in the text. For the correlated group, A is the most valid predictor of the US, and it consequently controls most conditioned responding—for example, blocking conditioning of X. For the uncorrelated group, despite the overall (but superficial) similarity in types of trials, all CSs are associated with the US on 50% of their presentations, and all CSs therefore come to control conditioned responding. (Because X is paired with the US more times than A or B, it is actually the best-conditioned CS in this arrangement.) Conditioning depends on the relative informativeness, validity, or predictive value of the CS.

Consistent with the role of "information value," the conditioning process is organized so that conditioning mainly accrues to the most valid predictors of the US. For example, in the experimental design illustrated in Figure 3.3–3, two groups of subjects received subtly different treatments that had markedly different consequences on learning and behavior. For the correlated group, on some of the trials, CSs A and X were presented together (in a "compound") and always paired with a US. On other trials, B and X occurred together, and the US was never presented. After a number of such AX and BX trials, the learning process treated A as the best predictor of the US—that stimulus blocked learning to X, despite the fact that X was paired with the US on half the occasions on which it was

Telegram: @medical_k

www.konkur.in

presented. In contrast, in the uncorrelated group, X was also paired with the US half the time, but the results were very different. For this group, X was also combined with cues A and B half the time, but A and B were no more predictive of the US than X (the US was also presented on half the trials with either A or B). Because X was as valid a predictor as A or B, there was substantial learning to X. (In fact, because X was actually paired with the US twice as often as A or B, it was the best predictor of the US.) The pattern of results has been observed over a very wide range of conditioning methods, from fear conditioning in rats, category learning in humans, and sucrose conditioning in honey bees. It seems consistent with the view that, to understand conditioning, "the organism is [best] seen as an information seeker using logical and perceptual relations among events … to form a sophisticated representation of its world." The fact that conditioning tends to accrue to the most valid predictors of a US suggests that subtle differences in conditioning history can have a profound influence on an individual's learning and behavior. Thus, if two different drug users were to take a drug in a manner analogous to that of the correlated and uncorrelated groups, one abuser would have tolerance and craving elicited almost exclusively by CS A, whereas the other would have tolerance and craving elicited strongly by A, B, and especially X.

To account for Pavlovian learning, most theorists now suppose that conditioning is not determined by CS–US pairings, but by the discrepancy between (1) the US predicted by all CSs present on a trial, and (2) the US that actually happens on the trial. That discrepancy is often referred to as *prediction error.* One implication is that, depending on the size and direction of the discrepancy or error, the pairing of a CS and traumatic US, for example, can cause an increase in fear conditioning, no change in conditioning, or even a decrease in conditioning. The latter idea has implications for understanding inhibition. A new CS can acquire a negative value if the US is smaller than that which other CSs present predict. Casually speaking, then, a conditioned inhibitor is really a CS that predicts "less US than expected." And a conditioned excitor is a CS that predicts "more US than expected."

These principles have been given formal power in the Rescorla–Wagner model, which asserts that the change in associative strength to a CS on any conditioning trial will be a function of the difference between the strength of the US that occurs on that trial and the extent to which the US is predicted by other CSs that are also present:

Telegram: @medical_k

www.konkur.in

$$\Delta V_{CS} = \alpha\beta(\lambda - \Sigma V)$$

where Δ_{CS} is the change in associative strength (V) to the CS, λ is the strength of the US, and ΣV is the summed associative strengths of all other CSs that are present on the trial (the extent to which the US is already predicted). The α and β terms are merely fractions that influence the rate of learning by influencing the amount of associative change that will occur on the trial (they are based on the salience of the CS and US, respectively). In this theory, CSs can acquire either positive or negative values which correspond to excitation and inhibition, respectively. Several later theories have expanded this conceptualization and have emphasized a number of cognitive psychological processes, such as surprisingness of the US and the CS, short-term memory, memory priming, and also attention to the CS in accounting for this deceptively simple form of learning.

Classical conditioning is most robust if the CS and US are intense or salient. It is also best if the CS and US are novel. For example, in *latent inhibition*, repeated exposure to the CS alone before conditioning can diminish its ability to elicit responding when it is paired with the US. In the *US pre-exposure effect*, repeated exposure to the US before conditioning can likewise decrease the conditioning that later occurs when a CS and the US are paired. One idea is that the CS and the US must be "surprising" at the time of their pairing for learning to occur. Thus, the effects of pairing a CS with trauma or drug USs may depend in subtle ways on the individual's prior experience with the CS and the US. Conditioning theories that followed the Rescorla–Wagner model captured this idea by emphasizing that CSs or USs that were already "primed" in short-term memory by either recent presentation or by a retrieval cue were not surprising and commanded less mental processing necessary for learning. Other theories have also emphasized a critical role for attention to the CS, which is thought to increase under circumstances where its consequence is not known and decrease when its consequence is known. Thus, with extended conditioning, the organism may respond to the CS automatically without much attention or mental processing devoted to it.

There are also important variants of classical conditioning. In *sensory preconditioning*, two stimuli (A and B) are first paired, and then one of them (A) is later paired with the US. Stimulus A evokes conditioned

Telegram: @medical_k

www.konkur.in

responding, of course, but so does stimulus B—indirectly, through its association with A. One implication is that exposure to a potent US like a panic attack may influence our reactions to stimuli that have never been paired with the US directly; the sudden anxiety to stimulus B might seem spontaneous and mysterious. A related finding is *second-order conditioning*. Here, A is paired with a US first and then subsequently paired with stimulus B. Once again, both A and B will evoke responding. Sensory preconditioning and second-order conditioning increase the range of stimuli that can control conditioned response. A third variant worth mentioning occurs, as indicated above, when the onset of a stimulus becomes associated with the rest of itself, as when a sudden increase in heart rate caused by the onset of a panic attack comes to predict the rest of the panic or feeling the onset of a drug may predict the rest of the drug effect. Such intraevent associations may play a role in many of the body's regulatory functions, such that an initial change in some variable (e.g., blood pressure or blood glucose level) may come to signal a further increase in that variable and therefore initiate a conditioned compensatory response.

Emotional responses can also be conditioned through observation. For example, a monkey that merely observes another monkey being frightened by a snake can learn to be afraid of the snake. The observer learns to associate the snake (CS) with its own emotional reaction (US/UR) to the other monkey being afraid. Although monkeys readily learn to fear snakes, they are less likely to associate other salient cues (such as colorful flowers) with fear in the same way. This is an example of *preparedness* in classical conditioning—some stimuli are especially effective signals for some USs because evolution has made them that way. Another example is the fact that tastes are easily associated with illness but not shock, whereas auditory and visual cues are easily associated with shock but not illness. Preparedness may explain why human phobias tend to be for certain objects (snakes or spiders) and not others (knives or electric sockets) that may as often be paired with pain or trauma.

Erasing Pavlovian Learning

If Pavlovian learning plays a role in the etiology of behavioral and emotional disorders, a natural question is how to eliminate it or undo it. As mentioned previously, Pavlov studied *extinction*: Conditioned responding

Telegram: @medical_k

www.konkur.in

decreases if the CS is presented repeatedly without the US after conditioning. Extinction is the basis of many behavioral or cognitive behavioral therapies designed to reduce pathologic conditioned responding through repeated exposure to the CS (*exposure therapy*), and it is presumably a consequence of any form of therapy in the course of which the patient learns that previous harmful cues are no longer harmful. Another elimination procedure is *counterconditioning*, in which the CS is paired with a very different US/UR. Counterconditioning was the inspiration for *systematic desensitization*, a behavior therapy technique in which frightening CSs are deliberately associated with relaxation during therapy.

Although extinction and counterconditioning reduce unwanted conditioned responses, they do not destroy the original learning, which remains in the brain, ready to return to behavior under the right circumstances. For example, conditioned responses that have been eliminated by extinction or counterconditioning can recover if time passes before the CS is presented again (*spontaneous recovery*). Conditioned responses can also return if the patient returns to the context of conditioning after extinction in another context or if the CS is encountered in a context that differs from the one in which extinction has occurred (all are examples of the *renewal effect*). The renewal effect is important because it illustrates the principle that extinction performance depends on the organism being in the context in which extinction was learned. If the CS is encountered in a different context, the extinguished behavior may relapse or return. Recovery and relapse can also occur if the current context is associated again with the US ("reinstatement") or if the CS is paired with the US again ("rapid reacquisition"). One theoretical approach assumes that extinction and counterconditioning do not destroy the original learning, but instead entail new learning that gives the CS a second meaning (e.g., "the CS is safe" in addition to "the CS is dangerous"). As with an ambiguous word, which likewise has more than one meaning, responding evoked by an extinguished or counter-conditioned CS depends fundamentally on the current context.

Table 3.3–1.
Effective Contextual Stimuli Studied in Animal and Human Research Laboratories

Exteroceptive context:
Room, place, environment, other external background stimuli
Interoceptive context:
Drug state
Hormonal state
Mood state
Stress state
Deprivation state
Recent behaviors
Recent events
Expectation of events
Passage of time

Research on context effects in both animal and human learning and memory suggests that a wide variety of stimuli can play the role of context (Table 3.3–1). Drugs, for example, can be very salient in this regard. When rats are given fear extinction while under the influence of a benzodiazepine tranquilizer or alcohol, fear is renewed when the CS is tested in the absence of the context provided by the drug. This is an example of *state-dependent learning*, in which retention of information is best when tested in the same state in which it was originally learned. State-dependent fear extinction has obvious implications for combining therapy with drugs. It also has implications for the administration of drugs more generally. For example, if a person were to take a drug to reduce anxiety, the anxiety reduction would reinforce drug taking. State-dependent extinction might further preserve any anxiety that might otherwise extinguish during natural exposure to the anxiety-eliciting cues. Thus, drug use could paradoxically preserve the original anxiety, creating a self-perpetuating cycle that could provide a possible explanation of the link between anxiety disorders and substance abuse. One point of this discussion is that drugs can play multiple roles in learning: They can be USs or reinforcers on one hand, and CSs or contexts on the other. The possible complex behavioral effects of drugs are worth bearing in mind.

Telegram: @medical_k

www.konkur.in

Another general message is that contemporary theory emphasizes the fact that extinction (and other processes like counterconditioning) entails new learning rather than a destruction of the old, an idea that has been incorporated in contemporary cognitive behavioral therapies that emphasize inhibitory learning during exposure. Recent psychopharmacologic research has also built on this idea: If extinction and therapy constitute new learning, then drugs that might facilitate new learning might also facilitate the therapy process. For example, there has been considerable recent interest in D-cycloserine, a partial agonist of the N-methyl-D-aspartate (NMDA) glutamate receptor. The NMDA receptor is involved in long-term potentiation, a synaptic facilitation phenomenon that has been implicated in several examples of learning. Of interest, there is evidence that administration of D-cycloserine can facilitate extinction learning in rats and possibly humans undergoing exposure therapy for anxiety disorders. In the studies supporting this conclusion, the administration of the drug increased the amount of extinction that was apparent after a small (and incomplete) number of extinction trials. Although such findings are promising, it is important to remember that the context dependence of extinction, and thus the possibility of relapse with a change of context, may easily remain. Consistent with this possibility, although D-cycloserine allows fear extinction to be learned in fewer trials, it does not appear to prevent or reduce the strength of the renewal effect. Such results further underscore the importance of behavioral research—and behavioral theory—in understanding the effects of drugs on therapy. Nonetheless, the search for drugs that might enhance the *learning* that occurs in therapy situations will continue to be an important area of research.

Another process that might theoretically modify or erase a memory is illustrated by a phenomenon called *reconsolidation*. Newly learned memories are temporarily labile and easy to disrupt before they are consolidated into a more stable form in the brain. The consolidation of memory requires the synthesis of new proteins and can be blocked by administration of protein synthesis inhibitors (e.g., anisomycin). Animal research suggests that consolidated memories that have recently been reactivated might also return briefly to a similarly vulnerable state; their “reconsolidation” can likewise be blocked by protein synthesis inhibitors. For example, several studies have shown that the reactivation of a conditioned fear by one or two presentations of the CS after a brief fear

Telegram: @medical_k

www.konkur.in

conditioning experience can allow it to be disrupted by anisomycin. When the CS is tested later, there is little evidence of fear—as if reactivation and then drug administration diminished the strength of the original memory. However, like the effects of extinction, these fear-diminishing effects do not necessarily mean that the original learning has been destroyed or erased. There is some evidence that fear of the CS that has been diminished this way can still return over time (i.e., spontaneously recover) or with reminder treatments. This sort of result suggests that the effect of the drug is to somehow interfere with retrieval or access to the memory, rather than an actual "reconsolidation."

Generally speaking, the elimination of a behavior after therapy should not be interpreted as erasure of the underlying knowledge. For the time being, it may be safest to assume that after any therapeutic treatment, a part of the original learning may remain in the brain, ready to produce relapse if retrieved. Instead of trying to find treatments that destroy the original memory, another therapeutic strategy might be to accept the possible retention of the original learning and build therapies that allow the organism to prevent or cope with its retrieval. One possibility is to conduct extinction exposure in the contexts where relapse might be most problematic to the patient. Others are to conduct therapy in multiple contexts (to encourage generalization across contexts) and to encourage retrieval strategies (such as retrieval cues like reminder cards) that might help remind the patient of the therapy experience.

OPERANT/INSTRUMENTAL LEARNING

The Relation Between Behavior and Payoff

As noted earlier, operant learning has many parallels with Pavlovian learning. As one example, extinction also occurs in operant learning if the reinforcer is omitted following training. Although extinction is once again a useful technique for eliminating unwanted behaviors, just as we saw with Pavlovian learning, it does not destroy the original learning—spontaneous recovery, renewal, reinstatement, and rapid reacquisition effects still obtain. Another phenomenon known as *resurgence* also occurs: If a new behavior is taught to replace an old behavior while the old one undergoes extinction, the old behavior can return ("resurge") when the replacement behavior is itself extinguished. All of these effects are consistent with the

Telegram: @medical_k

www.konkur.in

idea that extinction of an operant behavior, like a Pavlovian response, can be specific to the context in which it is learned.

Although early accounts of instrumental learning beginning with Thorndike emphasized the role of the reinforcer as “stamping in” the action, more modern approaches tend to view the reinforcer as a sort of guide or motivator of behavior. A modern, “synthetic” view of operant conditioning (see later discussion) holds that the organism associates the action with the outcome in much the way that stimulus–outcome learning is thought to be involved in Pavlovian learning.

Operant behavior has traditionally been studied in its own right, in part because so much human behavior seems voluntary, rather than directly elicited by antecedent cues. Human behavior is influenced by a wide variety of reinforcers, including social ones. For example, simple attention from teachers or hospital staff members has been shown to reinforce disruptive or problematic behavior in students or patients. In either case, when the attention is withdrawn and redirected toward other activities, the problematic behaviors can decrease (i.e., undergo extinction). Human behavior is also influenced by verbal reinforcers, like praise, and more generally, by *conditioned reinforcers,* such as money, which have no intrinsic value except for the value derived through association with more basic, “primary,” rewards. Conditioned reinforcers have been used in schools and institutional settings in so-called *token economies* in which positive behaviors are reinforced with tokens that can be used to purchase other valued items. In more natural settings, reinforcers are always delivered in social relationships, where their effects are dynamic and reciprocal. For example, the relationship between a parent and child is full of interacting and reciprocating operant contingencies in which the delivery (and withholding) of reinforcers and punishers shapes the behavior of each. Like Pavlovian learning, operant learning is always operating and always influencing behavior.

Research on operant conditioning in the laboratory has offered many insights into how action relates to its payoff. In the natural world, few actions are reinforced every time they are emitted; instead, most actions are reinforced only intermittently. There are several well-studied ways in which reinforcers can be scheduled intermittently. In a *ratio reinforcement schedule*, the reinforcer is directly related to the amount of work or responding that the organism emits. That is, there is some work requirement that determines when the next reinforcer will be presented. In

Telegram: @medical_k

www.konkur.in

a “fixed ratio schedule,” every *x*th action is reinforced; in a “variable ratio schedule,” there is an average ratio requirement, but the number of responses required for each successive reinforcer varies. Ratio schedules, especially variable ratio schedules, can generate high rates of behavior, as one observes in behavior directed at a casino slot machine. In an *interval reinforcement schedule*, presentation of each reinforcer depends on the organism emitting the response after some period of time has also elapsed. In a “fixed interval schedule,” the first response after *x* seconds have elapsed is reinforced. In a “variable interval schedule,” there is an interval requirement for each reinforcer, but the length of that interval varies. A person checking for email throughout the day is being reinforced on a variable interval schedule—a new message is not present to reinforce each checking response, but the presence of a new message becomes available after variable timepoints throughout the day. Interestingly, on interval schedules, response rate can vary substantially without influencing the overall rate of reinforcement. (On ratio schedules, there is a more direct relationship between behavior rate and reinforcement rate.) In part because of this, interval schedules tend to generate slower response rates than ratio schedules.

Classic research on operant behavior underscores the fact that the performance of any action always involves *choice*. That is, whenever the individual performs a particular behavior, they choose to engage in that action over many other possible alternatives. When choice has been studied by allowing the organism to perform either of two different operant behaviors (paying off with their own separate schedules of reinforcement), the rate of operant behavior depends not only on the behavior’s own rate of reinforcement, but also on the rate of reinforcement of all other behaviors in the situation. Put most generally, the strength of Behavior 1 (e.g., the rate at which Behavior 1 is performed) is given by

$$B_1 = K^* R_1/(R_1 + R_O)$$

where B_1 can be seen as the strength of Behavior 1, R_1 is the rate at which B_1 has been reinforced, and R_O is the rate at which all alternative (or “other”) behaviors in the environment have been reinforced; K is a constant that corresponds to all behavior in the situation—and may have a different value for different individuals. This principle, known as the *quantitative law of effect,* captures several ideas that are relevant to

Telegram: @medical_k

www.konkur.in

psychiatrists and clinical psychologists. It indicates that an action can be strengthened either by increasing its rate of reinforcement (R_1) or by decreasing the rate of reinforcement for alternative behaviors (R_O). Conversely, an action can be weakened either by reducing its own rate of reinforcement (R_1) or by increasing the rate of reinforcement for alternative behaviors (R_O). The latter point has an especially important implication: In principle, one can slowdown the strengthening of new undesirable behavior by providing an environment that is otherwise rich in reinforcement (high R_O). Thus, an adolescent who experiments with drugs or alcohol would be less likely to engage in this behavior at a high rate (high B_1) if their environment were otherwise rich with reinforcers (e.g., provided by extracurricular activities, outside interests, and so forth). Figure 3.3–4 illustrates this point by showing how the rate of an action (B_1) is predicted to increase as a function of its rate of reinforcement in environments with high or low R_O. The principle can also be used in treatment. For example, *contingency management* treatments have been successful at reducing smoking and drug taking (among other behaviors) by providing vouchers and lottery tickets as reinforcers for alternative behaviors. One effect of such treatments is to increase R_O, although in this case the reinforcers are also usually provided only if the client abstains from the original behavior.

Choice between actions is also influenced by the size of their corresponding reinforcers and how soon the reinforcers will occur. For example, individuals sometimes have to choose between an action that yields a small but immediate reward (e.g., taking a hit of a drug) versus another that yields a larger but delayed reward (going to a class and earning credit toward a GED). Individuals who choose the more immediate reward are often said to be “impulsive,” whereas those who choose the delayed reward are said to exercise “self-control.” Of interest, organisms often choose immediate small rewards over delayed larger ones, even though it may be maladaptive to do so in the long run. Such “impulsive” choices are especially difficult to resist when reward is very imminent. A leading explanation is illustrated by Figure 3.3–5. Choice is thought to be determined by the relative value of the two rewards, with that value being influenced by both the reinforcer’s size and its delay. As the figure illustrates, the bigger the reinforcer the better is the value, and the more immediate the reinforcer the better too: When a reward is

Telegram: @medical_k

www.konkur.in

delayed, its value decreases or is “discounted” over time. When offered a choice, the organism will always choose the action that leads to the reward whose value is currently higher. Thus, if choice is made available at Time 1, when both rewards are coming soon, the value of the more immediate reward is higher than the value of the delayed one, and the organism may impulsively choose the immediate reward. If choice is available at Time 2, however, when the rewards are more distant in time, their relative values are reversed. The organism might now choose the delayed reward and demonstrate self-control. One implication is that “impulse control” can be achieved if choice (and commitment to that choice) can be made long before the rewards are about to happen. If the client can commit themself early (further left on the abscissa), it will be easier to choose the larger delayed reward. According to theory, other techniques that would help achieve impulse control would be to further increase the value of the delayed reward (e.g., by providing additional reinforcers for choosing it) and/or decrease the value of the immediate reward (e.g., by adding a cost or punishment for choosing it).

FIGURE 3.3–4. The quantitative law of effect predicts that the extent to which a behavior (B_1) is influenced by its reinforcement rate (R_1) depends crucially on the rate of reinforcement of other behaviors in the background (R_O).

Telegram: @medical_k

www.konkur.in

FIGURE 3.3–5. The current value of a reinforcer depends on both its magnitude and its delay. Choice is influenced by current value. Thus, at Time 1, a smaller and more immediate reward has more value than a large delayed reward. However, at Time 2, the larger reward has more value than the smaller reward, despite the same difference in their delay. Behavior is more "impulsive" if choice is made possible at Time 1 than Time 2. (Reproduced from Bouton ME. *Learning and Behavior: A Contemporary Synthesis*. 2nd ed. Theories of Reinforcement

It is possible to use the foregoing principles of operant conditioning without knowing in advance what kind of event or stimulus will be reinforcing for the individual patient. None of the reinforcement rules described in the previous section say much about what sorts of events in an organism's world will play the role of reinforcer. B. F. Skinner was famously silent about this. He defined a reinforcer empirically, by considering the effect it had on an operant behavior. A reinforcer was defined as any event that could be shown to increase the strength of an operant if it was made a consequence of the operant. This empirical (some would say "atheoretical") view can be valuable because it allows idiosyncratic reinforcers for idiosyncratic individuals. For instance, if a

Telegram: @medical_k

www.konkur.in

therapist works with a child who is injuring himself, the approach advises the therapist merely to search for the consequences of the behavior and then manipulate them in order to bring the behavior under control. So if, for example, the child's self-injurious behavior decreases when the parent stops scolding him for doing it, then the scold is the reinforcer, which might seem counterintuitive to everyone (including the parent who thinks the scold should function as a punisher). On the other hand, it would also be useful to know what kind of event will reinforce an individual before the therapist has to try everything.

This void is filled by several approaches to reinforcement that allow predictions ahead of time. Perhaps the most useful is the *Premack principle* (named for researcher David Premack), which claims that, for any individual, reinforcers can be identified by giving the individual a preference test in which they are free to engage in any number of activities. The individual might spend the most time engaging in activity A, the second-most time engaged in activity B, and the third-most time engaged in activity C. Behavior A can thus said to be preferred to B and C, and B is preferred to C. The Premack principle asserts that access to a preferred action will reinforce any action that is less preferred. In the example above, if doing activity C allowed access to doing A or B, activity C will be reinforced—it will increase in strength or probability. Similarly, activity B will be reinforced by activity A (but not C). The principle accepts large individual differences. For example, in an early study, some children given a choice spent more time eating candy than playing pinball, while others spent more time playing pinball than eating candy. Candy eating reinforced pinball playing in the former group. In contrast, pinball playing reinforced candy eating in the latter group. There is nothing particularly special about food (eating) or any particular kind of activity as a possible reinforcer. Any behavior that is preferred to a second behavior will theoretically reinforce the second behavior.

The principle has been refined over the years. At the present point in time, it is recognized that even a less-preferred behavior can reinforce a more-preferred behavior if the organism has been deprived of doing the low-preferred behavior below its ordinary level. In the foregoing example, even the low-preference activity C could reinforce A or B if it were suppressed for a while below its baseline level of preference. However, the main implication is that, in the long run, a person's reinforcers can be

Telegram: @medical_k

www.konkur.in

discovered by simply looking at how they allocate their activities when access to them is free and unconstrained.

Motivational Factors

Instrumental action is often said to be goal oriented. As Edward Tolman illustrated in many experiments conducted in the 1930s and 1940s, organisms may flexibly perform any of several actions in order to get to a goal; instrumental learning thus provides a variable means to a fixed end. Tolman's perspective on the effects of reinforcers has returned to favor recently. He argued that reinforcers are not necessary for learning, but instead are important for motivating instrumental behavior. The classic illustration of this point is the *latent learning* experiment. Rats received several trials in a complex maze in which they were removed from the maze without reward once they got to a particular goal location. When arriving at the goal was suddenly rewarded, the rats suddenly began working through the maze with very few errors. Thus, they had learned about the maze without benefit of the food reinforcer, but the reinforcer was nonetheless important for motivating them to get through the maze efficiently. The reinforcer was not necessary for learning, but it gave the organism a reason to translate its knowledge into action.

Subsequent research has identified many motivating effects of reward. For example, organisms that have had experience receiving a small reward may show *positive contrast,* when they are suddenly reinforced with a larger reward. That is, their instrumental behavior may become more vigorous than that in control subjects who have received the larger reward all along. Conversely, organisms show *negative contrast* when they are switched from a high reward to a lower reward—their behavior becomes weaker than control subjects who have received the same smaller reward all along. Negative contrast involves frustration and emotionality. Both types of contrast are consistent with the idea that the current effectiveness of a reinforcer depends on what the organism has learned to expect; an increase from expectation causes elation, whereas a decrease from expectation causes frustration. There is a sense in which receiving a reward that is smaller than expected might actually seem punishing.

Negative contrast is an example of a *paradoxical reward effect*—a set of behavioral phenomena given the name because they show that rewards can sometimes weaken behavior and that nonreward can

Telegram: @medical_k

www.konkur.in

sometimes strengthen it. The best known is the *partial reinforcement extinction effect*, in which actions that have been intermittently (or "partially") reinforced persist longer when reinforcers are completely withdrawn than actions that have been continuously reinforced. The finding is considered paradoxical because an action that has been reinforced (say) half as often as another action may nonetheless be more persistent. One explanation is that the action that has been partially reinforced has been reinforced in the presence of some frustration—and is thus persistent in new adversity or sources of frustration. Other evidence suggests that effortfulness is a dimension of behavior that can be reinforced. That is, human and animal participants that have been reinforced for performing effortful responses learn a sort of "industriousness" that transfers to new behaviors. One implication is that new behaviors learned in therapy will be more persistent over time if high effort has been deliberately reinforced.

The effectiveness of a reinforcer is also influenced by the organism's current motivational state. For example, food is more reinforcing for a hungry organism and water is more reinforcing for a thirsty one. Such results are consistent with many theories of reinforcement (e.g., the Premack principle), because the presence of hunger or thirst would undoubtedly increase the organism's preference ranking for food or water. But recent research indicates that effects of motivational states on instrumental actions are not this automatic. Specifically, if a motivational state is going to influence an instrumental action, the individual needs first to learn how the action's reinforcer will influence the motivational state. The process of learning about the effects the reinforcer has on the motivational state is called *incentive learning*.

Incentive learning is best illustrated by an experimental example. In 1992, Balleine trained rats that were not hungry to lever press to earn a novel food pellet. The animals were then food deprived and tested for their lever pressing under conditions where the lever press no longer produced the pellet. The hunger state had no impact on lever press rate; that is, hungry rats did not lever press any more than rats that were not food deprived. On the other hand, if the rat had been given separate experience eating the pellets while it was food deprived, during the test it lever pressed at a high rate. Thus, hunger invigorated the instrumental action only if the animal had previously experienced the reinforcer in that state—which allowed it to learn that the specific substance influenced the

Telegram: @medical_k

www.konkur.in

state (incentive learning). The interpretation of this result, and others like it, will be developed further later in this section. The main idea is that individuals will perform an instrumental action when they know that it produces an outcome that is desirable in the current motivational state. The clinical implications are underexplored but could be significant. For example, persons who abuse drugs will need to learn that the drug makes them feel better in the withdrawal state before withdrawal will motivate drug seeking. Persons suffering from anxiety might not be motivated to take a beneficial medication while anxious until they have actually had the opportunity to learn how the medication makes them feel when they are in the anxious state, and a person suffering from depression may need to learn what natural reinforcers really make them feel better while they are depressed. According to theory, direct experience with a reinforcer's effect on depressed mood might be necessary before the person will be interested in performing actions that help ameliorate the depressed state.

PAVLOVIAN AND OPERANT LEARNING TOGETHER

Avoidance Learning

From the previous discussion, it is easy to appreciate that there is more going on in operant learning than merely associating an action with a reinforcer. Indeed, theories of the motivating effects of reinforcers have usually emphasized the fact that Pavlovian CSs in the background are also associated with the reinforcer, and that the expectancy of the reinforcer (or conditioned motivational state) they arouse increases the vigor of the operant response. This is *two-factor* or *two-process theory:* Pavlovian learning occurs simultaneously and motivates behavior during operant learning.

The interaction of Pavlovian and instrumental factors is especially important in understanding avoidance learning (Fig. 3.3–1). In avoidance situations, organisms learn to perform actions that prevent the delivery or presentation of an aversive event. The explanation of avoidance learning is subtle because it is difficult to identify an obvious reinforcer. Although preventing the occurrence of the aversive event is obviously important, how can the nonoccurrence of that event reinforce? The answer is that cues in the environment (Pavlovian CSs) come to predict the occurrence of the aversive event, and consequently arouse anxiety or fear. The avoidance response can therefore be reinforced if it escapes from or

Telegram: @medical_k

www.konkur.in

reduces that fear. Pavlovian and operant factors are thus both important: Pavlovian fear conditioning motivates and allows reinforcement of an instrumental action through its reduction. Escape from fear or anxiety is thought to play a significant role in many human behavior disorders, including the anxiety disorders. Thus, the obsessive-compulsive patient checks or washes their hands repeatedly to reduce anxiety, the agoraphobic stays home to escape fear of places associated with panic attacks, and the bulimic learns to vomit after a meal in order to reduce the learned anxiety evoked by eating the meal.

Although two-factor theory remains an important view of avoidance learning, excellent avoidance can be obtained in the laboratory without reinforcement. Specifically, if an animal is required to perform an action that resembles one of its natural and prepared fear responses—so-called *species-specific defensive reactions* (*SSDRs*)—it will quickly learn to avoid. For example, rats will readily learn to freeze (remain motionless) or flee (run to another environment) to avoid shock, two behaviors that have evolved to escape or avoid predation. Freezing and fleeing are also respondents rather than operants; they are controlled by their antecedents (Pavlovian CSs that predict shock) rather than being reinforced by their consequences (escape from fear). Thus, when the rat can use an SSDR to avoid, the only necessary learning is Pavlovian—the rat learns about environmental cues associated with danger, and these arouse fear and evoke natural defensive behaviors including withdrawal (negative sign tracking; Fig. 3.3–2). To learn to perform an action that is not similar to a natural SSDR requires more feedback or reinforcement through fear reduction. A good example is lever pressing, which is easy for the rat to learn when the reinforcer is a food pellet but difficult to learn when the same action avoids shock. More recent work with avoidance in humans suggests an important role for CS–aversive event and response–no aversive event expectancies. The larger point is that Pavlovian learning is important in avoidance learning; when the animal can avoid with an SSDR, it is the only learning necessary; when the required action is not an SSDR, Pavlovian learning permits the expectation of something bad.

A cognitive perspective on aversive learning is also encouraged by studies of *learned helplessness.* In this phenomenon, organisms exposed to either controllable or uncontrollable aversive events differ in their reactivity to later aversive events. For example, the typical finding is that a subject exposed to inescapable shock in one phase of an experiment is

Telegram: @medical_k

www.konkur.in

less successful at learning to escape shock with an altogether new behavior in a second phase, whereas subjects exposed to escapable shock are normal. Both types of subjects are exposed to the same shock, but its psychological dimension (its controllability) creates a difference, perhaps because subjects exposed to inescapable shock learn the independence of their actions and the outcome. Although this finding (and the interpretation that the inescapably shocked organism actively learned "helplessness") was once seen as a model of depression, the current view is that the ability to control stressors primarily reduces their stressfulness and modulates their negative impact.

One of the main implications of work on aversive learning is that there are both biologic (i.e., evolutionary as well as physiologic) and cognitive dimensions to instrumental learning. The possibility that so much instrumental learning in the laboratory can be controlled by Pavlovian contingencies, as suggested by the role of SSDRs, is also consistent with research in which animals have learned to respond for positive reinforcers. For example, pigeon subjects have been widely used in operant learning experiments since the 1940s. In the typical experiment, the bird learns to peck at a plastic disk on a wall of the chamber (a response "key") in order to earn food. Although pecking seems to be an operant response, it turns out that the pigeon's peck can be entrained by merely illuminating the key for a few seconds before presenting the reinforcer on a number of trials. Although there is no requirement for the bird to peck the key, the bird will begin to peck at the illuminated key—a Pavlovian predictor of food—anyway. It does so even if the experimenter arranges things so that pecks actually prevent delivery of food (which is otherwise delivered on trials without pecks); here the birds will continue to peck over many trials. (Although the peck has a negative correlation with food, key illumination remains a weakly positive predictor of food.) Thus, this classic "operant" behavior is at least partly a Pavlovian one. Pavlovian contingencies cannot be ignored. When rats are punished with mild footshock for pressing a lever that otherwise produces food, they stop lever pressing at least partly (and perhaps predominantly) because they learn that the lever now predicts shock and withdraw from it. A child might likewise learn to stay away from the parent who delivers punishment, rather than refrain from performing the punished behavior. A great deal of behavior in operant learning settings may actually be controlled by Pavlovian learning and sign tracking rather than true operant learning.

Telegram: @medical_k

www.konkur.in

FIGURE 3.3–6. Any instrumental/operant learning situation permits a number of types of learning, which are always occurring all the time. S, stimulus in the background; R, operant behavior or instrumental action; O, biologically significant outcome (e.g., reinforcer, US, etc.).

A Synthetic View of Instrumental Action

The idea, then, is that behavior in any instrumental learning situation is controlled by several hypothetical associations that are illustrated in Figure 3.3–6. As just discussed, much behavior in an instrumental learning arrangement can be controlled by a Pavlovian factor, in which the organism associates background cues (CSs) with the reinforcing outcome (O). As discussed earlier, this type of learning can allow the CS to evoke a variety of behaviors as well as emotional reactions (and motivational states) that can additionally motivate instrumental action.

In modern terms, the instrumental factor is represented by the organism learning a direct (and similar) association between the instrumental action (R) and the reinforcer (O). Evidence for this sort of learning comes from experiments on *reinforcer devaluation* (Fig. 3.3–7). In such experiments, the organism can first be trained to perform two instrumental actions (e.g., pressing a lever and pulling a chain), each paired with a different reinforcer (e.g., food pellet vs. a liquid sucrose solution). In a separate second phase, one of the reinforcers (e.g., pellet) is paired with illness,

Telegram: @medical_k

www.konkur.in

which creates the conditioning of a powerful taste aversion to the reinforcer. In a final test, the organism is returned to the instrumental situation and is allowed to perform either instrumental action. No reinforcers are presented during the test. The result is that the organism no longer emits the action that produced the reinforcer that is now aversive. In order to perform this way, the organism must have (1) learned which action produced which reinforcer and (2) combined this knowledge with the knowledge that it no longer likes or values that reinforcer. The result cannot be explained by the simpler, more traditional view that reinforcers merely stamp in or strengthen instrumental actions.

We have already seen that organisms also need to learn how reinforcers influence a particular motivational state—the process called "incentive learning." Incentive learning is crucially involved in instrumental learning as a process through which the animal learns the value of the reinforcer. Thus, in the reinforcer devaluation experiment shown in Figure 3.3–7, an important thing that occurs in the second phase is that the organism must actually contact the reinforcer and learn that it does not like it. As described earlier, incentive learning is probably always involved in making outcomes (and the associated actions that produce them) more or less desirable.

Telegram: @medical_k

www.konkur.in

FIGURE 3.3–7. The reinforcer devaluation effect. **A:** Experimental design (see text). **B:** Results of the test session. The result indicates the importance of the response–reinforcer association in operant learning. For the organism to perform the way it does during testing, it must learn which action leads to which reinforcer and then choose to perform the action that leads to the outcome it currently liked or valued. (Reproduced from Bouton ME. *Learning and Behavior: A Contemporary Synthesis*. 2nd ed. Copyright © 2007 by Sinauer Associates, Inc, with permission of Oxford University Press. Data from Colwill RM, Rescorla RA. Associative Structures in Instrumental Learning. In: Bower GH, ed. *The Psychology of Learning and Motivation, Vol. 20.* Academic Press; 1986:55–104.)

The Pavlovian factor is represented by the S-O association in Figure 3.3–6. As noted earlier, whenever organisms earn reinforcers, they can also associate cues in the environment with them. Such S-O (Pavlovian) learning can have the many effects on behavior that were reviewed earlier: S may evoke approach behaviors, and S may elicit many other responses that generally get the organism ready for O. S may also remind the organism of O—it serves as a retrieval cue. In addition, as also mentioned earlier, the presentation of S may excite or motivate the instrumental response through Pavlovian-instrumental transfer: When a CS that is associated with a US (O) is presented while an organism performs an instrumental action that earns O, the rate of responding increases. CSs that predict the O (excitors) increase the rate of the

Telegram: @medical_k

www.konkur.in

instrumental behavior, whereas CSs that predict the nonoccurrence of O (inhibitors) decrease it. An S that predicts O can excite instrumental behaviors that lead to other Os that are motivationally similar—such as two different types of food. On the other hand, CSs are especially likely to increase responses that are associated with the *same* O. Thus, in addition to motivating instrumental responding in a general way, Pavlovian cues can influence choice of some actions over others. This capacity is presumably exploited by advertisers who create Ss in the form of television commercials, for example, whose presentation can motivate the consumer to buy a particular brand of pizza or a particular brand of beer.

Other experiments have illustrated the other associations to the stimulus that are represented in Figure 3.3–6. In addition to being directly associated with the reinforcer, a stimulus can signal a relation between an action and an outcome. This is called *occasion setting*: Instead of eliciting a response directly, stimuli in operant situations can set the occasion for the operant response. There is good evidence that they do so by signaling a specific response–reinforcer relationship. For example, in one experiment, rats learned to lever press and chain pull in the presence of a background noise and a background light. When the noise was present, lever pressing yielded a pellet reinforcer and chain pulling yielded sucrose. In contrast, when the light was present, the relations were reversed: Lever pressing yielded sucrose and chain pulling yielded pellet. There was evidence that the subjects (rats) learned the corresponding relationships. In a second phase, pellets were associated with illness, so the rat no longer valued the pellet. In a final test, the rats were allowed to lever press or chain pull in extinction in the presence of noise or light present during separate tests. In the presence of the noise, the animals chain pulled rather than lever pressed. When the light was present, the animals lever pressed rather than chain pulled. Thus, the noise informed the rat that lever press yielded pellet, and the light informed the rat that the chain pull did. This is the occasion-setting function illustrated in Figure 3.3–6.

It is worth noting that other stimuli besides lights and noises set the occasion for operant behavior. Modern research on learning in animals has underscored the importance of other stimuli such as contexts (see Table 3.3–1), temporal and spatial cues, and certain perception and memory processes. A particularly interesting example of research on the *stimulus control* of operant behavior is categorization. Pigeons can be

Telegram: @medical_k

www.konkur.in

shown images of different cars, chairs, flowers, and humans on a computer screen positioned on the wall of a Skinner box. Pecking one of four keys in the presence of these images is reinforced in the presence of any picture containing a car, a chair, a flower, or a human. Of interest, as the number of exemplars in each category increases, the pigeon makes more errors as it learns the discrimination. However, more exemplars creates better learning in the sense that it is more ready to transfer to new test images—after many examples of each category, the pigeon is more accurate at categorizing (and responding accurately to) new stimuli. One implication is that training new behaviors in a variety of settings or ways will enhance generalization to new situations.

The final association in Figure 3.3–6 is simple *habit learning*, or a direct association between the stimulus and the response. Through this association, triggering cues in the background may elicit the instrumental action quite directly, without the intervening cognition of R-O and the valuation of O. Although S-R learning was once thought to dominate learning, the current Zeitgeist envisions it as developing only after extensive and consistent practice. In effect, actions that have been performed repeatedly (and repeatedly associated with the reinforcer) become automatic and routine. Habit learning has been recognized by psychologists dating back (at least) to William James in the 19th century. It is thought to be functional, because automatic, “mindless” responses can free the behaving individual to process other things besides moment-to-moment behavior. Of course, habits can also become maladaptive and are thought to play a role in obsessive-compulsive and addictive behaviors. Interestingly, habit learning can be hastened in laboratory animals by exposure to many drugs of abuse.

Habits can be distinguished from goal-directed actions (those that depend on processing R-O) experimentally. One source of evidence is the fact that the reinforcer devaluation effect—which implicates a kind of cognitive mediation of operant behavior—no longer occurs after extensive instrumental training, as if the animal reflexively engages in the response without remembering the actual outcome it produces. It seems reasonable to expect that many pathologic behaviors that come into the clinic might also be automatic and blind through repetition. Interestingly, the evidence suggests that the eventual dominance of the S-R habit in behavior does not replace or destroy more cognitive mediation by learned S-O, R-O, and/or S-(R-O) relations. Under some conditions, even a habitual

Telegram: @medical_k

www.konkur.in

response might be brought back under the control of the action–reinforcer association and become goal-directed again. The conversion of actions to habits, the role of habit in addiction, and the relation of habit to cognition is currently an active area of research.

3.4 Biology of Memory

Shruti Dave, Ph.D., and Joel L. Voss, Ph.D.

Telegram: @medical_k

www.konkur.in

The topic of memory is fundamental to the discipline of psychiatry. Memory is the glue that binds mental life, the scaffolding for personal history. Personality is in part an accumulation of habits that have been acquired, many very early in life, which create dispositions and influence behavior. In the same sense, many psychiatric illnesses often involve learning—anxieties, phobias, and maladaptive behaviors that result from particular experiences. Psychotherapy itself is a process by which new habits and skills are acquired through the accumulation of new experiences. In this sense, memory is at the theoretical heart of psychiatry's concern with personality, the consequences of life experience, and the possibility of growth and change.

Memory is also of clinical interest because disorders of memory and complaints about memory are common in neurologic and psychiatric illnesses, such as dementia and schizophrenia. Memory impairment is also a side effect of certain treatments, such as electroconvulsive therapy. Accordingly, the effective clinician needs to understand something of the biology of memory, the varieties of memory dysfunction, and how memory can be evaluated.

MULTIPLE TYPES OF MEMORY

What is ordinarily meant by the term memory in everyday language typically falls within the definition of *declarative memory*. Declarative memory supports the conscious recollection of facts and events, including memory for episodes of experience, routes, lists, faces, melodies, objects, odors, and other verbal and nonverbal material across multiple sensory modalities. However, memory is not a single faculty of the mind but consists of various subtypes. Skill learning, habit learning, and simple forms of conditioning are included in a collective set of abilities termed *nondeclarative memory*.

Initial conceptualizations of human memory systems were derived from patients with amnesia. Individuals with amnesia typically show specific impairments of declarative memory alongside broad preservation of nondeclarative memory. Therefore, early information about the brain regions supporting acquisition and access to memories spotlighted declarative memory.

Declarative Memory in Amnesia

Telegram: @medical_k

www.konkur.in

The hallmark of *amnesia* is a loss of new learning ability that extends across all sensory modalities and stimulus domains. This *anterograde amnesia* can be explained by understanding the role of brain structures critical for acquiring information about facts and events. Typically, anterograde amnesia occurs together with *retrograde amnesia,* a loss of knowledge that was acquired before the onset of amnesia. Retrograde deficits often have a temporal gradient, following a principle known as the Ribot law; deficits are most severe for information that was most recently learned. A patient with a presentation of amnesia exhibits severe memory deficits in the context of preservation of other cognitive functions, including language comprehension and production, reasoning, attention, immediate memory, personality, and social skills. The selectivity of the memory deficit in these cases implies that intellectual and perceptual functions of the brain are separated from the capacity to maintain in memory the records that ordinarily result from engaging in intellectual and perceptual work.

The Anatomy of Anterograde Amnesia

Studies of a patient with severe amnesia, known as HM, stimulated intensive investigation of the role of the *medial temporal lobe* in memory. HM became amnesic in 1953, at 27 years of age, when he sustained a bilateral resection of the medial temporal lobe to relieve severe epilepsy. The removal included approximately one-half of the hippocampus, the amygdala, and most of the neighboring entorhinal and perirhinal cortices (Fig. 3.4–1). After the surgery, HM's seizure condition was much improved, but he experienced profound forgetfulness. His intellectual functions were generally preserved. For example, HM exhibited normal immediate memory, and he could maintain his attention during conversations. After an interruption, however, HM could not remember what had recently occurred. HM's dense amnesia was permanent and debilitating. In HM's words, he felt as if he were just waking from a dream because he had no recollection of what had just taken place.

Telegram: @medical_k

www.konkur.in

Another well-characterized patient, EP, was diagnosed with herpes simplex encephalitis at 72 years of age. Damage to the medial temporal lobe region (Fig. 3.4–1) produced persistent and profound amnesia. During testing sessions, EP was cordial and talked freely about his life experiences, but he relied exclusively on stories from his childhood and early adulthood. He would repeat the same story many times. Strikingly his performance on tests of recognition memory was no better than would result from guessing (Fig. 3.4–2A). Tests involving facts about his life and autobiographical experiences revealed poor memory for the time leading up to his illness but normal memory for his childhood (Fig. 3.4–2B). EP also had good spatial knowledge about the town in which he lived as a child, but he was unable to learn the layout of the neighborhood where he lived after he became amnesic (Fig. 3.4–2C).

Damaged tissue is indicated by bright signal in these T2-weighted axial images. Both patients sustained extensive damage to medial temporal structures as the result of surgery for epilepsy in HM and as the result of viral encephalitis in EP. Scale bar: 2 cm. L, left side of the brain. (H.M. image from Corkin S, Amaral EG, González RG, Johnson KA, Hyman BT. HM's medial temporal lobe lesion: findings from magnetic resonance imaging. *J Neurosci*. 1997;17:3964. doi:10.1523/JNEUROSCI.17-10-03964.1997. Copyright © 1997 Society for Neuroscience.) (E.P. image from Stefanacci L, Buffalo EA, Schmolck H, Squire LR. Profound amnesia after damage to the medial temporal lobe: a neuroanatomical and neuropsychological profile of patient E.P. *J Neurosci.* 2000;20:7024. doi:10.1523/JNEUROSCI.20-18-07024.2000. Copyright © 2000 Society for Neuroscience.)

Given the severity of the memory problems experienced by EP and other patients with amnesia, it is noteworthy that these patients nonetheless perform normally on certain kinds of memory tests, as described below. The impairment selectively concerns memory for factual knowledge and autobiographical events, that is, declarative memory. Amnesia presents as a global deficit in that it involves memory for information presented in any sensory modality, but the deficit is limited in that it covers only memory for facts and events.

Telegram: @medical_k

www.konkur.in

In another patient, RB, an episode of global ischemia after cardiac surgery led to moderately severe anterograde amnesia and retrograde amnesia, less severe than in patients HM and EP. After his death 5 years later, a detailed histologic study of his brain revealed that amnesia in RB was the result of a circumscribed bilateral lesion of hippocampal field CA1 (Fig. 3.4–3). Similar histologic evidence of hippocampal damage has been obtained in other patients with amnesia.

Hippocampal pathology in patients with anterograde amnesia was also revealed using high-resolution magnetic resonance imaging (MRI). Such studies indicate that damage limited to the hippocampus results in clinically significant memory impairment. In addition to the hippocampus, other medial temporal lobe regions also make critical contributions to memory. Thus, a moderately severe memory impairment results from CA1 damage (as in patient RB), whereas a more profound and disabling amnesia results from medial temporal lobe damage that includes the hippocampus and adjacent cortex (as in patients HM and EP).

Amnesia due to medial temporal lobe damage is also typical in patients with Alzheimer disease. Hallmark neuropathologic features of Alzheimer disease begin in the medial temporal lobes and then spread throughout the brain with disease progression. Thus, declarative memory impairments are chief cognitive symptoms early in the disease progression, including in the prodromal period of “amnestic mild cognitive impairment,” with substantial cognitive deficits in addition to declarative memory dysfunction increasing with progression.

Amnesia can also result from damage to structures of the *medial diencephalon*. The critical regions damaged in diencephalic amnesia include the mammillary nuclei in the hypothalamus, the dorsomedial nucleus of the thalamus, the anterior nucleus, the internal medullary lamina, and the mammillothalamic tract. However, uncertainty remains regarding which specific lesions are required to produce diencephalic amnesia. *Alcoholic Korsakoff syndrome* is the most prevalent and best-studied example of diencephalic amnesia, and in these cases, the damage is found in brain regions that may be especially sensitive to prolonged bouts of thiamine deficiency and alcohol abuse. Patients with alcoholic Korsakoff syndrome typically exhibit memory impairment due to

Telegram: @medical_k

www.konkur.in

a combination of diencephalic damage and frontal lobe pathology. Frontal damage alone produces characteristic cognitive deficits along with certain memory problems (e.g., in effortful retrieval and evaluation); in Korsakoff syndrome, the pattern of deficits thus extends beyond what is commonly found in other cases of amnesia (Table 3.4–1).

Telegram: @medical_k

www.konkur.in

FIGURE 3.4–2. Formal test results from patient EP show severe anterograde and retrograde deficits, with intact remote memory. **A:** Scores were combined from 42 different tests of recognition memory for words given to patient EP and a group of five healthy control subjects. The testing format was either two-alternative forced-choice or yes–no recognition. Brackets for EP indicate the standard error of the mean. Data points for the control group indicate each participant's mean score across all 42 recognition memory tests. EP's average performance (49.3% correct) was not different from chance and was approximately five standard deviations (SDs) below the average performance of control subjects (81.1% correct; SD, 6.3). **B:** Autobiographical remembering was quantified by using a structured interview known as the autobiographical memory interview. Items assessed personal semantic knowledge (maximum score: 21 for each time period). Performance for the recent time period reflects poor memory for information that could have been acquired only subsequent to the onset of his amnesia. For EP, performance for the early adult period reflects retrograde memory deficits. Performance for the childhood period reflects good remote memory. Similar results for semantic and episodic remembering were obtained from these time periods. (Data from Kopelman MD, Wilson BA, Baddeley AD. The autobiographical memory interview: a new assessment of autobiographical and personal semantic memory in amnesic patients. *J Clin Exp Neuropsychol*. 1989;11:724 and Reed JM, Squire LR. Retrograde amnesia for facts and events: findings from four

Telegram: @medical_k

www.konkur.in

new cases. *J Neurosci*. 1998;18:3943.) **C:** Assessments of spatial memory demonstrated EP's good memory for spatial knowledge from his childhood along with extremely poor new learning of spatial information. Performance was compared to that of five individuals (*empty circles*) who attended EP's high school at the same time as he did, lived in the region over approximately the same time period, and, like EP (*filled circle*), moved away as young adults. Normal performance was found for navigating from home to different locations in the area (familiar navigation), between different locations in the area (novel navigation), and between these same locations when a main street was blocked (alternative routes). Subjects were also asked to point to particular locations while imagining themselves in a particular location (pointing to landmarks), or they were asked about locations in the neighborhoods in which they currently lived (new topographical learning). EP showed difficulty only in this last test because he moved to his current residence after he became amnesic. (Adapted from Teng E, Squire LR. Memory for places learned long ago is intact after hippocampal damage. *Nature.* 1999;400:675.)

There are also a variety of neocortical areas that work in concert with the medial temporal lobes and diencephalon to accomplish declarative memory. In particular, anatomical studies in nonhuman primates have identified specific areas of medial prefrontal, lateral temporal, and medial and lateral parietal cortex that are reciprocally connected to the medial temporal lobe and noninvasive neuroimaging has confirmed this distributed network of the hippocampus in humans (Fig. 3.4–4). Even small brain lesions within this network can produce a similar amnestic syndrome as that resulting from bilateral hippocampal damage. Thus, declarative memory is not accomplished only by the hippocampus and diencephalon, but rather a large and distributed network makes crucial contributions.

In summary, the ability to remember factual and autobiographical events depends on the integrity of a large-scale brain network centered on the hippocampus. Thus, studies point to a critical role for medial temporal and diencephalic brain areas, in concert with widespread areas of the neocortex, during the formation and storage of declarative memories (Fig. 3.4–5).

Retrograde Amnesia and Memory Consolidation. Whereas memory loss in amnesia typically affects recent memories more than remote memories (Fig. 3.4–6), temporally graded amnesia also has been demonstrated retrospectively in studies of amnesic patients and prospectively in studies of monkeys, rats, mice, and rabbits. These

Telegram: @medical_k

www.konkur.in

findings have important implications for understanding the nature of the memory storage process. Memories are dynamic, not static. As time passes after learning, some memories are forgotten, whereas others become stronger due to a process of *consolidation* that depends on cortical, medial temporal, and diencephalic structures.

The study of retrograde amnesia has therefore been important for understanding how memory changes over time. The dynamic nature of memory storage can be conceptualized as follows. An event is experienced and encoded by virtue of a collection of cortical regions that are involved in representing a combination of different event features. At the same time, the hippocampus and adjacent cortex receive pertinent high-level information from all sensory modalities. Later, when the original event is recalled, the same set of cortical regions is activated. If a subset of the cortical regions is activated, the hippocampus and related structures can facilitate recall by facilitating the activation of the remaining cortical regions (i.e., pattern completion). When the original event is retrieved and newly associated with other information, hippocampal–cortical networks can be modified. In this way, a gradual consolidation process occurs that changes the nature of memory storage (Fig. 3.4–4). The neocortical components representing some events can become so effectively linked together that ultimately a memory can be retrieved without any contribution from the medial temporal lobe. As a result, amnesic patients can exhibit normal retrieval of remote facts and events, as well as autobiographical memories. Distributed neocortical regions are the permanent repositories of these enduring memories.

prefer an odorous food as the result of an encounter with another rat with that odor on its breath. Percent preference for the familiar food was observed for three training-surgery intervals. At 1 day after learning, the control group performed significantly better than the rats with lesions (P < .05). At 30 days, the two groups performed similarly, and both groups performed well above chance. *Error bars* show standard errors of the mean. (Part B reprinted from Clark RE, Broadbent NJ, Zola SM, Squire LR. Anterograde amnesia and temporally graded retrograde amnesia for a nonspatial memory task after lesions of hippocampus and subiculum. *J Neurosci.* 2002;22:4663. doi:10.1523/JNEUROSCI.22-11-04663.2002. Copyright © 2002 Society for Neuroscience.)

In contrast to what is observed after damage restricted to the hippocampus, extensive retrograde impairments for facts and events from the distant past can also occur. Damage to the *frontal lobes*, for example, can lead to difficulty in organizing memory retrieval. Accurate retrieval often begins with the activation of lifetime periods and proceeds to the identification of general classes of events and then more specific events, but this process becomes difficult following frontal damage. Damage to other cortical regions can also impair memory storage. Networks in the anterolateral temporal cortex, for example, are critical for retrieving stored information because these areas are important for long-term storage itself. Patients with *focal retrograde amnesia* exhibit substantial retrograde memory impairments together with only moderately impaired new learning ability. Some capacity for new learning remains, presumably because medial temporal lobe structures are able to communicate with other areas of the cortex that remain undamaged.

Although amnesia does not typically occur after limited frontal damage, the frontal lobes are fundamentally important for declarative memory. Patients with frontal lesions have a poor memory for the context in which information was acquired, they have difficulty in unaided recall, and they may even have some mild difficulty on tests of item recognition. More generally, frontal patients have difficulty implementing memory retrieval strategies and evaluating and monitoring their memory performance.

www.konkur.in

Patient BG suffered an infarction restricted to the right frontal lobe, resulting in substantial false remembering. He had an abnormal tendency to claim that some stimuli were familiar, even though they had not been presented for study. His false responses probably arose because he relied on a general feeling of familiarity for the kind of stimuli that had been presented rather than on specific memories for the stimuli.

THE ROLE OF SLEEP IN MEMORY CONSOLIDATION. The speculation that memories are processed during sleep has a long history. Freud noted that dreams could reveal fragments of recent experiences in the form of day residues. Although many questions about how and why memories may be processed during sleep remain unresolved, recent experiments have provided new empirical support to bolster the idea that memory processing during sleep serves an adaptive function related to memory consolidation. It is now clear that memory performance can be facilitated when sleep occurs after initial learning and that sleep-related facilitation can be observed for many different types of memory.

Memory consolidation appears to be specifically aided by processing during deep sleep in the nights after learning, especially in the stage of sleep known as *slow-wave sleep,* and probably also in other sleep stages. Some results indicate that slow-wave sleep facilitates the storage of declarative memories but not nondeclarative memories. Direct evidence for this proposal has been obtained using stimulation with olfactory stimuli (Fig. 3.4–7), stimulation with direct-current electrical input at the approximate frequency of EEG slow oscillations, and other methods. A fruitful approach for studying memory processing during sleep is to use sensory stimulation to activate specific memories, which then may be subject to modification. Neuronal recordings in animals have revealed a phenomenon of hippocampal replay, whereby activity patterns expressed during the day are later observed during sleep. Research is now focused on delineating the neurophysiologic events that transpire when memories are reactivated and altered during sleep. A novel conjecture, supported by some recent empirical findings, is that adapting these procedures for memory modification during sleep could be used to treat unwanted learned associations, such as those involved in nicotine craving (Fig. 3.4–8). In summary, declarative memories acquired during waking can be

Telegram: @medical_k

www.konkur.in

processed again during sleep, and this processing can influence the likelihood of subsequent memory retrieval when the individual is awake.

FIGURE 3.4–7. Evidence for memory processing during sleep. Subjects first learned object location associations when a rose odor was present. Following learning, subjects slept wearing a device for delivering odors to the nose, and the rose odor was administered during the first two slow-wave sleep periods of the night (in 30-s periods to prevent habituation). Memory facilitation was observed when object–location associations were tested the following morning in the absence of odor stimulation. Facilitated memory was not found when stimulation occurred during slow-wave sleep but not during learning, when stimulation occurred during learning and then during REM sleep, or when subjects were kept awake. Moreover, odor stimulation during slow-wave sleep was found to produce anterior and posterior hippocampal activation (**lower panels**). (From Rasch B, Büchel C, Gais S, Born J. Odor cues during slow-wave sleep prompt declarative memory consolidation. *Science*. 2007;315:1426. Reprinted with permission from AAAS. doi:10.1126/science.1138581.)

Olfactory aversive conditions during sleep reduces cigarette-smoking behavior. *J Neurosci.* 2014;34:15382–15393. doi:10.1523/JNEUROSCI.2291-14.2014.)

Nondeclarative Memory

The acquisition of perceptual, perceptual–motor, and cognitive skills—that is, nondeclarative memory—can occur independent from declarative memory, and patients with amnesia acquire these skills at rates equivalent to the rates at which healthy individuals acquire the skills. For example, patients with amnesia can learn to read mirror-reversed text normally, they exhibit the normal facilitation in reading speed with successive readings of normal prose, and they improve as rapidly as healthy individuals at speed reading repeating nonwords. In addition, patients with amnesia can, after seeing strings of letters generated by a finite-state rule system, classify novel strings of letters as rule based or not rule based. Classification performance is normal despite the fact that patients with amnesia are impaired at remembering the events of training or the specific items they have studied.

Priming

Telegram: @medical_k

www.konkur.in

Priming refers to the facilitation of the ability to detect or to identify a particular stimulus based on a specific recent experience. Many tests have been used to measure priming in amnesia and show that it is intact. For example, words might be presented in a study phase and then again, after a delay, in a test phase when a priming measure such as reading speed is obtained. Patients are instructed to read words as quickly as possible in such a test, and they are not informed that memory is being assessed.

In one priming test, patients named pictures of previously presented objects reliably faster than they named pictures of new objects, even after a delay of a week. This facilitation occurred at normal levels, despite the fact that the patients were markedly impaired at recognizing which pictures had been presented previously. Particularly striking examples of preserved priming come from studies of patient EP (Fig. 3.4–9), who exhibited intact priming for words but performed at chance levels when asked to recognize which words had been presented for study. This form of memory, termed *perceptual priming,* is thus a distinct class of memory that is independent of the medial temporal lobe regions typically damaged in amnesia.

Another form of priming reflects improved access to meaning rather than percepts. For example, subjects study a list of words, including *tent* and *belt,* and then are asked to free associate to other words. Thus, they are given words such as *canvas* and *strap* and asked to produce the first word that comes to mind. The result is that subjects are more likely to produce *tent* in response to *canvas* and to produce *belt* in response to *strap* than if the words *tent* and *belt* had not been presented recently. This effect, called *conceptual priming,* is also preserved in patients with amnesia, even though they fail to recognize the same words on a conventional memory test (Fig. 3.4–10).

Yet, not all types of priming are preserved in amnesia. Some priming tests have been designed to examine the formation of new associations. When priming tests are based not on pre-existing knowledge but rather on the acquisition of new associative knowledge, priming tends to be impaired. In other words, priming in certain complex situations can require the same type of linkage among multiple cortical regions that is critical for declarative memory.

CORTICAL ORGANIZATION OF MEMORY

Telegram: @medical_k

www.konkur.in

Contributions from Animal Models

Findings from human patients with amnesia helped to motivate the creation of animal models examining the locus of memory storage in the brain. In the 1920s, Karl Lashley searched for the site of memory storage by studying the behavior of rats following the removal of different amounts of cerebral cortex. He recorded the number of trials needed to relearn a maze problem that rats learned prior to surgery, and he found that the deficit was proportional to the amount of cortex removed. The deficit did not seem to depend on the particular location of cortical damage. Lashley concluded that the memory resulting from maze learning was not localized in any one part of the brain but instead was distributed equivalently over the entire cortex.

www.konkur.in

FIGURE 3.4–9. Preserved priming in patient EP relative to seven control subjects. **A:** Stem-completion priming on six separate tests. Priming reflected a tendency for subjects to complete three-letter stems with previously encountered words when they were instructed to produce the first word to come to mind (e.g., MOT___ completed to form MOTEL). Priming scores were calculated as percent correct for studied words minus percent correct for

Telegram: @medical_k

www.konkur.in

baseline words (guessing). **B:** Perceptual-identification priming on 12 separate tests. Subjects attempted to read 48 words that were visually degraded. Priming scores were calculated as percent correct identification of previously studied words minus percent correct identification of nonstudied words. Brackets indicate the standard error of the mean. (Copyright © 1997 by American Psychological Association. Reproduced with permission. Hamann SB, Squire LR. Intact perceptual memory in the absence of conscious memory. *Behav Neurosci*. 1997;111:850. No further reproduction or distribution is permitted without written permission from the American Psychological Association.)

Subsequent research has led to reinterpretations of these results. Maze learning in rats depends on different types of information, including visual, tactile, spatial, and olfactory information. Importantly, neurons that process these various types of information are segregated into different areas of the rat cerebral cortex, and memory storage is segregated in a parallel manner. Thus, the correlation between maze learning abilities and lesion size that Lashley observed is a result of progressive encroachment of larger lesions on specialized cortical areas serving the many components of information processing relevant for maze learning.

www.konkur.in

FIGURE 3.4–10. Preserved conceptual priming in amnesia. In the free association test, subjects studied a set of words (e.g., lemon) and 5 minutes later viewed cue words that included associates of studied words (e.g., orange). Subjects were asked to produce the first word that came to mind in response to each cue word. Results are shown separately for the control group (CON, n = 12), amnesic patients with large medial temporal lobe lesions (MTL, n = 2), and amnesic patients with lesions thought to be limited to the hippocampal region (H, n = 3). The **left panel** shows conceptual priming scores computed as the percentage of studied words produced in the free association test minus a baseline measure of the likelihood of producing those words by chance. All the groups performed similarly in the conceptual priming test. The **right panel** shows results from a yes–no recognition memory test using comparable words. Both patient groups were impaired relative to the control group. The *dashed line* indicates chance performance. The data points for the MTL and H groups show the scores of individual patients averaged across four separate tests. *Brackets* show standard errors of the mean for the control group. (From Levy DA, Stark CEL, Squire LR. Intact conceptual priming in the absence of declarative memory. *Psych Sci*. 2004;15:680.)

In monkeys, many parallels to human amnesia have been demonstrated following surgical damage to anatomical components of the medial temporal lobe. Cumulative study of the resulting memory impairment eventually identified the medial temporal structures and connections that are crucial for memory. These include the hippocampus —which includes the dentate gyrus, hippocampal fields CA1, CA2, and CA3, and the subiculum—and also the adjacent cortical regions, including the entorhinal, perirhinal, and parahippocampal cortices.

The cortical areas responsible for processing and storing visual information have been studied most extensively in nonhuman primates, with nearly one-half of the primate neocortex specialized for visual functions. As shown in Figure 3.4–11, the cortical pathways for visual

Telegram: @medical_k

www.konkur.in

information processing begin in the primary visual cortex (V1) and proceed from there along parallel pathways or streams. One stream projects ventrally to the inferotemporal cortex and is specialized for processing information concerning the identification of visual objects. Another stream projects dorsally to the parietal cortex and is specialized for processing spatiotemporal information. These distinct processing streams converge on the medial temporal lobe and hippocampus, motivating the theoretical view that the hippocampus serves its critical role in memory based on its ability to bind information about what is perceived with its spatiotemporal context.

Specific visual processing areas in the dorsal and ventral streams, together with areas in the prefrontal cortex, register the immediate experience of perceptual processing. The results of perceptual processing are first available as *immediate memory.* Immediate memory refers to the amount of information that can be held in mind (like a telephone number) so that it is available for immediate use. Immediate memory can be extended in time by rehearsing or otherwise manipulating the information, in which case what is stored is now said to be in *working memory.*

Regions of the visual cortex in the forward portions of the dorsal and ventral streams serve as the ultimate repositories of visual memories. The inferotemporal cortex, for example, lies at the end of the ventral stream, and inferotemporal lesions lead to selective impairments in both visual object perception and visual memory. Yet, such lesions do not disrupt elementary visual functions, such as acuity. Electrophysiologic studies in the monkey show that neurons in area TE, which is one part of the inferotemporal cortex, register specific and complex features of visual stimuli, such as shape, and respond selectively to patterns and objects. The inferotemporal cortex can thus be thought of as both a higher-order visual processing system and a storehouse of the visual memories that result from that processing.

In sum, memory is distributed and localized in the cerebral cortex. Memory is distributed in the sense that, as Lashley concluded, there is no cortical center dedicated solely to the storage of memories. Yet, memory is localized in the sense that different aspects or dimensions of events are stored at specific cortical sites—namely, in the same regions that are specialized to analyze and process what is to be stored.

Classical Conditioning

Telegram: @medical_k

www.konkur.in

The study of classical conditioning has provided many insights into the biology of memory. Classical conditioning has been especially well studied in rabbits using a tone as the conditioned stimulus and an air puff to the eye (which automatically elicits a blink response) as the unconditioned stimulus. Repeated pairings of the tone and the air puff lead to a conditioned response, in that the tone alone elicits an eye blink. Reversible lesions of the deep nuclei of the cerebellum eliminate the conditioned response without affecting the unconditioned response. These lesions also prevent initial learning from occurring, and when the lesion is reversed, rabbits learn normally. Thus, the cerebellum contains essential circuitry for the learned association. The relevant plasticity appears to be distributed between the cerebellar cortex and the deep nuclei.

An analogous pattern of cerebellar plasticity is thought to underlie motor learning in the vestibulo-ocular reflex and, perhaps, associative learning of motor responses in general. Based on the idea that learned motor responses depend on coordinated control of changes in timing and strength of the response, it has been suggested that synaptic changes in the cerebellar cortex are critical for learned timing, whereas synaptic changes in the deep nuclei are critical for forming an association between a conditioned stimulus and an unconditioned stimulus.

FIGURE 3.4–11. Summary of cortical visual areas and some of their connections. Two major cortical pathways begin from area V1, also known as striate cortex or primary visual cortex, and which receives visual input from the retina by way of the lateral geniculate nucleus of the thalamus. The processing stream for object vision follows a ventral route into the temporal lobe, and the processing stream for spatial vision follows a dorsal route into the parietal lobe, which then projects into the temporal lobe. The convergence of these two processing streams in the medial temporal lobe, including hippocampus, provides an anatomical rationale for the key role of this area in constructing and retrieving memories comprised different sorts of episodic and

Fear conditioning and fear-potentiated startle are types of learning that serve as useful models for anxiety disorders and related psychiatric conditions. For example, mice exhibit freezing behavior when returned to the same context in which aversive shock was delivered on an earlier occasion. This type of learning depends on the encoding of contextual features of the learning environment. Acquiring and expressing this type of learning requires neural circuits that include both the amygdala and the hippocampus. The amygdala may be important for associating negative affect with new stimuli. The hippocampus may be important for representing the context. With extinction training, when the context is no longer associated with an aversive stimulus, the conditioned fear response fades. The frontal cortex is thought to play a key role in extinction.

Contributions from Neuroimaging

The understanding of memory derived from studies of amnesia and animal models has been extended through studies using various methods for monitoring brain activity in healthy individuals. For example, studies of brain activity measured using positron emission tomography (PET) and functional MRI show that posterior prefrontal regions are involved in strategic processing during retrieval, as well as in working memory. Anterior frontal regions near the frontal poles have been linked with functions such as evaluating the products of retrieval. Frontal connections with posterior neocortical regions support the organization of retrieval and the manipulation of information in working memory. Consistent with the evidence from patients with frontal lesions, frontal–posterior networks can be viewed as instrumental in the retrieval of declarative memories and in the online processing of new information.

Neuroimaging has also identified contributions to memory made by the parietal cortex. Multiple parietal regions (including inferior and superior parietal lobules, precuneus, posterior cingulate, and retrosplenial cortex)

Telegram: @medical_k

www.konkur.in

are activated in conjunction with remembering recent experiences. Although many functions have been hypothesized to explain this parietal activity, a consensus position has not yet been reached, and it may be the case that several different functions are relevant.

Neuroimaging studies have also illuminated priming phenomena and how they differ from declarative memory. Perceptual priming appears to reflect changes in the early stages of the cortical pathways that are engaged during perceptual processing. For example, in the case of stem-completion priming, where subjects study a list of words (e.g., MOTEL) and then are tested with a list of stems (e.g., MOT___) and with instructions to complete each stem with the first word to come to mind, neuroimaging and divided visual-field studies have implicated visual processing systems in extrastriate cortex, especially in the right hemisphere. In contrast, conscious recollection of remembered words engages brain areas at later stages of processing. Neural mechanisms supporting priming and declarative memory retrieval have also been distinguished in brain electrical activity recorded from the scalp (Fig. 3.4–12). In sum, priming differs from declarative memory in that it is signaled by brain activity that occurs more efficiently during memory retrieval and that originates in different brain regions. Recent findings suggest that brain activity related to both priming and declarative memory often occurs together, suggesting that multiple co-occurring memory processes are normally involved in memory retrieval. The degree to which processes involved in priming versus declarative memory work together to support healthy memory function is unknown and remains an intriguing focus of contemporary research.

www.konkur.in

FIGURE 3.4–12. Brain potentials associated with perceptual priming versus declarative memory retrieval. Paller et al. (2003) studied 16 volunteers who took a memory test involving three sorts of faces: new faces, faces they had seen recently and remembered well, and faces they had seen but did not remember because the faces had been presented too briefly to process effectively. In a companion experiment with a priming test, speeded responses were found indicative of priming. Frontal recordings of brain waves elicited by the primed faces included negative potentials from 200 to 400 ms after face presentation that differed from the brain waves elicited by new faces. These differences were particularly robust for trials with the fastest responses (data shown were from trials with responses faster than the median reaction time). Remembered faces uniquely elicited positive brain waves that began about 400 ms after face presentation. Brain potential correlates of face recollection occurred later than those for perceptual priming and were larger over posterior brain regions. (Adapted with permission from Paller KA, Hutson CA, Miller BB, Boehm SG. Neural manifestations of memory with and without awareness. *Neuron.* 38(3):507–516. FIGURE 3.4–13. Activity in the left and right hippocampal regions measured with functional magnetic resonance imaging (fMRI) during declarative memory retrieval. Data were collected from 11 participants who saw words at study and test and from 11 different participants who saw pictures of namable objects at study and test. Recognition memory accuracy was 80.2% correct for words and 89.9% correct for objects. Areas of significant fMRI signal change (targets vs. foils) are shown in sagittal sections as color overlays on averaged structural images. The *green box* indicates the area in which reliable data were available for all subjects. **A:** With words, retrieval-related activity was observed in the hippocampus on the left side. **B:** However, retrieval-related activity was not observed in the right hippocampus. **C–D:** With namable objects, retrieval-related activity was observed in the hippocampus on both the left side and the right side. (Adapted from Stark CE, Squire LR. Functional magnetic resonance imaging (fMRI) activity in the hippocampal region during recognition memory. *J Neurosci.* 2000;20:7776. doi: 10.1523/JNEUROSCI.20-20-07776.2000. Copyright © 2000 Society for Neuroscience.)

Hippocampal activity associated with the formation and retrieval of declarative memories has also been investigated with neuroimaging. In keeping with the neuropsychological evidence, the hippocampus appears to be involved in the recollection of recent events (Fig. 3.4–13). Retrieval-related hippocampal activity has been observed in memory tests with many different types of stimuli. The hippocampus is also active during the

Telegram: @medical_k

www.konkur.in

initial storage of information. Whereas the left inferior prefrontal cortex is engaged as a result of attempts to encode a word, hippocampal activity at encoding is more closely associated with whether encoding leads to a stable memory that can later be retrieved (Fig. 3.4–14). These findings confirm and extend the idea that medial temporal and frontal regions are important for memory storage and that they make different contributions.

Neuroimaging has also been useful in identifying the distributed network of brain regions involved in memory as well as how this network is disrupted by neurologic and psychiatric disorders. For instance, fMRI can be used to define the network of brain areas that presumably interact with the hippocampus by measuring correlations in brain activation while individuals perform memory tasks in addition to when they quietly rest in the MRI scanner. The strength of activity correlation within this hippocampal network predicts declarative memory performance. Many studies have identified reductions or increases in hippocampal network interactions in conditions such as schizophrenia and major depressive disorder (MDD) using fMRI, indicating that this is a promising method for identifying the neurobiologic causes of memory impairment in such disorders.

MEMORY SYSTEMS

One scheme for conceptualizing multiple types of memory appears in Figure 3.4–15. Declarative memory depends on medial temporal and midline diencephalic structures along with large portions of the neocortex. This system provides for the rapid learning of facts (*semantic memory*) and events (*episodic memory*). Nondeclarative memory depends on several different brain systems. Habits depend on the neocortex and the neostriatum. The cerebellum is important for the conditioning of skeletal musculature, the amygdala for emotional learning, and the neocortex for priming. This schematic is an oversimplification in the sense that it does not adequately account for the many examples of memory and other cognitive functions that are shared across regions that are ascribed to distinct “systems.” It is nonetheless a useful starting place for broadly matching observed impairments in individuals with neurologic or psychiatric disorders with potential causes in altered functional neuroanatomy.

FIGURE 3.4–14. Functional activations of prefrontal and medial temporal regions that were predictive of later memory performance. Single words were presented visually, each followed by an instruction to remember (R cue) or to forget (F cue). Trials were sorted based on the remember or forget instruction and on subsequent recognition performance. Activity in the left inferior prefrontal cortex and left hippocampus was predictive of subsequent recognition but for different reasons. **A:** Left inferior prefrontal activation was associated with the encoding attempt, in that responses were largest for trials with a cue to remember whether or not the word was actually recognized later. **B:** The time course of activity in this region was computed based on responses that were time locked to word onset (time 0). Left inferior prefrontal activity increased for words that were later remembered, but there was a stronger association with encoding attempt, as responses were larger for words followed by an R cue that were later forgotten than for words followed by an F cue that were later remembered. **C:** In contrast, left parahippocampal and posterior hippocampal activation was associated with encoding success. **D:** As shown by the time course of activity in this region, responses were largest for words that were subsequently remembered, whether the cue was

Telegram: @medical_k

www.konkur.in

to remember or to forget. (Adapted from Reber PJ, Siwiec RM, Gitelman DR, Parrish TB, Mesulam MM, Paller KA. Neural correlates of successful encoding identified using functional magnetic resonance imaging. *J Neurosci.* 2002;22:9541. doi: 10.1523/JNEUROSCI.22-21-09541.2002. Copyright © 2002 Society for Neuroscience.)

FIGURE 3.4–15. A taxonomy for subtypes of memory. Declarative memory refers to conscious recollection of facts and events. Nondeclarative memory refers to a collection of abilities wherein performance changes as the result of experience but without affording access to conscious memory of the original experience. Nonassociative learning includes habituation and sensitization. (Adapted with permission from Squire LR, Zola-Morgan S. The medial temporal lobe memory system. *Science*. 1991;253(5026):1380–1386. doi:10.1126/science.1896849.)

Declarative and nondeclarative memories differ in important ways. Declarative memory is phylogenetically more recent than nondeclarative memory. In addition, declarative memories are available to conscious recollection. The flexibility of declarative memory permits the retrieved information to be available to multiple response systems. Nondeclarative memory is inaccessible to awareness and is expressed only by engaging specific processing systems. Nondeclarative memories are stored as changes within these processing systems, changes that are encapsulated such that the stored information has limited access to other processing systems.

Semantic memory, which concerns general knowledge of the world, has often been categorized as a separate form of memory. Typically, facts that are committed to memory become independent of the original episodes in

Telegram: @medical_k

www.konkur.in

which the facts were learned. Patients with amnesia can sometimes acquire information that would ordinarily be learned as facts, but the patients learn it by relying on a different brain system than the system that supports declarative memory.

Consider a test requiring the concurrent learning of eight object pairs. Healthy individuals can rapidly learn which is the correct object in each pair, whereas patients with severe amnesia like EP learn only gradually over many weeks, and at the start of each session, they cannot describe the task, the instructions, or the objects. In patients who do not have severe amnesia, factual information is typically acquired as consciously accessible declarative knowledge. In these cases, the brain structures that remain intact within the medial temporal lobe presumably support learning. In contrast, when factual information is acquired as nondeclarative knowledge, as in the case of EP's learning of pairs of objects, learning likely occurs directly as a habit, perhaps supported by the neostriatum. Humans thus appear to have a robust capacity for habit learning that operates outside of awareness and independently of the medial temporal lobe structures that are damaged in amnesia.

FROM SYNAPSES TO MEMORY

Memory is a special case of the general biologic phenomenon of *neural plasticity.* Neurons can show history-dependent activity by responding differently as a function of prior input, and this plasticity of nerve cells and synapses is the basis of memory. In the last decade of the 19th century, researchers proposed that the persistence of memory could be accounted for by nerve cell growth. This idea has been restated many times since, and the current understanding of the synapse as the critical site of change is founded on extensive experimental studies in animals with relatively simple nervous systems. Experience can lead to structural change at the synapse, including alterations in the strength of existing synapses and alterations in the number of synaptic contacts along specific pathways.

Plasticity

Neurobiologic evidence supports two basic conclusions. First, short-lasting plasticity, which may last for seconds or minutes, depends on specific synaptic events, including an increase in neurotransmitter release. Second, long-lasting memory depends on new protein synthesis,

Telegram: @medical_k

www.konkur.in

the physical growth of neural processes, and an increase in the number of synaptic connections.

FIGURE 3.4–16. Neural substrates of false memories. **A:** Functional magnetic resonance imaging data were acquired in a learning phase when subjects read names of objects and visualized the referents. One-half of the names were followed 2 seconds later by a picture of the object. **B:** In a surprise memory test given outside the scanner, subjects listened to object names and decided whether they had seen a picture of the corresponding object. On some trials, subjects claimed to have seen a picture of an object that they had only imagined. **C:** Results showed that the left inferior prefrontal cortex and left anterior hippocampus were more active during learning in response to pictures later remembered compared to pictures later forgotten. **D:** Several different brain areas showed a greater response to words in the learning phase that were later falsely remembered as pictures, compared to words not misremembered. Activations that predicted false remembering were found in a brain network important for the generation of visual imagery in response to object names (precuneus, inferior parietal cortex, and anterior cingulate, shown in left, middle, and right images, respectively). (C and D adapted from Gonsalves B, Reber PJ, Gitelman DR, Parrish TB, Mesulam MM, Paller KA. Neural evidence that vivid imagining can lead to false remembering. *Psychol Sci*. 2004;15:655–660.)

A major source of information about memory has come from the extended study of the marine mollusk *Aplysia californica.* Individual neurons and connections between neurons have been identified, and the wiring diagrams of some simple behaviors have been described. *Aplysia* is capable of associative learning (including classic conditioning and operant conditioning) and nonassociative learning (habituation and sensitization). *Sensitization* had been studied using the gill-withdrawal reflex, a defensive reaction whereby tactile stimulation causes the gill and

Telegram: @medical_k

www.konkur.in

siphon to retract. When tactile stimulation is preceded by sensory stimulation to the head or tail, gill withdrawal is facilitated. The cellular changes underlying this sensitization begin when a sensory neuron activates a modulatory interneuron, which enhances the strength of synapses within the circuitry responsible for the reflex. This modulation depends on a second-messenger system whereby intracellular molecules (including cyclic adenosine monophosphate or cAMP and cAMP-dependent protein kinase) lead to enhanced transmitter release lasting for minutes in the reflex pathway. Both short- and long-lasting plasticity within this circuitry are based on enhanced transmitter release. The long-lasting change uniquely requires the expression of genes and the synthesis of new proteins. Synaptic tagging mechanisms allow gene products that are delivered throughout a neuron to increase synaptic strength selectively at recently active synapses. In addition, the long-term change, but not the short-term change, is accompanied by the growth of neural processes of neurons within the reflex circuit.

In vertebrates, memory cannot be studied quite as directly as in the simple nervous system of *Aplysia.* Nevertheless, it is known that behavioral manipulations can also result in measurable changes in the brain's architecture. For example, rats reared in enriched as opposed to ordinary environments show an increase in the number of synapses ending on individual neurons in the neocortex. These changes are accompanied by small increases in cortical thickness, in the diameter of neuronal cell bodies, and in the number and length of dendritic branches. The behavioral experience thus exerts powerful effects on the wiring of the brain.

Many of these same structural changes have been found in adult rats exposed to an enriched environment, as well as in adult rats given extensive maze training. In studies of maze training, vision was restricted to one eye, and the corpus callosum was transected to prevent information received by one hemisphere from reaching the other hemisphere. The result was that structural changes in neuronal shape and connectivity were observed only in the trained hemisphere. This rules out a number of nonspecific influences, including motor activity, indirect effects of hormones, and overall level of arousal. Long-term memory in vertebrates is thought to be based on morphologic growth and change, including increases in synaptic strength along particular pathways.

Telegram: @medical_k

www.konkur.in

Long-Term Potentiation

The phenomenon of long-term potentiation (*LTP*) is a candidate mechanism for mammalian long-term memory. LTP is observed when a postsynaptic neuron is persistently depolarized after a high-frequency burst of presynaptic neural firing. LTP has a number of properties that make it suitable as a physiologic substrate of memory. It is established quickly and then lasts for a long time. It is associative in that it depends on the co-occurrence of presynaptic activity and postsynaptic depolarization. It occurs only at potentiated synapses, not all synapses terminating on the postsynaptic cell. Finally, LTP occurs prominently in the hippocampus, a structure important for memory.

The induction of LTP is known to be mediated postsynaptically and to involve activation of NMDA receptors, which permit the influx of calcium into postsynaptic neurons. Administration of NMDA receptor antagonists (e.g., competitive antagonists, e.g., APV) has been tied to LTP blockage in rat models, including in brain regions known to be critical for memory. Antagonist dosage blocking the induction of LTP impairs the acquisition of novel information.

After initial learning, LTP is expressed and maintained by an increase in the number of postsynaptic AMPA (non-NMDA) receptors and also possibly by increased transmitter release. As such, when NMDA antagonists are delivered *after* the initial acquisition of task information, the dosage has little to no effect on the recall of information learned before antagonist delivery. Postsynaptic NMDA-mediated changes also support the opposing phenomenon of *long-term depression* (LTD), which involves temporary decreases in synaptic efficacy following low-frequency synaptic stimulation. The encoding of long-term memories could involve modification of synaptic connections through LTP and LTD. A promising method for further elucidating molecular mechanisms of memory relies on introducing specific mutations into the genome. By deleting a single gene, mice can be produced with specific receptors or cell-signaling molecules inactivated or altered. For example, in mice with a selective deletion of NMDA receptors in the CA1 field of the hippocampus, many aspects of CA1 physiology remain intact, but the CA1 neurons do not exhibit LTP, and memory impairment is observed in behavioral tasks. Genetic manipulations introduced reversibly in the adult are particularly advantageous in that specific molecular changes can be induced in developmentally normal animals. In particular, by using optogenetics, it is

Telegram: @medical_k

www.konkur.in

possible to engineer specific populations of neurons such that certain wavelengths of light systematically modify their activity, with specific mutations allowing for light-induced excitation or inhibition. This optogenetic approach for controlling neural activity with high spatial and temporal precision has been used to provide evidence for the involvement of LTP and LTD at specific synapses in long-term memory.

MEMORY IMPAIRMENTS IN PSYCHIATRIC ILLNESS

The biologic description of memory provided by studies of individuals with amnesia, functional neuroimaging, and animal models has deepened the understanding of memory impairments in individuals with a variety of psychiatric illnesses. Abnormal memory is crucial to the etiology of some psychiatric illnesses, such as the pathologic associations between innocuous stimuli and fear that occur in phobias, as well as the intrusive and contextually inappropriate recollections of traumatic events that occur in post-traumatic stress disorder. These disorders have been associated with structural, neurochemical, and functional abnormalities of medial temporal and frontal regions. As further evidence implicating declarative memory, such patients often have moderate impairments of declarative memory for emotional as well as neutral material, suggesting generalized disruption. It remains unclear whether declarative memory disruptions identified in these disorders resulted from premorbid individual differences that conferred risk for the disorder versus whether brain abnormalities accrued over time as part of the disorder. Nonetheless, understanding of biologic processes supporting memory, especially those operating in medial temporal structures, has led to promising developments in the treatment of these disorders. For instance, the extinction of learned fear occurs in a therapeutic setting during cognitive behavioral therapy for phobias and is associated with NMDA-receptor signaling crucial for LTP in the basolateral amygdala. D-cycloserine is a partial agonist of these receptors and has been shown in a number of preclinical and clinical studies to enhance fear extinction and the effectiveness of cognitive behavioral therapy for phobia. Neurochemical modulation of medial temporal structures thus holds promise for the treatment of anxiety disorders and post-traumatic stress disorder.

Memory impairments also occur in psychiatric illnesses that don’t have obvious linkages to memory, such as schizophrenia and major

Telegram: @medical_k

www.konkur.in

depression. Memory impairments likely occur because these conditions are associated with disruptions of the structure and/or function of medial temporal, midline diencephalic, and frontal neocortical structures that are core components of memory systems. For instance, although schizophrenia is chiefly characterized by delusions, hallucinations, and abnormal emotion, speech, and motivation, patients can experience reduced declarative memory abilities that linger even when core symptoms are pharmacologically treated with success. Patients with schizophrenia perform poorly on memory tests that are highly sensitive to hippocampal structural abnormalities, such as transitive inference and across-domain association learning, and these impairments have been associated with abnormal hippocampal shape and reduced volume and functional activity. These hippocampal structural and functional abnormalities have been shown to worsen with disease progression and are not observed as reliably in other psychotic illnesses, such as psychotic bipolar disorder. Frontal cortex structural and functional abnormality has also been reliably identified in schizophrenia, generally in association to poor working or short-term memory abilities, suggesting impairments in the structuring and organization of information that could further limit declarative memory ability.

Memory impairments are similarly present in major depression. Although memory abnormalities in depression are not core symptoms of the illness and are sometimes understood as mere ramifications of negative affect (e.g., bias toward recall of negative material and rumination on recollection of negative autobiographical episodes), depression patients also exhibit reduced recollection of specific details from previous episodes. Such patients tend to favor overly general or schematic information, even for memories with little emotional content. Again, these memory abnormalities have been associated with structural and functional alterations of medial temporal structures. Thus, schizophrenia and depression are clear examples of conditions in which memory impairments occur in the context of disrupted memory systems and present challenges for patients beyond the symptoms typically associated with the illness. Memory assessment, therefore, could be used to assist clinicians and caregivers in understanding and treating psychiatric patients. Furthermore, lingering cognitive challenges such as memory impairment remain salient barriers to healthy long-term outcomes in patients even when primary symptoms are successfully treated. Greater

Telegram: @medical_k

www.konkur.in

focus is therefore needed on the development of treatments for memory impairments in a variety of psychiatric disorders.

ASSESSMENT OF MEMORY FUNCTIONS

A variety of quantitative methods are available to assess memory functions in neurologic and psychiatric patients. Quantitative methods are useful for evaluating and following patients longitudinally as well as for carrying out a one-time examination to determine the status of memory function. It is desirable to obtain information about the severity of memory dysfunction, as well as to determine whether memory is selectively affected or whether memory problems are occurring, as they often do, against a background of additional intellectual deficits. The following section presents a rationale for evaluating memory and identifies areas of memory function that should be evaluated in any comprehensive assessment. Although some widely available tests, such as the Wechsler Memory Scale, provide useful measures of memory, most single tests assess memory rather narrowly. Even general-purpose neuropsychological batteries provide for only limited testing of memory functions. A complete assessment of memory usually involves a number of specialized tests that sample intellectual functions, new learning capacity, remote memory, and memory self-report.

The assessment of general intellectual functions is central to any neuropsychological examination. In the case of memory testing, information about intellectual functions provides information about a patient's general test-taking ability and a way to assess the selectivity of memory impairment. Useful tests include the Wechsler Adult Intelligence Scale; a test of object naming, such as the Boston Naming Test; a rating scale to assess the possibility of global dementia; a test of word fluency; and specialized tests of frontal lobe function.

New Learning Capacity

Memory tests are sensitive to impaired new learning ability when they adhere to either of two important principles. First, tests are sensitive to memory impairment when more information is presented than can be held in immediate memory. For example, one might ask patients to memorize a list of 10 faces, words, sentences, or digits, as 10 items is more than can be held in mind. The paired-associate learning task is an especially

Telegram: @medical_k

www.konkur.in

sensitive test of this kind. In the paired-associate task, the examiner asks the patient to learn a list of unrelated pairs of words (e.g., queen–garden and office–river) and then to respond to the first word in each pair by recalling the second word.

Second, tests are sensitive to memory impairment when a delay, filled with distraction, is interposed between the learning phase and the test phase. In that case, examiners typically ask patients to learn a small amount of information and then distract them for several minutes with conversation to prevent rehearsal. Recollection is then assessed for the previously presented material. Memory can be tested by the unaided recall of previously studied material (free recall), by presenting a cue for the material to be remembered (cued recall), or by testing recognition memory. In multiple-choice tests of recognition memory, the patient tries to select previously studied items from a group of studied and unstudied items. In yes–no recognition tests, patients see studied and unstudied items one at a time and are asked to say “yes” if the item was presented previously and “no” if it was not. These methods for assessing recently learned material vary in terms of their sensitivity for detecting memory impairment, with free recall being most sensitive, cued recall intermediate, and recognition least sensitive.

The specialization of the function of the two cerebral hemispheres in humans means that left and right unilateral damage is associated with different kinds of memory problems. Accordingly, different kinds of memory tests must be used when unilateral damage is a possibility. In general, damage to medial temporal or diencephalic structures in the left cerebral hemisphere causes difficulty remembering verbal material, such as word lists and stories. Damage to medial temporal or diencephalic structures in the right cerebral hemisphere impairs memory for faces, spatial layouts, and other nonverbal material that is typically encoded without verbal labels. Left medial temporal damage can lead to impaired memory for spoken and written text. Right medial temporal damage can lead to impaired learning of spatial arrays, whether the layouts are examined by vision or by touch. A useful way to test for nonverbal memory is to ask a patient to copy a complex geometric figure and then, after a delay of several minutes, without forewarning, ask the patient to reproduce it.

Remote Memory

Telegram: @medical_k

www.konkur.in

Evaluations of retrograde memory loss should attempt to determine the severity of any memory loss and the time period that it covers. Most quantitative tests of remote memory are composed of material in the public domain that can be corroborated. For example, tests have been used that concern news events, photographs of famous persons, or former one-season television programs. An advantage of these methods is that one can sample large numbers of events and can often target particular time periods. A disadvantage is that these tests are not so useful for detecting memory loss for information learned during the weeks or months immediately before the onset of amnesia. Most remote memory tests sample time periods rather coarsely and cannot detect a retrograde memory impairment that covers only a few months. Also, these tests can make it difficult to take into account what the patient might have learned years ago.

In contrast, autobiographical memory tests can potentially provide fine-grained information about a patient's retrograde memory. In the word-probe task, first used by Francis Galton in 1879, patients are asked to recollect specific episodes from their past in response to single-word cues (e.g., bird and ticket) and to date the episodes. The number of episodes recalled tends to be systematically related to the time period from which the episode is taken. Most memories normally come from recent time periods (the past 1 or 2 months), whereas patients with amnesia often exhibit temporally graded retrograde amnesia, drawing few episodic memories from the recent past, but producing as many remote autobiographical memories as normal subjects (Fig. 3.4–6). Endeavors to assess remote memories are hampered by the fact that decades-old autobiographical memories tend to lose some detail, and these memories may also be subject to further modification if memory functions are intact. Patients who have amnesia for a long time may also adopt strategies or habits that promote gist-based memory retrieval that may interfere with retrieving specific details from remote events.

Memory Self-Reports

Patients can often supply descriptions of their memory problems that are extremely useful for understanding the nature of their impairment. Tests of the ability to judge one's own memory abilities are called tests of *metamemory.* Self-rating scales are available that yield quantitative and qualitative information about memory impairment. As a result, it is

Telegram: @medical_k

www.konkur.in

possible to distinguish memory complaints associated with depression from memory complaints associated with amnesia. Depressed patients tend to rate their memory as poor in a rather undifferentiated way, endorsing all the items equally on a self-rating form. By contrast, patients with amnesia tend to endorse some items more than others; that is, there is a pattern to their memory complaints. Patients with amnesia do not report difficulty in remembering very remote events or in following what is being said to them, but they do report having difficulty remembering an event a few minutes after it happens. Indeed, self-reports can match rather closely the description of memory dysfunction that emerges from objective tests. Specifically, new learning capacity is affected, immediate memory is intact, and very remote memory is intact. Some patients with amnesia, however, tend to have poor awareness of their memory impairment, sometimes overestimating and sometimes underestimating their ability. In patients with Korsakoff syndrome, for example, their poor metamemory stems from frontal lobe dysfunction. In any case, querying patients in some detail about their own sense of impairment and administering self-rating scales are valuable and informative adjuncts to more formal memory testing.

Psychogenic Amnesia

Patients sometimes exhibit memory impairment that differs markedly from the typical patterns of memory loss that follow brain damage. For example, some cases of amnesia present with a sudden onset of retrograde amnesia, a loss of personal identity, and minimal anterograde amnesia. These patients may even be unable to recall their own name. Given the psychological forces that prompt the onset of amnesia in these cases, they are commonly termed *psychogenic amnesia,* or sometimes *hysterical amnesia, functional amnesia,* or *dissociative amnesia.*

Differentiating psychogenic amnesia from a memory disorder that results from frank neurologic injury or disease is often straightforward. Psychogenic amnesias typically do not affect new learning capacity. Patients enter the hospital able to record a continuing procession of daily events. By contrast, new learning problems tend to be at the core of neurologic amnesia. The main positive symptom in psychogenic amnesia is extensive and severe retrograde amnesia. Patients may be unable to recollect pertinent information from childhood or from some part of their past. Formal neuropsychological testing has shown that the pattern of

Telegram: @medical_k

www.konkur.in

memory deficits varies widely from patient to patient. This variability may reflect a patient's commonsense concepts of memory, even when symptoms are not the result of conscious attempts to simulate amnesia. Some patients may only perform poorly when they are asked to remember past autobiographical events. Other patients may fail as well at remembering past news events. Some patients perform well when memory tests appear to assess general knowledge, such as remembering the names of celebrities or cities. Learning new material is usually intact, perhaps because such tests appear to concern the present moment, not traveling into the past. Occasionally, patients with psychogenic amnesia exhibit broad memory deficits such that they cannot perform previously familiar skills nor identify common objects or common vocabulary words.

By contrast, patients with neurologic amnesia never forget their names, and remote memory for the events of childhood and adolescence is typically normal unless there is damage to the lateral temporal or frontal lobes. Patients with psychogenic amnesia sometimes have evidence of head trauma or brain injury, but nevertheless, the pattern of deficits cannot be taken as a straightforward result of neurologic insult. The clinician's challenge is not to distinguish psychogenic amnesia from neurologic amnesia but to distinguish psychogenic amnesia from malingering. Indeed, the diagnosis of psychogenic amnesia can be difficult to substantiate and may be met with skepticism by hospital staff. Some features that argue in favor of a genuine psychogenic disorder include (1) memory test scores that are not as low as possible and never worse than chance levels; (2) memory access improved by hypnosis or Amytal interview; and (3) a significant premorbid psychiatric history. In some cases, psychogenic amnesia has been observed to clear after a period of days, but in many cases, it has persisted as a potentially permanent feature of the personality.

Telegram: @medical_k

www.konkur.in

Patient CB was a 29-year-old man evaluated for memory loss. He reported having severe retrograde amnesia for the past 3months. A medical evaluation revealed swelling of the left side of his head due to recent head trauma. CT head scan was normal. 3months prior to this evaluation, he had been arrested for intoxication and taken to jail. Upon awakening the next day, he was unable to recall his past life. At the time of the evaluation, he indicated that he knew his name, but it was not clear whether he knew his name only because he had relearned it. He also had some difficulty recalling old vocabulary words. He had essentially no memories of events that had occurred before the onset of his amnesia. He was, however, able to relearn about his past life as he was told about it. He also learned new information well. He sometimes did not recognize vocabulary words and had to look them up. He reported that he had recently relearned how to drive a car with a manual transmission.

It was notable that he described himself as having a new personality since the onset of memory problems. Previously he had been very outgoing, a heavy drinker of alcohol, and was feared by some people. He had been "obnoxious but likable." Since the onset of memory problems, he was less outgoing, more introspective, and better at getting along with other people. He did not like his personality from before the onset of memory problems, and, in fact, he had adopted his former middle name as a new first name. He hoped that he would be able to regain all of his old memories and experiences without the return of his old personality. During a 20-month follow-up period, his severe retrograde amnesia persisted. (Case history from Kritchevsky M, Chang J, Squire LR. Functional amnesia: clinical description and neuropsychological profile of 10 cases. *Learn Mem*. 2004;11:213.)

IMPLICATIONS

Memory Distortion

The current understanding of the biology of memory has significant implications for several fundamental issues in psychiatry. Given the selective and constructive nature of autobiographical remembering and the imperfect nature of memory retrieval more generally, it is surprising

Telegram: @medical_k

www.konkur.in

that memory is so often accurate. How much can memories be trusted? Subjective feelings of confidence are apparently not perfect indicators of retrieval accuracy. And memory distortion can clearly lead to unfortunate consequences, such as when mistaken eyewitness testimony harms an innocent individual.

The fact is that it is possible to confidently remember events that never happened. For example, it is possible to confuse an event that was only imagined, or dreamed about, with an event that actually occurred. One factor that contributes to memory distortion is that similar brain regions are important both for visual imagery and for the long-term storage of visual memories (Fig. 3.4–16). Another factor that contributes to memory distortion is that memory functions best in remembering the gist of an event, not the particulars from which the gist is derived. In a noted demonstration, people listen to a list of words: *candy, sour, sugar, tooth, heart, taste, dessert, salt, snack, syrup, eat,* and *flavor.* Subsequently, when asked to write down the words they heard, 40% of them wrote down the word *sweet,* even though this word did not appear in the list. Thus, many people in this demonstration failed to discriminate between the words that had been presented and a word that was strongly associated with all the words but had not itself been presented. The word *sweet* can be thought of as a gist word, a word that represents the other words and that captures the meaning of the whole list. Presumably, the words in the study list evoked a thought of the word *sweet,* either at the time of learning or during the memory test, and people then tended to confuse merely thinking of the word with actually hearing it.

The reconstructive nature of recollection means that the interpretation of eyewitness testimony is not straightforward. Whole episodes are not available in the neocortex but rather must be pieced together based on fragmentary components and in the context of potentially misleading influences present at the time of retrieval. Studies in adults and in children have documented that illusory memories can be created. Children are particularly susceptible to these effects, especially when subjected to leading questions and false suggestions.

In view of these features of memory, when a memory of childhood abuse is remembered after many years, it is prudent to ask whether the memory is accurate. Genuine examples of memory recovery have been documented, whereby an individual produces a veridical memory for a past traumatic event after not recalling the event for extended time

Telegram: @medical_k

www.konkur.in

periods. Numerous examples of apparent memory recovery have also been subsequently discovered to be instances of false memory. Unfortunately, there is no perfect method at present, in the absence of independent corroboration, for determining whether a recollective experience is based on a real event or not.

Infantile Amnesia

The biology of memory has also provided insights relevant to the phenomenon of infantile amnesia, the apparent absence of conscious memory for experiences from approximately the first 3 years of life. Traditional views of infantile amnesia have emphasized repression (psychoanalytic theory) and retrieval failure (developmental psychology). A common assumption has been that adults retain memories of early events but cannot bring them into consciousness. However, it now appears that the capacity for declarative memory does not become fully available until approximately the third year of life, whereas nondeclarative memory emerges early in infancy (e.g., classical conditioning and skill learning). Thus, infantile amnesia results not from the adult's failure to retrieve early memories but from the child's failure to store them adequately in the first place.

Nevertheless, studies in young infants show that a rudimentary capacity for declarative memory is present even at a few months of age. As a child develops, memories can be retained across increasingly long intervals, and what is represented becomes correspondingly richer and more full of detail. Medial temporal and diencephalic regions seem to be sufficiently developed during these early months and years. What limits the capacity for declarative memory appears to be the gradual development and differentiation of the neocortex.

As the neocortex develops, the memories represented there become more complex, language abilities allow for more elaborate verbal descriptions of events, and a developing sense of self supports autobiographical knowledge. As new strategies emerge for organizing incoming information, declarative memories become more persistent, more richly encoded, and better interconnected with other information. It is not the case that fully formed childhood memories are stored but cannot be retrieved. The perspective consistent with the current understanding of the biology of memory is that declarative memories formed very early in life are fragmentary, simple, and tied to the specific context of an infant's

Telegram: @medical_k

www.konkur.in

understanding of the world. They are unlike typical declarative memories in adults, imbued with meaning and a complex understanding of events.

Technologic Interventions for Memory Impairment

The biology of memory has motivated recent attempts to rescue memory impairments via stimulation-based neurotechnology. For instance, conventional forms of noninvasive brain stimulation such as transcranial magnetic stimulation (TMS) cannot directly affect the core regions that are dysfunctional in memory disorders, such as the hippocampus, but they can readily influence portions of the broader hippocampal network as defined via fMRI. Several studies have shown improvements in declarative memory ability following multisession TMS of the hippocampal network, including positive results from early-stage trials in individuals with memory decline due to aging and early-stage Alzheimer disease. There are also promising findings that memory functions supported by the frontal lobes, such as working memory, can be improved using transcranial electrical stimulation when delivered at appropriate times relative to the targeted cognitive processing. Thus, there are several promising avenues for the rescue of memory impairments via noninvasive stimulation technologies.

Other experiments have evaluated deep brain stimulation (DBS) for memory enhancement. DBS is an FDA-approved treatment for movement disorders such as Parkinson disease, essential tremor, and dystonia. DBS has also recently been approved to treat epilepsy and obsessive-compulsive disorders. These recent advances have bolstered interest in its application for neuropsychiatric and memory disorders.

Converging evidence from stimulation of depth electrodes implanted in patients with epilepsy and mouse models suggests that DBS of the fornix may improve learning or memory consolidation. In sheep, high-frequency DBS of the fornix further effected changes in electrical activity in the hippocampus. However, studies examining DBS of the hippocampus or mesial temporal regions are relatively inconclusive. Further, effects of stimulation applied at the fornix in recent Phase 1, and 2 clinical trials in Alzheimer disease demonstrate that while stimulation is safe and tolerable for patients, DBS has variable long-term outcomes for subsequent memory decline. Exploratory analyses indicate that DBS may be most beneficial for Alzheimer patients who are in the early stages of the disease, but DBS had little to no effect in a large clinical trial of early

Telegram: @medical_k

www.konkur.in

Alzheimer patients under the age of 65. The therapeutic efficacy of forniceal DBS thus remains relatively unclear but will continue to be examined across ongoing Phase 2 and 3 clinical trials.

Memories and the Unconscious

The existence of multiple memory systems also has implications for issues central to psychoanalytic theory, including the construct of the *unconscious.* How past experience influences current behavior depends on what view one takes of the nature of memory. By the traditional view, memory is a unitary faculty, and representations in memory vary mainly in strength and accessibility. Material that is unconscious is below some threshold of accessibility but could potentially be made available to consciousness.

The modern, biologic view begins with the distinction between a kind of memory that can be brought to mind—declarative memory—and other kinds of memory that are, by their nature, unconscious. Stored nondeclarative memories are expressed through a performance without affording any conscious memory content. Personalities are shaped by nondeclarative memories in the form of numerous habits and conditioned responses. In this view, one's behavior is indeed affected by events from early life, but the effects of early experience persist in a nondeclarative form without necessarily including an explicit, conscious record of the events. Learned behavior can be expressed through altered dispositions, preferences, conditioned responses, habits, and skills, but exhibiting such behavior need not be accompanied by the awareness that behavior is being influenced by past experience, nor is there a necessity that any particular past experience has been recorded as a complete episode. That is, an influence from early experience does not require the memory of any specific episode. One can be afraid of dogs without remembering being knocked down by a dog as a child. In this case, the fear of dogs is not experienced as a memory. It is experienced as a part of personality. Furthermore, a strong fear of dogs carries with it no implication that the brain retains a specific record of any early experience that subsequently resulted in fear of dogs.

Behavioral change can occur by acquiring new habits that supersede old ones or by becoming sufficiently aware of a habit that one can to some extent isolate, countermand, or limit the stimuli that elicit it. However, one need not become aware of any early formative event in the same sense

Telegram: @medical_k

www.konkur.in

that one knows the content of a declarative memory. The unconscious does not become conscious. Various forms of nondeclarative memory simply influence behavior without having the additional capacity for these influences to become accessible to conscious awareness.

ACKNOWLEDGMENT

3.5 Normality and Mental Health

George E. Vaillant, M.D.

Too often, psychiatry has been only preoccupied with mental illness. To paraphrase Mark Twain's quip about the weather, psychiatry is always talking about mental health, but nobody ever does anything about it. Science has conceptualized the building blocks of nuclear fission more readily than the building blocks of mental health. Thus, with the notable exception of the chapter by Daniel Offer and Melvin Sabshin in the early editions of this textbook, a review of other recent major psychiatric textbooks reveals virtually no serious discussion of mental health. One reason for this lack of attention is that the study of positive mental health is a very new field. Only within the last three decades has mental health per se been addressed empirically instead of platonically.

There has been an implicit assumption that mental health could be defined as the antonym of mental illness. In other words, mental health was the absence of psychopathology and synonymous with "normal." Achieving mental health through the alleviation of gross pathologic signs and symptoms of illness is also the definition of the mental health model strongly advocated by third-party payers. Indeed, viewing mental health as simply the absence of mental illness is at the heart of much of the debate concerning mental health policies. The great epidemiological studies of the past half-century have also focused on who was mentally ill and not who was well. Only the Sterling County Studies by Alexander Leighton came close to defining positive mental health operationally. Mental illness, after all, is a condition that is easy to define reliably, and its limits are relatively clear. As a result, it has been argued that achieving above-average mental or physical health is not the province of medicine but of education. Such a definition ignores concepts of positive health like physical fitness and cardiac reserve.

Like physical fitness, however, positive mental health is too important to be ignored. To believe mental health is a Global Assessment of Function score of 70 is to underestimate human potential. Sports medicine does

Telegram: @medical_k

www.konkur.in

more than mend a skier's broken legs; sports medicine rehabilitates the skier to ski advanced trails once more. Starting early in the last century, internists began studying physiology at high altitudes and devising measures of positive physical health for athletes, pilots, and finally astronauts. In 1929–1930 at the University of California at Berkeley, the Institute of Human Development was founded by Howard Jones, Nancy Bayley, and Jean McFarlane. Originally founded to study healthy child development, the Institute was to provide a seminal influence on Erik Erikson's model of healthy adult development. A decade later, in the late 1930s, Arlie Bock, an internist trained in high-altitude physiology and interested in positive physical health, began at the Harvard University Health Services, The Study of Adult Development. The study was designed as an interdisciplinary study of both mental and physical health. Results from that study, lasting for 70 years, have informed many facets of this chapter.

Although above-average mental health is more difficult to define than above-average physical fitness, it is important for psychiatrists to emulate sports medicine in order to provide precise definitions and measures of positive mental health. Psychologists have already learned to quantify not only "normal" but better than normal intelligence. Thus, the antonym of mental retardation is not regarded as an intelligence quotient (IQ) of 100 but as an IQ over 130. Psychiatry must follow suit.

Certainly, over the last 70 years, psychiatrists have become increasingly involved in mental health consultations with agencies. Rather than merely deciding who is too sick for a job, they are called on to make decisions about who is mentally healthy enough for certain positions—like air controllers and submariners. Analogous to cardiac reserve, the measurement of resilience and the capacity to withstand adversity is on psychiatry's psychometric wish list. In addition, interest in the empirical evaluation of psychiatric therapy outcomes has also brought the issue of positive mental health into focus. Indeed, one of the weaknesses of much existing work on psychotherapy assessment has been a lack of clarity regarding outcome definitions. *For health is not the absence of negatives but the presence of positives.*

But the definition of positive mental health is not easy. Several cautionary steps are necessary. The first step in discussing mental health is to note that "average" is not healthy; it always includes mixing in with the healthy the prevalent amount of psychopathology in the population.

Telegram: @medical_k

www.konkur.in

For example, in the general population, “average” weight or eyesight is unhealthy; and if all sources of biopsychosocial pathology were excluded from the population, the average IQ would be significantly above 100. For as with Garrison Keillor’s description of Lake Wobegon youth, mentally healthy children “are all above average.” Being at the center of a normal bell curve of distribution may or may not be healthy. In the case of red blood count, body temperature, or mood, the middle of the bell curve *is* healthy. In the case of eyesight, exercise tolerance, or empathy, only the upper end of the bell curve is healthy; and in the case of serum cholesterol, bilirubin, and narcissism, only the low end of the curve is healthy.

The second cautionary step in discussing mental health is to appreciate the caveat that what is healthy sometimes depends upon geography, culture, and historical moment. Sickle cell trait is unhealthy in New York City, but in the tropics where malaria is endemic, the sickling of red blood cells may be lifesaving. Punctuality is a virtue in Germany and sometimes a failure in Brazil. Indeed, some aboriginal Australian languages do not even have a word for time. General George Patton’s competitive temperament was for him a psychological liability in times of peace but a virtue in two World Wars. In World War II, paranoid personalities made very poor submariners but excellent airplane spotters.

A third cautionary step is to make clear whether one is discussing *trait* or *state.* Who is physically healthier: an Olympic miler disabled by a simple but temporary (state) sprained ankle or a Type 1 diabetic (trait) with temporarily normal blood sugar? In cross-cultural studies, such differences become especially important. Superficially, an Indian mystic in a state of trance may resemble a catatonic schizophrenic but not over time.

In defining mental health, the fourth and most important cautionary step is to appreciate the twofold danger of “contamination by values.” On the one hand, cultural anthropology teaches how fallacious any definition of mental health can be. Competitiveness and scrupulous neatness may be healthy in one culture and regarded as a personality disorder in another. And, if mental health is “good,” what is it good for? The self or the society? For “fitting in” or for creativity? For happiness or survival? And who should be the judge? Since every culture differs in its diet, the World Health Organization (WHO) should never be called upon to design restaurant menus. For ten years, Adolf Hitler was a better leader of his country than

Telegram: @medical_k

www.konkur.in

Jimmy Carter; but by every definition that the author knows, Carter had better mental health than Hitler.

Thus, common sense, not postmodernism, must prevail. Biology trumps anthropology. Health is the activity of a living body in accordance with its specific excellences.

"What, for example, is a healthy squirrel?" asked Kass, a research professor in bioethics and neurology, "Not a picture of a squirrel, not really or fully the sleeping squirrel, not even the aggregate of his normal blood pressure, serum calcium, total body zinc, normal digestion, fertility, and the like. Rather, the healthy squirrel is a bushy-tailed fellow, who looks and acts like a squirrel; who leaps through the trees with great daring, who gathers, buries, and covers but later uncovers and recovers his acorns; who perches out on a limb cracking his nuts, sniffing the air for smells of danger, alert, cautious, with his tail beating rhythmically; who chatters and plays and courts and mates and rears his young in large improbable looking homes at the tops of trees; who fights with vigor and forages with cunning; who shows spiritedness, even anger, and more prudence than many human beings … health is a natural standard or norm—not a moral norm, not a 'value' as opposed to a 'fact,' not an obligation but a state of being that reveals itself in activity."

It is true that cultural anthropology teaches that almost no form of behavior is considered abnormal in all cultures, but that does not mean that the tolerated behavior is mentally healthy. It would be an error for the WHO to ignore the universal importance of vitamins or the four basic food groups. Just because, until recently, Portugal did not recognize alcoholism as an illness does not reduce the contribution of alcoholism in Lisbon to morbidity. Just because the American Constitution protected the right to own slaves as inalienable did not make slavery mentally healthy for slaves or for the slave owner. Just because martinis and Coca-Cola outsell carrot juice does not make the former healthier. The best way to enrich the current understanding of what constitutes mental health is to study a variety of healthy populations from different perspectives, in different cultures, and for a long period of time.

This chapter will contrast eight different empirical approaches to mental health. Significantly, the empirical underpinnings of all eight models have emerged only in the past 50 years. First, mental health can be conceptualized as *Above Normal* and a mental state that is objectively desirable—as in Sigmund Freud's alleged definition of mental health was

Telegram: @medical_k

www.konkur.in

the capacity to work and to love. Second, mental health can be conceptualized as *Positive Psychology*—as epitomized by the presence of multiple human strengths. Third, from the viewpoint of healthy adult development, mental health can be conceptualized as *Maturity.* Fourth, mental health can be conceptualized as *Resilience,* as the capacity for successful adaptation, "grit," and homeostasis. In such a view, mental health, analogous to a competent immune system, allows the individual to function well despite stressful or dangerous environments. Fifth, mental health can be conceptualized as *Emotional Intelligence* and wise and successful object relations. Sixth, mental health can be conceptualized as *Subjective Well-Being* (*SWB*)—a mental state that is subjectively experienced as happy, contented, and desired. Seventh, mental health can be conceptualized as ***Positive or "Spiritual" Emotions***.

MODEL A: MENTAL HEALTH AS ABOVE NORMAL

This first perspective differs from the traditional medical approach to health and illness. Until recently, being without manifest psychopathology equaled mental health. In this medical model, if one were to put all individuals on a continuum, normality would encompass the major portion of young adults, and abnormality would be the small remainder. This definition of health correlates with the traditional role model of the doctor who attempts to free his patient from grossly observable signs of illness. In other words, in this context, health refers to a reasonable, rather than an optimal, state of functioning.

Yet, as already pointed out, mental health is not normal; it is above average. Indeed, some believe that true mental health is the exception, not the rule. Moreover, until recently, some believed mental health was imaginary. Many postwar psychiatrists continued to agree with Sigmund Freud, who had dismissed mental health as "an ideal fiction." In the late 1950s, two of the world's most distinguished psychiatrists could dismiss the term entirely. Sir Aubrey Lewis wrote in 1958, "Mental health is an invincibly obscure concept," and in 1957, Fritz Redlich asserted, "We do not possess any general definition of normality and mental health from either a statistical or a clinical viewpoint."

Certainly, the absence of illness and the presence of health overlap but do not always coincide. In the military, the mental health of a jet pilot must exceed the draft board's 1-A. In primary school teachers and in Supreme

Telegram: @medical_k

www.konkur.in

Court justices, it is more than simply freedom from symptoms or Freud's capacity to work and to love that is looked for. However, to avoid quibbling over what traits characterize mental health, it is helpful to adopt the analogy of a decathlon champion. What constitutes a "track star"? Is it muscle strength, or speed, or endurance, or grace, or competitive grit? Does not the definition differ from nation to nation and from century to century? Not really. The salience of a given facet of track or of mental health may vary from culture to culture, but all are important. A high score on the decathlon has conveyed behavioral skill in track for millennia and in every country of the world—even as the hair splitters argue over the right words with which to describe a track athlete.

As with excellence in the decathlon, no single measure defines mental health, but all measures are highly intercorrelated. Table 3.5–1 illustrates how multifaceted and unique each model of positive mental health can be and how very different the semantics can be. But the familial resemblance of each definition to each other is unmistakable.

In 1835 Adolphe Quetelet published the first important book on normality ever written. Rather than focus on pathology, he tried "to approach more closely to what is good and beautiful," and his goal was the statistical analysis of healthy humans. He challenged generations of future investigators with his introductory sentence, "Man is born, grows up, and dies, according to certain laws which have never been properly investigated" (p. 5).

Until World War II, however, Quetelet's challenge to mental health workers went largely unnoticed. When in 1941, John Clausen and his coworkers were commissioned to assess mental health for the draft board, they were embarking on a novel task. As a way of assessing the mental health of recruits, they focused on the absence of psychosomatic symptoms. Although limited, their approach was not abandoned until the 1970s, and questions about psychosomatic symptoms still form an important part of the Hopkins SCL-90 and of scales assessing neuroticism.

Table 3.5–1.
Three Contrasting Definitions of Mental Health

Telegram: @medical_k

www.konkur.in

Model A Mental Health/Normality	Model B Positive Psychology	Model C Maturity
Marie Jahoda, as summarized by Daniel Offer and Melvin Sabshin	Christopher Peterson, Martin Seligman	William Menninger
Ability to love, work, and play Possesses empathy adequacy in interpersonal relations	**Love:** Intimacy/reciprocal attachment Kindness/generosity/nurturance Social intelligence/emotional intelligence	**The capacity for love** The capacity for a variety of mutually fulfilling and lasting relationships The need to seek a major source of fulfillment in productive work
Efficient in problem-solving Perceives reality Resistance to stress Environmental mastery	**Temperance:** Forgiveness/mercy Modesty/humility Prudence/caution Self-control/self-regulation	Free of stereotyped and nonproductive patterns of problem-solving Ability to discharge hostility without harming others or oneself The capacity to adapt to change and endure frustration and loss
Invested in life Self-actualization Oriented toward future	**Wisdom and Knowledge:** Curiosity/interest Love of learning Judgment/open-mindedness	A realistic acceptance of the destiny imposed by one's

Telegram: @medical_k

www.konkur.in

	Perspective Creativity/originality/ingenuity	time and place in the world
Autonomy Recognition of needs In touch with their own identity and feelings	**Courage:** Valor Honesty/authenticity Industry/perseverance Zest/enthusiasm	Appropriate expectations and goals for oneself Ability to respond to the uncertainties of reality in a manner consistently free of domination by one's wishes or peers
	Justice: Citizenship/loyalty/teamwork Equity/fairness Leadership	
	Transcendence: Awe/wonder Gratitude Hope/future mindedness Spirituality/faith Playfulness/humor	**Having the capacity for hope** An altruistic concern for other human beings outside one's own group and beyond one's own time and place The capacity to suspend one's adult identity and engage in childish play at appropriate times

After World War II, influential works on normal adaptive behavior began to be published—Roy Grinker and John Spiegel's *Men under Stress,*

Telegram: @medical_k

www.konkur.in

Robert White's *Lives in Progress,* Leo Sroles' *Mental Health in the Metropolis,* and Alexander and Dorothea Leightons' *Cove and Woodlot* were four of the more important. Although all four studies concentrated on the adaptation of nonpatient or normal populations, they still put their emphasis on *not pathological* rather than on *above-normal mental health.*

Then, in 1958, Marie Jahoda's report to the Joint Commission on Mental Illness and Health led to a psychiatric sea change regarding the existence of mental health. As illustrated in Table 3.5–1, Jahoda suggested that mentally healthy individuals should (1) be in touch with their own identity and their own feelings. (2) They should be oriented toward the future, and over time they should remain fruitfully invested in life. (3) Their psyches should be integrated and provide them resistance to stress. (4) They should possess autonomy and recognize what suits their needs. (5) They should perceive reality without distortion and yet possess empathy. (6) They should be masters of their environment—able to work, to love, and to play, and to be efficient in problem-solving. Instead of emphasizing the absence of negative symptoms, Jahoda underscored a number of positive traits. Nevertheless, although the purpose of Jahoda's report was to rid the term, mental health, of "vague, elusive and ambiguous connotation," at the time she published her criteria, there was still no evidence to prove that her plausible definition was more than mere platitudes that reflected her own culture-bound values.

Thus, it was with Roy Grinker's 1962 studies of "homoclites" that investigators began the empirical study of positive mental health. Grinker's homoclites were physical education majors selected for normality but studied only briefly. A second longitudinal study was the elimination process by which out of 130 healthy jet pilots already selected for mental health, the seven original astronauts were selected. The process underscored both the importance and the commonsensical nature of mental health. The final seven astronauts enjoyed not only exemplary work records but also were competent at loving. All came from intact, happy, small-town families; they all were married with children. Although venturesome test pilots, they all had very few accidents during their years of flying or even earlier. They could tolerate both close interdependent association and extreme isolation. They trusted others and were uncomplaining under discomfort. They manifested a great capacity for withstanding frustration; nevertheless, emotions both negative and positive were strongly experienced. Not introspective, the astronauts

Telegram: @medical_k

www.konkur.in

seldom dwelt on their inner emotions; but they were sensitive to their emotions and could describe them when asked. They were aware of the feelings of others, and they avoided interpersonal difficulties. Unlike most people, their performance improved under stress (e.g., working at a simulated altitude of 65,000 feet in a poorly functioning pressure suit). Their group neuroticism (Maudsley Personality Inventory) score was the lowest of any group reported in the literature. Although each of the astronauts was very different, they all would have starred in a mental health "decathlon."

A still more influential study of mental health was the Menninger Psychotherapy Project. In order to cut through the hair-splitting of projective tests and the subjectivity of pencil and paper tests Menninger psychologist, Lester Luborsky devised a behavioral guide (health-sickness rating scale or HSRS) to assess psychological functioning on a scale of 0 to 100. In 1976 because Luborsky's scale had been designed to evaluate candidates for psychotherapy rather than for general epidemiological studies, two of the architects of DSM-III developed a revision of the HSRS called the global assessment scale (GAS). Rater reliabilities for both instruments and between the two instruments were about 0.85 to 0.95. In cross-cultural comparison, investigators noted that "the usefulness of HSRS as an international thermometer of mental health is strongly supported." A modified version of the GAS was introduced in DSM-III-R as the global assessment of functioning (GAF).

On Luborsky's scale, a score of 95 to 100 reflected "an ideal state of complete functioning integration, of resiliency in the face of stress, of happiness and social effectiveness." On the GAF, a score of 95 to 100 equaled "no symptoms, superior functioning in a wide range of activities; life's problems never seem to get out of hand; the patient is sought out by others because of his warmth and integrity." The words differ, but the melody is the same.

By 1978 *The Report to the President* by the President's Commission on Mental Health forcefully reiterated the importance of clearly defining what is meant by mental health. Nevertheless, it was not until 15 years later, when evidence emerged to support the validity of Axis V, DSM-IV did psychiatry finally possess a metric for the measurement of "above average" mental health. The World Health Organization Disability Assessment Schedule replaced it in the DSM-5, but the new tool is still a

Telegram: @medical_k

www.konkur.in

measure of mental illness rather than health: all 36 questions contain the words “difficulty,” “problem,” “drain,” or “health condition.”

In order to identify mental health empirically, behavioral data are needed, and a longitudinal biopsychosocial perspective must be maintained. Two very different life histories from Harvard’s Study of Adult Development illustrate what is meant by “above normal” mental health. One man, “Alfred Paine,” received an “average” score for mental health (GAF = 72); he never sought psychiatric care. In contrast, “Richard Luckey” received an above-normal score for mental health (GAF = 95). These two (disguised) case histories help to underscore that objective and subjective mental health are not merely value-ridden “ideal fictions.” Both men had been selected at 18 for mental health and were prospectively observed for a lifetime. Confounding variables like gender, education, social class, ethnicity, age, and birth cohort were held constant. Neither man had ever sought psychiatric help nor been diagnosed with mental illness, but there is no question who was the healthier.

Telegram: @medical_k

www.konkur.in

Alfred Paine was a master of cheerful denial. On questionnaires, he described himself as a social drinker, in quite good physical health, and close to his children. It was only by interviewing him personally, talking with his wife, examining his medical record, reading the disappointing questionnaires from his children—and then, finally, by reading his obituary—that Alfred Paine's misery could be fully appreciated

The ancestors of Alfred Paine had been successful New England clipper ship captains. All his grandparents had graduated from high school. One grandfather became a merchant banker, and the other the president of a Stock Exchange. Paine's father had graduated from Harvard and his mother from a fashionable boarding school. When Alfred Paine was two weeks old, his mother died from the complications of childbirth. When he was 2 years old, his father died. Paine was bottle-fed by a variety of surrogates and raised by his grandmother. As a young boy, Paine was a head-banger; in adolescence, he was a "lone wolf."

In college Alfred Paine was often in love, but for Paine being in love meant having someone to care for him. His three marriages were all unhappy—in part because of the alcohol abuse that he maintained that he did not have, and in part because he was frightened of intimacy. At 50, Paine answered "true" to the statements "Sexually most people are animals" and "I would have preferred an asexual marriage."

At 47, Paine recalled the ages from 1 to 13 as the unhappiest in his life. At age 70, he believed that the ages from 20 to 30 were the unhappiest. But there had never been a time that Paine was happy. Nevertheless, on a pencil and paper test of depression, Paine achieved one of the best scores in the study. He had never sought psychotherapy, and none of his doctors ever called him mentally ill. His alcohol abuse never led to an arrest or to missed days of work. At 70, Paine wrote that his own physical health was "excellent," but in fact, he was seriously overweight, afflicted by hypertension and gout, and suffered from obstructive pulmonary disease—the result of life-long smoking. By 75, he had lost all his teeth; both his kidneys and his liver were failing; and he was cursed with mild dementia, the result of a drunken fall.

Telegram: @medical_k

www.konkur.in

Although he had made a good living over the years at a job he disliked, by 75, Paine's trust fund and his pension had been eroded through multiple divorces and self-inflicted tax troubles. His house looked as if furnished from yard sales, and little other than television now absorbed him. On his age 75 questionnaire, Paine refused to answer the part that dealt with life enjoyment. Thus, his subjective lack of joy in life had to be inferred from the fact that over the past 20 years, there was no area of his life other than his religious activities in which he had expressed satisfaction. On average, he saw his three children once every two years, and he grumbled that "They hardly let me see my grandchildren." Although Paine's third wife was protective and quite loving towards him, he was quite disrespectful and uncaring towards her. Asked how he and his wife collaborated, he replied, "We don't. We lead parallel lives." Since age 50, he had engaged in no pastimes with friends; and at 73, when asked to describe his oldest friend, he growled, "I don't have any." Often in his life, Paine had found love, but he could not let it inside.

Telegram: @medical_k

www.konkur.in

In contrast, Richard Luckey was a well-loved child who took excellent care of himself. Unlike Alfred Paine, Luckey had come from more modest beginnings. None of his four grandparents had gone beyond grade school. His father graduated from high school and went on to become a successful businessman. After college Luckey became head of two successful businesses (one of which he created), both at the same time. He loved his work.

At 70, when looked at through the eyes of his internist, Richard Luckey's objective physical health had seemed actually worse than Alfred Paine's. Luckey had high blood pressure, atrial fibrillation, a cardiac pacemaker, and pancreatitis. He was even more overweight than Paine. But if Luckey was ill, he certainly did not feel sick. Over the next 10 years, Paine sickened unto death, and Luckey's health got steadily better. Thus, by 76, Lucky had completely recovered from his pancreatitis. He still wore a pacemaker; and, his blood pressure remained high, but in his doctor's words—not just his own—"Mr. Luckey continues to enjoy relatively good health … he continues to be active physically and also mentally." As Luckey, himself, expressed it, "I have done less chainsawing, but I still split wood." At age 76, Luckey spent two months downhill skiing in Austria.

Another crucial difference was that Luckey had never smoked, and he had used alcohol in moderation. "Almost everything we do," Luckey explained, "is family-oriented. His wife amplified, "We rarely go out, but we will have groups for supper such as the church fellowship group or the basketball team for a weekend of skiing or a vestry meeting at the house." Luckey was also commodore of his yacht club, and he had friends with whom he exercised regularly.

Richard Luckey described not only his hobbies, his religion, and his income-producing work as "very satisfying," but, more important, he experienced his relationships with his wife and with his children as "very satisfying." His wife and children's questionnaires revealed a similar satisfaction with him. Luckey's daughter had described her parent's marriage as "better than my friends"; then, for good measure, she had added two pluses. Luckey's wife gave her marriage a "nine" out of "nine," and on her questionnaire, she wrote the study, "My husband is my best friend; I like looking after him. We have grown closer and fonder every year." Asked how his marriage had lasted for 40 years, Luckey replied, "I really love Chrissie, and she loves me. I

Telegram: @medical_k

www.konkur.in

really respect her, highly esteem her, and she is a real person." Luckey was close to his brother, with whom he regularly fished in the summer. He stayed in touch with and took great pleasure from his children and his grandchildren. It was so easy for Luckey to take in, to "metabolize," any love that he was offered.

Asked about his retirement Richard Luckey replied, "I think it is all pretty nice. I don't have a day when I don't have something to do that I want to do … creativity is absolutely necessary for someone to be healthy. With painting," he added dreamily, "you forget everything, and that is why it is so very relaxing." In church, Luckey sang both solo and in the choir. Despite an indifferent college scholastic record, at age 75, Lucky was making a serious effort to master the technology of a research institute of which he had become a trustee.

In other words, health is based on an active, joyous, energetic engagement with the world. Such a naturalistic model of health is congruent with the increasing attention to "flow," a concept recently elaborated on and empirically studied by psychologist Mihaly Csikszentmihalyi and his students. "Flow" involves focused attention and psychic absorption, which is characteristic of meditation, but unlike meditation, with "flow," the "clutch" is engaged, and skilled behavior takes place. With "flow," the participant feels alive and in the world. In "flow," experiences with emotions are not just contained and channeled; they are energized and aligned with the consciousness of the task at hand. Action, cognition, and feeling are merged into one. Often, when manifested in intense experiences like advanced tennis, technical rock climbing, or violin playing, the "flow" experience has required hours of prior practice until much of the effort involved has become second nature.

Csikszentmihalyi's concept of "flow" is distinct from Freud's libido. "Flow" occurs when a task is challenging and requires both skill and concentration when there are clear goals and immediate involvement when time seems to stop and one's sense of self vanishes, and when one finds themself both deeply involved—and in control. A species does not survive just by reproducing; it also has to produce and face new challenges.

Telegram: @medical_k

www.konkur.in

MODEL B: MENTAL HEALTH AS POSITIVE PSYCHOLOGY

The fact that psychologists have approached mental health somewhat differently from psychiatry has led to the second model. Psychologists, like physiologists, look at continua (traits) rather than categories, while in medicine, you either have an illness, or you do not. In psychology, interventions to improve adequate intelligence or social skills are common, while in medicine, to meddle with adequate thyroid function, a healthy hematocrit, or a normal mood is only to cause trouble. In the healthy rested individual, virtually all psychopharmacological interventions will, over time, make the brain function worse; in contrast, many psychological interventions (e.g., literacy training, stress management) will make the brain function better. Thus, the medical goal of using medication to remove pathology is different from the psychologists' goal of fostering joy, enthusiasm, curiosity, and love for others in an educative model. As a result, physicians and psychologists draw attention to quite different—if complementary—models of mental health.

In the 20th century, medicine became increasingly concerned with concrete pathology, while psychology remained interested in education and in platonic and utopian virtue. The model of positive psychology conceives mental health as "the best possible" and has provided the basis for the positive psychology movement.

The last century witnessed not only psychologist John Dewey's idealism regarding education but also the work of Carl Jung and William James (physicians by training, but psychologists in spirit) concerning the search for and discovery of deeper meanings in life. In the last 70 years, Abraham Maslow's concept of self-actualization and his emphasis on humanistic psychology have drawn attention to the "full use and exploitation of talents, capacities, potentialities." But until the 21st century, such humanistic psychology has not undertaken empirical research and has ignored predictive validity and follow-up. Humanistic psychology has emphasized "happiness" and the "self" at the expense of collective well-being and has spawned myriad self-help movements that have benefited clients more through the placebo effect than from controlled and replicated therapeutic interventions. As early as 1925 psychiatrist, Adolf Meyer was already warning of the need to stop "moralizing" about utopian

Telegram: @medical_k

www.konkur.in

mental health. Mental health, he suggested, should be studied through "conscientious and impartial study" and "constructive experimentation."

Recently, two popular books by a distinguished psychologist, Martin Seligman, *Learned Optimism,* and *Authentic Happiness,* have served notice that positive psychology is beginning to follow Adolph Meyer's rules of conscientious and impartial study and constructive experimentation. Seligman's concepts of "learned optimism" and positive psychology incorporate the empirical advances in cognitive psychology that have taken place over the past 3 decades. Creating a positive attributional style not only serves as a cognitive-behavioral treatment for depression but can lead to positive mental states.

Positive psychology wishes to learn how to build the qualities that help individuals and communities, not just to endure and survive but also to flourish. Formally introduced in the January 2000 issue of *American Psychologist,* positive psychology hopes to render the psychology of strength and well-being amenable to scientific study and intervention. In that issue Martin Seligman and Mihalyi Csikszentmihalyi wrote:

> "At the individual level, it is about positive individual traits; the capacity for love and vocation, courage, interpersonal skill, aesthetic sensibility, perseverance, forgiveness, originality, future mindedness, spirituality, high talent, and wisdom…Psychology is not just a branch of medicine concerned with illness or health; it is much larger. It is about work, education, insight, love, growth, and play. And in this quest for what is best, positive psychology does not rely on wishful thinking, faith, self-deception, fads, or hand waving; it tries to adapt what is best in the scientific method to the unique problems that human behavior presents to those who wish to understand it in all its complexity." (Copyright © 2000, American Psychological Association. Reproduced with permission. Seligman ME, Csikszentmihalyi M. Positive psychology. An introduction. *Am Psychol*. 2000;55(1):5–14. doi: 10.1037//0003-066x.55.1.5.)

Over the past 40 years, cognitive therapists have demonstrated that altered cognition cannot only change behavior it can also alter brain function. If pessimism is the dominant cognition of the depressed, optimism appears as the dominant cognition of the mentally healthy. If learned helplessness leads to depression, learned optimism and self-efficacy lead to mental health. Even if the depressed often appears to view reality more realistically, such accurate reality testing avails depressed individuals of nothing.

In part, the importance of optimism to positive mental health depends upon an attributional cognitive style that asserts the good things that happen to someone will last forever and are pervasive. The bad things

Telegram: @medical_k

www.konkur.in

that happen to someone are limited and unlikely to happen again. In addition, optimism includes hope, a facet of mental health as old as the Greek myth of Pandora, yet hope is a topic to which psychiatry up to now has given little formal consideration. In contrast, the explanatory style of many chronically depressed individuals is that bad events, for which one may be responsible, will last forever and will generalize, while he or she bears no responsibility for good events, which not only occur only by chance but are limited and fleeting. How much better to take responsibility for the good events and conceive of them as lasting and pervasive, while the bad events are bad luck, isolated instances, and unlikely to happen again?

Longitudinal studies reveal that an optimistic attributional style improves physical health and wards off depression rather than merely "prolonging human suffering," as Nietzsche feared. In addition, the so-called illusion of optimism permits one to contemplate and plan for rather than deny the future. As longitudinal studies have repeatedly shown, future-mindedness is a critical ingredient of mental health. In addition, in major depression, the hopeful illusion of the placebo effect accounts for roughly 50% of the variance between the effect size produced by selective serotonin reuptake inhibitors (SSRIs) and no treatment. Thus, experimentally and longitudinally, optimism has been linked to positive mood and good morale, perseverance and effective problem-solving, to longevity, and to succeed in a wide spectrum of activities.

A critical distinction, of course, is the degree to which optimism distorts and to which pessimism accurately perceives reality. The pessimism of psychotic depression, like the psychotic optimism of acute mania, involves reality-defying delusion. But the comforting illusions of the mentally healthy do not interfere with learning that stoves are hot, while the pessimistic perceptions of the dysthymic, while often accurate, can still inhibit future efforts to cook. In the prevention of future mental illness, one of psychiatry's most powerful tools may be the inculcation in the young of optimism, hope, and future-mindedness. But to be effective, the optimistic must pull into consciousness emotional awareness of future pain and discomfort (see *anticipation* in Model D).

Recently, advocates of positive psychology have divided positive mental health into four components: *Talents, Enablers, Strengths,* and *Outcomes. Talents* are inborn, genetic, and are not much affected by interventions (e.g., high IQ or being an easy baby). *Enablers* reflect benign social

Telegram: @medical_k

www.konkur.in

conditions, interventions, and environmental good luck (e.g., a strong family, a good school system, living in a democratic meritocracy); enablers can be experimentally modified to enhance strengths. *Strengths* (see Table 3.5–1) are character traits like curiosity and openness that reflect facets of mental health that are amenable to change. The 24 *Strengths* are currently an essential component of modern positive psychology and can be self-assessed via the Internet. *Outcomes* reflect dependent variables (improved GAF, social relationships, SWB) that can be used to provide evidence for the predictive validity that efforts by clinicians to enhance *Strengths* are not just wishful thinking.

Admittedly, which so-called *strengths* are most associated with mental health is open to debate. Wisdom, kindness, and the capacity to love and be loved are strengths with which few would argue. But should courage be included as a strength, and why were intelligence, perfect musical pitch, and punctuality excluded? The answer is that the 24 strengths listed in Table 3.5–1 may be subjected to a variety of tests. First, they must have been recurrent positive values across cultures and across centuries—why punctuality was excluded? Second, they must be valued in their own right and not just as a means to ends. Third, like intelligence and perfect musical pitch, they are not inborn talents.

There are several pitfalls to positive psychology. First, the perspective of mental health as a Utopia is one of the bogeymen of national health policymakers. They are afraid, without directly expressing it, that this perspective will put a backbreaking burden on health insurance. Thus, there is considerable debate within the mental health professions about whether helping people achieve greater SWB is a process that any insurance program should reasonably be expected to cover. Helping people achieve their potential for community participation is perhaps a more laudable goal. But that, too, is highly value-laden and culture-bound. Over time society will have to decide who should pay for positive mental health: the individual, the educational system, third-party payers, religious organizations, or a combination of all four.

A second caution to positive psychology is the danger of the culturally insensitive prescription of parochial virtues. The dangers of value judgments are enormous. “Virtues,” even Aristotelian virtues, need to be distinguished from health. Keeping wounds clean is healthy but not a virtue. Body hygiene in public places is a virtue but not necessarily healthy.

Telegram: @medical_k

www.konkur.in

A third controversial facet of positive psychology is its emphasis on optimism. Since the late 19th century, many social scientists, especially those in Europe, have mistrusted optimistic cognition, especially religious optimism, as a maladaptive “American” illusion interfering with an accurate perception of reality. Nietzsche, Freud, Marx, and Darwin all perceived optimism as evidence of ingenuous cultural adolescence, not of mature mental health. Opponents of optimism believed that it was healthier to face the hard facts of life. In addition, for most of the 20th century, investigators like Pavlov and Skinner have viewed the study of cognitions of all kinds, of which optimism is one, as inferior to the study of behavior. Only in the last 20 years has psychiatry begun to see the value of positive psychology.

MODEL C: MENTAL HEALTH AS MATURITY

Unlike other organs of the body that are designed to mature in the first 2 decades and then remain functionally static but gradually less robust until death, the brain is different. The brain can develop new functions until the 8th decade and develop anatomically (more efficiently myelinated) until the 6th. Therefore, just as optimal brain development requires almost a lifetime, so does the assessment of positive mental health. A 10-year-old’s lungs and kidneys are more likely to reflect optimal function than are those of a 60-year-old, but that is not true of their central nervous systems. To some extent, then, adult mental health reflects a continuing process of maturational unfolding. Statistically, physically healthy 70-year-olds are mentally healthier than they were at 30; and prospective studies reveal that individuals are less depressed and show greater emotional modulation at age 70 than they did at age 30.

But if prospective studies of adult development reveal that the immature brain functions less well than the mature, does that mean adolescents are mentally healthier than toddlers? And are the middle-aged mentally healthier than adolescents? The answer is both yes and no, but the question illustrates why to understand mental health, one must understand what is meant by maturity.

In some respects, in 1950, Erik Erikson anticipated Jahoda and Grinker when he provided the first model of adult social development. He viewed each of his well-known eight “stages” of human development as a “criterion of mental health.” Subsequently, Jane Loevinger provided a

Telegram: @medical_k

www.konkur.in

model of adult ego development. Lawrence Kohlberg has provided a model of adult moral development, and most recently, James Fowler has provided a model of spiritual development. Implicit in all these models is the assumption that greater maturity reflected better mental health. Arguably, the best definition of mental health that is available is William Menninger's definition of maturity depicted in Table 3.5–1. In his model, maturity is not only the antonym of narcissism, but it is quite congruent with other models of mental health.

To confirm the hypothesis that maturity and positive mental health are almost synonymous, the study of the behavior and feeling states of persons studied over a lifetime becomes necessary. Although such longitudinal studies have come to fruition only recently, all illustrate the association of maturity with increasing mental health. After 50, of course, the association between mental health and maturity is contingent upon a healthy central nervous system. The ravages of brain trauma, major depression, arteriosclerosis, Alzheimer, alcoholism, and schizophrenia must all be avoided. But if so, with good physical health, intellectual functions can remain virtually unimpaired until eighty. Common folklore bemoans that millions of neurons are lost with each decade of adulthood until the value of selective pruning is recognized. Remember, 5-year-olds have twice as many neurons as adults do at 20.

The association of mental health with maturity is mediated not only by progressive brain myelinization into the 6th decade but also by the evolution of emotional and social intelligence through experience. Erikson conceptualized that such development produced a "widening social radius." In such a view, life after age 50 was no longer to be a staircase leading downwards, as in the Pennsylvania Dutch cartoons of lifespan development, but a path leading outwards. In Erikson's model, the adult social radius expanded over time through the mastery of the four tasks of "identity vs. identity diffusion," "intimacy vs. isolation," "generativity vs. stagnation," and "integrity vs. despair." On the basis of empirical data from Harvard's Study of Adult Development, Vaillant has added two more tasks —career consolidation and keeper of the meaning or guardian—to Erikson's four (see Fig. 3.5–1). The mastery of such tasks appears relatively independent of education, gender, social class, and probably culture.

In such a model, the social radius of each earlier adult developmental task fits inside the next. First, adolescents must achieve an *Identity* that

Telegram: @medical_k

www.konkur.in

allows them to become separate from their parents, for mental health and adult development cannot evolve through a false self. The task of *Identity* requires mastering the last task of childhood: sustained separation from social, residential, economic, and ideological dependence upon the family of origin. Identity is not just a product of egocentricity, of running away from home, or of marrying to get out of a dysfunctional family. There is a world of difference between the instrumental act of running away from home and the developmental task of knowing where one's family values end and one's own values begin. Such separation derives as much from the identification and internalization of important adolescent friends and nonfamily mentors as it does from simple biologic maturation. For example, accents become relatively fixed by age 16 and reflect those of one's adolescent peer group rather than the accents of one's parents.

FIGURE 3.5–1. A schematic model of the expanding social radius of maturing individuals during adulthood.

Then, young adults should develop *Intimacy,* which permits them to become reciprocally, and not selfishly, involved with a partner. But living

Telegram: @medical_k

www.konkur.in

with just one other person in an interdependent, reciprocal, committed, and contented fashion for years and years may seem neither desirable nor possible to a young adult. Once achieved, however, the capacity for intimacy may seem as effortless and desirable as riding a bicycle. Sometimes the relationship is with a person of the same gender; sometimes, it is completely asexual; and sometimes, as in religious orders, the interdependence is with a community. Superficially, mastery of intimacy may take very different guises in different cultures and epochs, but "mating-for-life" and "marriage-type love" are developmental tasks built into the developmental repertoires of many warm-blooded species, including the human species. Nevertheless, recent lifetime studies of marriage reveal "mating" for life is not always the rule—or even desirable. Personalities often change over a lifetime.

Career Consolidation is a task that is usually mastered together with or that follows the mastery of intimacy. Mastery of this task permits adults to find a career as valuable as they once found play. On a desert island, one can have a hobby but not a career, for careers involve being of value to other people. There are four crucial developmental criteria that transform a "job" or hobby into a "career": contentment, compensation, competence, and commitment. Obviously, such a career can be "wife and mother"—or in more recent times, "husband and father." To the outsider, the process of career consolidation often appears "selfish," but without such "selfishness," one becomes "selfless" and has no "self" to give away in the next stage of Generativity. Not only schizophrenics but also individuals with a severe personality disorders often manifest a lifelong inability to achieve either intimacy or sustained, gratifying employment. In short, they fail to grow up.

Mastery of the fourth task, *Generativity,* involves the demonstration of a clear capacity to care for and guide the next generation. Existing research reveals that sometime between the ages 35 and 55, the need for achievement declines, and the need for community and affiliation increases. Depending on the opportunities that society makes available, generativity can mean serving as a consultant, guide, mentor, or coach to young adults in the larger society. Like leadership, generativity means being in a caring relationship in which one gives up much of the control that parents retain over young children. Good mentors learn "to hold loosely" and to share responsibility. Generativity reflects the capacity to give the self—finally completed through mastery of the first three tasks of

Telegram: @medical_k

www.konkur.in

adult development—away. Its mastery is strongly correlated with successful adaptation to old age. This is because in old age, there are inevitable losses, and these may be overwhelming if one has not continued to grow beyond his or her immediate family.

The penultimate life task is to become a *Guardian* (in anthropological terms, Keeper of the Meaning). Like grandparenthood, this task involves passing on the traditions of the past to the future. Generativity and its virtue, *care,* require taking care of one person rather than another. While keeper of the meaning and its virtues of *wisdom* and *justice* are less selective, justice, unlike care, means not taking sides. Indeed, mastery of this fifth task is epitomized by the role of the wise judge. The focus of a *Guardian* is on the conservation and preservation of the collective products of mankind—the culture in which one lives and its institutions—rather than just the development of its children.

Just as "selfless" coaches play a different role from "selfish" athletes; just so the organizers, judges, and guardians of the Olympic Games play a very different role from the Games' more generative but still parochial coaches. Clearly, caretakers and grandparents are not mentally healthier than caregivers and parents. The only distinction is that grandparents are usually better at the tasks of Keepers of the Meaning than are 30-year-olds.

Finally, in old age, it is common to feel that some life exists after death and that one is part of something greater than one's self. Thus, the last life task in Erikson's words is *Integrity,* the task of achieving some sense of peace and unity with respect both to one's own life and to the whole world. Erikson described integrity as "an experience which conveys some world order and spiritual sense. No matter how dearly paid for, it is the acceptance of one's one and only life cycle as something that had to be and that, by necessity, permitted of no substitutions." One of the study subjects, age 88, described integrity in more mundane terms "I need to go to the Department of Motor Vehicles to discover if the world would be safer if I no longer drove a car." How different the concerns of the elderly adult are from the adolescent seeking identity.

Admittedly, healthy adult development does not follow rigid rules. Some individuals, often due to great stress, tackle developmental tasks out of order or all at once. On the one hand, Alexander the Great, General Lafayette, Napoleon Bonaparte, and Joan of Arc were inspirational and generative leaders in their 20s. On the other hand, William Osler, one of

Telegram: @medical_k

www.konkur.in

the most generative physicians of all time, did not confront the task of intimacy until he married at age 40—well after he had established his career as a brilliant professor of medicine. Ludwig van Beethoven enjoyed a brilliant, committed career but never enjoyed intimacy.

Finally, it must be kept in mind that mastery of one life task is not necessarily healthier than mastery of another, for adult development is neither a foot race nor a moral imperative. Rather, these six sequential tasks above are offered as a road map to help psychiatrists make sense of where they are and where their patients might be located. One can be a happily married 20-year-old; that is usually healthy. One can be a chronically unemployed single 50-year-old; that is usually unhealthy. Acquiring a social radius that extends beyond oneself by definition allows more flexibility and SWB and thus is always healthier than self-preoccupation.

MODEL D: MENTAL HEALTH AS RESILIENCE

In 1856, Claude Bernard, a French physiologist and a founder of experimental medicine, started the current understanding of positive health when he wrote, “We shall never have a science of medicine as long as we separate the explanation of the pathological from the explanation of normal, vital phenomena.” For example, coughing and pus in response to infection seemed pathologic but, in fact, were often healing. In other words, it is not stress that kills people, but healthy mastery of stress that permits people to survive.

In 1925, Adolf Meyer, a founder of modern American psychiatry, introduced the current understanding of mental health when he asserted that there were no mental diseases; there were only characteristic reaction patterns to stress. Meyer’s point was that although adaptive mental “reaction patterns” like denial, phobias, and even projections can appear to reflect illness, they may, in fact, be “normal, vital phenomena” related to healing. Just as immune mechanisms, clotting mechanisms, and callous formation heal by distorting bodily equilibrium; just so equally involuntary coping mechanisms heal by distorting mental processes.

Of course, the symptoms of organic brain damage usually reflect disease and not adaptation. Manic-depressive psychosis is due to genetic defects; the mental devastation produced by alcoholism is due to poisoning, and the negative symptoms of schizophrenia reflect brain

Telegram: @medical_k

www.konkur.in

defects and not adaptation. Nevertheless, much so-called mental illness is more like the healthy but red and tender swelling that immobilizes a fracture so that it may heal. Much of what is called mental illness in the current diagnostic nomenclature—the symptoms of many anxiety disorders, some depressions, and most personality disorders—are the outward manifestations of homeostatic struggles to adapt to life. Admittedly, analogous to acne and autoimmune disease, such reaction patterns often reflect rigid, poorly modulated, and pathologic efforts at adaptation.

To set the stage, there are three broad classes of coping mechanisms that humans use to overcome stressful situations. First, there are the ways in which an individual elicits help from appropriate others: namely *consciously seeking social support.* Second, there are *conscious cognitive strategies* that are intentionally used to master stress. Third, there are *adaptive involuntary coping mechanisms* (often called "defense mechanisms") that distort the perception of internal and external reality in order to reduce subjective distress, anxiety, and depression.

By 1970, the term *defense mechanisms,* like many psychoanalytic metaphors, had been largely discarded by empirical social scientists. Consistency of definition and rater reliability was lacking. But over the last 40 years, the idea of involuntary coping has entered the literature of empirical cognitive psychology under such rubrics as "hardiness," "grit," "self-deception," "emotional coping," and "illusion." In recent years experimental strategies for assessing such mechanisms, especially with videotape and the Q-sort, have also improved reliability. Several empirical studies, well-reviewed by Skodol and Perry, have clarified the current understanding of healthy and unhealthy involuntary adaptive mechanisms (a.k.a. defenses). Nevertheless, no one has yet developed a method for assessing defenses, which meets conventional standards for psychometric reliability. As a result, the axis of adaptive involuntary coping mechanisms has been excluded from DSM-5.

This third class of *involuntary adaptive coping mechanisms* reduces conflict and cognitive dissonance during sudden *changes* in internal and external reality. If such changes in reality (e.g., the unanticipated crisis of 9/11) are not "distorted" and "denied," they can result in temporarily disabling anxiety and/or depression. In summary, such homeostatic mental "defenses" shield people from sudden changes in the four

Telegram: @medical_k

www.konkur.in

lodestars of conflict: affect, reality, relationships, and conscience (see Fig. 3.5–2).

First, such involuntary mental mechanisms can restore psychological homeostasis by ignoring or deflecting sudden increases in the lodestar of impulse, affect, and emotion. (The emotions of terror, grief, longing, and dependency loom just as important as sources of conflict as do lust, fear, and rage.) Psychoanalysts call this lodestar "id," fundamentalists call it "sin," cognitive psychologists call it "hot cognition," and neuroanatomists point to the hypothalamic and limbic regions of the brain.

Second, such involuntary mental mechanisms can provide a mental time out to adjust to sudden changes in *reality* and self-image, which cannot be immediately integrated. Individuals who initially responded to the television images of the sudden destruction of New York's World Trade Center as if it were a movie provide a vivid example of denial of an external reality that was changing too fast for voluntary adaptation. Sudden good news—the instant transition from a student to a physician or winning the lottery—can evoke involuntary mental mechanisms as often as can an unexpected accident or diagnosis of leukemia.

Telegram: @medical_k

www.konkur.in

FIGURE 3.5–2. The four lodestars of human conflict.

Third, involuntary mental mechanisms can mitigate sudden irresolvable conflict with important *people,* living or dead. People become a lodestar of conflict when one cannot live with them and yet cannot live without them. Death is such an example; another is an unexpected proposal of marriage. And since people exist within one's self as well as without, internal representations of important people may continue to haunt someone and cause conflict for decades after they have ceased to live with them and thus evoke an involuntary mental response.

Finally, the fourth source of conflict or anxious depression is social learning or conscience. Psychoanalysts call it "superego," anthropologists call it "taboos," behaviorists call it "conditioning," and neuroanatomists point to the associative cortex and the amygdala. This lodestar is not just the result of admonitions from one's parents that are absorbed before age 5 but is formed by one's whole identification, with one's culture, and sometimes by irreversible learning resulting from overwhelming trauma.

Telegram: @medical_k

www.konkur.in

There are many ways that one can ignore or distort one or more of these four lodestars in order to mitigate intrapsychic conflict. These coping mechanisms or “defenses” can abolish impulse (e.g., by reaction formation), or social learning (e.g., by acting out), or other people (e.g., by schizoid fantasy), or reality (e.g., by psychotic denial). They can abolish one’s conscious recognition of the subject (e.g., by projection), or the object of a conflict (e.g., by turning against the self), or awareness of the idea (e.g., by repression), or of the affect associated with the idea (e.g., isolation of affect).

All classes of adaptive involuntary coping mechanisms are effective in “denying” or defusing conflict and in “repressing” or minimizing stress, but they differ greatly in the psychiatric diagnoses assigned to their users and in their consequences for long-term biopsychosocial adaptation. In the most pathological category, are found distortion and denial of external reality. These mechanisms are common in young children, in one’s dreams, and in psychosis. To breach them requires altering the brain by neuroleptics or waking the dreamer.

More common to everyday life are the relatively maladaptive, “narcissistic,” or “immature” defenses. They include projection, passive aggression, schizoid fantasy, hypochondriasis, dissociation, and “acting out.” Defenses in these categories are common in adolescents, immature adults, and individuals with personality disorders. They often make others more uncomfortable than the user. Such defenses are consistently and negatively correlated with a global assessment of mental health, and they profoundly distort the affective component of interpersonal relationships.

Less maladaptive mechanisms include repression, intellectualization, reaction formation (i.e., turning the other cheek), and displacement (i.e., directing affect at a more neutral object). They are often associated with anxiety disorders and with the psychopathology of everyday life. In contrast to the “immature” defenses, these intermediate defenses are manifested clinically by phobias, compulsions, obsessions, somatizations, and amnesias. Such users often seek psychological help and such “compromise formations” respond more readily to interpretation. Such defenses usually cause more conscious suffering to the user than to other people. They are common to everyone from 5 years old until death. They are neither healthy nor unhealthy.

The “mature” still distort and alter feelings, conscience, relationships, and reality, but they achieve these alterations gracefully and flexibly.

Telegram: @medical_k

www.konkur.in

These mechanisms allow the individual consciously to experience the affective component of interpersonal relationships but in a tempered fashion. Thus, the beholder regards the involuntary mature defenses as virtues, just as the beholder may regard the prejudice of projection and the tantrums of acting out as sins.

Doing as one would be done by (altruism), keeping a stiff upper lip or deploying Grit (suppression), keeping future pain in awareness (anticipation), the ability not to take one's self too seriously (humor), and turning lemons into lemonade (sublimation) are the very stuff from which positive mental health is made. Unfortunately, like tightrope walking, without months of practice, mature mechanisms cannot easily be deployed voluntarily and only then by those with innate balance.

Identification of defenses is difficult. Rarely can people identify their own defenses, and people often fail to recognize them in others or, still worse, "project" their own defenses onto them. To identify a defense, an objective observer needs to triangulate past truth with present behavior and subjective report. For example, one woman wins community praise for founding a shelter for battered women (altruism), but she dismisses her behavior as "a need to rent my house." Another woman is imprisoned for breaking her toddler daughter's arm in a tantrum (acting out), but she dismisses her behavior as an accident. In fact, social agency records from 30 years before reveal that both women had been taken at age 2 from the care of physically abusive, alcoholic mothers. Whether one ultimately views another's coping response as healthy or psychopathic depends on the results of their involuntary efforts. Ultimately, like other facets of mental health, the reliable identification of healthy but involuntary coping mechanisms requires longitudinal study.

Healthy Involuntary Mental Mechanisms

Longitudinal studies from both Berkeley's Institute of Human Development and Harvard's Study of Adult Development have illustrated the importance of mature defenses to mental health.

Humor. Everyone recognizes that humor makes life easier. As Freud suggested, "Humor can be regarded as the highest of these defensive processes," for humor "scorns to withdraw the ideational content bearing the distressing affect from conscious attention, as repression does, and thus surmounts the automatism of defense." With humor, one sees all,

Telegram: @medical_k

www.konkur.in

one feels much, but one does not act. Humor permits the discharge of emotion without individual discomfort and without unpleasant effects upon others. Mature humor allows one to look directly at what is painful, whereas dissociation and slapstick distract one to look somewhere else. Yet, like the other mature defenses, humor requires the same delicacy as building a house of cards—timing is everything.

Altruism. When used to master conflict, altruism involves getting pleasure from giving to others what that person themselves would have liked to receive. For example, using reaction formation, a former alcohol abuser works to ban the sale of alcohol in his town and annoys his social drinking friends. Using altruism, the same former alcoholic serves as an Alcoholics Anonymous sponsor to a new member—achieving a transformative process that may be lifesaving to both the giver and receiver. Obviously, many acts of altruism involve a free will, but others involuntarily soothe unmet needs.

Sublimation. The sign of a successful sublimation is neither careful cost accounting nor shrewd compromise but rather psychic alchemy. By analogy, sublimation permits the oyster to transform an irritating grain of sand into a pearl. In writing his Ninth Symphony, the deaf, angry, and lonely Beethoven transformed his pain into triumph by putting Schiller's "Ode to Joy" to music. But like humor, sublimation does not usually occur on purpose.

Suppression. Suppression is a defense that modulates emotional conflict or internal/external stressors through stoicism. Suppression minimizes and postpones but does not ignore gratification. Empirically, this is the defense most highly associated with other facets of mental health. Used effectively, suppression is analogous to a well-trimmed sail; every restriction is precisely calculated to exploit, not hide, the winds of passion. Evidence that suppression is not simply a conscious "cognitive strategy" is provided by the fact that jails would empty if delinquents could learn to just say "No." Over the last decade, Angela Duckworth has carried out cutting-edge empirical research on suppression, which she relabeled as "Grit."

Anticipation. If suppression reflects the capacity to keep the current impulse in mind and control it, anticipation is the capacity to keep an

Telegram: @medical_k

www.konkur.in

affective response to an unbearable future event in mind in manageable doses. The defense of anticipation reflects the capacity to perceive future danger affectively as well as cognitively and by this means to master conflict in small steps. Examples would be the fact that moderate amounts of anxiety before surgery promote postsurgical adaptation and that anticipatory mourning facilitates the adaptation of parents of children with leukemia.

As with the use of altruism and suppression, the use of anticipation can often be voluntary and independent of conflict. But it is in cases of "hot cognition" that these defenses can become involuntary and lifesaving.

Just as psychiatry needs to understand how a GAF of 75 might become 90, just so, psychiatry needs to understand how best to facilitate the transmutation of less adaptive defenses into more adaptive defenses. One suggestion has been first to increase social supports and interpersonal safety and second to facilitate the intactness of the central nervous system (e.g., rest, nutrition, and sobriety). The newer forms of integrative psychotherapies using video recording can also catalyze such change by allowing patients to see their involuntary coping style.

MODEL E: MENTAL HEALTH AS SOCIOEMOTIONAL INTELLIGENCE

High socioemotional intelligence reflects above-average mental health in the same way that a high IQ reflects above-average intellectual aptitude. Such emotional intelligence lies at the heart of positive mental health. In the *Nicomachean Ethics,* Aristotle defined socioemotional intelligence as follows: "Anyone can become angry—that is easy. But to be angry with the right person, to the right degree, at the right time, for the right purpose, and in the right way—that is not easy." Nevertheless, as recently as 40 years ago, a textbook on intelligence dismissed the concept of such Aristotelian social intelligence as "useless."

All emotions exist to assist basic survival. While the exact number of primary emotions is arguable, seven emotions are currently distinguished by characteristic facial expressions connoting anger, fear, excitement, interest, surprise, disgust, and sadness. The capacity to identify these different emotions in one's self and in others plays an important role in mental health. The benefits of being able to read feelings from nonverbal cues have been demonstrated in almost a score of countries. These

Telegram: @medical_k

www.konkur.in

benefits included being better emotionally adjusted, more popular, and more responsive to others. Empathic children do better in school and are more popular than their peers even if they are no more intelligent than the other children. Head Start found that early school success was achieved not by intelligence but by knowing what kind of behavior is expected, how to rein in the impulse to misbehave, being able to wait, and how to get on with other children. At the same time, the child must be able to communicate their own needs and turn to teachers for help.

Ethologically, emotions are critical to mammalian communication. Since such communications are not always consciously recognized, the more skilled one is in identifying his or her own emotions, the more skilled he or she will be in communicating with others and empathically recognizing their emotions. Put differently, the more one is skilled in empathy, the more one will be valued by others, and so the greater will be their social supports, self-esteem, and intimate relationships.

Social and emotional intelligence can be defined by the following criteria:

- Accurate conscious perception and monitoring of one's own emotions.
- Modification of one's emotions so that their expression is appropriate. This involves the capacity to self-soothe one's own anxiety and to shake off hopelessness and gloom.
- Accurate recognition of and response to emotions in others.
- Skill in negotiating close relationships with others.
- Capacity for focusing emotions (motivation) toward the desired goal. This involves delayed gratification and adaptively displacing and channeling impulses.

Some behavioral scientists divide emotions up into positive and negative as if negative emotions were unhealthy. This is probably an error. As with pus, fever, and cough, the negative emotions of sadness, fear, and anger are also important to healthy self-preservation. Positive emotions like joy, love, hope, gratitude, and compassion are associated with subjective contentment. While negative emotions interfere with contentment, their expression can be equally healthy.

Over the last 15 years, three important empirical steps have been taken in the current understanding of the relationship of socioemotional intelligence to positive mental health. The first step is that both functional MRI (fMRI) and ingenious neurophysiological experimentation have led to

Telegram: @medical_k

www.konkur.in

advances in the current understanding of the integration of the prefrontal cortex with the limbic system, especially with the amygdala and its connections. These research advances have brought psychiatrists closer to understanding emotions as neurophysiological phenomena rather than as platonic abstractions. We have learned that the prefrontal cortex is the region of the brain responsible for working memory and that the frontal lobes, through their connections to the amygdala, hippocampus, and insula, encode emotional learning in a manner quite distinct from both conventional conditioning and declarative memory.

The second step forward has been the slow but steady progress in the conceptualizing and even the measuring of “emotional intelligence.” Over the last decade, measures of emotional intelligence are evolving rapidly.

The third advance is the use of video recording to chart emotional interaction. Videos of sustained family interactions reveal that the most important aspect of healthy infant development, adolescent development, and marital harmony is how partners or parents respond to emotions in others. To ignore, to punish, and to be intimidated or contemptuous of how another feels spells disaster. Children of emotionally attuned parents are better at handling their own emotions and are more effective at soothing themselves when upset. Such children even manifest lower levels of stress hormones and other physiological indicators of emotional arousal.

Where the passive study of positive mental health ends and active primary prevention begins is unclear, but, like the model of positive psychology, the model of socioemotional intelligence is potentially interventionist. Just as someone can have an above-average musical skill or physical coordination, which they can improve with training, someone can learn to enhance emotional modulation. Until late in the Cold War, empirically researched techniques for “getting to yes” in negotiations were not in any academic curricula.

There are now many exercises in handling relationships that help couples, business executives, and diplomats become more skilled at conflict resolution and negotiation. In the past decade, there has also been an increasing effort to teach schoolchildren core emotional and social competencies, sometimes called “emotional literacy.” The relevance of these advances in psychology to psychiatry includes teaching emotion recognition and differentiation in eating disorders, teaching anger modulation, and finding creative solutions to social predicaments for behavior disorders.

Telegram: @medical_k

www.konkur.in

MODEL F: MENTAL HEALTH AS SUBJECTIVE WELL-BEING

In this chapter, "happiness" will be construed to refer to *SWB*—a relatively neutral and, more importantly, a long-lasting state of affairs. The term "happiness," however, has multiple meanings. For example, happiness can also be construed to mean nothing more than selfish pleasure. This interpretation has given Positive Psychology the disparaging reputation of "happyology." To underscore this aspect, the author prefers to define "happiness" as selfish *drive reduction* and "joy" to refer to the equally satisfying, less autistic, *and longer-lasting interpersonal connection.* The search for happiness can appear selfish, narcissistic, superficial, and banal. Happiness is often based on illusion or on dissociative states. Pleasures can come easily and be soon gone. Illusory happiness is seen in the character structure associated with bipolar and dissociative disorders, with the maladaptive denial of Pollyanna and Voltaire's Dr. Pangloss and with the exaltation of "me" advocated by much pop psychology. Examples of maladaptive "happiness" can be the excitement of risk-taking, from being "high" on drugs, and from "turning on" to any unmodulated but gratifying primitive need like binge eating, tantrums, promiscuity, and revenge. Such maladaptive happiness can bring temporary bliss but has no sticking power. It is because of such ambiguity of meaning that, throughout this section, the term *SWB* will be substituted for happiness.

National well-being has been used more appropriately than "national happiness" by political scientists to describe the "health" of nations. The demographic variables assessed include women's rights, lack of corruption, percent live births, and freedom of the press.

The importance of the term *SWB* addresses the question is it better to meet some expert's definition of mental health, or is it better to feel subjectively fulfilled? The answer is "both." For positive mental health does not just involve being a joy to others; one must also experience SWB. Long before humankind considered definitions of mental health, they pondered criteria for subjective happiness. For example, objective social support accomplishes little if subjectively the individual cannot feel loved. Thus, the capacity for SWB becomes an important model of mental health. Put differently, happiness and SWB are always congruent if they involve positive emotions. Negative emotions like Greed, Lust, Hate, and

www.konkur.in

Vengeance are all about *me* and lead only to fleeting satisfactions. The eight great positive emotions: Gratitude, Love, Joy, Compassion, Forgiveness, Trust (Faith), Hope, and Awe are all about the other and can lead to lasting well-being.

SWB is never categorical. Healthy blood pressure is the objective absence of hypotension and hypertension, but SWB is less neutral. SWB is not just the absence of misery but the presence of positive contentment. Nevertheless, if SWB is an inescapable dimension of mental health, it is often regarded with ambivalence or ignored altogether. If through the centuries philosophers have sometimes regarded "happiness" as the highest good, psychologists and psychiatrists have tended to be as oblivious to SWB as they are to mental health. An electronic search of psychological abstracts since 1987 turned up 57,800 articles on anxiety and 70,856 on depression, but only 5,701 mentioned life satisfaction and only 851 mentioned joy.

On the one hand, "no man is happy who does not think himself so," but this will be true only if the "happiness" comes from unselfish positive emotions or "selfish" behaviors that also gratify others:for example, self-efficacy, play, and "flow" (deep but effortless involvement). Spirituality (e.g., prayer, meditation, and belief in a power greater than the self) all rid the individual of narcissistic focus on shame, resentments, and the "poor-me's." Fostering the 24 Strengths in Table 3.5–1, model B is perhaps the most important prescription for SWB from Positive Psychology.

The mental health issues involved in SWB are complicated and clouded by historical relativism, value judgment, and illusion. Europeans have always been skeptical of American concern with happiness. Only in the last decade have investigators like Barbara Fredrickson, Martin Seligman, and David Snowdon pointed out that a primary function of positive emotional states and optimism is that they facilitate self-care. SWB makes available personal resources that can be directed towards innovation and creativity in thought and action. Thus, SWB, like optimism, becomes an antidote to learned helplessness. Again, controlling for income, education, weight, smoking, drinking, and disease, happy people are only half as likely to die at an early age or become disabled as unhappy people.

A distinction can be made between *pleasure* and *gratification.* Pleasure is in the moment, is closely allied with happiness, and involves the satisfaction of impulses and biological needs. Pleasure is highly susceptible to habituation and satiety. In contrast, gratification can be

Telegram: @medical_k

www.konkur.in

equated with what Aristotle called *eudaimonia* and Csikszentmihalyi terms "flow." In such a distinction, if pleasure involves satisfaction of the senses and emotions, gratification involves joy, the satisfaction of "being the best you can be," and of meeting aesthetic and spiritual needs. This can be manifested by a child lost in play, a mountaineer transported by rock climbing, or a father marveling at his daughter's first solo on a bicycle.

But once again, the role of value judgment clouds the view of whether any given form of happiness is good or bad. Is the happiness of helping others better than the happiness of gratifying creative play? The jury is still out. In addition, all emotions exist to promote survival as well as to communicate with others. Subjective (unhappy) distress can be healthy. As ethologically minded investigators have long pointed out, subjective negative affects (e.g., fear, anger, and sadness) can be healthy reminders to seek environmental safety and not to wallow in SWB. If positive emotions facilitate faith, hope, optimism, and contentment, fear is the first protection against an external threat; sadness protests against loss and summons replacement, and anger signals trespass.

Positive emotion generates exploration and promotes mastery. Unlike negative emotions, which generate zero-sum, win-lose situations, positive emotions generate win-win situations. However, tolerance of negative emotions may characterize some periods of the lifecycle more than others. The relative absence of depression and anxiety over time is healthy in grammar school children from 8 to 10 and in young submariners in their 20s. But increasing capacity to tolerate and bear subjective depression and anxiety distinguishes healthy adolescents from healthy fifth graders and healthy (generative) submarine skippers from healthy enlisted men. There is a time to hope and a time to fear. Human development is complex.

Until recently, the scientific parameters of SWB were as vague as those for objective mental health. A 1967 definition suggested that a happy person is "*young, healthy, well-educated, well paid,* extroverted, optimistic, *worry-free,* religious and married with high self-esteem, a good job, morals, and *modest aspirations.*" In the last 30 years, however, research has shown that such a vacuous generalization only partly corrects and that the italicized adjectives are untrue or true only with qualifications.

The Nun Study by Snowdon and Danner provides perhaps the most convincing link between subjective happiness and physical health. In their 20s, 180 nuns were asked to write a 2 to 3-page autobiography. Of those

Telegram: @medical_k

www.konkur.in

who expressed the most positive emotion, only 24% had died by 80. In contrast, by age 80, 54% of those who expressed the least positive emotion had died.

Only in the last 3 decades have investigators, especially Edward Diener, made a serious effort to attend to definitional and causal parameters of SWB and thereby address important questions. One such question is: Is SWB more a function of environmental good fortune, or is it more a function of an inborn, genetically based temperament? Put differently, does SWB reflect trait or state? If SWB reflects a safe environment and the absence of stress, it should fluctuate over time, and those individuals who are happy in one domain or time in their lives might not be happy in another.

A second question but one related to the first is what is the cause and what is the effect. Are happy people more likely to achieve enjoyable jobs and good marriages, or do conjugal stability and career contentment lead to SWB? Or are such positive associations the result of still a third factor? For example, the absence of a genetic tendency for alcoholism, for major depression, for trait neuroticism, and even for the presence of a chronic wish to give socially desirable answers (impression management) might conflate both SWB and reports of a good marriage and career contentment.

Research over the last 3 decades has provided a tentative answer to the first question. Modern research has confirmed the aphorism of Duc de La Rochefoucauld, “Happiness and misery depend as much on temperament as on fortune.” SWB is highly heritable and relatively independent of demographic variables. SWB is due more to “top-down” processes—temperamental factors governing SWB—rather than due to “bottom-up factors”—for example, high income leading to SWB.

As with physiological homeostasis, evolution has prepared to make subjective adjustments to environmental conditions. Thus, one can adapt to good and bad events so that he or she does not remain in a state of either elation or despair. But they have a harder time adjusting to their genes. Studies of adopted away twins have demonstrated that half the variance in SWB is due to heritability. The SWB of monozygous twins raised apart is more similar than the SWB of heterozygous twins raised together. Among the heritable factors making a significant contribution to high SWB are low trait neuroticism, high trait extraversion, absence of alcoholism, and absence of major depression. In contrast to tested

Telegram: @medical_k

www.konkur.in

intelligence, when heritable variables are controlled, SWB is not affected by environmental factors like income, parental social class, age, and education.

For example, investigators have been startled that a significant number of acquired immunodeficiency syndrome (AIDS) victims perceive that their illness has enhanced the quality of their subjective lives. Paraplegic victims of spinal injuries adapt so that within 2 months after injury, their SWB returns to a state where positive emotion exceeds negative emotion. Similarly, after a few weeks of temporary elation, lottery winners also return to baseline. Some of the homeostatic mental mechanisms underlying such adaptation were elaborated on in a prior section.

If SWB were due largely to the meeting of basic needs, then there should be a relatively low correlation between SWB in work and SWB in recreational settings or between SWB in social versus SWB in solitary settings. However, in most studies, the correlations between SWB in different facets of life are very high—higher than the correlation between height and weight. People who are satisfied with their lives at one point in time are more likely to be satisfied with their jobs in the future, and people with high job satisfaction are more likely to report satisfaction with retirement. Admittedly, a few studies exist where correlations are low between satisfaction with different facets of life. Again, more work is needed.

Since women experience more objective clinical depression than men do, the fact that gender is not a determining factor in SWB is interesting. One explanation is that women appear to report both positive and negative affects more vividly than men. In one such study, gender accounted for only 1% of the variance in happiness but 13% of the variance in the intensity of reported emotional experiences.

Telegram: @medical_k

www.konkur.in

FIGURE 3.5–3. The independence of a 240% increase in US individual income (adjusted for inflation) from subjective well-being over 40 years.

Consistently, relationships are more important to SWB than money. In a representative study of 800 college alumni, respondents who preferred high income, occupational success, and prestige to have very close friends and a close marriage were twice as likely to describe themselves as “fairly” or “very” unhappy. Over the last 2 decades, the doubling of net disposable income (controlling for inflation) in the Western world (Fig. 3.5–3) did not affect SWB. Additional evidence that environmental events are much less important to SWB than might be expected comes from cross-cultural studies. Mean life satisfaction in socioeconomically challenged Brazil and China is higher than in socioeconomically blessed Japan and Germany.

In some instances, the environment *can* be important to SWB. Young widows remain subjectively depressed for years. Even though their poverty has been endured for centuries, respondents in very poor nations, like India and Nigeria, report lower SWB than do other more prosperous nations. The loss of a child never stops aching. Although achieving concrete goals, like money and fame, does not lead to a sustained

Telegram: @medical_k

www.konkur.in

increase in SWB, social comparison (i.e., watching one's next-door neighbor become richer than you) does exert a negative effect on SWB.

Maintaining self-efficacy, agency, and autonomy make additional environmental contributions to SWB. For example, surprisingly, elders will use their discretionary income to live independently, even though this means living alone rather than with relatives. SWB is usually higher in democracies than in dictatorships. Assuming responsibility for favorable or unfavorable outcomes (internalization) is another major factor leading to SWB. Placing the blame elsewhere (externalization) significantly reduces SWB. In other words, the mental mechanisms of paranoia and projection make people feel worse rather than better.

Over the past 30 years, methodological solutions have accelerated understanding of SWB just as they have accelerated understanding of objective mental health. Longitudinal studies, multivariate analysis, and causal modeling have each done much to free investigators from correlational reasoning. Nevertheless, efforts to measure SWB have been quite varied and lack a gold standard. Some investigators measure SWB as simply global life satisfaction; other investigators assess more specific domains like work, marital satisfaction, and positive affect. However, the question "How do you feel about your life as a whole?" answered on a simple 7-point scale ranging from "delighted" to "terrible" works surprisingly well.

More refined methods of measurement of subjective states of mind have included the the positive and negative affect scale (PANAS), which assesses both positive and negative affect, each with ten affect items. *The Satisfaction with Life Scale* represents the most recent evolution of a general life satisfaction scale. Most recently, the widely validated SF-36 has allowed clinicians to assess the subjective cost–benefits of clinical interventions. Because short-lived environmental variables can distort SWB, the consensus is emerging those naturalistic experience-sampling methods are the most valid way to assess SWB. With such sampling methods, research subjects are contacted by beeper at random times during the day for days or weeks, and at each interval are asked to assess their SWB. This method provides a more stable report of SWB. Finally, in order to tease verbal self-report from actual subjective experience, physiological measures of stress (e.g., measures of galvanic skin response, salivary cortisol, and recording facial expression by concealed cameras) have also proven useful.

Telegram: @medical_k

www.konkur.in

In the 21st century, investigators like Fredrickson, Vaillant, and Damasio have found instruments like the PANAS too cognitive and replaced "positive affects" like Joviality, Self-Assurance, Attentiveness, and Serenity with more limbic affects like Joy, Love, Compassion, Trust, and Gratitude. However, these latter, more significant positive affects (described in the next model) do not lend themselves to rating scales.

MODEL G: MENTAL HEALTH AS POSITIVE OR "SPIRITUAL" EMOTIONS

In the 19th century, psychiatrists wrote about concepts like "moral insanity" and "good character," and mental health was deemed related to morality and religious observance. During the 20th century, the rise of cultural anthropology, psychoanalysis, behaviorism, molecular biology, and secularism, in general, all led psychiatrists to doubt there was any relationship between morality and health. Recently, with advances in neuroscience, that viewpoint has begun to change.

Model G as a reflection of positive ("spiritual") emotions, however, was not included in the 8th edition of this textbook because the science was not yet in place to support its inclusion. Recent advances in neuroscience and in the biological understanding of positive emotion have necessitated psychiatry taking "positive psychology" seriously. In the last 10 years, however, positive emotions, previously relegated to popular songs, pastoral counseling, and humanistic psychology, have been rendered scientifically tangible.

Fifty years ago, medical students were taught mainly about hypothalamic emotions like lust, hunger, fear, and rage. Such emotions are common also to lunatics, alligators, and decorticate cats. Prosocial emotions like empathy, compassion, and parental love were thought to be learned behaviors and, therefore, placed in the neocortex and in the curricula of schools of education.

In the 1960s, Paul MacLean, with his focus on the limbic system unique to mammals, and Harry Harlow and John Bowlby, shifting attention to love as an attachment rather than as Eros and lust, created the basis for neuroscience to provide substance to the platitudes of Jahoda, Abraham Maslow, and even of St. Paul with his "theological virtues" of faith hope and love.

Telegram: @medical_k

www.konkur.in

Positive emotions arise from the inborn prosocial mammalian capacity for unselfish parental love. Thus, they are grounded in evolutionary heritage. Research over the last 20 years has placed these emotions firmly in the limbic system. Remove a mother hamster's cortex, and she cannot do mazes but remains a competent mother. Damage her limbic system, however, and she can still do mazes but not parent her pups.

Model G defines both mental and spiritual health as the amalgam of the positive emotions that bind to other human beings. Love, hope, joy, forgiveness, compassion, faith, awe, and gratitude comprise the important positive and "moral" emotions included in this model. Of great importance, the eight selected positive emotions all involve human connection. None of the eight emotions listed is just about the self. These positive emotions appear to be a common denominator of all major faiths. Omitted from the list are five other positive emotions—excitement, interest, contentment (happiness), humor, and a sense of mastery, for a person can feel these latter five emotions alone on a desert island.

Negative emotions originating in the hypothalamus, such as fear and anger, are elaborated in the human amygdala (larger in humans than in other mammals). Of tremendous importance to individual survival, negative emotions are all about "me." In contrast, positive emotions, apparently generated in the limbic system and unique to mammals, have the potential to free the self from the self. People feel both the emotions of vengeance and of forgiveness deeply, but the long-term results of these two emotions are very different. Negative emotions are crucial for survival in the time present. The positive emotions are more expansive and help to broaden and build. In time future, they widen one's tolerance for strangers, expand one's moral compass, and enhance one's creativity. Careful experiments by neuroscientists like Jaak Panksepp and Richard Davidson and psychologists like Barbara Fredrickson and Sonja Lyubomirsky document that while negative emotions narrow attention and miss the forest for the trees, positive emotions, especially joy, make thought patterns more flexible, creative, integrative, and efficient.

The effect of positive emotion on the autonomic (visceral) nervous system has much in common with the relaxation response to meditation. In contrast to the metabolic and cardiac arousal that the fight-or-flight response of negative emotion induces in the *sympathetic* autonomic nervous system, positive emotion via the *parasympathetic* nervous system reduces basal metabolism, blood pressure, heart rate, respiratory

Telegram: @medical_k

www.konkur.in

rate, and muscle tension. fMRI studies of Kundalini yoga demonstrate that meditation increases the activity of the hippocampus and the right lateral amygdala, which in turn leads to parasympathetic stimulation and the sensation of deep peacefulness.

Positive emotions have a biological basis, which means that they have evolved through natural selection. The prosocial emotions probably reflect adaptations, which permitted the survival of relatively defenseless Homo sapiens and their extremely defenseless children in the African savannah 1 to 2 million years ago.

Evidence for Positive Emotions

However, it has taken recent developments in neuroscience and ethology make positive emotions a fit subject for scientific study. For example, infantile autism, a not uncommon genetic disorder of emotional attachment, was not discovered until 1943 by a Johns Hopkins child psychiatrist, Leo Kanner—in his own son. Until then, it was not possible for medicine to articulate a positive emotion as basic, but as cognitively subtle, as an attachment. Today, the congenital lack of empathy and difficulties of attachment in childhood autism can be recognized by any competent pediatrician.

It was in the years 1945 to 1950 that psychoanalyst John Bowlby's ethological studies first convinced physicians that orphans needed affection as much as food. It was in the 1950s that Harry Harlow's objective findings of attachment behavior in rhesus monkeys rendered nonsexual love a tangible biologic reality for psychologists. Two decades later, Paul Ekman, doubting Margaret Mead's assertion that emotions and their facial expression were culturally based, traveled as far afield as the New Guinea highlands to demonstrate that social emotions were biological and not cultural in origin.

Locating positive emotion in the mammalian limbic system has been a slow, arduous process. In 1955, James Olds, an innovative neuropsychologist, observed that 35 out of 41 electrode placements within the limbic system of rats, but only 2 out of 35 placements outside of the limbic system, proved sufficiently rewarding to lead to self-stimulation. In the 1950s, also, neurobiologist Paul MacLean pointed out that the limbic structures govern the mammalian capacity to remember (cognition) but also to play (joy), to cry out at separation (faith/trust), and to take care of

Telegram: @medical_k

www.konkur.in

own (love). Except for rudimentary memory, reptiles express none of these qualities.

Not until the last 20 years, however, have fMRI studies demonstrated that when individuals subjectively experience existential states of fear, sadness, or pleasure, blood flow increases in limbic areas and decreases in many higher brain areas. Various studies have located pleasurable human experiences (tasting chocolate, winning money, admiring pretty faces, enjoying music, and orgasmic ecstasy) in limbic areas—especially in the orbitofrontal region, anterior cingulate, and insula. These diverse structures are closely integrated and organized to help to seek and to recognize all that falls under the rubric of mammalian love and human spirituality. Only in the last 20 years have neuroscientists like John Allman and Giacomo Rizzolatti identified the limbic spindle (von Economo) neurons and mirror cells that undergird prosocial human mentation.

The *anterior cingulate gyrus* links valence and memory to create attachment. Along with the hippocampus, the anterior cingulate is the brain region most responsible for making the past meaningful. In terms of mediating attachment, the anterior cingulate receives one of the richest dopaminergic innervations of any cortical area. Thus, the cingulate gyrus provides motivational salience not only for lovers but also for drug addicts. The anterior cingulate is crucial in directing whom one should approach and whom one should avoid. Maternal touch, body warmth, and odor via the limbic system and especially via the anterior cingulate regulate a rat pup's behavior, neurochemistry, endocrine release, and circadian rhythm. Brain imaging studies reveal that the anterior cingulate gyrus is aroused neither by facial recognition of friends per se nor by sexual arousal per se. Rather, anterior cingulate fMRI images light up when a lover gazes at a picture of a partner's face or when a new mother hears her own infant's cry.

Perhaps no area of the brain is more ambiguous in its evolutionary heritage or more crucial to mental health than the *prefrontal cortex.* The prefrontal cortex is in charge of estimating rewards and punishments and plays a critical role in adapting and regulating the emotional response to new situations. Thus, the prefrontal lobes are deeply involved in emotional, "moral," and "spiritual" lives.

From an evolutionary standpoint, the human frontal lobes are not different from chimpanzees in terms of the number of neurons. Rather, it is the frontal lobe white matter (the connectivity between neurons through

Telegram: @medical_k

www.konkur.in

myelinated fibers), which accounts for the larger frontal lobes of humans. This connectivity to the limbic system underscores its “executive” function which includes the ability to delay gratification, comprehend symbolic language, and, most importantly, establish temporal sequencing. By being able to connect memory of the past to “memory of the future,” the frontal lobes establish for Homo sapiens predictable cause and effect.

Surgical or traumatic ablation of the ventromedial prefrontal cortex can turn a conscientious responsible adult into a moral imbecile without any other evidence of intellectual impairment. Destroy the medial prefrontal lobes of the neocortex as was done by the tamping rod that penetrated the skull of the legendary 19th-century railroad worker, Phineas Gage, and one destroys the capacity for obedience to social mores. Phineas Gage had been a responsible foreman until an explosion drove the tamping rod that he was using to place a dynamite charge through the orbit of his left eye and out through the top of his skull. Although he survived, his medial frontal lobes were destroyed, as was his capacity for socially appropriate and empathic behavior. His intellect remained intact, but lacking empathy, he was no longer mentally healthy.

The *insula* is another part of the limbic system that is only beginning to be understood. The insula is a medial cortical gyrus located between the amygdala and the frontal lobe. The brain has no sensation; humans feel emotion only in their bodies. The insula helps to bring these visceral feelings into consciousness: the pain in one’s heart of grief, the warmth in one’s heart of love, and the tightness in one’s gut from fear all make their way into consciousness through the insula.

Both the limbic anterior cingulate and insula appear active in the positive emotions of humor, trust, and empathy. The higher apes are set apart from other mammals by a unique neural component called the spindle cell. Humans have 20 times more spindle cells than either chimps or gorillas. (Adult chimpanzees average about 7,000 spindle cells. Human newborns have four times more, and human adults have almost 200,000 spindle cells.) Monkeys and other mammals, with the possible exception of whales and elephants, are totally lacking in these special cells. These large, cigar-shaped spindle or “von Economo” neurons appear central to the governance of social emotions and moral judgment. Spindle cells may have helped the great apes and humans integrate their mammalian limbic system with their expanding neocortex. Spindle cells are concentrated in the anterior cingulate cortex, the prefrontal cortex, and the insula. More

Telegram: @medical_k

www.konkur.in

recently, scientists have discovered a special group of “mirror neurons” that reside in the insula and anterior cingulate. These neurons are more highly developed in humans than in primates and appear to mediate empathy—the experience of “feeling” the emotions of another.

While the practical applications of this newest model of mental health are still many years away, these findings provide further evidence that the brain and mind are one. In several studies, the prosocial biological activity of the anterior cingulate cortex and insula was highest in individuals with the highest levels of social awareness (based on objectively scored tests). In other words, there are not only individual biological differences for negative mental health but also for positive mental health.

FUTURE DIRECTIONS

In the 19th century, mental health was deemed related to morality, and psychiatrists wrote of “moral insanity” and “good character.” But in the latter half of the 20th century, with a 19th-century boost from Sigmund Freud, religion and spirituality were expunged from psychiatry.

Religiosity is consistently and positively correlated with well-being, but there may be a chicken-egg relationship between social support and religious observance. For example, among churchgoers, it is difficult to disentangle where spiritual faith ends and community support begins. Nevertheless, it makes sense that positive faith should enhance SWB. Heightened spirituality provides hope that bad events will diminish and lends wonder and joy to ordinary events. While the concept of spirituality still remains too value-laden to serve as a 7th model of mental health, increasingly sophisticated neurological research on the positive emotions by investigators like Jan Panksepp, Marco Iacoboni, Barbara Fredrickson, and Andrew Newberg may find in the 21st century a role for spirituality among the models for mental health.

Table 3.5–2.
Cross-Correlation Between Four Different Models of Mental Health at Midlife (Age 47) and Their Positive Prediction of Late Life (Age 65) Mental Health and Their Independence from Parental Social Class and Childhood Environment

	A	C	D	F
Model A: Ais V	—			
Model C: Maturity	0.61	—		
Model D: Social intelligence	0.57	0.50	—	
Model F: Resilience	0.81	0.57	0.51	—
Subjective well-being age 65	0.44	0.32	0.42	0.35
Mental health at 65	0.52	0.38	0.43	0.50
Parental social class	0.08	0.05	0.12	0.06
Warm childhood environment	0.19	0.12	0.16	0.13

$N = 160$.
Correlations >0.25 significant at $p < 0.001$, $n = 137–143$.
Correlations >0.15 significant at $p < 0.05$.

This chapter has so far suggested six conceptually distinct ways to assess a single construct—mental health. It would be a terrible mistake to believe any one of these six models is superior to the others. From different vantage points, they all measure the same thing. For example, case example, Richard Luckey not only had a GAF of 95, but another independent rater saw him as highly generative, and a third rater saw him using defenses largely from level VII. He radiated SWB. Contrasting case example, Alfred Paine had a GAF of 72, was not generative, used largely level II–V defenses, and was chronically dissatisfied with his life. “Dilip Jeste has recently developed a seventh clear definition and the neurobiological underpinning for “Wisdom” as a construct for mental health.

Table 3.5–2 (from the Study of Adult Development at Harvard) provides an empirical illustration of the interrelationship of these different models in a 75-year prospective study of nondelinquent inner-city men. Not only was each of the four models (measured by independent raters) significantly correlated with the other three, but also each model predicted objective global mental health and SWB assessed 20 years later. Significantly, none of the four models was well predicted by parental social class or a warm childhood environment.

Telegram: @medical_k

www.konkur.in

In Table 3.5–2, Axis V was assessed by Luborsky's HSRS. Maturity was determined by an assessment of the presence or absence of Generativity. SWB at 55 was quantified by summing each man's report of satisfaction over the past 20 years (on a 5-point scale) in four life areas (marriage, children, job, and friends) and, then, adding his best score from one of four additional areas (hobbies, sports, community activities, and religion). Social intelligence was assessed by objective evidence of good relations with friends, workmates, spouses, children, and siblings. Resilience was measured by the relative frequency with which men deployed the five **mature defenses** against the relative frequency with which they used **the five immature** (*level II–V*) defenses. Mental Health at 65 reflected success at work, relationships, play, and not using psychiatrists. Parental social class used the method of Hollingshead and Redlich (parental residence, education, and occupation). Warm Childhood Environment reflected good relations with mother, father, siblings, and a cohesive home at age 14.

Currently, four of this chapter's models are capable of being assessed psychometrically—above-average normality by the GAF (Axis V), maturity by the presence or absence of Generativity, SWB by self-report, and resilience by defense level on the optional DSM-IV axis. As already noted, measures to assess psychometrically the other two models—the Strengths of Positive Psychology and socioemotional intelligence are underway.

The concept of mental health also raises the issue of therapeutic interventions to achieve it. What facets of mental health are fixed and which are susceptible to change? With Clozapine or with cognitive-behavioral therapy, one can raise a GAF from 40 to 70, but how would one raise a GAF from 70 to 90? Chemicals can alleviate mental illness but do not improve healthy brain function. One can enhance mental health only through cognitive, behavioral, and psychodynamic education.

One can change some facets of brain function better than others. By analogy, the most intensive educational intervention in individuals who are not severely deprived will raise their IQ by only about seven points, but sustained therapeutic intervention can change individuals utterly illiterate in Italian into fluent Italian conversationalists. Admittedly, a correct accent to go with the words is harder to teach.

In concluding this chapter, it seems important to review some of the safeguards for a study of positive mental health. First, mental health must

Telegram: @medical_k

www.konkur.in

be broadly defined in terms that are culturally sensitive and inclusive. Second, the criteria for mental health must be empirically and longitudinally validated. Third, validation means paying special attention to cross-cultural studies. In somatic medicine, criteria have been developed so that people of widely varying backgrounds and beliefs can agree upon what constitutes rational therapy for a disease. The same criteria for mental health need to be developed. Fourth, although mental health is one of humanity's important values, it should not be regarded as an ultimate good in itself. One must proceed in efforts toward trying to improve mental health while maintaining due respect for individual autonomy.

There is no logically perfect method of analysis by which one can distinguish private bias and culturally determined value judgment from a culturally universal and scientifically valuable definition of mental health. Predictive validity remains the best guide. A parable offered by the protagonist in Gotthold Lessing's great 18th-century play, *Nathan the Wise,* will help to illustrate why mental health can only be identified by longitudinal study. In Lessing's play, an angry sultan had asked Nathan, a Jew, on pain of death, to identify the one true religion—Christianity, Islam, or Judaism. Nathan gently pointed out the need to maintain a longitudinal perspective.

"A man lived in the East,
Who owned a ring of marvelous worth,
Given to him by a hand beloved.
The stone was opal, and possessed the secret power
To make the owner loved of God and man,
If he but wore it in this faith and confidence…"

The ring was sought as an inheritance by each of Nathan's three sons. Since he loved him all equally, the doting father gave each son an identical ring. After their father's death, the three sons hurried off to a judge and demanded that the judge identify the lucky owner of one true ring. The judge exclaimed,

"But stop! I've just been told that the right ring,
Contains the wondrous gift to make its wearer loved,
Agreeable alike to God and Man.

Telegram: @medical_k

www.konkur.in

That must decide, for the false rings will not have this power…
Let each one strive to gain the prize of proving by results
The virtue of his ring and aid its power
With gentleness and heartiest friendliness…
The virtue of the ring will then
Have proved itself among your children's children."

In the future, it is incumbent upon psychiatry to understand the implications of each of these six models of mental health. In conducting research on positive mental health, it is important for psychiatrists to recognize which model they use. Equally important, in the area of national health policy, one needs a clear understanding of not only what constitutes positive mental health but also of who is responsible for intervention and who is responsible for paying for it.

Finally, primary prevention is clearly superior to treating disease once it has occurred. Thus, we need to study individuals with positive mental health the way agronomists study wheat that is resistant to drought and blight. Psychiatry also needs to be able to measure and record mental health. The Global Assessment of Functioning provides the same reliability and has much greater predictive validity than the presence or absence of most psychiatric diagnoses. No psychiatric chart should be without an assessment of functioning. The capacities to work and to love over time are extremely important indices of mental health. They are far more important than the cross-sectional presence or absence of anxiety, depression, or illegal drug use. But the capacity to work and to love must be assessed longitudinally. "How many years since age 21 have you spent employed?" is more useful than, "What is your present job?" Again, "Tell me about your longest intimate relationship" is more useful than "Are you married?"

Finally, the assessment of maturational development provides the best prediction of future clinical courses. Thus, the mental status and diagnostic formulation should both reflect an assessment of social maturation and coping style. If the person is 35, have they mastered Erikson's task of intimacy? If they are 40, have they achieved competence in, commitment to, contentment with, and compensation from their career? If they are over 50, have they mastered Generativity and learned to care less about themselves and more about their children? Again, when the going gets tough, do they eschew less mature mental mechanisms

3.6 Neuroscience of Psychoanalytic Object Relations Theory

Dragan M. Svrakic, M.D., Ph.D., Charles F. Zorumski, M.D., and Otto F. Kernberg, M.D.

Object relations theory is a major modification of classical (Freudian) psychoanalysis. It places the innate instinct to bond, rather than pleasure-seeking, as the driving mechanism of mind development. Early experiences with first "objects" (primary caretakers, usually the mother), so the theory goes, are forgotten as specific episodes but continue to influence adult personality and significant relations in a self-reinforcing fashion. The tenets of object relations theory have been inferred from observations of infants and children. For decades, the sole empirical support for the validity of object relations theory has been the efficacy of psychoanalytic psychotherapy[1] in the treatment of personality disorder, a syndrome paradigmatic for partial (fragmented) object relations. In this selective overview, object relations theory is discussed through the prisms of cognitive- and basic neuroscience, dynamical systems theory, coordination dynamics theory, and complex systems science. Our main postulates are (i) recent advances in the understanding of neural encoding and systems-consolidation of episodic memory provide a framework to outline the neural mechanisms of object relations theory[2]; (ii) dynamical system theory, natural network and computational network science provide a framework to outline object relations as the primordial[3] attractor memory that governs self-organization of BrainMind[4] in a self-reinforcing fashion, and (iii) functional neuroimaging and cognitive neuroscience provide a framework to explain the emergence and the potential neural substrate of the sense of self.

As groundwork for our discussions, we first review basic aspects of brain and mind organization and then the tenets of object relations theory. Each following section is discussed through a dual prism of object relations theory and neuroscience. As the chapter is limited to 30 references, acknowledgments provide a list of authors whose work was

used but could not be explicitly cited. Portions of this text have been previously published.

BASICS OF BRAIN AND MIND SELF-ORGANIZATION

The Brain: A Self-Organizing Biological Complex

The brain is understood to be an open, self-organized, dynamical, complex, and adaptive biologic system. Such characteristics beget the brain's ability to generate outcomes new to itself ("emergent properties"), the most global of which is the mind. The concepts of self-organization, complexity, and dynamical systems, attributed to the brain, are the subject of physics, mathematics, biology, cybernetics, and network- and complexity science. Because these fields might be new to some readers, we discuss them briefly as an introduction. We first discuss the terms mind, psyche, mental function, and personality, as these are used inconsistently in the literature.

Mind, Psyche, Mental Function, Personality. The terms mind, mental function, and psyche are equivalent as they derive from Latin mens for mind or from Greek (ψυχη´—psyche) for "soul" or "spirit." The *mind* is best conceptualized as a progressively differentiated but initially global capacity to store previous dynamics in existing brain matter in order to predict the environment, change it, or adjust to it. Functional neuroimaging indicates that *personality* likely reflects a specific configuration of the mind in any given individual, a unique ontogenetic outcome of the general phylogenetic capacity of human beings to develop mind. Caterina Gratton and colleagues report that functional connectivity networks across normal subjects show a stable general structure but also unique and stable individual differences. Individually unique network variants were most pronounced for top-down control networks regulating attention, executive function, salience, and emotion. A network variant shows stability over time within a person (i.e., trait-like) and can accurately identify that specific individual from a large group, likened to a fingerprint. The elementary topography of these networks is present at birth, but network connectivity (topology) continues to interactively self-organize into early adulthood. The outcome is influenced by person-specific factors (genetic polymorphisms, unique environments), thus creating individual differences in mental faculties and behavioral traits called personality.

www.konkur.in

Self-Organization of Open Biologic Systems. A true self-organizing system achieves and maintains order without a “teacher” but through local interactions of its constituting components governed by intrinsic properties. Self-organization in complex biologic systems improves the system in some respect, for example, unadaptable components are self-organized into an adaptable whole in the given environment. This means that some extrinsic criterion, usually adaptive demands, informs the process. In fact, biologic adaptive systems are thermodynamically open (they operate unbalanced, “far-from-equilibrium,” with a net macroscopic flow of matter or energy) but may be stabilized by input and output. Such systems import order (information, energy) and export entropy or disorder (e.g., the brain dissipates heat by various mechanisms). The brain self-organizes in part based on intrinsic prenatal network development (an immature language network is set in place before birth) and in part by importing order (e.g., the language network self-organizes into its mature form from speech input). Open dynamical biologic systems, in other words, participate in their own organization rather than truly self-organize. With this stipulation in mind, we use the term self-organization in reference to BrainMind.

Complexity and Emergence. Different types of neurons and glia are engaged in different relationships that follow local synaptic rules, for example, interdependencies, competitions, autoregulation, etc. Such microscopic complexity is necessary for higher-order emergence, a macroscopic event that is not a property of and cannot be reduced to any of the microscopic constituting elements. Applied to neuroscience, emergence (e.g., cognitive concepts) is a more or less predictable macroscopic consequence of the underlying collective dynamics of less complex individual neurons. For example, simple semantic concepts called “prototypes” arise in the brain’s convergence zones (e.g., the prefrontal cortex [PFC], among others) from sensory processing within individual neurons at lower levels. The concept of chair encompasses different designs that are unified by the shared essence of an object being intended for sitting. Here, emergence is one level, as the higher level of abstraction emerges from details implemented by the lower sensory level; the concept of chair is thus unexpected given the properties and principles of the lower-level domain, but predictable albeit not in full detail. Emergence can be multilevel, with many positive and negative feedback

Telegram: @medical_k

www.konkur.in

loops governing the individual activity of billions of neurons. This gives rise to “new world” emergence, with completely new roles while the old roles disappear. The most notable example of such multilevel emergence is the mind (although some consider the mind to be a weak emergence, one level above the neurons–see section on MindBody debate).

Feedback and Learning. Feedback is essential for the self-organization of open biologic systems as it drives learning. Feedback is a circular process (“looping”) in which output is returned (“fed back”) to its input to regulate future output. Negative feedback (higher output reduces further input) levels differences in the collective behavior of neurons leading to stability that counteracts change. Positive feedback (higher output increases further input) amplifies differences and reinforces the direction of change. In complex dynamical systems, where learning has to incorporate proximal consequences, feedback is the means to such learning.

Dynamical, Adaptive, and Scale-free Systems in Biology. A system is said to be *dynamical* if it changes in time through the iterated application of an underlying transition rule (“dynamical rule”). Given the current state of a dynamical system (a collection of points in an appropriate state space), the dynamical rule predicts the immediate future of all state variables, thereby describing the temporal evolution of the system. Applied to neuroscience, a current state in dynamical brain development is defined by phase-specific gene activity (epigenetic programs) and phase-specific environmental factors (change with age) acting upon the previous phase. Each new phase is influenced by the degree of success at the previous phase and indirectly by the degree of success at all previous phases. In other words, the future behavior of a dynamical system, here the brain, depends not only on the initial conditions but also on the history. This is called *path dependence* and is typically mediated by positive feedback loops that top-down channel lower levels to continue to produce input of the same kind.

A biologic dynamical system is *adaptive* if it has the ability to reorganize in response to changing conditions in the environment. New adaptive demands may render the current configuration of an open complex system adaptively suboptimal. The system then learns (imports order) and rapidly self-organizes toward a fitter organization-function (development). Such punctuated transitions are natural and age-selective in BrainMind

Telegram: @medical_k

www.konkur.in

development, especially frequent in the first decade of life. For example, temperament traits are the main communication avenue of infancy but become suboptimal to meet the growing demand for bilateral interactions in toddlerhood. Around 2 to 3 years of age, the mental sense of "I" (self) in the form of passive noticing of one's own selfhood ("phenomenal self") relatively abruptly differentiates in the mind, now fitter to communicate with itself and the environment.

Scale-free dynamics are characteristic of self-organizing dynamical adaptive systems such as the brain's large-scale networks. A network is said to be scale-free when the distribution of connections between nodes[5] decreases as a power-law function of the number of nodes in the network: a few nodes are highly connected with other nodes in the network ("hubs") while the majority of nodes have only a few connections. Such "power law" distribution is sometimes referred to as the "80–20 law," in which 20% of "rich" nodes have 80% of connections. There is no true average number of connections, making the network difficult to measure or scale ("scale-free"). Self-organization and scale-free connectivity underlie important features of the brain: (i) robustness at a system level against global failure, provided that a sufficient number of vital hubs are not compromised at the same time ("targeted attack"), in which case a cascading failure could occur; (ii) ability to incorporate substantial imperfections, genetic and environmental, and still stay within the range of normalcy, that is, without affecting function in a significant way, again provided that key hubs are not affected. This ability is known as "developmental homeostasis," described by John Alcock.

Power law degree distribution is usually, but not always, suggestive of a brain network functioning *near criticality*, that is, very near the critical point of transition between two different states, one being subcritical (when the network transitions into rigid order, unable to process complexity (e.g., contradictory experience with the same person), the other being supercritical (increased network activity that may result in chaos/disorder, unable to process coherent outcomes). Such operating regime near the critical point of transitions to either rigidity or disorder allows cortical networks to dynamically screen alternatives and process complexity. See section Self-Organizing Criticality of the Brain for more details.

The Concept of Attractors in Dynamical System Theory. All complex adaptive systems, including BrainMind, are also dynamical as they

Telegram: @medical_k

www.konkur.in

change in time. The evolution of such systems is governed by stable attractors, a conditionally stable state of an evolving system for given internal and/or external conditions. In computational neuroscience, an attractor is a network state that governs the dynamical process of time evolution of the network into its stable, self-sustaining attractor state from large classes of initial network states ("basin of attraction"). Such attractor networks have a high degree of feedback that funnels the collective firing of individual neurons toward desired coherent outcomes. Applied to neuroscience, cortical network activity begins with microscopic complexity where heterogeneously connected heterogeneous types of neurons and glia, interlinked by recurrent excitatory connections, interact in nonlinear and nontrivial fashions. "Nontrivial" means that the final, stable state of an attractor network (stable pattern of firing, self-sustenance) provides feedback, positive or negative, that brakes the symmetry of individual firing and funnels it toward a desirable outcome. For example, differences in luminescence, processed by dedicated neurons in the visual network, are governed by attractor dynamics and feedback toward the collective behavior of all neurons in this network, resulting in a coherent visual percept of an object. Neural networks are thus deterministically self-organized to produce coherent macroscopic complexity (coherent vision, memory, hearing, etc.) out of incoherent microscopic complexity (individually firing neurons). Once the deterministic outcome is achieved, the network relaxes into its stable pattern of baseline firing that sustain the network when neuronal activation by external inputs is absent. The concept of stable attractor networks with persistent self-sustaining baseline activity corresponds to the brain's resting-state functional connectivity (RSFC) networks.

Most Brain Networks Are Pre-assembled In Utero by Intrinsic Activity that Predates Experience. Spontaneous neural activity, either intrinsic to neurons or generated by synaptic interactions, may synchronize local and large-scale embryonic brain networks before afferent signals reach the cortex. The fundamental topography of these earliest networks is genetically predetermined. For example, synchronized bursts of spontaneous activity govern the formation of thalamocortical circuits (these relay sensory information to the cortex, among other functions) and early intracortical networks (sensory-motor, memory, language, etc.). The postnatal surge in sensory input is processed by

Telegram: @medical_k

www.konkur.in

preassembled thalamocortical circuits and relayed to the cortex, thereby (i) forming a loop to modulate itself (the thalamo–cortico–thalamic loop) and (ii) modulating the a priori intracortical networks with input from the environment. Preassembled intrinsic networks predate experience, as noted. They act as “best guess” or “seed” templates that serve as attractors for selective input, ultimately self-organizing into respective mature networks (language, vision, etc.). For example, in 2-day-old neonates, brain regions that are parts of the auditory language network[6] are fully activated in both hemispheres by speech-input. This immature interhemispheric language network is likely generated by intrinsic synapses governed by genetic programs, before speech input. It provides a biologic basis to develop language, as an attractor network for speech-input that learns to systematize phenomes into words and syntax. The immature inter-hemispheric language network dynamically self-organizes into a left-lateralized intrahemispheric (mature) auditory language network characterized by relative stability (language acquisition). To summarize, intrinsic embryonic networks mainly serve as experience-independent attractors (codes, templates, seeds, molds) for the development of mature brain networks based on subsequent experience-dependent input from their selective internal and external stimuli.

Resting-State Functional Connectivity. RSFC of the brain is spontaneous and maintained in the absence of any particular sensory input or motor output. RSFC forms macroscale spatio–temporal frames of distributed coactive regions linked by function (“functional” or “information coupling”). Takamitsu Watanabe and colleagues show that resting state functional networks (RSNs) involved in attention-demanding cognitive tasks (e.g., the frontoparietal network [FPN]) are (roughly) governed by monostable attractor dynamics with a coarse-grained global basin of attraction, the latter governed by multistable attractor dynamics. In other words, like all complex dynamical systems, RSNs can be characterized by a large number of realizable stable dynamical states. These states are schematically illustrated in Figure 3.6–1 with different levels of coarse-graining; the horizontal axis represents various configurations of the network, while the vertical axis is the corresponding energy. The network evolves toward the lowest energy states (valleys). At the lowest level of coarse-graining (top of the graph), the number of stable attractor states, represented by the valleys, is large, and the whole graph describes

Telegram: @medical_k

www.konkur.in

multistable attractor states, visualized by a rough dark gray curve. With higher-levels coarse-graining (light gray curve), the number of attractors becomes successively smaller as low-level valleys merge, typically by some mechanism of hierarchical clustering ("deep" learning), and smooth out toward a monostable, single attractor state (the deepest valley in the blue curve). From the original multistability states (dark gray curve), one obtains a funneled representation (light gray curve) in which the number of attractors (valleys) is reduced into a (roughly) monostable state. In contrast to FPN, the Watanabbe study shows, the default mode network (DMN) to which the brain relaxes when not on task, was governed by multistable attractor dynamics. This is suggestive of subcomponent attractor networks that may support memory maintenance with different memory states (see below) as well as that DMN may underlie the conscious sense of self (DMN can be conceived as the largest RSN, composed of all other RSNs).

FIGURE 3.6–1. Multistability and monostability of brain networks. delta E, shift in energy mediated by funneling (roughening) of multiple initial network states. (Courtesy of Charles H. Martin, Ph.D.)

The above results may be summarized as follows: when a RSN performs attention-demanding tasks, they are governed by multistable

Telegram: @medical_k

www.konkur.in

attractor dynamics, allowing the brain to travel from one relatively stable state to another, either in a spontaneous manner or triggered by external input. At rest, however, RSNs show monostable attractor dynamics that serve as algorithms for deep, gist-like learning from a large amount of data. To this end, multiple layers are used to progressively learn higher-level features from the raw input. Simply put, functional brain networks become better at performing their selective tasks ("automation") as they dynamically reconfigure to incorporate learning by training. Karolina Finc and colleagues report that the autonomy of DMN as well as integration among task-positive networks were modulated by training.

Homeostatic (intrinsic) brain plasticity may play a role in the different appearances of RSNs at work and at rest. An emerging consensus is that resting-state neuronal activity results from the modification of strengths of connections recapitulating common recruitment during task-evoked activity. Such recapitulation tailors RSNs configurations to reflect (i) individual history and experience, and (ii) stable, trait-like individual differences in functional brain networks. The internal "tuning" of these networks by self-organization may involve homeostatic plasticity,[7] aka metaplasticity, that is, the capacity of neurons to autoregulate their own excitability based on network activity. A self-organized system tunes itself as it evolves toward criticality by constantly adjusting the control parameter to the critical value by a decentralized feedback mechanism intrinsic to the network: the control parameter spontaneously decreases when the system is in a supercritical phase and increases when in a subcritical phase. Ma and colleagues recently reported that homeostatic regulation of inhibition plays an important role in generating criticality in excitatory networks.

Moreover, RSFC is defined by covariance at rest, which is independent of mean activity. If anything, this covariance increases when brain regions are not actively engaged in task-specific processing. Abraham Snyder and Timothy Laumann interpret that high spontaneous brain activity at rest may have a role in off-line neural plasticity and homeostasis (e.g., resetting ionic balances, deep learning, memory maintenance) among others.

In the last 15 years, more than 2,500 research papers on RSFC have been published but, individually, report different topology, topography, and taxonomy for these networks. Lucina Q. Udin and colleagues made a commendable attempt to put forward a universal taxonomy for RSNs, but

Telegram: @medical_k

www.konkur.in

updates will likely be needed to incorporate new data. Thus far, about a dozen macro-scale RSFC attractor networks have been identified, among others are:

- *DMN (or medial FPN) network* is involved in the formation, temporal binding, and dynamic reconfiguration of associative representations based on current goal-states. DMN also detects the associative relevance of internal and external stimuli, provides value coding to perceived events, accommodates predictive coding, semantic associations, and plays a role in continuously monitoring the environment, among other functions; this network is believed to be the neural substrate of the sense of self, or at least a large element of this sense (discussed later in more detail).
- *Dorsal FPN attention network* (driven by internally chosen goals, “internal attention”);
- *Lateral FPN attention network aka central executive network–CEN* (involved in working memory, executive function, external stimulus-driven attention); This network maintains and manipulates information in working memory, one function of which is executive, that is, decision-making and problem-solving in the pursuit of disciplined behavior; working memory, as suggested by Marvin Chun and colleagues, lies closest to the intersection between external and internal attention.
- *Salience network (SN)* or midcingulo-insular network as a combined ventral attention network (detects salient stimuli in the environment, especially when unattended) and cingulo-opercular network (involves the detection of behaviorally relevant environmental stimuli but may include internally generated remembered information). Lucina Udin and colleagues argue that the ventral attention network instantiates the larger, bilateral midcingulo-insular network; the former appears to function mainly during exogenous salience detection, whereas the midcingulo-insular SN plays a broader role, engaging across domains during processing of personally relevant inputs. This network also mediates the dynamic switching between DMN and CEN;
- *Auditory network* (inferior frontal gyrus, superior temporal gyrus, the insula);
- *Visual network* (subcortical geniculate, primary and association visual cortices)
- *Sensory-motor network* (the insula, selective cortical regions);

Telegram: @medical_k

www.konkur.in

- *Long- and short-term memory network* (is a multicomponent network involving cortical and subcortical structures, such as posterior–parietal, anterior–prefrontal, the limbic–temporal association areas, and the medial temporal lobe, with input from subcortical survival circuits and brainstem), and, we suggest,
- *The language network* (left-dominant network that comprises parts of the inferior temporal gyrus, premotor cortex, upper temporal lobe, and temporo-parietal interface).

Self-Organized Dynamical Oscillatory Motifs may be the Mechanism of the Brain's Functional Connectivity. In the early 2000s, John Beggs and Dietmar Plenz described spontaneous sharp negative deflections from local field potentials (nLFPs) in cortical neuronal assemblies at rest. As used by the authors, the term "neuronal assemblies" corresponds to attractor networks. Each nLFP self-organizes from local field potentials, the latter representing a summed macroscopic synchrony of microscopic spiking of individual neurons. Such population synchrony results from phase coupling between theta frequencies (4 to 8 Hz, stable attractor rhythm) and gamma frequencies (25 to 35 Hz, inhibitory rhythm, modulates the rhythm of principal neurons). Such phase coupling is known as "theta-gamma nests," where the phase of slow rhythm modulates the power of faster oscillations. These nLFPs are short-lived (milliseconds), separated by several seconds of quiescence, and appear across many spatial scales. They are believed to embed other spontaneous self-organized dynamical motifs that capture macroscopic synchrony of microscopic activity of individual neurons, such as network "up-state," neural avalanches[8] and coherence potentials (both consist of contiguous frames of nLFPs). Neural avalanches are comprised of frames of nLFPs, those with up to two standard deviations above a minimal amplitude threshold of the ongoing LFP amplitude fluctuations. Coherence potentials are composed of frames of nLFPs with ≥3 standard deviations above this amplitude. When arranged as statistical dependencies, contiguous frames of nLFPs self-organize as a cascade event (wave-like neuronal avalanches and coherence potentials) that capture the emergence of population synchrony at many local sites. The above four self-organized dynamical oscillatory motifs occur in a network engaged in spontaneous self-sustaining activity in the absence of input. This spontaneous activity is called "network up-state" in which network supports theta/gamma nests, nLFPs, neural avalanches, and coherence

Telegram: @medical_k

www.konkur.in

potentials, all involved in self-sustenance. These motifs are only weakly modulated by stimulus presentation, a characteristic of most RSNs.

To summarize, microscopic spiking of individual neurons governed by the attractor state of network near-criticality,[9] reaches synchrony as LFPs (theta/gamma nests) out of which nLFPs, neural avalanches, and coherence potentials self-organize across cortical sites forming diverse spatiotemporal patterns. It is plausible that the distributed brain attractor networks are functionally unified in the context of critical phenomena that maximize information transmission, information storage, dynamic range, metastable states, and computational power.

Multistability and Metastability are Basic Principles of Brain Computation. The brain continuously communicates with facets of internal and external environments for taking specific inputs and giving outputs. The first ingredients in the process are multiple functional attractor networks (e.g., visual, auditory, memory, language, etc.), each with a selective basin of attraction (aka stimulus- or demand-selectivity), each settling in a stable self-sustained pattern of firing once its selective stimulus has been processed (resting state). Energy inputs in the form of changes in control parameters (e.g., a mismatched demand or noise of random firing that indicates the weakness of the attractor network for the given event) may cause switching among functional attractor states, known as multistability[10] of a complex system. Multistability enables the brain to flexibly shift focus between attractor networks as conditions change. During resting states, a network shows (roughly) monostability that reflects deep learning (see Fig. 3.6–1).

Metastability of attractor networks may provide the basis for global brain function. As Scott Kelso points out, the origin of metastability lies in multistability: weak oscillatory coupling and broken asymmetry in discrete attractor networks at near-criticality allow for self-organization of a metastable regime where stable (attractor) and unstable (repellor) synchronization states no longer exist, and activity of individual elements obeys neither the intrinsic dynamics of the elements nor the dynamics dictated by the assembly. Such weakened fixed-point attractors, now “ghost attractors,” enable memory networks to process complexity.

Self-Organizing Criticality of the Brain. In the seminal concept of self-organized criticality, Per Bak posits that stable attractors allow open dynamical systems to function at near-criticality. The brain criticality

Telegram: @medical_k

www.konkur.in

hypothesis holds that neural networks self-organize into a critical state, at a boundary between different types of dynamics, between stability and instability, order and disorder. As open dynamical systems move away from equilibrium (high entropy, disorder, incoherence) toward stable attractor states (rigidity, order), they eventually reach a point ("critical point, tipping point, bifurcation point, "criticality") at which the system may either devolve to randomness (disorder) or to the inflexibility of stable attractor state. Right before the critical point ("near-criticality"), an optimally self-organized attractor network may reach the level of complexity to embed a metastable state that hovers between order and disorder, thus able to generate emergent properties new to the network itself. As the largest number of metastable states exists at a point near the bifurcation, the brain can access the largest repertoire of neuronal processing in a flexible way and from distributed processing regions. At this point, network dynamics is weak attraction, close but not equal to neutral. Figuratively, the brain at a near-critical state is metastable but maintains a "sweet spot" of coherent complexity and emergence.

nLFPs, neural avalanches, and coherence potentials are characterized by a power law distribution in size and a branching parameter of 1, in which one nLFP, on average, begets only one other nLFP in the next time step. With branching parameter of 1, the number of repeating avalanches patterns is maximized into effective functional connectivity. This is suggestive of a balanced propagation of activity from one active group of neurons to another in a cascade within and across brain networks operating at near-criticality. Spatiotemporal patterns of avalanches are stable beyond chance and recur over several hours as predictable successive frames of nLFPs to which the brain returns repeatedly. Experimental work has shown that activity in living neural networks can propagate as a critical branching process that revisits many metastable states. Repeated neural avalanches capture the most metastable states of attractor networks. Oren Shriki and colleagues demonstrated neuronal avalanches in RSNs in humans, by using in vivo magnetoencephalography. Of note, criticality has been mainly investigated in neural activity during the resting state dynamics, only occasionally during task-induced changes and in the presence of external stimuli (summarized by Roxana Zeraati and colleagues).

To summarize, self-organized criticality as the general principle of the brain's function is gaining ground over alternative proposals. Diverse

Telegram: @medical_k

www.konkur.in

evidence demonstrates a precise regulation between self-sustaining network up-states, nested theta-gamma oscillations, neuronal avalanches, and coherence potentials that follow power laws and a critical branching parameter of 1. These phenomena involve a balanced homeostatic GABA-mediated inhibition and glutamate–dopamine-mediated excitation in superficial layers of the cortex. Self-organized criticality maximizes the brain's information transmission, information storage, dynamic range, metastable states, and computational power.

Basics of Mind Self-Organization

The biologic self-organization of brain networks is believed to be foundational to the global emergent property of the mind. The brain and the mind progress through development in a highly parallel manner, where the maturation of brain networks generally coincides with the emergence of new functions of the mind. Such parallelism is suggestive of BrainMind coevolution. The mechanism of coevolution may involve activity-dependent codetermination, that is, reciprocal modifying influences between structure and function that constrain each to compatible paths of differentiation. Change in either is seen in terms of coevolution rather than as adaptation to separate and distinct environments. The fundamental principles of self-organization of open complex systems apply to both the brain and the mind: modularity, adaptability, robustness/resiliency, functional plasticity, progression from local to global, and dynamical growth. Important differences may reflect differing principles inherent to coevolving structure and function. In contrast to the highly modular organization of the brain, with hierarchical but independent processing units, the mind is modular as well, but in a more modest sense of domain-specificity and dissociability. Each mental faculty (cognition, emotion, motivation), each temperament trait, the sense of self and each of its subsystems (identity, character, morality) are domain-specific and phenomenologically discernible, each is autonoetic (personal happenings) and accessible to introspection.

Autonoesis, Noesis, Anoesis. These concepts are elaborated here to facilitate the discussion of the phenomena of self and consciousness. Neural traces of episodic memory are nonconscious first-order neural states of that memory encoded as "engram complexes." Episodic memories are experienced as autonoetic, that is, that the episode

happened to the person remembering ("personal happening," autonoesis), only if, during the retrieval process, the sense of self, ownership, agency, and subjective temporality (the event happened in one's past), are integrated into retrieval. Such integration may be mediated by the works of DMN, the so-called "self-network," which is also coinvolved in memory processes, including recollection. Without autonoesis, episodic memory would merely be retrieved as a context-rich form of semantic memory. Semantic memory involves noesis ("knowing") of factual data not experienced as personal happening. Anoesis ("not knowing") refers to perceptual registration, neural representation, and behavioral responses, temporally and spatially bound to the present environment, that do not involve neocortical cognitive processing and consciousness, such as procedural skills ("not knowing of knowing").

The MindBody Debate. The centuries-old MindBody philosophical debate has evolved into three main approaches. First, the physical-identity approach (MindBody monism, materialism), pioneered by Christian von Wolff, holds that each type of mental state is identical to a particular type of neural state. Second, the functionalist approach (reviewed by Janet Levin in the Stanford Encyclopedia of Philosophy) holds that the identity of a mental state is to be determined by its causal relations to sensory stimulations, other mental states, and behavior. Functionalism leans toward MindBody monism but allows for mental faculties (cognition, emotion, motivation) to be understood as function-to-function emergence, ultimately embedded in the brain. Third, the dual-aspect monism is the view that the mental and the material are different aspects of the same underlying undivided ("neutral") reality in which they do not exist as separate domains. It is left up to the science of metaphysics to define what such neutral, dually-potent reality, shared by BrainMind, might be. The concept of the mind as a multilevel emergent property of interacting brain networks is incompatible with dual-aspect monism. Is the mind an emergent property of the brain (monism, functionalism) or not an emergent property of the brain at all (monism, dual-aspect monism)? In the latter case, the mind's self-organization is independent from the brain's self-organization, but they are inseparable from each other by means of shared ancestor. If functionalism is adopted, does the mind represents a weak, one-level emergence (only unexpected given the principles of the lower-level domain of the brain) or a strong,

Telegram: @medical_k

www.konkur.in

multilevel emergence (not deducible even in principle from the laws of lower-level domains). Here, we adopt the functionalist model of the mind as a strong, multiple-level emergence not deducible from the laws of lower-level brain networks, but ultimately embedded in these networks. The brain and the mind are best conceptualized as open, self-organizing, complex, and dynamical coevolving systems providing order to each other during their coadaptation to the same environment. If, as noted, intrinsic neonatal networks act as stable seed attractors for brain self-organization, the question is what attractors govern the self-organization of the mind?

Attractor Dynamics May Have Been Predicted by Object Relations Theorists. Melanie Klein's concept of "focal points" for ego integration[11] corresponds in principle to the concept of stable attractors governing evolution of open dynamical systems in biology. In "Notes on some schizoid mechanisms," M Klein introduced the notion of focal points for ego integration and associated it with the first good internal object, that is, the earliest phantasy of the gratifying "good breast" internalized under the hedonic quality of pleasure (sweet breast milk, an unconditioned pleasure). The frustrating "bad breast" (failure to feed) instantiates the unconditioned hedonic quality of displeasure (hunger, fear for survival) and is said to repel normal mind development. In the same paper, M Klein argues that the first good internal object acts as a "focal point in the ego … counteracts the processes of splitting and dispersal, makes for cohesiveness and integration, and is instrumental in building up of the ego" … "a precondition for normal development." The concepts of "comfort zones" (psychology) and "attractor dynamics" (discussed earlier) are helpful to link M Klein's concept of focal points in mind development with psychology and network science. The concept of comfort zones refers to the mental state of ease (low anxiety), underpinned by the brain's physiology of low stress (low cortisol, low epinephrine), in which the person feels they are in control. In Jaak Panksepp's affect theory, comfort zones are understood to be homeostatic set points for survival. Negative hedonic qualities (displeasure), motivation (dread), and behaviors (avoidance, fear, panic, defensive rage) mark deviations from the set point of comfort. These negative affects index danger zones that inform about circumstances that may endanger survival. Positive hedonic qualities (pleasure), motivations (desire), and behaviors (bonding, joy, lust) mark the return toward the set point of comfort and affirm survival. Once the

Telegram: @medical_k

www.konkur.in

comfort zone is reached, positive affects subside, and the mind idles, de-energized, engaged in familiar routines, not learning, and thus not developing. Through the prism of the dynamical system theory, comfort zones (psychology) and focal points (object relations theory) can be thought of as stable attractors that govern mind development. Between the inertia of comfort zones (de-energized mind) and the threatening anxiety of danger zones, the mind may operate in the zone of "optimal performance" for learning and development.[12] The zone of optimal performance may represent a near criticality regime of the mind, optimally self-organized to reach the level of complexity (e.g., creative thought) while hovering above comfort and anxiety. M Klein recognized the competing tendencies between integration and dispersal in mind development. Thus she might have conceived the mind as an initially dissipative system that evolves around focal stable attractor points but would dissipate without such governance. One can only speculate whether M Klein, based solely on field observations, introduced the concept of focal points for mind development and thus intuitively captured the essence of the forthcoming concepts of "attractors" and the dynamical systems theory.

Object Relations are the Basic Building Units of the Mind. Psychoanalysis postulates that "all psychological experience, from the most fleeting fantasy to the most stable structure, is organized by object relations … the basic units of all experience" (from Auchincloss and Samberg). First we ask the question "what is experience"?

EXPERIENCE, SUBJECTIVE EXPERIENCE, CONSCIOUSNESS. According to the Merriam-Webster dictionary, the term experience comes from Latin experiri (extracting, taking away something by trial or risk). Experience is thus a fundamental function to record nature and the specific form of it. In biology, experience is embedded in events of matching patterns, a fundamental mechanism of acquiring knowledge of all biologic life. Perception, from the Latin perceptio, meaning gathering or receiving, is the means by which an organism gathers experience.[13] Veridical sensory memory[14] is a plausible neural substrate of experience. As recently reviewed by Mario Vaneechoutte, all biologic life comes equipped with innate pattern recognition systems operating at different organismal levels, from enzymes that match their substrates, via gustatory receptors

Telegram: @medical_k

www.konkur.in

that match their tastant molecules, to attractor memory networks that match their selective basin of attraction. These phylogenetic molds predate real perception and thus enable an organism to predict external environment. Marsel Mesulam reports that unimodal sensory information (vision, hearing, taste, etc.) is processed through a collection of parallel processing networks, each network is modality selective or "unimodal," that is, specialized for a particular type of information. The selective match between the unimodal input and the recognizing receptor triggers neuronal processing along five successive synaptic processing levels: lower-order (early) synaptic levels produce output that is streamed to later stages (higher-order synaptic levels), making information representation increasingly complex as the stages are passed through. For example, the primary visual cortex feeds information about edges, angles, light contrasts, etc., into higher-order processing cells that create more complex outputs that then converge and diverge onto yet higher-order processing cells (visual association zones), eventually resulting in unimodal visual representation of the entire object. Such within-system convergence creates stable and predictable integrations (emerging macro-property) that by nature cannot be a property of any basic element. Over time, each processing level memorizes conditional dependencies among unobservable causes of sensory input ("hidden states") and the observed consequences ("sensory states"), and each encodes conditional expectations (Bayesian "degree of beliefs") about hidden states that best explain sensory input at lower levels. Hidden states and causes are abstract probability estimates that the brain uses to top-down explain or predict actual sensations, akin to predicting the trajectory of a moving object in one's visual field. For example, top-down connections with lower-level synaptic processing of visual input ("unimodal downstream") allow higher-level feedback predictions of affordance of lower-level visual input (bars, edges, contrasts, etc.), thereby creating prediction error in the lower levels (mismatches between predicted and actually perceived). Only prediction error and new features (the data not predicted) are feedforwarded to the higher levels ("unimodal upstream"), where they update conditional expectations (novel data are represented as new combinations of familiar features). The updated top-down predictions reduce the occurrences of mismatches in the lower levels, thus enabling the brain to actively construct explanations for its sensory inputs. To summarize, perception is pattern expectation, a product of memory

Telegram: @medical_k

www.konkur.in

encoded within sensory networks that dictates one's interpretation of sensory data. Up to the point of heteromodal association cortices and posterior insula, sensory processing conveys veridical information about the organism's internal condition, position/movement, and external stimuli, that is, it does include the perceiver's learned pattern expectations, but not the perceiver's emotion and/or motivation. Such veridical reporting by the senses (sensory memory) is what should be called "experience" (*subjective* experience is discussed below). Sensory memory accounts for the brain's ability to retain impressions of sensory information for a few 100's of milliseconds after the original stimulus has ceased. Sensory memory, although vast, cannot hold all aspects of the internal or external environment but can be conceived as a snapshot of veridical information in the unit of time (milliseconds) and allocated to the current event.

The phrase *subjective experience* (a "subject" can be an animal or a human) means that veridical sensory information is top-down edited by personal salience attributed to the incoming sensory perception. Such edited experience reflects the salience properties rather than the surface properties of sensory events. Marsel Mesulam provides a cogent account for such personal editing. The highest level of sensory-fugal synaptic processing occurs within several highly connected "convergence" or "transmodal" zones that lack specificity for any single modality of sensory input, but receive afferents from lower-level unimodal areas and from other transmodal regions ("multimodal convergence"). These transmodal areas include prefrontal cortices ("anterior association area"), mid-temporal cortex including the parahippocampal gyrus and amygdala ("limbic association area") and the junction of occipital, temporal, and parietal lobes including the insula ("posterior association area"), among others. Most convergence zones, but especially the medial and lateral regions of PFC and insula, downstream modulate lower synaptic levels, providing attentional, motivational, historical, and emotional editing of veridical sensory stimuli. Such editing creates a subjective sensory reality rich in salience for each individual, that is, subjective experience.

Consciousness is commonly defined as "subjective experience." The term consciousness comes from Latin "cum" and "sciere,"–"to know about," implies some reflective properties of consciousness. Subjective and personal are synonyms, but neither corresponds to consciousness, the experience about experience, to know about experience. Note that the subjectivity of experience, as described above, means one's unique

Telegram: @medical_k

www.konkur.in

motivation, attentional priorities, and memory that bias perception in the presence of stimuli. Phenomenal properties of experience, “for there being something that it is like for one … to be in a particular state of having experience” …. e.g., seeing red, require introspection either by passive noticing (“thought-like”, as J LeDoux and R Brown refer to this reflective noticing) or by active scrutiny (deliberate reflection of one’s phenomenal experience), both can occur in the absence of stimuli. Introspection is said to be mediated by attention, working memory, and metacognition. Phenomenal consciousness is noetic (semantic, factual) unless information about the self (one’s self-schema, autobiographical memory, identity, etc.) is included in the retrieval when it becomes “self-aware” (autonoetic or personal happening). Consciousness is thus more accurately conceptualized as one’s passive or deliberate introspection of one’s experience (summarized by Mario Vaneechoutte). Symbolic language, a cognitive function that frames and organizes thought, is pivotal for both passive and deliberate introspection. Higher animals certainly may have subjective (“personal”) experience as defined above. Such experience may be represented in working memory and may guide behavioral priority, but is not accessible to introspective reflection mediated by language. Whether animals are capable of passive noticing of … being in the state of particular sensory experience is actively debated but, in our opinion, doubtful. Even passive noticing involves thought-like reflection as noted, which must involve some form of symbolism or language. Subjective experience that lacks reflection corresponds to awareness, common to all higher animals (see section on Nonconscious vs. Unconscious. Alertness vs. Awareness). In other words, animal awareness is not phenomenally conscious as introspectively accessed qualia. Rather, memorized hedonic qualities (liking vs. disliking), motivations (desire vs. dread), and incentive salience (wanting vs. not wanting) may give rise to affects and reward predictions that bias the animal, say a dog, toward selective foods in the here-and-now awareness.

Going back to the psychoanalytic postulate that object relations represent as the basic units of all experience. Dynamical system theory, cognitive- and systems-neuroscience of schema-forming, and expansion[15] provide a potential mechanism for this theorizing. Early object relations engage peak unconditioned hedonic qualities (displeasure, pleasure), rudimentary motivation (dread, desire), and rudimentary cognition (primitive imagery of the self and the world of

Telegram: @medical_k

www.konkur.in

objects). Axel Guskjolen and colleagues report that, in infant mice, episodic memories are forgotten as specific events ("infantile amnesia") but are not neurally erased and may be activated in adulthood by optogenetic stimulation of tagged neurons combined with natural re-exposure. These forgotten but neurally preserved cognitive-affective engrams complexes may serve as primordial fixed-point implicit attractor memories to interpret one's survival status and helpfulness of others in a self-reinforcing fashion. Andrzej Nowak and colleagues devise computational models of personality self-organization that support this hypothesis. In such models, fixed-point attractors consisting of cognitive-affective loops (correspondent to object relations) govern personality development. Most brainstem-limbic-medial prefrontal cortex (mPFC) regions involved in early object relations are integrated as nodes into the general networks of cognition–GNC, thus presenting hedonic quality and motivation (liking/desire, disliking/dread) for vertical integration into the infrastructure of cognition. With this in mind, the primordial schema of early object relations may indeed be a *bona fide* basic unit of the mind that governs the self-organization of emotion, cognition, and motivation in a self-reinforcing fashion. This primordial fixed-point attractor is indivisible to subsets that are attractors themselves and has no disjoint basins of attraction. Figuratively early object relations may represent the nonconscious operating system, the BIOS of the mind.

NONCONSCIOUS VERSUS UNCONSCIOUS. ALERTNESS VERSUS AWARENESS. The term "nonconscious" is used to refer to the contents of the mind not reaching active or passive awareness. The term "unconscious" is better suited for medical syndromes where the basal level of neuronal activity for perceptual registration and responses to sensory input is compromised. Brain trauma, for example, may render a person unconscious, that is may result in loss of alertness, interruption in awareness of oneself and one's surroundings, and unresponsiveness to external stimuli. Brain activity can be "nonconscious" (the brain is still online, but mental processes take place outside awareness), while an "unconscious" brain is offline, traumatized. Alertness denotes the basal level of neuronal activity to register perceptions and generate adequate responses to stimuli, for example, to respond to a question. Awareness derives from Old English–gewaer, English ware, and German gewahr, all meaning "aware," having knowledge of something, something one notices. Awareness thus arises

Telegram: @medical_k

www.konkur.in

from ultrashort sensory memory that is deemed salient by stimulus-driven (perceptual) attention and thus enters short-term memory (15 to 30 seconds). Short-term memory is a cognitive system that holds a limited amount (7 ± 2 items) of salient information, and can be driven by external stimuli or internal goals. Recent work suggests that short-term memory may be a function of phase locking by attention rather than of retention by an active memory trace. Mario Vaneechouette summarizes that awareness has evolved as a crucial evolutionary advantage that filters the unimportant out of all experiencing in sensory memory. Such filtering enables an organism to be aware of only novel or salient sensory information in the here-and-now. The filtering process is influenced by phylogenetically given molds (e.g., attractiveness of sexual partners), age (e.g., growing up changes priorities), previous experiences (e.g., habituation, education), other current experiences (e.g., the current state of internal motivation, like being hungry or not) and the interaction among all of these; the above "decides" which pattern is to be perceived or recognized, which experience is to become aware experience. It follows that, for animals, nonreflective awareness may be the main form of subjective experience that involves memorized affects, motivations, and incentives in prior experiences of the same kind. The concept of awareness in psychology corresponds to the concept of short-term memory in neuroscience.

Mind Development and Differentiation. Nenad Svrakic and colleagues pioneered the concept that mind development proceeds as punctuated homeostasis, a dynamic process whereby periods of relative stability (maintained by homeostasis) are punctuated by more or less abrupt transitions ("optimization of fitness") toward a higher level of organization and functioning ("development"). Development is both informed and energized by adaptive demands that provide order (new information) to an open system. The term "fitness," as applied to the mind, reflects the closeness of the mind's current organization (the one being optimized) to the optimal organization (which guides the optimization process) for the given set of adaptive demands. Stage-like punctuated transitions are frequent early in mind development whenever the existing organization of the mind becomes suboptimal to meet changing adaptive demands. Early adulthood marks the period when significant fitness-driven optimizations of the mind subside. Around this time, adaptation

Telegram: @medical_k

www.konkur.in

becomes more quantitative (facets of the same) than qualitative (novel). Notwithstanding, neither the brain nor the mind ever completely loose plasticity to learn from and adapt to change.

We submit that mind differentiation involves two inter-related paths, (i) development of mental faculties (cognition, emotion, and motivation) and (ii) development of temperament traits, the sense of self, and its subsystems (character, identity, morality). These two paths are discussed in turn.

Mental faculties (cognition, emotion, motivation) are thought to emerge from interactions of large-scale functional connectivity networks. As such, mental faculties roughly correspond to two-level emergence, as the lower-level emergent functional connectivity implements the details of the higher-level emergent mental faculty by a small number of rules. Jochen Fromm points out that such weak emergence is flexible, predictable in principle but not in every detail, and characterizes open systems with active entities.

Cognition (thought) refers to human capacities such as memory, language, problem-solving, and planning, among others. These faculties are believed to emerge from works of the GNC (defined by J LeDoux and R Brown). The GNC encompasses partially overlapping large-scale functional connectivity networks (and their composite subnetworks) that spread across medial and lateral parietal and frontal regions; these networks dynamically interact to produce various facets of cognition. They include, among others,

1. the lateral FPN or CEN[16] (anchored in dorsolateral prefrontal and posterior parietal cortices) engaged in working memory, top-down goal-driven executive function, and attentional control,
2. the SN (anchored in dorsal anterior cingulate and orbital frontoinsular cortices) is involved in detecting and filtering personally salient stimuli, switching between CEN and DMN, as well as in recruiting relevant functional networks,
3. the DMN, is thought to comprise an integrated system for self-related cognitive activity, including autobiographical, self-monitoring, as well as social cognition, such as the theory of mind of others and, we submit here,
4. the language network[17] (left and right temporal and left frontal cortex, with coactivity in the auditory cortex and hippocampus).

Telegram: @medical_k

www.konkur.in

Emotion (meaning) is defined as any conscious mental state with high intensity and hedonic content–pleasure/displeasure. The neural substrate of emotion may involve, among others, the hedonic hot-spots in the brain, notably those in the nucleus accumbens (NAc)-ventral pallidum, the extended amygdala processing network (includes the central medial amygdala, sublenticular substantia innominata, and the bed nucleus of the stria terminalis), the salience- and the explicit memory network.

Intrinsic *motivation* (goals) (the undertaking of an activity for its inherent satisfying qualities) may involve multiple modules:

i. The NAc-ventral pallidum hedonic keyboard mechanism, discovered by Kent Berridge and colleagues, engenders motivations (desire, dread) based on the enhanced hedonic quality of sensory stimuli,
ii. the mesolimbic ventral tegmentum (VTA)–NAc dopaminergic reward pathway (incentive salience, “wanting/not wanting”) and
iii. the orbitofrontal cortex (reward-based risky decision-making, valuation of reward, and expected reward). In addition, dorsolateral PFC has been shown to initiate motivated behavior by integrating and transmitting representations of reward to the mesolimbic and mesocortical dopamine systems. In many cases, intrinsic and extrinsic motivations[18] work in concert, as the brain assesses the cost/benefit ratio as to how much effort is needed to obtain the intrinsically wanted goal.

The mental faculties can be thought of as the “tools of the mind” that, each from a different angle and with variable representation in different types of experience, enable the mind to communicate with itself (metacognition), the inner world (introspection) and the outer world (prediction), and to change and/or adapt to both.

The second path of mind development involves the differentiation of temperament traits as well as the sense of self and its subsystems,[19] that is, identity, character, and morality.

Temperament is the most biologic subsystem of the mind. Dragan Svrakic and Mirjana Divac-Jovanovic at first conceived temperament as one of the subsystems of the self. However, this is unlikely because temperament traits, notably harm avoidance (HA), reward dependence (RD), and novelty seeking (NS) emerge around midinfancy, before the emergence of the sense of self. Notwithstanding, temperament does influence one’s self-schema, as one’s semantic knowledge about one’s usual reactions to danger and unfamiliar situations. At the root of

Telegram: @medical_k

www.konkur.in

temperament are innate dispositions to affect reactivity (biology) which are interactively molded (classical and operant conditioning) into stable mental biases (psychology) toward social gratification, danger, and novelty. Temperament traits refer to behavior tendencies that show relative stability over lifetime. For example, a person's usual, *a priori* approach to unfamiliar situations is either stably cautious (HA), risky (RD), or exploratory (NS). Temperament corresponds to weak, one-level emergence from neural dispositions to affect reactivity.

The sense of self is likely engendered by the works of DMN, itself an emergent functional connectivity (see section "DMN could be the neural substrate of the self") and thus corresponds to two-level emergence, much like the mental faculties of cognition, emotion, and motivation. The *subsystems* of the self (identity, character, morality) can be understood as multiple-level emergence, the first two levels being functional connectivity and mental faculties involved in the sense of morality or character. The subsystems of the self can be understood as emerging coalitions of relevant cognition, emotion, and motivation self-organized into adaptive solutions to selective stimuli. For example, character emerges in adolescence as a self-organized, semistable solution for social demands for cooperation and tolerance, thus facilitates one's social adaptation. Each subsystem carries a specific adaptive function that contributes to the adaptive fitness of the self as a whole. For example, cooperativeness and acceptance of others are character traits that peak in teenagers, who are thus fitter to respond to the pressure for social adaptation.

In parallel with the sense of self emerges the subsystem of *identity*, a repository of autobiographical memories. The main adaptive function of identity may be to provide continuity to the sense of self that, despite numerous updates, has historical coherence and future direction at any phase in one's life. To this end, the subsystem of identity must align past and present self-images and personal goals into a coherent narrative, which usually requires some falsification of autobiographical memories. Such alignment, however, allows prospection, that is, generation and evaluation of mental representations of possible futures, an important adaptive capacity of the self/mind. Identity also encompasses one's consistent view of others, which reinforces the coherent narrative of the self. Complex interconnectedness between the self and autobiographical knowledge is called the self-memory system introduced by Martin Conway: different types of memory provide data that constrain the current

Telegram: @medical_k

www.konkur.in

working self, but in turn, memory is also reciprocally controlled for accessibility by the current working self. The question is whether identity represents a subsystem of the self or simply one of the associative, “glue” functions of one’s self.

C. Robert Cloninger and Dragan Svrakic report that the subsystem of *character* emerges around 8 to 9 years of age. Character traits, such as cooperativeness, helpfulness, and acceptance of others, are rooted in empathy, prosocial attitudes, and helping behaviors, observable in all group-living animals (bats, bees, wolves, etc.). Karen Wynn and colleagues documented such prosocial behaviors in human infants and toddlers, presumably those who have attained self- and object-constancy and secure attachment (i.e., those not preoccupied with self-related mentation). These emotional forerunners of character are later amended by internalized socio-cultural standards as cognitive facets of character, represent one’s social principles.

In parallel with character and with much overlap, the subsystem of *morality*[20] emerges, enabling moral judgments of our own behavior and that of others. Linguistic expressions that utilize such judgements include “ought, should, right, wrong, good, bad, fair, unfair,” etc. Like character, the subsystem of morality is anchored in the sense of empathy, fairness, justice, and reciprocity of early childhood. These emotional forerunners of morality are later amended by learned moral norms (cognitive component) to become internalized moral principles by mid-to-late–adolescence. Both character and morality maximize the fit between one’s self-centered needs and restrictive social norms,[21] enabling the individual to achieve “functional adaptation,” that is, to fit in the society with a healthy tone of self-interest. As a unique feature, internalized morality enables self-evaluation, the mind’s inner censor of right and wrong. Neurally, the DMN has been implicated in social and moral cognition. The SN may also be important to bring semaniticized knowledge of one’s character and moral traits into conscious working memory to inform decision-making in social and moral tasks. Recently, the CEN and SN were found to be associated with voluntary selection of choices (decisions), including choices that pivot around moral issues.

Adult character traits and moral values reflect voluntary choices that don’t always result in the most gainful outcomes for a person. As discussed, character and morality are piloted by innate prosocial attitudes, empathy, and a sense of fairness, which are then expanded by learning

Telegram: @medical_k

www.konkur.in

(instruction), and finally internalized as attractor memory that contains one's character and moral schemas. The latter refers to autobiographical memories of one's usual social or moral choices, one's knowledge about social and moral standards in the given culture, etc. Such schemas provide information to working memory where it is used to guide new choices but only to an extent. Namely, new social/moral challenges may harbor new elements that will either revise the pre-exiting character and moral schemas or establish a new attractor for that particular experience.

We understand the subsystems of the self as canonical rather than hierarchical, semistable rather stable. Functional coalitions of emotion, motivation, and cognition that coalesce into the subsystems of the self are not dynamical (constantly reconfiguring) but semistable (functionally adaptable). Adult character and morality are represented by stable principles that retain functional plasticity (a concept close to that of semistability). A semistable equilibrium is one with multiple but not unlimited solutions to stable attractors, here internalized social and moral norms. Such systems are thus capable of transforming by self-organizing around new attractors if sufficiently energized by changing demands. For example, a person's principled morality (a semistable subsystem within the self) may change into opportunism during a war (physical survival takes priority over moral purity), but not at work despite opportunities for a minor promotion that may require some "soft" immorality, for example, use flattery to win over the boss. Such minor promotion is a weaker attractor relative to the stronger attraction of maintaining one's moral integrity.

BASICS OF OBJECT RELATIONS THEORY

Object relations theory is a major modification of classical (Freudian) psychoanalysis. Central to Freudian psychoanalysis is the perpetual conflict between innate "drives," pleasure ("libido") seeking satisfaction ("pleasure principle"), and the restrictive reality of the environment ("reality principle"). Pleasure-seeking (said to be embedded in the "id") inevitably clashes with social restrictions, thus necessitating the development of a balancing structure (the ego) and a controlling structure (the superego). This dynamics is known as the "drive-structure" model, whereby innate drives both instigate the development of psychic structures and are regulated by those same psychic structures. By contrast, central to object relations theory is the innate need to bond ("object-seeking"), a survival

Telegram: @medical_k

www.konkur.in

instinct conserved across mammalian species. The bonding instinct puts the child–caretaker relationship at the center of mind development. M Klein observed that infants manifest an immediate deep bond with their mother and that these early experiences modulate mind development. M Klein's theorizing departed from the "drive-structure" doctrine of Freud. This departure marked the birth of object relations theory, albeit still rooted in the main postulates of Freudian psychoanalysis, the dual-drive theory (libido and aggression) and tripartite structure (id, ego, and superego). Over the years, a number of more or less radical revisions have molded the theory into its present form. Ronald Fairbairn observed that the innate need for an emotional bond with an object drives mind organization rather than pleasure-seeking as the goal itself. While working in an orphanage, Fairbairn described "schizoid factors in personality,"[22] a major contribution to object relations theory. He theorized that early "splits" between rejection and acceptance allow an orphaned child to repress the rejecting parent, thus opening the way to accept the loving caretaking by others. Such deep splits in the mind (e.g., feeling of artificiality, "plate-glass" feeling about own self or the world, etc.) are seen occasionally in normalcy under severe stress and regularly in schizoid phenomena (hysteria, personality disorder, among others). As pointed out by Stephen Mitchell, Fairbairn's "relational/structure model" posits that "the interpersonal and the intrapsychic realms create … each other." Heinz Hartmann and Edith Jacobson pioneered the concept of self, hitherto unaccounted for by M Klein and Fairbairn, who used the terms "mind," "ego," and "self" interchangeably. Incidentally, Susan Isaacs and Edith Jacobson hinted that episodic memory might be the neural mechanism of object relations, seconded in this overview. Heinz Hartmann, Edith Jacobson, and Otto Kernberg viewed libido and aggression as primary but not innate motivation systems; rather, they cogently argued, the two drives consolidate from the hedonic tone of early interactions, pleasurable affects (pleasure, lust) coalesce into libido, unpleasurable (fear, rage) into aggression. Kernberg further advanced the integration of object relations theory with ego-psychology, revolutionized the concept of personality disorder, and pioneered interest in the neurobiologic mechanisms of object relations. Perhaps most importantly, Fairbairn, Hartmann, and Jacobson reconceptualized object relations insofar that what the infant internalizes is not an image of the object, a position long held by M Klein, but rather the interactive experience with the object, a position now widely

Telegram: @medical_k

www.konkur.in

accepted in theory and practice. This shift provides the rationale to frame object relations through the prism of affect-enhanced episodic memory, the main point of this overview.

What Is an Object Relation?

The term “object relation” refers to the internalization of early interactive experiences with significant objects. “Significant objects” are those into whom one invests strong emotions, whose interactive impact has been internalized and continues to influence the mind from within, as pointed out by Elizabeth Spillius and colleagues. The first significant object is usually the mother or the primary caretaker. Subsequent significant objects can be anyone or anything into whom/which one invests strong emotions, human beings, systems of knowledge or beliefs (political, scientific, or religious), one’s work, an idea, etc. An object relation consists of three mental components: a self-representation, an object representation, and a representation of the affect that characterized the interaction, pleasure, or displeasure.

Our focus at the moment is the most influential object relations, those acquired over the first 2 to 3 years of life, during the most vulnerable phases in BrainMind development. These early object relations can be conceived as primordial cognitive-affective loops (schemas) that serve as implicit templates that regulate subsequent mind development. The intensity of affects (hedonic quality–pleasure, and displeasure) and motivations (desire or dread) evoked by early caretaking are a function of the child’s heritable affect-reactivity and/or the quality of caretaking. These earliest interactive episodes occur in the setting of absolute dependency upon a powerful object. In such a setting, interoceptive distress (hunger, pain, etc.) or comfort (satiety, affectionate touch, etc.) narrowly evoke a sense of either a threat to or affirmation of own survival. The experience is processed by the amygdala circuitry involved in “implicit emotional learning and memory,” as described by Elizabeth Phelps and Joseph LeDoux. Object relation theory posits that primordial affect-enhanced episodic memories of infancy and toddlerhood are forgotten as specific episodes but are not neurally erased and are foundational to the ensuing BrainMind organization.

Objects in Psychoanalysis: Real, Internal, External. Contemporary interpersonal-, relational-, and many object relations theorists use the

Telegram: @medical_k

www.konkur.in

term “object” both to refer to a real person and to that real person as it is represented in one’s mind. In Kleinian psychoanalysis, “external object” refers to a mental representation of another person that is modified by projections and reintrojections of one’s own mental issues and thus may not accurately represent that person. The term “internal object” refers to a mental representation of another person that one invests with strong emotions (“significant objects”), whose impact has been internalized as implicit memory and continues to influence the mind from within. A complex interplay, so the theory goes, continues throughout life between internal objects and those in the real world as they are represented in the mind, a solipsistic but plausible view that external objects only exist in the self of the beholder.

Object Relations Through the Lens of Neuroscience and Dynamical Systems Theory

In rodent models of infantile amnesia, enhanced episodic memories are forgotten but are neurally preserved and retrievable in adult rodents, as discussed. In human infants, the rudimentary topology of the long-term memory network is likely in place at birth. Such seed immature network is able to neurally preserve the memory but not to render the memory declarative/explicit.[23] Moreover, the sense of self, which fortifies perception and episodic memory by self-referenced cognition, has yet to fully self-organize in young toddlers. Self-reference provides a form of associative glue for perception, memory, and decision-making and, through this, acts as a central mechanism in information processing, as Jie Sui and Glyn Humphreys cogently argue.

Consistent gratifying and frustrating episodic memories with caretakers, albeit implicit, are thought to semanticize into preconceptual schema-affect loops that, thereafter, top-down regulate the relevance and preferential assimilation of new experience. In the dynamical systems theory parlance, the forgotten memories of object relations may act as implicit attractor memories that set a dynamical rule for a personalized self-organization of brain’s networks. A suggested mechanism of such personalized brain organization is “metaplasticity,” meaning that outcome feedback may enhance synaptic plasticity in similar contexts. Such “plasticity of synaptic plasticity” ensures that one’s personal goals or rules are enabled in the appropriate context. The mechanism of metaplasticity may involve activity-dependent neural changes that modulate their own

Telegram: @medical_k

www.konkur.in

plasticity threshold; in turn, these threshold changes modify the ability of such primed neurons to express plasticity in subsequent novel but similar experiences. For example, in infants, chronic stress may affect the synaptic organization, dendritic lengths, and dendritic spine density in cortical networks, ultimately modifying cortical metaplasticity. Such changes can prime cortical networks to take an abnormal developmental trajectory in response to later experiences that might otherwise be benign. Inversely, positive interactive experiences may exert a metaplastic effect that ultimately enhances the plasticity of these networks to similar positive social experiences later in life.

THE PRENATAL SOMATOSENSORY ORIGINS OF THE MIND

Emotion and motivation likely arise from the dynamic interaction of large-scale functional networks involved in vertical integration. These networks integrate processing in evolutionarily older regions with more recent brain systems from the brainstem, via the limbic system, to multiple cortical regions. Brainstem and limbic processing engenders the fundamental hedonic aspects of affects, motivation, and incentive salience (pleasure/displeasure, dread/desire, wanting/not wanting) that serve as input for higher-level integrations by rostral cortical systems. Our goal here is not to parcel a few regions for their independent function. Rather, our point is that brainstem and limbic processing valuates the hedonic-motivational-incentive quality of sensory inputs before they get integrated into complex functional networks of emotion, motivation, and cognition. Such caudal valuation may be foundational for innate dispositions to affect reactivity, the most important modulator of BrainMind self-organization in neonates and young infants, including a major impact on early object relations.

The “Emotional” Brainstem[24] and Individual Differences in Affect Reactivity

Many, but not all, brainstem functions are “emotionless,” for example, conduction of proprioceptive and tactile information to the cortex and cerebellum. The “emotional brainstem”:

i. participates in fixed, affect-charged response patterns in the face of threat (fight, flight, freeze)[25] and

Telegram: @medical_k

www.konkur.in

ii. contributes to the earliest hedonic valuation of sensory input as appetitive ("liking") versus aversive ("disliking") our focus here. Hedonic "hotspots" involve opioid, endocannabinoid, and orexin (but not dopamine) signaling. Per Kent Berridge and Morten Kringelbach, the hotspots are distributed across the brainstem, NAc shell, ventral pallidum, insula, and orbitofrontal cortex, forming a hedonic network that enhances the core liking of a stimulus. The basic sensory-motor circuitry for unconditioned hedonic preference (liking sweet, disliking bitter) operates in the brainstem, mainly guiding ingestion. The brainstem and the limbic system are primary hedonic enhancer in utero and at birth thus foundational for early affect reactivity which, in turn, influences BrainMind self-organization. Caroline Kelsey and colleagues report that, in neonates and 1-month-old infants, innate dispositions to either negative- or positive affect-reactivity contrastingly influence the self-organization of functional networks, especially those involved in attentional regulation and behavior control. Neonates and infants predisposed to negative affect-reactivity show *hyper*-connectivity in DMN (manifested as preoccupation with stimulus-independent self-referential thought and mind-wandering), *hypo*-connectivity in FPN (manifested as slow reorientation of attention and poor executive control of emotion/behavior), and *hyper*-connectivity in the interhemispheric homologous network (HIN) between frontal, temporal, and parietal lobes[26]; the HIN has been implicated in emotion regulation. In contrast, neonates and infants predisposed to positive affect-reactivity show *hypo*-connectivity in DMN (self-referential processes are in balance with attentiveness to the external environment) and *hyper*-connectivity in FPN (manifested as effective regulation of attention and executive control of emotion and behavior). To summarize, functional connectivity that regulates attention, emotion, and behavior in neonates and young infants systematically maps onto individual differences in affect-reactivity and predicts adult personality and social health and pathology. Prenatally established disposition to positive- or negative affect-reactivity may act, respectively, as a protective versus risk factor for mental health versus disorder. Positive affect-reactivity appears to facilitate functional connectivity that is balanced between internally driven mental processes and attentiveness to the external environment, as well as good executive regulation of emotion and behavior. This pattern of network balance may be protective against psychopathology. In contrast, chronic stress, either gestational and/or early postnatal, may shunt functional connectivity toward diverse psychopathologies

www.konkur.in

characterized by a hypofunctional PFC and hyper-functional amygdala, for example, attentional and personality disorders, among many others.

The Neonate: How Intero-, Proprio-, and Exteroception Mediate BrainMind Development

Bodily sensations, exteroceptive (smell, taste, touch), interoceptive (hunger, pain, affectionate touch),[27] and proprioceptive (limb/body position and movement) inaugurate pre- and postnatal BrainMind development. Early bodily sensations engender the neonate's body schema (body from the outside), body homeostasis (body from the inside), and body ownership (body in the mind), each relevant for the sense of physical boundary with others and for the differentiation of the sense of self. These are discussed in turn.

Angelo Maravita and colleagues define *body schema* as a body-part-centered[28] representation of space in one's immediate proximity —"peripersonal space." Multisensory correlations between vision, touch, and proprioception relate the proprioception of limb/body position with the peripersonal space in which they act. Such body schema is updated by movement. Bimodal, visual-and-tactile neurons are believed to be involved in multisensory correlations. These bimodal neurons, characterized by spatial selectivity,[29] are found in the premotor cortex but also other cortical and subcortical regions. Simply put, body schema is a spatial map of body/limb position/configuration as a three-dimensional object moving in space with nearby objects. This spatial map of the body engages the premotor cortex (voluntary motor system), among other regions, which enables motoric navigating of movement around objects in pursuit of behavioral goals. Maria Filippetti and colleagues report that 5-month-old infants may have implicit body schema, a fundamental aspect of social perception, as indicated by differing temporal lobe activity during real-time versus delayed video display of self-initiated face and arm movement. Cortical regions activated in response to body-related contingencies are similar for infants and adults (temporal, parietal, inferior frontal regions, temporoparietal junction), much like other template networks that predate the arrival of their selective input. Incidentally, cortical sensory-motor body maps might be involved in the basic registration of self–other correspondences, which, in turn, facilitate the elementary sense of bidirectionality.

Telegram: @medical_k

www.konkur.in

Body ownership ("this body is and will always be mine") involves multisensory correlations similar to those involved in body schema, that is visual, tactile, and proprioceptive, but these two are different phenomena. To illustrate the difference, an amputee wearing a prosthesis maintains the body schema (movements in peripersonal space are carried out properly) but does not consider the prosthesis as own limb (no sense of body ownership). In contrast, Manos Tsakiris and Patrick Haggard report that a subject watching a rubber hand being touched synchronously with their own hand (the latter positioned to be out-of-sight) causes the rubber hand to be attributed to one's own body to ''feel like mine.'' The positive motion of own out-of-sight hand toward the rubber hand ("proprioceptive recalibration") was understood as a behavioral measure of the sense of rubber hand ownership. However, the multisensory events (visual, tactile) that caused the rubber hand to be attributed to one's own body are distinct from the personal experience that the "hand is mine." Such phenomenal incorporation of a rubber hand into one's internal body model correlates with activity in the right mid-insula and the right frontal operculum. The sense of body ownership gives somatosensory signals a special phenomenal quality of one of being embedded in one's body and thus is an important contributor to the development of the sense of self and the self-object boundary.

In contrast to the largely emotionless body schema and body ownership, *interoceptive sensation-feelings* (pain, heat, hunger, tickle, affectionate touch, etc.) naturally possess hedonic aspects (pleasant, unpleasant) and motivational goals (dread, desire) that indicate the body's homeostatic needs.[30] In seminal papers by Bud Craig, interception is understood to represent the ongoing homeostasis of the entire body, not only of the internal organs (visceroception) but also of the skin and brain. The lamina I spinothalamocortical system is a homeostatic afferent pathway that conveys the physiologic status of all tissues. This interoceptive information is integrated by the posterior insula, while the anterior insula generates phenomenal sensation feelings (pain, hunger, coldness) that reflect the interoceptive state of the body coupled with hedonic and motivational aspects. The insular cortex is the first fetal cortical structure to differentiate with a key influence on the self-organization of other cortical regions and networks. In neonates, the anterior insula likely contributes to the phenomenal noticing of the "material me."

Telegram: @medical_k

www.konkur.in

Based on Margaret Mahler's observational analyses, an infant develops a sense of physical separateness from others at about 5 to 7 months of life, a major milestone. Such "self-object boundary" likely does not represent the conscious self, but rather may reflect a nonconscious or an extremely thin phenomenal sense of "material or physical I" that establishes bidirectionality in interactions. This phenomenal sense of self-object boundary attained around midinfancy is likely a converging common outcome of body ownership ("this is my body"), body schema ("agency"—recognition of initiating and controlling own volitional actions), and "material I" (the interoceptive feeling of the body). The evolving recognition memory and selective attention at this period likely aid the attainment.

PHANTASY: THE BRAIN'S PHYLOGENETIC CODE FOR PRIMITIVE MENTAL FORMS

The spelling of phantasy is intended to convey the fundamental difference with fantasy, although they may overlap to some extent (see section "Fantasy" below). M Klein argues that, from the very beginning, recursive cycles of projections and introjections govern mind development. These abstract terms M Klein calls "mechanisms" that mediate exports and imports of mental contents, but provides no elaboration on the mechanisms themselves. The first attempt to reify infantile projection and introjection is the concept of "primary phantasy" (Susan Isaacs) or, as Sigmund Freud called it, "primal phantasy," the term used here. Primal phantasy refers to phylogenetically inherited *a priori* knowledge about the world that predates real experience and is embedded in survival instincts. For example, the sensation-feeling of hunger (an unconditioned displeasure, threat to survival) triggers the survival instinct to forage and the impulse to devour (a survival response), aiming the hungry mammal at the nipple (the rooting instinct finds an appropriate object to feed). These neural processes are said to be mentally represented as phantasy of desire that aims survival instincts toward appropriate means.[31] M Klein and S Freud attributed such primal phantasies to the work of the nonconscious mind (the "id").[32] Nonconscious phantasy is preconceptual and fully sequestered from reality testing. It operates below the level of conscious fantasy, long before the development of symbolic language. The earliest phantasies mainly bind olfactory-gustatory sensations and

Telegram: @medical_k

www.konkur.in

oral impulses, such as sucking, devouring (incorporation), tearing, biting, etc. With time, phantasy becomes less connected with bodily sensations and more symbolic as the child becomes increasingly able to differentiate between real and phantasized objects. Nonetheless, primal phantasy continues to underlie all mental activity as the mental penumbra inherent to bodily events and survival instincts. Exploration of phantasy as it appears in dreams and transference is an important aspect of psychoanalysis and some psychodynamic approaches.

Fantasy

In contrast to the concept of phantasy, fantasy involves conscious wishful distortions of reality (colloquially “wishful thinking” or “day-dreaming”) that gratify impulses or solve one’s inner problems. Reality testing is intact but temporarily divested in working memory. As either a gratifying or defensive operation, fantasy may and frequently does contain elements of deeper, nonconscious primal phantasies. This may occur when primal phantasies of desire or destruction bleed into conscious wishes of revenge or unconditional love, flavoring them with rage, paranoia, bizarreness, idealization, adoration, etc. Such phantasy/fantasy blend is commonly referred to as “primitive fantasy,” a key compensatory mechanism in personality disorder. Here, reality testing is not lost (as in psychosis) and not temporarily divested (as in daydreaming), but subtly disturbed, especially in interpersonal relationships. Childhood phantasy and fantasy have a structuring influence on self- and object representations.

Science of Phantasy: Plausibility, Analogies, and Survival Circuits

Object relations theory understands phantasy as a phylogenetically inherited code that *predictably* amalgamates sensations, survival instincts, and impulses into archaic motivated behaviors. This is a plausible hypothesis because randomness at early stages of mind development seems implausible from an evolutionary perspective. In the absence of direct evidence, Thomas Ogden reviews examples of “psychological deep structures” that support the concept of phantasy by analogy. Recent work on attractor networks that are created by intrinsic neuronal activity and predate experience corresponds to the concept of psychological deep structures. One robust example is the “innate capacity for language,” universal for all humans, as the pre-existing brain system that governs the

Telegram: @medical_k

www.konkur.in

acquisition of language from speech input without any knowledge of syntax. This famous thesis of Noam Chomsky has been substantiated by the discovery of an immature “template” language network in neonates two days after birth. Clearly, this immature network predates significant speech input but is trained by speech input to self-organize toward the syntactic and semantic architecture of adult language. Survival circuits are another example of preassembled deep structures in the brain, operational at birth, ready for selective input to activate survival instincts. At this early age, survival instincts are mainly related to fluid- and nutrition balance and thermoregulation. Some functions are automatic reflexes (e.g., shivering when cold), while some involve motivated instincts aimed at a goal (rooting for a nipple when hungry). Survival circuits are said to unify affects, motivation, reinforcement, and arousal into survival functions (survival instincts) that allow organisms to survive and thrive. Such amalgamate of sensation, affects, motivation, reinforcement, arousal, and impulses aimed at a goal inherent to survival circuits is exactly what psychoanalysis refers to as phantasy. It is thus plausible, if not likely, that human phantasy originates in survival circuits and may be in genetic continuity with archaic motivations of desire and destruction shared by all mammals.

Survival Circuits, Survival Functions, and Survival Instincts. J LeDoux introduced the concept of survival circuits and functions that are preserved across mammalian species, notably thermorelgulation, fluid balance, energy supply/nutrition, defense, and reproduction. In his words, focusing on survival functions and circuits allows phenomena related to emotion, motivation, reinforcement, and arousal to be treated as components of a unified process that unfolds when an organism faces a challenge or opportunity. These experiences are not only critical for survival but also for BrainMind development. The original five survival circuits and functions may need to be revised to include the survival instinct to bond, also conserved across mammalian species, and also of major importance in human BrainMind development. The neuroanatomy and manifestations of the instinct to bond with a parent have been outlined by Panksepp. Three out of six survival circuits concern homeostatic maintenance of the body, that is, thermoregulation, energy supply/nutrition, fluid balance), two concern self-preservation (bonding, defense), and one species-preservation (reproduction). The concept of

Telegram: @medical_k

www.konkur.in

survival functions is more inclusive than that of survival instincts. Survival functions range from very simple (e.g., automatic homeostatic adjustments—adipolysis in starvation, shivering in thermoregulation, etc.), via reflexive (e.g., automatic reflex-pattern responses—fight-flight-freeze), to complex behavior responses, conditioned (e.g., hiding from predators, playing dead) or preplanned (building shelters). Not all survival functions convey the essence of survival instincts, that is, the innate neurosensory dispositions molded into survival behavior by learning. As Konrad Lorenz demonstrated, the instinct to imprint on the mother in precocial birds exemplifies such duality, the innateness and the selective learning of survival instincts: newly hatched chicks are genetically predisposed to modulate the gross sensory input of the imprinting object within a critical period of hours after hatching, which is usually the mother in a stable ecosystem (an instinct to imprint on the mother, vital for survival). With this clarification, the term “survival instincts” is used in this overview.

RECURSIVE CYCLES OF PROJECTION AND INTROJECTION ORGANIZE THE INNER AND THE OUTER WORLD

In psychoanalysis, the term projection (literary, “expelling things in front”) usually refers to a defense mechanism whereby one attributes own thoughts or impulses to another person. The term “introjection” (literary, “taking things in”) is used for the process whereby one “takes in” real or phantasized aspects of the outside world as more or less distorted mental representations of that world.

The hedonic and motivational reality of earliest sensations, neurally processed by subcortical survival circuits, is mentally represented by phantasy, which is, in turn, recursively updated by actual experiences that approximate it. It follows that phantasy is presented for reality testing from the earliest days. For example, the newborn’s phantasy of desire for food (an expectation inherent to survival instincts, a projection) is aimed at the nipple (an appropriate object to feed) and thus brought into contact with realizations (actually experienced) that approximate to the desire (feeding, no feeding). The blend updates the phantasy (an introjection), thus resulting in revised phantasies (revised expectations) which then enter the cycle of projections and reintrojections in future encounters. Similar dynamics characterize the works of cognitive-affective schemas that

Telegram: @medical_k

www.konkur.in

expect experience based on previous experience (projection) and schema updates via memory (introjection).

The Origin of Inaugural Self- and Object Representations

Kleinian psychoanalysis holds that the first internal objects are inherent in biologic instincts[33] and mentally created by phantasy, the mental penumbra of the instincts. Phantasy, so the theory goes, amalgamates bodily sensations harboring innate hedonic and motivational qualities (pleasure/displeasure, desire/dread) with instinctual impulses (devour, destroy) aimed at controlling the causative sensation felt by the neonate as “presence,” “something.” This “presence,” threatening or nurturing, is what is theorized to be the first object internalized by the mind. The “presence” soon begins to differentiate between the inside and the outside. Phantasies engendered by the brainstem’s hedonic valuations of interoceptive sensations such as pleasure or displeasure and the related reflexes to swallow or expulse, may pioneer the first tracings of the inside as the precursors of the self-object boundary. With this in mind, earliest self-representations are embedded in the inaugural internal objects and arise from the neonate’s nonconscious recognition of their own sensations. A self-representation thus shares affective valence and develops in tandem with object representation, with which it is initially confused as being its part (first noted by Edith Jacobson in 1964). We refer to these early sensations as “survival-level,” as they automatically activate survival circuits and functions in the context of absolute dependency on caretakers.

Object Relations as Episodic Memory

Object relation theorists (Susan Isaacs) and ego-psychologists (Edith Jacobson) pioneered the idea that introjection, a mental reproduction of the outside world, must have its neural substrate in memory. Introjection allows BrainMind to record the history of interactions between the individual and the world of objects or, more precisely, to record the individual’s interpretation of these interactions. As such, object relations play a major role in mental life, from early self- and object representations to one’s acquisition of culture. Object relations are implicitly learned during survival-level experiences with caretakers and thus evoke intense hedonic qualities, pleasure, and displeasure. The biologic basis of such learning likely involves memory, here affect-enhanced episodic memory. Episodic

Telegram: @medical_k

www.konkur.in

memory can be conceived as the brain's information processing system by which self-related events like early survival-level episodes are neurally encoded as memory traces ("engrams") and operate inside the mind as a sustained, albeit implicit presence (see section, "Engrams or Neuronal Memory Traces" below). The incidence of experiences narrowly related to survival decreases with increasing mental and physical autonomy. Deborah Talmi and colleagues report that affect-enhanced episodic memories continue after childhood but become mostly concerned with experiences that either promote or frustrate one's current goals.

Engrams or Neural Memory Traces. An "engram" refers to lasting offline physical and/or chemical changes in a subpopulation of neurons elicited by neuronal plasticity that requires temporal precedence (cell A fires just before, not at the same time as cell B). Such Hebbian wiring of neurons (*engram cells*) encodes the newly formed memory associations. Susumu Tonegawa and colleagues define engram cells as populations of cells that constitute critical cellular components of a given engram (i) activated by the learning experience, (ii) physically or chemically modified by the learning experience, and (iii) reactivated by subsequent presentation of the stimuli that were present at learning, resulting in episodic memory retrieval. An "*engram ensemble*" refers to the collection of engram cells distributed across brain regions, with each ensemble supporting a component of multimodal memory. A given memory is supported by an "*engram complex,*" composed of dispersed engram ensembles that are interconnected by an *engram complex pathway.*

PARTIAL OBJECT RELATIONS

Theory

Neonates and infants suffer a great deal of unconditioned fear about their own survival, caused by the trauma of delivery and, post-delivery, by interoceptive sensations (pain, hunger, thirst, etc.). Although normally infrequent, such experiences are inevitable, except in theoretically perfect conditions. Per M Klein, distress is phantasized to represent threats of annihilation by a dangerous persecutor that fails to feed and protect. This early phantasy harbors paranoid fears for own survival and aggression-to-destroy. Aggression is projected not only into the malicious persecutor (of which the prototype is the frustrating breast) but also against the inside of

Telegram: @medical_k

www.konkur.in

their own body (felt to be a part of the breast). Positive sensations (pleasure) create the phantasy of desire but remain split from the phantasy of dread and destruction ("partial object relations"). Such splitting of contradictory experience, so the theory goes, protects the good internal object from being destroyed by internalized bad objects from within. In 1946, M Klein used the phrase "division between love and hate" to describe the unrealistic but protective split between contradictory experiences toward the same object, internalized and real, and toward their own self (which she refers to as "ego"). As a reminder, self-representations derive from object representations and are thus dichotomized into good and bad (gratified and frustrated), for they share the same hedonic valence with respective gratifying or frustrating object representations. M Klein understood early splitting to be a purely mental mechanism that protects the good internal object, the "focal point" for mind organization, as discussed. In extreme cases, M Klein argued that massive negative self- and object representations might lead to mind disintegration, as "early ego lacks cohesiveness and … a tendency toward integration alternates with a tendency toward disintegration, a falling into bits … especially during the first few months of life." Mathematical models of personality development, drawing from dynamical systems theory, support this theorizing. Nenad Svrakic and colleagues report that, during the early formation of personality (an evolving dynamical system), the trajectory leading to chaos can be included, a nondesirable outcome, but nevertheless a result of development here failing to self-organize in the context of prevalent adversity and repelling attractor memories.

Neuroscience of Partial Object Relations: Dichotomization of Sensory Stimuli into Dreadful versus Desirable as the First Organizer of the Mind

Studies of contextual fear conditioning in rodents use recombinant DNA technology and optogenetics (described in the next section) to delineate cellular encoding and systems consolidation of affect-enhanced episodic memories. Susumu Tonegawa and colleagues demonstrate that the semantic-like content ("what happened"), contextual semantic-like hedonic valence (factual knowledge that an event was pleasant or unpleasant, not in itself an affect), and spatio-temporal context ("where," "when") are processed by the hippocampus. The amygdala process the actual affect evoked by the experience (contextual affect).

Telegram: @medical_k

www.konkur.in

Recombinant DNA and Optogenetics Bridge the Gap between Cellular- and Systems-Neuroscience of Episodic Memory. Recombinant DNA refers to engineered DNA, combining sequences from various species and with various roles (e.g., transgenes, promoters, repressors, operators, among others). Manfred Gossen and Herman Bujard introduced "Tetracycline-Controlled Transcriptional Activator," a method of inducible gene expression where transcription is reversibly turned on and off in the respectively, absence or presence of doxycycline, aka "tet-OFF" system. In some current uses, "tet-OFF" is engineered to be transcriptionally active under the control of *c-fos* proto-oncogene promoter, an immediate early gene encoding a transcription factor, c-fos protein, induced by the recent activity of a neuron encoding a memory. The brain region of interest is transfected with an adenovirus-associated viral promoter, under the control of "tet-OFF," to initiate transcription of a transgene that encodes light-activated membrane ion-channels ("channelrhodopsins"). Light-sensitive ion channels open or close in response to light of different wavelengths ("optogenetics"), selectively in active neurons that initiated the cascade, that is, those expressing the c-fos protein. The tagged neurons can then be activated or silenced by light in different training paradigms for associative learning, allowing not only for precise identification of neurons involved in systems consolidation of contextual fear memory but also for selective retrieval of those memories. Retrograde tracing of monosynaptic neural pathways with, for example, cholera B toxin and in vivo imaging of calcium-dependent neuronal activity is combined with the above approaches for, respectively, pathway-level identification and cell-level visualization of neuronal processes in episodic memories.

The hippocampus forms an index of distributed neural events that were active during the actual episodic experience. The contextual affect evoked by the experience is memorized by the amygdala (reported by Takashi Kitamura and colleagues) by neurons genetically programmed to encode either rewarding or frustrating affects (reported by Joshua Kim and colleagues). As they are being encoded via synaptic plasticity, hippocampal engrams simultaneously engage mPFC to form its corresponding engram that indexes distributed component engrams of multimodal information into a coherent episodic memory. The mPFC engram is at first silent but matures[34] within several weeks to become the active episodic memory of the event, now "systems-consolidated."

Telegram: @medical_k

www.konkur.in

Optogenetic and/or contextual activation of recent hippocampal episodic memory engrams (day 2 after memory formation) drives firing in the amygdala engrams bearing affect-memory of the episode (here fear, panic) and recreates freezing. The hippocampal originals then become silent (14 days after memory formation), in the sense that they show a decreased density of dendritic spines and can be reactivated only by optogenetic stimulation, not by natural clues; whether the hippocampus eventually loses the memory information is contested. The amygdala also provides input to the mPFC during the formation of mPFC engrams but, unlike the hippocampus, remains active in providing the affect-memory of fear during remote recall of the episodic event. The process of contextual fear memory is described here, but a similar process is likely for reward-enhanced memories, both types qualifying as episodic-like (see the summary). Amygdala activation is enhanced during both pleasant and unpleasant imagery but is correlated with rated emotional *arousal,*[35] thereby enhancing emotional learning and memory. As the hedonic quality of episodic events (pleasure, displeasure) is assigned by the NAc shell and ventral pallidum, an interesting possibility is that amygdala forms an index of distributed regions that coparticipate in an affect (arousal, hedonic quality, motoric reactions).

More recent reports by the Tonegawa group indicate that engram cell ensembles that encode individual components of an episodic memory are distributed brain-wide, across many connected regions, many of which are also functionally connected to hippocampal and amygdala engrams. Together, these inter-connected engram ensembles establish a “unified engram complex” that encodes the whole multimodal episode, including the contextual affects and semantic-like content (“what happened”). This work supports the unified engram complex for a single memory, suggested by Richard Semon in 1904. Remote memory recall induced by chemogenetic activation of multiple engram cell ensembles is most comparable to natural memory. However, some brain regions, particularly the mPFC, may be more active in remote retrieval of episodic memory, particularly the mPFC. Another function of mPFC is to learn associations between contexts, locations, events, and corresponding adaptive responses, particularly emotional responses, as David Euston and colleagues review. This function is consistent with the semantization of episodic memory into a self-referential cognitive-affective schema (discussed in more detail below) and may be the neural substrate of

Telegram: @medical_k

www.konkur.in

object relations. In other words, the mPFC appears to be involved in systems-consolidation, schematization, and remote retrieval of schematized autobiographical memory. Forgotten but neurally preserved early object relations that are schematized within the mPFC autobiographical memory process the here-and-now episodic, social, and affective information at a preconceptual level and implicitly steer one's actions and emotion based on survival-level experiences of early childhood.

Extrapolated to human infants, contradictory affects evoked by frustrating versus rewarding interactions are likely encoded by separate groups of amygdala neurons, each group dedicated to only one of the valences. As each group provides only one pole of affect-information to mPFC, self- and object representations derived from these episodes are dichotomized by contextual affects into either rewarding or frustrating.[36] Dichotomized experience (gratifying as well as frustrating) are both episodic memory, thus likely coexist within the same mPFC episodic memory network. This may explain the bistable, exclusively gratifying versus exclusively frustrating object relations until around midinfancy, in the context of an immature mPFC. Normally, positive experiences of care, safety, comfort are prevalent and frequent. Attractor memory for positive experience operates as a stable fixed point attractor for new learning (development), thereby expanding its basin of attraction. In contrast, negative experiences of endangerment and discomfort are normally less frequent. Such memories are unstable attractors that repel learning and development. The psychoanalytic concept of splitting between dichotomized self- and object representations (aka partial object relations) may therefore originate in the anatomy and function of the amygdala. Until about midinfancy, partial object relations are maintained by an immature mPFC. Psychoanalysis and neuroscience appear to describe the same phenomenon, a bistable state of the mPFC episodic memory networks, but through the prisms of phenomenology and neuroanatomy. As anatomically segregated groups of amygdala neurons are genetically programmed to irreversibly encode only one affective valence of episodic memories, the dichotomies of partial object relations cannot be integrated in situ, only by higher-order cognitive synthesis, our next point.

INTEGRATED OBJECT RELATIONS: COGNITIVE RECONCILIATION OF AFFECTIVE DICHOTOMIES

Telegram: @medical_k

www.konkur.in

Two parallel developments mark the transition from partial (dichotomized) object relations to integrated (whole) object relations, a gradual process evolving from roughly midinfancy to 2- to 3-years of life[37] when self- and object-constancy are established. In the process, the infant/child becomes increasingly adept at:

i. integrating dichotomized experience into a realistic cognitive-affective frame whereby significant objects and own self are experienced as mostly gratifying and occasionally frustrating, and
ii. differentiating self- from object-mental representations; such mental boundary toward others allows the sense of self to be internally maintained and thus increasingly independent from the caretaker's affects and actions.

The phenomenology and mechanisms of whole object relations are discussed in more detail below.

Neuroscience of Whole Object Relations

Episodic-to-Semantic Memory Conversion: Generalization of Knowledge from Specific Experiences. Human thought would be inefficient, if not impossible, if episodic memories retained the level of contextual detail present at encoding. All episodic memory is first encoded by the hippocampus–amygdala memory system and within weeks systems-consolidated by mPFC, as discussed. Recurrent episodes get semanticized into a gist-like neocortical schema based on overlaps, statistical regularities, and abstractions. Such gist-like schemas govern one's expectations in new but similar episodes. The process is known as "schema-learning" or "episodic-to-semantic conversion." Schema-forming may involve *de novo* processing by mPFC, which would imply a new engram encoding the schema existing side-by-side with the episodic memory engram. Such engram has been hypothesized but is yet to be found. Alternatively, schema-forming may arise from "episodic-to-semantic conversion." The phrase, coined by Eric Kandel, refers to the natural tendency of consolidated episodic memories to decay over time, to lose spatio-temporal context-specificity ("when" and "where") but not the semantic-like information ("what happened") and the semantic-like valence information (a frustrating or a gratifying event, not itself an affect). Affects evoked in the event are memorized by the amygdala and are feed-forwarded to mPFC during the current event and in future similar events, as noted. Neurophysiology and epigenetics of schema-forming and self-

Telegram: @medical_k

www.konkur.in

reinforcing expansion in animals and humans have been described (summarized by Svrakic and Zorumski in 2021). Nikolaos Chrysanthidis and colleagues recently proposed that both Bayesian- and Hebbian synaptic plasticity might underlie the semantization of episodic memory.

Gist-like neocortical schemas can store information within an associative framework. Such schemas are independent of specific learning episodes. Their main function is to extract general knowledge from past experiences that can be applied across similar-but-novel situations. The ventral anterior cingulate, a part of mPFC, is connected with the amygdala, NAc, hypothalamus, hippocampus, and anterior insula, thus believed to be the interface between emotion and cognition. The mPFC is thought to harbor schemas related to the salience of emotion, motivational information, decision-making, and emotional behavior, much like implicit schemas suggested for early object relations.

Intrinsic Propensity of mPFC for Concept-Learning May Pilot the Inaugural Integration of Polarized Experience Around Mid-Infancy. M Klein observed the first signs of integrated object relations around midinfancy. She was criticized for attributing major cognitive capacities to young infants. However, intrinsic processing within mPFC, a convergence zone, is involved in simple rule and categorization memories as well as information on more complex schematic frameworks for episodic memories, as shown by Szu-Han Wang and colleagues. It is thus plausible that the inaugural integration of polarized experience by midinfancy entails a simple linear rule, a nonconscious or vaguely conscious concept that overarches contradictory episodes with the same object. This simple concept may be facilitated by the developing recognition memory, selective attention, and the capacity for object permanence, the latter recently demonstrated in 4-month-old infants by Renee Baillargeon and Julie DeVos, that is, 4 to 8 months earlier than proposed by Jean Piaget.

For normal BrainMind development, at the minimum, “good-enough” parenting[38] (helpful environment) and/or heritably moderate dispositions to negative affects (favorable genetics) are required. In such a setting, positive- and negative episodes with the same caretaker are encoded by the mPFC episodic memory network as dichotomized, occasional negative split off from common positive, each governed by its respective fixed point attractor subnetwork. Likely based on nonconscious Bayesian-

Telegram: @medical_k

www.konkur.in

type inference, an infant then develops a *degree of belief* in future interactive events. Under good-enough circumstances, the infant's implicit prediction is that interactions with the caretaker will be gratifying despite occasional frustrations. The gradual evolution from partial object relations of midinfancy into phenomenally conscious self- and object-constancy around 2 to 3 years of age corresponds to M Klein's concept of integrated object relations and depressive position. The transition from partial object relations (a bistable state of the mPFC memory network, unable to reconcile contradictions) to integrated object relations (a metastable state of the mPFC memory network, able to reconcile contradictions) allows BrainMind to handle complexity (next section), essential for further progression of mind development and social relations.

Metastability of the mPFC Episodic Memory Network May Be a Mechanism for Conscious Integration of Partial Object Relations in Toddlers. The unconditioned survival-level experiences of neonates and young infants occur in the context of helplessness and total dependency upon caregivers. In toddlers, care evolves toward more bilateral interactions with diversified and more frequent gratification and frustration by the same object (complexity). Bistable partial object relations (love *or* hate) are now adaptively suboptimal, as such exclusive dichotomization fails to meet increasing demands for relational complexity (love *and* hate). The mPFC episodic memory network processes positive and negative episodes that arrive from basins of attraction with so called "fractal basin boundaries." Namely, every point in the basin of positive experiences with the caretaker has pieces of another basin (negative experiences with the same caretaker) arbitrarily nearby; hence, small perturbations in the initial conditions can change the final fixed-point attractor state, positive or negative experiences ("complex memory network"). To handle relational complexity, mPFC must reconcile the dichotomies (integration) which in turn must remain quasi-independent to represent the reality of the actual interaction. A plausible mechanism for cognitive integration of bistable partial object relations may be metastability, a near-critical operating state of the mPFC episodic memory network. Metastability allows mPFC to reconcile the dichotomies by transitioning from bistability (dichotomization) to dynamic monostability (integration by hovering above both poles of dichotomized experiences that remain *quasi*-independent).

Telegram: @medical_k

www.konkur.in

The mPFC memory networks may transition from bistability to metastability as a function of a control parameter, here the complexity of contradictory experiences which collide with each other. Right before the critical point, where the network would either devolve into chaotic (experience fragmented to pieces) or become rigid (fixated idealization or hatred), the network reaches a state where neither stable attractor states (positive memories) nor unstable attractor states (negative memories) exist. Instead, S Kelso argues, attraction for their respective sensory-affective inputs remains where these fixed-point attractors used to be. Through the lens of neurophysiology, oscillatory phase-synchrony (theta-gamma nests), governs the attractor dynamics between a fixed-point attractor-memory (usually theta oscillations) and its incoming sensory-affective input (modulated by gamma oscillations). Contradictory inputs (complexity) may break such in-phase attractors by oscillatory mismatches. The network self-organizes to operate in a metastable regime that enables it to process complexity. The remnants of fixed point memory-attractor broken by complexity are called ghost attractors, as these represent weakly-stable partially-synchronized network states. Such ghost attractors may nevertheless reconcile contradicting experiences that now "dwell" around the remnants by means of phase-gathering (quasi-synchrony) but still remain quasi-independent by phase-dispersing. Relative to phase-synchrony and asynchrony, phase gathering and dispersing are weaker associations between a fixed-point attractor and the incoming input. Such self-organized metastable regime may enable the mPFC to dynamically screen network tendencies as "stationary transients,"[39] a more adaptive alternative relative to being locked in dichotomized stationary states. S Kelso viewed metastable states of attractor networks as a pivot toward the emergence of stable collective states, as in integrated object relations and self- and object-constancy.

Successive visits to the remnants of fixed-point attractors are intrinsic to the time course of activation of the mPFC episodic memory network and do not require stochastic noise or additional sources of energy input. In other words, no energy barriers need to be crossed to visit self-organized metastable tendencies, aka second-order, energy-free state transitions. In contrast to physics and chemistry, cortical metastability does not follow the dynamics of lower- and higher-energy states but rather activity-dependent transient oscillatory synchronizations that persist for some period as a deviation from the resting state of an attractor network. Such transient

Telegram: @medical_k

www.konkur.in

unions readily self-configure and readily dissolve as internal and external demands change. As a result, cortical capacity to deal with complexity is increased: local specialized functions are kept quasi-independent (positive and negative self- and object images are independently realistic) but at the same time coordinated into global integration that provides a more realistic frame for the long-term reality of the relationship.

Jakub Vohryzek and colleagues have demonstrated ghost attractors in RSNs in humans. These authors characterize spontaneous brain activity in the form of trajectories within the state space, calculating the fractional occupancy and the dwell times of each state, as well as the transition probabilities between states. They also demonstrate that within-subject reliability is maximized when including the high-frequency components of the BOLD signal (>0.1 Hz), indicating the existence of individual fingerprints in dynamical patterns evolving at least as fast as the temporal resolution of acquisition. In conclusion, these results reinforce the mechanistic scenario that resting-state networks are the expression of erratic excursions from a baseline synchronous stable state into weakly-stable partially-synchronized states of ghost attractors. The process of continuous transactions between integrative and segregative tendencies by metastability is likely nonconscious, as is the case with most other cognitive processing, but the outcome, that is, the experience of self- and object-constancy, reaches phenomenal consciousness in toddlers. Brain structures and neural processes involved in dichotomization and integration of object relations during normal development are summarized in Figure 3.6–2.

Mental Separation of Self- from Object Representations. In parallel with the integration of contradictory self- and object representations, the sense of self (the “I”), initially embedded in object representations, achieves enough phenomenologic autonomy to emerge as an independent phenomenal experience. Such mental separation between internalized self- and object representations is a developmental milestone first recognizable around 18 to 24 months of age, an approximation based on Margaret Mahler. PFC, and particularly mPFC, major hubs in the default mode “self-network,” develop rapidly during the first 24 months of life, thereby providing neuro-cognitive mechanisms for such differentiation to emerge. The revised higher-order theory of emotional consciousness—HOTEC, devised by J LeDoux and R Brown, has been challenged mainly

Telegram: @medical_k

www.konkur.in

regarding the origin of phenomenal consciousness (see section, "First-order, higher-order, and revised higher-order theories of consciousness and emotion" below). K Berridge and colleagues define "affect" in a way that may inform this debate (see section "Affect, emotion, feeling" below). Nonetheless, the HOTEC provides a cogent account of the development of the sense of self by cognitive processing of engramized episodic memories, at the core of which is the primordial self-schema embedded in early object relations.

FIGURE 3.6–2. Brain structures and neural processes involved in dichotomization and integration of object relations (normal development).

FIRST-ORDER, HIGHER-ORDER, AND REVISED HIGHER-ORDER THEORIES OF CONSCIOUSNESS AND EMOTION (FOT, HOT, AND HOTEC). The science of phenomenology studies the structure of experience from the first-person perspective. It does so by focusing on phenomena[40] or the appearances of things as they show up to one, such as colors, taste, memory, imagination, emotion, own thoughts, body awareness, etc. Sensory data about internal and external environments have an essential *first-person perspective*, for example, "what is it like for one" to have experience, to feel pain, to see red, etc., and *phenomenal quality of experience* (e.g., the taste of apples vs. pears, dental pain vs. wound pain). These subjective qualities of things or *qualia* are said to be secondary properties, not contained in objects being represented in experience but interpreted as

Telegram: @medical_k

www.konkur.in

such by one's mind and then attributed to the world. J LeDoux and R Brown point out that such phenomenal consciousness involves introspection, either by passive noticing or active scrutiny of qualia. Phenomenal consciousness is not penetrable by others, only reportable by the experiencing person. First-order theories (FOT) of consciousness (Ned Block, Jaak Panksepp, among others) hold that phenomenally conscious experience arises from neural processing of sensory stimuli, for example, from auditory cortex processing sounds, without higher-order monitoring. FOT holds that such "first-order neural states" of stimuli are felt as phenomenally conscious, called "perceptual consciousness" (Ned Block, his term used here) and "core consciousness" (Jaak Panksepp). Perception is traditionally considered anoetic, "not knowing of knowing." However, the FOT of perceptual consciousness refers to a state of consciousness that implicitly motivates behavior but itself evades conscious experience. In more recent revisions of FOT, Marie Vandekerckhove and Jaak Panksepp take a position that perceptual consciousness infact may not be accessible for introspective examination, may be truly nonconscious, but may become conscious and accessible to introspectiom by additional neocortical processing. Higher-order theories of consciousness (HOT) (discussed by J LeDoux and R Brown) hold that first-order, neural sensory representations alone are insufficient for phenomenal consciousness but need cognitive processing to reflect upon the first-order state in order to become conscious as a meta-representation of neural states. The aforementioned HOTEC holds that the first-order neural states of … tastes, visions, touches … are higher-order represented (HOR) in nonconscious working memory.[41] This first HOR provides a minimal inner awareness of one's ongoing neural states, hence the name "nonconscious working memory". Another HOR of this nonconscious HOR is needed in conscious working memory (HOR of HOR, HOROR) for a conscious phenomenal experience to emerge as passive noticing of "what is it like for one … to see red", figuratively a conscious recognizer of a nonconscious recognizer. Such HOROR allows one to be phenomenally conscious ("what is it like for one") about being in the first-order neural sensory state. Yet another HOR of HOROR in conscious working memory allows for reflective self-awareness ("I am the one who is in the state of noticing what is it like for me to see red"), a conscious recognizer of a conscious recognizer. Both HOROR and HOR

Telegram: @medical_k

www.konkur.in

of HOROR are phenomenal states, both are accessible to introspection, either by passive noticing or by active scrutiny.

AFFECT, EMOTION, FEELING. The terms "affect," "emotion," and "feeling" are frequently used interchangeably or, yet worse, as confusing blends, "affective feelings" or "emotional feelings." Such terminologic discord arises from the disparate concepts of affects, emotions, and drives vis-à-vis their origin (innate or learned), biologic role (informants of survival or triggers of survival), and the nature of experience (nonconscious brain states or phenomenally conscious experiences). What appears to be a point of agreement is that affects are associated with biologically relevant sensory stimuli, those that disturb homeostasis or impact the well-being of an organism. Examples include interoceptive sensation-feelings (e.g., hunger, thirst, sensual touch, pain, etc.), exteroceptive sensations (e.g., unconditioned gustatory stimuli—sweet vs. bitter taste), and prepotently conditioned sensory stimuli (the sight of a snake, fear of heights, etc.). K Berridge and colleagues have devised a concept of affects that may be informative to the seemingly endless debate between the FOT, HOT, and HOTEC. They define "affect" as the core hedonic quality of biologically relevant sensations that have been conserved in vertebrate evolution based on their objective consequences for survival and reproduction. These biologically relevant sensations harbor an inherent hedonic quality (pleasure-liking vs. displeasure-disliking), motivational aspects (desire or dread), and incentive salience (wanting or not wanting). Survival circuits might have incorporated the unconditioned hedonic quality of sensations as intrinsic physiologic cues that contribute to incentive salience which, in turn, enables learning by the conditioning of complex survival behaviors. Causative hedonic "hotspots" and "coldspots" in NAc and ventral pallidum involve opiate-mediated enhancement (gain-of-function) of core liking and disliking associated with sensory experience.[42] Such enhanced hedonic qualities of sensations are objective affects (neural affects). In addition, a "keyboard" mechanism embedded in the anatomy and function of the medial shell of NAc attaches motivation to enhanced liking and disliking, that is, desire versus dread as innate "neural motivations." This NAc hedonic keyboard can generate many mixtures of desire and dread: the most intensive pleasure/desire at the rostral medial shell becomes incrementally more aversive toward the caudal medial shell (dread/fearful escape attempts, distress calls, defensive bite attempts, etc.). It is

Telegram: @medical_k

www.konkur.in

plausible that all affects, both from the spectrum of pleasures to the spectrum of fears and rage, derive from the NAc-pallidal circuitry and the NAc keyboard mechanism. This circuitry, involved in enhanced core hedonic quality (enhanced liking vs. disliking) and the related enhanced motivations of desire versus dread, is independent of the incentive salience of wanting versus not wanting, the latter a separate mesolimbic dopamine-regulated system. Moreover, such "neural" (objective) hedonic/motivational/incentive qualities of sensory stimuli are HOR in the orbitorontal cortex[43] and anterior insula where they are processed into a phenomenally conscious experience of affects, now conscious emotion and conscious sensation-feelings. These findings seem to support the HOTEC: (i) hedonic quality of sensory experience is embedded in neuronal processing thereby creating a nonconscious bias in reactions without conscious emotion ("objective" or "neural" affects), (ii) the circuitry that processes neural and conscious aspects of affects are neurochemically distinct and (iii) neural affects are brain states that may become conscious emotions only after higher-order representation by the GNC in the orbitofrontal cortex and anterior insula. In support of the distinction between neural affects and conscious emotions, LeDoux and Brown review evidence that conscious emotion (e.g., fear) may not accompany behavioral and physiologic responses to threats regulated by subcortical survival circuits.

Following Bud Craig, the term "*feeling*" is used for sensation-feelings (or somatic feelings), for example, hunger, affectionate touch, temperature, pain, etc., that arise from interoception and are made phenomenally conscious by the anterior insula. The term "*mood* " is best suited for a general prevailing valence of the mind ("feeling good or feeling bad"), of low intensity, specificity, and provokability. As noted, interoception (hunger, temperature, pain, affectionate touch) inheres an affect (pleasure, displeasure), motivation (dread, desire), and incentive salience (wanting/not wanting). Interoception, the physiologic condition of one's own body, is thus a major determinant of feeling good or bad moods. Other determinants are "traditional" emotions, for example, sadness, happiness, fearfulness, unfairness, trust, etc. are conscious experiences that engage anterior insula and anterior cingulate, with input from ventral striatum, amygdala and hippocampus. Hence, these complex emotions combine cognitive and physiologic information, more so than the traditional sensation–feelings (hunger, pain, etc.) where physiologic

Telegram: @medical_k

www.konkur.in

correlates predominate. With this in mind, one “emotes” love and “feels” pain, although the latter verb can be used for both, due to the sensation–feeling component of traditional emotion. World affairs, weather, economy, and similar events also play a role in one’s mood via their relevance to one’s lifestyle, moral standards, immediate or future plans, etc. All of the above influence one’s subjective mood which in turn influences how people think, behave, make decisions, and interact with others.

The SN, embedding the stimulus-driven attention network, is anchored in the anterior insula and dorsal anterior cingulate, as noted. It is also connected with the amygdala (affect memory), nucleus accumbens, ventral tegmentum, orbitofrontal cortex (hedonic value, reward, incentive salience, emotional decisions) ventromedial, and dorsolateral PFC (executive function, working memory). Such interconnectedness helps integrate emotional, cognitive, and social information necessary for complex moral and social behaviors, among other functions.

COGNITIVE AND NETWORK NEUROSCIENCE OF THE EXPERIENCE OF SELF

A phenomenal experience of self predictably emerges around 2 to 3 years of age, as noted. It is believed to arise from one’s self-schema, a compilation of autobiographical memories and semantic knowledge about one’s own self, composed of:

i. explicit autobiographical events (“what has happened to one in own life”);
ii. semantic memory of one’s identity (“who am I” inside, plus name, date of birth, place of birth, etc.);
iii. semantic knowledge of one’s own personality traits (how one usually feels, acts, and thinks in particular situations); and
iv. one’s material “I” (body schema, body ownership, proprioception, interoceptive sensation-feelings).

These components of self-schema exist as nonconscious engram complexes and nonconscious body-sensing neural systems (posterior insula, cerebellum, sensory cortices) and are thus nonmental, first-order neural states. According to HOTEC, this neural self-schema becomes a conscious sense of self through a series of higher-order representations (self-HOR) and rerepresentations (HOR of self-HOR, or self-HOROR) by the GNC, first in nonconscious and then in conscious working memory.

Telegram: @medical_k

www.konkur.in

Each new representation is a higher-order cognitive reflection of the lower-order representation. The first HOR of the neural self-schema (self-HOR) is represented in nonconscious working memory and remains nonconscious. Its rerepresentation in conscious working memory (self-HOROR) allows for a passively noticed phenomenally conscious state of the self to emerge. The phenomenal sense of self is accessible to introspection as the first-person experience of "for there to be something that it is like for one … to have the sense of self"… For a self-aware phenomenal self to emerge ("I am the one who is experiencing what is it like for me … to experience my selfhood"), yet another re-representation of the passively noticed phenomenal self, a HOR of self-HOROR is required. The GNC, via cognitive processes of attention, metacognition, and working memory, may mediate such successive higher-order (re)representations of first-order neural states. Such first-person phenomenality of self, now participating in all experience, instantiates a mental boundary with objects as they are represented in the mind, figuratively a mental "I" coexisting with "you." The latter is at first "physical you" (object possesses no own needs), but in toddlerhood also "mental you" (object possesses own needs, rudimentary theory of mind of others). The capacity for introspection has been demonstrated in 2- to 4-year-old-children and is thought to be a key prerequisite for the capacity to theorize the mind of others (reviewed by Christoper Gonzales and colleagues). Phenomenal experience is only reportable to but not penetrable by a third person, as noted. For example, beginning around 2 years of age, children are increasingly able to keep secrets and tell lies. Both abilities are suggestive of the child's understanding that their mind is impenetrable. First mental clashes with the world also emerge around this age, aka "the terrible twos," coinciding with the emergence of "autonomy and will" in Erik Erikson's terms. The neurophysiology of attention and working memory has been generally outlined, each reflecting complex synchronization patterns between slow (theta, beta) and fast oscillatory frequencies (alpha, gamma). The same cannot be said for metacognition, mainly due to the lack of a good operational definition and methodology to study.

Language as a Cognitive Mechanism of Reflection

The term reflection derives from Latin *reflectere*, "bending backward" and 1670s English "turning of the thought back upon past experiences or ideas." Reflection, a cognitive function, may have been made possible by

Telegram: @medical_k

www.konkur.in

the development of symbolic language. Jointly considering genetic, archaeologic, paleontologic, and other evidence, language first evolved around 50,000 to 150,000 years ago, during the Middle Stone Age, roughly contemporaneous with the speciation of Homo sapiens. Noam Chomsky cogently argues that natural human language is a computational mechanism central to syntax that processes information into infinite sets of expressions formed by a finite set of rules operating on a finite vocabulary. In this bio-linguistic perspective, a person's language is a cognitive faculty that creates the world termed mental, while a result of "an organical structure such as the brain." Daniela Perani and colleagues have discovered the seed language attractor network in 4-day-old newborns, much like other documented intrinsic seed attractor networks. From its initial state that predates experience, this immature language network learns, governed by attractor dynamics, to reach a stable state around puberty. Such internalized symbolic language appears to have evolved primarily as a system of thought, a cognitive mode to create and interpret thought (N Chomsky). In fact, language for thought ("inner speech") might have evolved long before it was first used for communication ("outer speech"), and its design is unfit and too complex for communication. To summarize, language is primarily a cognitive faculty, only secondarily used to communicate. Animals can communicate information using vocal sounds, but do so only for linear, one-to-one type messages (predator approaching, etc.), while human symbolic language can assemble novel thoughts at any desired level of detail. This type of linear communication in animals may not indicate reflection (no symbolic language) but simply awareness, that is, presentation of salient sensory memory in short-term memory that keeps track of salient stimuli in the here-and-now environment. Such salient short-term memory may become working- and long-term memory by attentional potentiation. As reviewed by Peter Carruthers, primates and perhaps some other mammals like dogs, whales, etc. demonstrate task-dependent working memory in many respects homologous to human working memory, albeit with a more limited capacity of 2 versus 3 to 4 items manipulated at the time, and high susceptibility to interference. Without symbolic language, animals likely operate in the state of non-reflective awareness coupled with conditioned, task-dependent working memory to motivate and prioritize behaviors.

www.konkur.in

DMN Could Be the Neural Substrate of the Self. If there was a single network that could underlie the sense of self, the DMN is a prime candidate. The topography of DMN is present at birth, and around 2 years of age achieves adult state topology (reviewed by Amanda Hodel). The maturation of DMN roughly coincides with the emergence of the phenomenal experience of own self. The DMN is the largest RSFC network active at wakeful rest, engaging self-related cognition and internally driven attention independent of immediate perceptual input. The main DMN hubs are still a work in progress, but most reports include:

i. mPFC (implicated in social cognition related to self and others, autobiographical memory consolidation and reconsolidation during slow-wave sleep, and sense of agency, among others;
ii. posterior cingulate and precuneus have a pivotal role in DMN due to their involvement in autobiographical memory, self-referential processes, the phenomenal experience of positive hedonic states, the experience of agency;
iii. medial temporal lobe/hippocampus (implicated in episodic and semantic memory);
iv. angular gyrus (implicated in the retrieval of episodic and semantic memories with a contribution to one's experience of remembering);
v. the border between angular and middle temporal gyrus (implicated in bottom-up attention-to-memory processing); and
vi. thalamus and basal forebrain (respectively, a sensory traffic control center and incentive salience/reinforcement learning), both of central importance for the functioning of the DMN.

The brain relaxes to DMN during wakeful rest, disengaged from the external world but reflecting upon one's own autobiographical history, traits, motivations, engaged in social cognition and emotion (e.g., theory of mind of others, empathy, moral reasoning, social evaluations, etc.), and projecting oneself into the future. Together this is called "internal mentation," "a form of travel by mental simulation through our past, present, future, and the minds of others," as noted by Jessica Andrews. The DMN exhibits strong low-frequency (theta, delta) oscillations coherent during the resting state and is deactivated, although not completely, during attention-demanding goal-directed tasks. The DMN with dorsal mPFC as its key hub is considered pivotal for the sense of self and self-related emotional processing. mPFC is among brain regions having the highest baseline metabolic activity, which is attenuated but not absent

Telegram: @medical_k

www.konkur.in

across attention-demanding tasks, as reported by Debra Gusnard and colleagues. The incomplete deactivation of DMN and mPFC during attention-demanding cognition might be a mechanism of self-referential cognition, that is, of the continuous subpersonal representation of thought and self as a monitoring mechanism.[44] The DMN also appears to support the level of detail in experience during working-memory maintenance of active task states (reported by Mladen Sormaz and colleagues).

Internal Object or Objects: Singular or Plural? Deborah Talmi and colleagues demonstrate that emotionally enhanced episodic memories show increased binding with the encoding context, that is, semantic (what happened), temporal (when), spatial (where) it happened, and contextual affective valence ("how it felt"). The authors attribute such increased binding to the intrinsic neural organization of the encoding process, deficiencies in attention, executive function, and control of emotion, among other psychopathologies. As a plausible mechanism of enhancement, emotionally frustrating experiences activate peripheral stress hormones (epinephrine, cortisol), while enhanced positive experiences may involve a decreased autonomic arousal and processing in the precuneus. The latter appears to mediate the experience of happiness by integrating its emotional and cognitive components, as shown by Wataru Sato and colleagues. Enhanced episodic memories tend to cross-activate each other by semantic (natural) resemblance or by similar affects or by similarly intense affects. Such *en masse* activation of otherwise independent enhanced memories by a single affective or semantic clue might be the mechanism of what M Klein observed as a pervasive activation of a good or bad "internal object" (which also coactivates a pervasively good or bad experience of one's own self). It is plausible that M Klein used the singular to illustrate the cross-activated plurality of self- and object representations with the same affective valence. The above features of enhanced episodic memory may account for the psychoanalytic concepts of libido and aggression. Following Kernberg's concept of stratified motivation systems, the cross-activation of enhanced memories with the same valence may be the mechanism by which unconditioned hedonic qualities of pleasure and displeasure and motivations of dread and desire ("primary motivation system") coalesce as constituent components of libido and aggression ("supraordinate

Telegram: @medical_k

www.konkur.in

motivation system"), the latter encompassing all constructive versus destructive tendencies of a person.

Aaron Beck Cognitive Theory and Object Relations Theory Are Complementary in Some Instances. Both object relations theory and Beck cognitive theory concern schematized episodic experiences and autoreinforcing expansion patterns during infancy and toddlerhood (object relations) and childhood and adulthood (core beliefs). Beck cognitive theory considers core beliefs, that is, relatively advanced *valuative concepts* about self and others, to be the root source of autoreinforcing biases about self and others (reviewed by Judith Beck, Seth Disner, and colleagues). In contrast, object relations theory addresses *preconceptual* survival-level experiences of infants and toddlers, a developmental phase preceding that of valuative concepts about self and others. Adaptive (maladaptive) core beliefs include themes about self-worth (self-worthlessness), lovability (unlovability), and resourcefulness (helplessness). Maladaptive core beliefs arise from frustrating episodes with significant objects after survival needs are met, that is, after self- and object constancy have been established. Here, self- and object-constancy are eclipsed, but not wiped out in case of subsequent negative experience, and, in fact, may re-emerge after maladaptive core beliefs are restructured in cognitive-behavior therapy. Both adaptive and maladaptive core beliefs can be explicitly formulated if one journals one's conscious automatic thoughts in challenging situations. In other words, in contrast to implicit object relations, core beliefs are accessible by introspection. Beck cognitive model does not account for the preconceptual sense of endangerment in infants and toddlers exposed to adversity. Self- and object-constancy and adaptive core beliefs rarely develop in this context ("identity diffusion"). Instead, a fantasized compensatory grandiose self ("everyone admires me") may create the sense of safety and control over others. For normal development, however, Beck's concept of core beliefs fits into the sequence of progressively more complex cognitive-affective templates for predicting, interpreting, and assimilating experience. Such templates are piloted by object relations (preconceptual and implicit expectation of safety and helpful others), evolve into self-valuative core beliefs (phenomenally conscious themes about self-worth, lovability, and resourcefulness in 3- to 4-year-old children), and finally into cognitive-affective schemas (a compilation of core-beliefs forms broad frameworks

Telegram: @medical_k

www.konkur.in

of schematized expectations about one's self and the world). The term "cognitive schema" in Beck theory is somewhat misleading, as all schematized episodic memory is associated with respective affect information. For example, Seth Disner and colleagues note that cognitive theorists talk about *depressive* schemas created by adversity and characterized by negative self-referential beliefs. The limited effectiveness of cognitive-behavior therapy in personality disorders is discussed in Svrakic and Zorumski.

WORKING THROUGH AND BEYOND

Beyond the Integration of Dichotomies: Working through the Anxieties of the Depressive Position

Achievement of integrated object relations has been termed the "depressive position" by M Klein. The depressive position emerges when the dyadic object comes to be experienced by the child as a whole object, at times frustrating but predominantly rewarding. The adjective "depressive" relates to a number of new experiences inherent to integrated object relations that must be "worked through" (resolved) with good-enough parents, a gradual process from about 6 months to about 2 to 3 years of life and thereafter. In the process, paranoid fears about one's own safety (paranoid–schizoid position, rigidity) are complemented by anxieties about the safety of the object, whose unavailability is now feared to be a loss rather than a persecutory attack (integrated object relations, depressive position). Fear of losing the object laden with guilt about one's own retaliatory impulses that may destroy the object activate the drive for reparation in the child. Compassionate reassurance by a good-enough mother not only restores but also solidifies the child's positive internal representations of both. Working through the anxieties of depressive position with good-enough parents transforms guilt-riddled anxieties about the safety of the object into a genuine concern for the welfare of the object, joy in giving and mutual exchanges, empathy, and reciprocity. The destructive envy of the object's powers evolves into gratitude for the provided care and support, as noted by M Klein in "Envy and Gratitude." Successful working through sadness, guilt, envy, jealousy, and oedipal issues, is a prerequisite for the capacity for mature love[45] and for reciprocal interpersonal relationships. Unresolved anxieties of depressive position may increase vulnerability to maladaptive core beliefs and

Telegram: @medical_k

www.konkur.in

schemas that, in turn, underlie depression and anxiety in children and adults, despite integrated object relations. Here, cognitive-behavior therapy is usually effective. The concept of reversible depressive and paranoid–schizoid position is considered by many to be the most important of M Klein's contributions to understanding the human mind, as mature people may temporarily regress (become paranoid and revengeful) when faced with losses, but most can effectively recover with the help and empathy of close friends and loved ones.

Most Infants/Toddlers Have to Overcome the Headwind of Negative Affect States

Much like in other animals, the human brain appears wired to prioritize negative/aversive over positive/appetitive stimuli. In most cases, the potential impact of negative information outweighs the potential benefits of positive information. In general, emotionally enhanced episodic memories, rewarding *and* aversive, attract attention obligatorily and are prioritized for encoding and retrieval over nonemotional memory. At the tier of hedonic quality, however, aversive states take priority for encoding over rewarding states, as reported by Huang Po-Sheng and colleagues. Negative affect states, such as fear or rage, tend to reach higher intensity in comparison to positive counterparts. Infants and toddlers predisposed to heightened negative affect-reactivity may experience negative states at even higher peaks. To summarize, prenatal disposition to positive affect-reactivity expedites restoration of mental comfort (sense of safety) and neural comfort (lower autonomic arousal) in frustrating events. This dynamics promotes normal self-organization of brain networks and mental function. Heightened negative affect-reactivity (proneness to stress) tends to generate frequent and prolonged departures from comfort into mental and neural discomfort, thus disrupting BrainMind self-organization. All affects have associated ideas and fantasies, but this is especially true of intense survival fears in children predisposed to negative affect reactivity. Here, omnipotent primitive fantasies may safeguard a child from survival fears. Such fantasized safety (invincibility, omnipotence, machoism, grandiosity, etc.) might be the fundamental compensatory mechanism leading to adult personality disorder, as noted. In comparison to positive affects, which quickly subside upon return to comfort zone (a de-energized but safe mind), negative affect-states show inertia, likely mediated by hysteresis, a form of network memory. Hysteresis refers to the tendency of an attractor

Telegram: @medical_k

www.konkur.in

network, here the episodic memory network, to stay in phase with current sensory-affective input, even if the direction of the control parameter is reversed, for example, even if frustration is comforted by the caretaker. Hysteresis naturally appears when a network contains negative feedback that facilitates inertia rather than change, and most attractor memory networks involve such feedback. Hence, high energy input is required for a distressed infant/toddler to transition more rapidly to positive affect states. Simply put, positive affect states are harder to restore (a threshold effect that requires energy) than for negative states to remain (inertia, no energy required). This dynamics have direct implications for early parenting.

Auto-Regulated Self- and Object Constancy Promote Affect-Constancy

Once the new anxieties of the depressive position are resolved by working through with good-enough parents, a relatively stable, self-sustained good internal object is established in the mind, a successful outcome of the separation-individuation process, described by Margaret Mahler. Simultaneously, an autonomous self, self-sustained and internally-defined, capable of assimilating the objects' frustrating actions as exceptions, is also established. Both attainments set the stage for top-down stabilization of affects across contradictory interactions ("affect-constancy").

Summary

Object relations theory was inferred from observations of infants/children at play or while interacting with significant objects. For a century, it remained metapsychology without a neural basis. Modern neuroscience provides a framework that can help embed object relations theory into neural mechanisms. Although mechanistic studies have been done mainly in rodents, using the contextual fear conditioning paradigm, the processes involve homologous brain systems and fundamental neural functions shared with humans, making these studies potentially informative for human affect-enhanced episodic memory. Contextual fear conditioning may have its limitations to fully representing episodic memory. However, real-world emotional experiences likely engage both Pavlovian classical conditioning and episodic memory mechanisms. Recombinant DNA and optogenetic studies demonstrate that contextual fear conditioning may

Telegram: @medical_k

www.konkur.in

share neurobiologic systems involved in classical conditioning and episodic memory. The conditioned context (location in the cage) paired with unconditioned stimulus (foot shock) are initially encoded by the hippocampus, while the memory of fear is encoded by the amygdala which also drives avoidant behavior; the episode is systems-consolidated in mPFC. Remote memory expressed by the mPFC engram was "conditioned-context specific, suggesting that it is episodic-like" (Kitamura et al., 2017, p. 5, a position of Howard Eichenbaum as well). This research suggests that contextual fear conditioning may be conceived as a simple form of episodic memory.

The neuroscientific framework not only helps to validate object relations theory but also provides guidance on how to enhance psychodynamic therapy, a derivative of this theory (elaborated in Svrakic and Zorumski, 2021). Psychodynamic therapy is a treatment of choice for personality disorder, a common and severe but preventable and reversible form of BrainMind dysfunction. Perhaps most noteworthy is the question of whether we can take advantage of enhanced plasticity in the developing human brain for preventive purposes. Joan Luby and colleagues combine neuroimaging with income and parenting data to identify infants and toddlers at high risk for psychopathology. Informed early interventions that incorporate good-enough parenting can potentially steer developmental plasticity to dampen if not prevent BrainMind dysfunction that underlies personality disorder and deficiencies in attention, executive function, and control of emotion, among many other psychopathologies.

The plastic hippocampus–amygdala–mPFC circuitry is currently best described, but future studies will likely add other circuits relevant to this subject. Transdisciplinary integrations are heuristic models and thus always involve informed speculation, which can be tested through epistemic iterations as knowledge and technology advance. This overview offers testable directions in research that flow logically from our model:

i. to enhance healthy plasticity in critical neurocircuits to promote well-being,
ii. to activate this plasticity in children for early correction/prevention of multiple forms of psychopathology, and
iii. to enhance psychotherapy of children at risk for personality pathology and adults with personality disorder. The neuroscience of BrainMind development is a work in progress. This proposal is a primer that we hope may set a tone for further study and clarification.

---

[1]Psychoanalytic- and psychodynamic psychotherapy are synonyms; both refer to psychotherapy that relies on an emotional relationship between the therapist and the patient to draw conclusions about the nature of the patient's problems. This less-intensive, more personal approach has evolved from but then largely replaced classical psychoanalysis since mid-20th century.

Telegram: @medical_k

www.konkur.in

[2]To our knowledge, Edith Jacobson pioneered the postulate that accumulated episodic "memory traces" could be the neural substrate of the "endopsychic representations of the object world and of the self."

[3]The term "primordial" is used for the episodic events of object relations that are forgotten (infantile amnesia), but remain neurally preserved, thus active as implicit templates that define one's motivational priorities and interpersonal expectations.

[4]The phrase "BrainMind" was coined by Jaak Panksepp to affirm the brain-mind monism aka isomorphism; here, we use the phrase wherever a subject matter applies to or affects both.

[5]The *degree of a node* in a network is the number of connections it has to other nodes while the *degree distribution* is the probability distribution of these degrees over the whole network.

[6]These regions include left and right temporal and left frontal cortex, as well as co-activity in the auditory cortex and hippocampus.

[7]In contrast to Hebbian (extrinsic) plasticity, homeostatic plasticity, aka metaplasticity is intrinsic and facilitates the subsequent plasticity of that synapse, e.g., long-term potentiation or depression.

[8]The term avalanche was chosen to associate with Per Bak's description of relaxation dynamics in the form of avalanches in a sand-pile that is continuously being added grains of sand.

[9]Such near-critical states of brain networks are said to be a stable attractor for external conditions.

[10]Multistability refers to multiple stable states of a network and depends on how quickly the system returns to its stable state following a perturbation.

[11]The term "ego" today would be referred to as the "mind," or more precisely as "personality," a uniquely configured mind for any given individual, as shown by Caterine Gratton and colleagues.

[12]The experience of the difference between positive hedonic states (approaching comfort) and negative hedonic states (departing comfort) may result in learning by conditioning. In infants and toddlers, temperament traits (reward dependence, harm avoidance, novelty seeking) are thought to result from such learning.

[13]The term experience is also used to denote one's knowledge or skills acquired over time by direct observation of or participation in events ("an experienced machinist").

[14]Gyorgi Buzsaki argues that perception is an "action-based process" an exploration initiated by the brain. Things in the world acquire coherence only through brain-initiated actions. Ultimately brain does not represent the world but rather "extracts" aspects that have become relevant to the organism by exploration and Bayesian-type inference. This corresponds to subjective experience, as described above. Up to the level of posterior insula and association sensory cortices, inside-out perception does not include other aspects inherent to perception, for example, emotion and motivation, which are added by convergence zones. With this stipulation, we use the term "veridical".

[15]Marlieke Van Kesteren and colleagues and Dorothy Tse and colleagues have made seminal insights into the neural mechanisms of schema-forming, reinforcement, and expansion in, respectively, humans and rodents.

Telegram: @medical_k

www.konkur.in

[16]The CEN is generally the same as the lateral frontoparietal attention network, distinguished from the dorsal attention network involved in voluntary goal-orienting of attention.

[17]Noam Chomsky views symbolic language as a form of cognition that creates and interprets thought, thus enabling self-reflection, among other functions.

[18]Extrinsic motivation describes behaviors driven by external social or material rewards or punishments. Intrinsic and extrinsic motivation likely overlap in their neural substrates.

[19]The term “subsystem” rather than “structure” (Freud’s terminology) is used because there are no structures in the mind, which is entirely a function.

[20]The terms ethical and moral are not synonymous. An ethical code doesn’t have to be moral. Ethics refers to a set of rules for selected people to follow (e.g., American Bar Association, American Medical Association have created specific ethical codes for their respective fields). The term is also used for the science of morality.

[21]Kernberg (2014) speaks of character as an objective correspondent of identity or, figuratively, “who is me outside” (character) versus “who is me inside” (identity), with some overlap as both to an extent include mental representations of others and the society.

[22]Per Fairbairn some measure of splitting (a defense mechanism by dissociation) is invariably present at the deepest level of everyone’s mind/ personality. He argued that “the basic position in the mind is invariably a schizoid position,” even in normal individuals under conditions of extreme suffering, hardship, or deprivation. In 1935, M Klein postulated that the earliest position in mind development is “paranoid.” The position is characterized by the neonate’s aggression against the frustrating breast/mother, re-internalized as the “bad” persecuting internal object which stirs fears of retaliation from within. Influenced by Fairbairn, M Klein in her 1946 paper “Notes on some schizoid mechanisms,” revised the paranoid position into “paranoid-schizoid,” to account for persecutory fears co-existing with schizoid mechanisms (“splitting”) early in mind development (“schism,” Latin for division, split).

[23]Part of infantile forgetting is due to high levels of hippocampal neurogenesis for new memories which continually clears memories from the hippocampus by replacing synaptic connections in preexisting hippocampal memory circuits.

[24]Phrase coined by Anand Venkatraman and colleagues.

[25]This “emotional” motor system is distinct from nonemotinal corticospinal motor pathways passing through the brainstem to reach the musculature.

[26]Functional connectivity in neonates and 1-month old infants was studied by functional near-infrared spectroscopy (fNIRS). fNIRS is limited to monitoring activity from (superficial) cortical structures, this study could not fully measure activity from deeper cortical and subcortical regions (e.g., corpus callosum, a passage for most cross-hemispheric connections, among others). This drawback may explain the paradoxical finding of hyper-connectivity between homologous cross-hemispheric regions with infants with negative emotionality and poor emotion regulation.

[27]Traditionally, pain and temperature have been considered to be aspects of touch (exteroception) but are now considered interoception. In contrast to discriminative and crude touch and proprioception, pain and temperature reflect the physiologic state of a

Telegram: @medical_k

www.konkur.in

tissue and inherently harbor affective and motivational aspects, much like other interoceptive stimuli. Also, sensual (affectionate) touch (grooming, cuddling, etc.) harbors an emotional and motivational aspects that mediate neurobiologic and emotional effects of parenting.

[28]The “body-schema” and “peripersonal space” are body-part centered. These are network phenomena involving different cortical and subcortical regions of the brain, each processing multisensory information in a reference frame appropriate to the body part concerning which it receives information, and with which responses are to be made.

[29]A bimodal, visual-tactile neuron with a tactile receptive field on one hand (say left) will typically increase its rate of firing as the visual stimulus approaches the left hand.

[30]The same sensory-affective-motivational multiplex characterizes exteroceptive sensations (pleasant vs. unpleasant, desired or dreaded, smell, taste, sounds, etc.).

[31]Phantasy therefore may be framed as “object-seeking” in accord with the Fairbairn’s line of thought.

[32]Such sensation-to-phantasy transformation would today be understood to reflect nonconscious processing in subcortical survival circuits, particularly the opiate modulated NAc-ventral pallidum processing (hedonic quality liking/disliking, motivation of desire/dread) as well as the mesolimbic dopaminergic pathway where incentive salience of waning/not wanting is formed.

[33]Psychoanalytic literature inconsistently uses the terms instincts and drives, but the way the term is used in the context of phantasy corresponds to survival instincts or as J LeDoux calls them “survival circuits and functions.”

[34]Both the creation of silent cortical engrams and their subsequent maturation require an intact hippocampus and may include, among other mechanisms, immediate early genes, epigenetic modifications, and sharp-wave ripple-mediated replay of activity of hippocampal engrams (reviewed in Tonegawa et al., 2018).

[35]NAc and mPFC activity were each correlated with the rated *pleasure* of imagery.

[36]As split-off contradictory “good” versus “bad” self- and object-representations appear to be genetically hardwired in the anatomy and function of the amygdala (Kitamura et al., 2017), the object is necessarily encoded (“introjected”) as dyadic from birth, leaving open to question the Margaret Mahler’s concept of full symbiosis (mental fusion with the object) and Fairbairn’s concept of an internalized pre-ambivalent all-good object of the earliest oral phase. O Kernberg, in fact, holds that a sharp differentiation between self- and object-representations evolves from birth on, while it takes 2 to 3 years to achieve integration of their dichotomized aspects.

[37]An approximation, based on Margaret Mahler’s separation-individuation timeline, likely varies in individual instances.

[38]Donald Winnicott coined the phrase “good-enough” to emphasize the importance of natural instincts of normal devoted parents and healthy families, in an attempt to counterbalance the potential idealization of parenting implicit in Klein’s concepts of “all-good breast/mother.” The phrase “bad enough” refers to neglectful or abusive caregivers and dysfunctional families, sufficiently stressful to cause BrainMind pathology, as in personality disorder. Occasional manageable frustrations are necessary for the child to develop self-reliance, as observed by Heinz Kohut).

Telegram: @medical_k

www.konkur.in

[39]A phrase coined by Scott Kelso.

[40]From Greek, phainomenon, Latin phaenomenon, means “that which shows itself.”

[41]Nonconscious working memory is activity silent, occurs outside of focal attention, but is susceptible to implicit cognitive influences. Its mechanism is actively debated, but may involve intracellular calcium dynamics. This form of memory is understood to be a “stop” in memory retrieval where homeostatic optimizations of memory being retrieved may occur to maintain the mind’s current conditional equilibrium despite challenging reality. The psychonalaytic concept of nonconscious defense mechanism may be neurally explained by nonconscious working memory. Defense mechanisms are in fact implicit memories that develop through early interactions with significant objects for the purpose of regulating anxiety, emotional pain, anger, and self-esteem. These implicit memories intervene in nonconscious working memory to modify disturbing experiences before they enter conscious working memory.

[42]Opioid-stimulated coldspots suppress the “liking” and approach responses and increase dread and avoidant/aggressive responses.

[43]Orbitofrontal cortex (anatomically synonymous with ventromedial PFC—a component of the limbic system) is the rostral projection of the mesolimbic VTA - NAc - mPFC dopamine pathway. Orbitofrontal cortex harbors its own opiate-mediated hedonic hotspots, so it does not only process the reward value and expected reward value but also the subjective pleasantness/unpleasantness of stimuli. Orbitofrontal cortex is said to encode contingencies in a flexible manner, encode value, inferred value, inhibit responses, learning changes in contingency, emotional appraisal, etc. The anatomically distinct mesocortical dopaminergic pathway (VTA-mPFC) is involved in cognition and the regulation of executive functions (e.g., attention, working memory, inhibitory control, planning, etc.).

[44]Alternatively, thought and self may be inherently personal but arrived at automatically, apparently without requiring higher order inference in working memory (reviewed by Richard Brown and colleagues).

[45]Guilt and sadness are inherent parts of love and deepen it profoundly (M Klein and J Riviere, 1937).

Contribution of the Social Sciences

4.1 Neurocentrism: Implications for Addiction and the Courtroom

Sally L. Satel, M.D., and Stephen J. Morse, J.D., Ph.D.

In the early 21st century, neuroscience has captured the public imagination like never before. Understanding the brain is helpful, perhaps essential, to developing treatments for devastating illnesses like schizophrenia and Parkinson disease. More abstract but no less compelling, the functioning of the brain is intimately tied to one's identity, memories, behavior, and aspirations. But the excitement to explore the brain has spawned a new fixation that one might call *neurocentrism*—the view that all human behavior can be best explained by looking solely or primarily at the brain.

In the view of some critics, neurocentrism poses a threat to psychiatry because it risks oversimplifying a number of complex issues. In its extreme form, it devalues the importance of psychological explanations and environmental factors, such as familial chaos and stressors, for understanding disturbances of mood, thought, and overt behavior. In turn, neurocentrism may pose a distraction from seeking effective and perhaps more enduring solutions, including psychotherapies, and may imply that pharmaceutical approaches should be the strongly preferred first-line interventions for addictions and other behavioral problems.

Telegram: @medical_k

www.konkur.in

The prime impetus behind this enthusiasm is noninvasive functional neuroimaging techniques and the now-iconic, vibrant and arresting brain images that grace the science pages of the daily newspaper. Author Tom Wolfe was characteristically prescient when he wrote of fMRI in 1996, 5 years after its introduction, “Anyone who cares to get up early and catch a truly blinding twenty-first-century dawn will want to keep an eye on it.” Why the fixation? First, there is the very subject of the scans: the brain itself. More complex than any structure in the known cosmos, the brain is a masterwork of nature endowed with cognitive powers that far outstrip the capacity of any silicon machine built to emulate it. Containing roughly 85 billion brain cells, or neurons, each of which communicates with thousands of other neurons, this 3-lb universe cradled between the ears has more connections than there are stars in the Milky Way. How this enormous neural edifice gives rise to subjective feelings, a question often called the “hard problem” of consciousness, is one of the greatest mysteries of science and philosophy. Moreover, the brain is more temporally spatially proximal to human behavior than more distal environmental and interpersonal variables. Combine these factors with the fact that multicolored images—in this case, brain scans—can be powerful because vision is the most developed sense and occupies the largest share of cortical space.

There are good evolutionary reasons for this arrangement: The major threats to our primate ancestors were apprehended visually, as were their sources of food. Plausibly, the survival advantage of vision gave rise to our reflexive bias for believing that the world is as they perceive it to be, an error that psychologists and philosophers call naive realism. This misplaced faith in the trustworthiness of one’s perceptions is the wellspring of two of history’s most famously misguided theories: that the world is flat and that the sun revolves around the earth. For thousands of years, people trusted their raw impressions of the heavens. Yet, as Galileo understood all too well, the eyes can deceive. He wrote in his *Dialogues* of 1632 that the Copernican model of the heliocentric universe commits a “rape upon the senses”—it violates everything the eyes reveal.

Trusting the patterns on brain scans to reveal nuanced mental contents is a form of neurorealism, a term coined by University of Montreal researcher Eric Racine. A first cousin of naive realism, neurorealism denotes the fallacious but tempting propensity to regard brain images as inherently more “real” or valid than other types of behavioral data. As

Telegram: @medical_k

www.konkur.in

Stanford neuroeconomist Paul Zak has described in his work on the neurobiology of trust, a brain scan “lets me embrace words like ‘morality’ or ‘love’ or ‘compassion’ in a non-squishy way. These are real things.” Or take the psychological impact of combat. A researcher at the Minneapolis VA tells TIME magazine that brain imaging shows that PTSD is “not a made-up disorder.” In both quotes, it is not clear that brain images truly provide novel information; such images are not required to conclude that love or PTSD is genuine. These are “diagnosed” behaviorally in the first instance.

As a tool for exploring the biology of the mind, neuroimaging has given neuroscience not merely a huge scientific boost but a strong cultural presence. As one scientist remarked, brain images are now “replacing Bohr’s planetary atom as the symbol of science.” With its implied promise of decoding the brain, it is easy to see why brain imaging would beguile almost anyone interested in pulling back the curtain on the mental lives of others: politicians hoping to manipulate voter attitudes, marketers tapping the brain to learn what consumers really want to buy, agents of the law seeking an infallible lie detector, addiction researchers trying to gauge the pull of temptations, psychologists and psychiatrists seeking the causes of mental illness, and defense attorneys fighting to prove that their clients lack malign intent or even responsibility (often mistakenly called “free will”). This tendency has produced a torrent of allegedly new fields, such as neuroeconomics, neuromarketing, neuroethics, and neurolaw, to name just a few. At the same time, this fascination is a double-edged sword, as it may lead eager audiences to accept dubious neuroscience claims without adequate scrutiny.

Some misapplications of neuroscience are merely amusing and may be essentially harmless. Take, for instance, the new trend of neuromanagement books, such as one entitled *Your Brain and Business: The Neuroscience of Great Leader.* The latter advises nervous CEOs “to be aware that anxiety centers in the brain connect to thinking centers, including the PFC [prefrontal cortex] and ACC [anterior cingulate cortex].” The fad has, perhaps not surprisingly, also infiltrated the parenting and education markets. Parents and teachers are easy marks for “brain gyms,” “brain-compatible education,” and “brain-based parenting,” not to mention dozens of other unsubstantiated techniques. Although these methods may not be dangerous *per se,* they may incur both direct financial costs and opportunity costs arising from a failure to seek out

Telegram: @medical_k

www.konkur.in

more efficacious interventions. Once again, unwarranted neurocentrism may blind us to more efficacious interventions.

For the most part, these enterprises merely dress up or repackage good advice with neuroscientific findings that add little or nothing to the overall program. As one cognitive psychologist quipped, “Unable to persuade others about your viewpoint? Take a Neuro-Prefix—influence grows or your money back.” But reading too much into brain scans can be a problem when real-world concerns hang in the balance. Consider the law. When a person commits a crime, who is at fault: the perpetrator or their brain? This is a false choice. If biology teaches anything, it is that “my brain” versus “me” is a false distinction. Still, if biologic roots can be identified—and better yet, captured on a brain scan as juicy blotches of color—it is too easy for nonprofessionals to assume that the behavior under scrutiny must be “biologic” and therefore “hardwired,” that is, involuntary or uncontrollable. Criminal defense lawyers, not surprisingly, are drawing increasingly on brain images supposedly showing a biologic defect that “made” their clients commit murder. At present, such cases are relatively few, but the numbers will increase.

Looking to the future, some neuroscientists envision a dramatic transformation of criminal law. They anticipate a time when scientists will be able to attach a detailed biologic explanation to many types of bad behavior and eventually come to think about the decision making that gave rise to such behavior in the same way one thinks about any physical process, such as diabetes or lung disease. It is plausible that, as highly detailed mechanical accounts become possible in the future. The prediction that jurors will necessarily come to see criminals as less blameworthy if at all accountable, will become far less certain and potentially problematic, as this chapter will show.

But this may not be the correct conclusion to draw from neuroscientific data. After all, if every behavior is eventually traced to detectable correlates of brain activity, does this mean that all troublesome behavior will one day be understood on a “don’t-blame-me-blame-my-brain” of misbehavior? Will no one ever be judged responsible? This chapter is intended to show why thinking through these profoundly important questions hinges on how one understands the relationship between the brain and the mind.

BRAIN AND MIND—WHY THEY ARE DIFFERENT

Telegram: @medical_k

www.konkur.in

We must begin with the observation that despite all the advances in neuroscience, we do not remotely understand the basic relation between the brain, the mind, and action. We know that the brain enables the mind and action. A person with a dead brain has no mind and does not act. Despite this limited understanding, it is commonly accepted that "the mind" is basically what the brain (and the rest of the central nervous system) does, but the mind and the brain are not identical.

They are different because they represent different levels of analysis. Virtually all neuroscientists, psychiatrists, and psychologists certainly do not believe that brain and mind occupy materially separate domains. Few are Descartian substance dualists. Every subjective experience, from the ache of nostalgia to the frisson of a Christmas morning, corresponds to physical events in the brain. The mind—the realm of feelings, desires, ideas, memories, intentions, and subjective experience—is produced by the action of neurons and brain circuits. This leads many to claim that the brain and the mind are identical, but this claim is controversial. It is by no means clear that the armchair speculation that the mind is identical to the matter that produces it is true. It simply means that there is no clear scientific or philosophical answer at present, and there is much argument and evidence to the contrary. So, to say that the brain and the mind are different is not necessarily evidence of scientific ignorance, as some have alleged. For example, one cannot use the physical rules from the cellular level to completely predict activity at the psychological or behavioral level, and it seems unlikely that this will ever be true.

As an analogy, consider the words Shakespeare wrote on a page. They are, of course, "material," but one could not capture the meaning of his plays by conducting a chemical analysis of the ink in which the letters of his words were written. The brain and the mind are different levels of explanation of the same phenomenon; the brain refers to mechanisms enabling perception, emotion, and cognition; the mind to subjective experiences such as awareness and meaning. Because brain and mind are different levels of description, they have different properties. This position is called *property dualism.* It must be distinguished from substance dualism, which implies that brain and mind are materially different and somehow in causal relation with each other.

From the standpoint of property dualism, one cannot rely on the brain alone to predict or understand everything important about human subjectivity or behavior. This is because many psychological phenomena

Telegram: @medical_k

www.konkur.in

are emergent properties of lower-order constituents, such as neural circuits, neurons, proteins, and genes. “Constitutive” reductionism—reducing complex entities to the sum of their component parts to facilitate study—is not controversial in the scientific community. In contrast, radical or “eliminative” reductionists go a crucial step further. They insist that everything mental will ultimately be *explained* fully at the material level of analysis. This variant of reductionism ultimately eliminates the need for the psychological level of analysis, not to mention all other levels—social, cultural, and so on. (Of course, one may reasonably ask why the reduction should end at the level of the brain, rather than “say” at the level of physics that underlies the brain.)

Adherents of eliminative reductionism speculate that such properties (the painting in full) will ultimately prove reducible to more basic elements (the paint). At one level, the purely physical, that may be true. But at the level that matters esthetically and emotionally, it is false. For the foreseeable future, valuable information is often lost when descending from higher explanatory levels, such as mental states, to lower levels, such as neuronal systems. To be sure, the neural level of explanation is appropriate for certain scientific questions, such as the nature and treatment of Alzheimer disease, wherein research targets amyloid plaques that disrupt communication among neurons, the neurofibrillary tangles that degrade them, and other aspects of brain anatomy and physiology.

Other times, however, a neural explanation can lead one astray. Consider depression. Although depression is clearly influenced by biologic factors, including a genetic predisposition, this does not mean that it is necessarily best treated by medication. In fact, certain psychological treatments, especially cognitive-behavioral and interpersonal psychotherapies, appear to be at least as effective as medications for depression while having no known physical side effects and often showing superior prevention of future episodes. Even treatments from one level of explanation seem helpful in treating depression. It does not follow that the cause or the primary cause can be found at that level. Claiming otherwise is known as the treatment-etiology fallacy.

LEVELS OF ANALYSIS, ADDICTION, AND THE BRAIN DISEASE FALLACY

Telegram: @medical_k

www.konkur.in

Distinguishing brain from mind, or criticizing the excesses of brain imaging, is hardly a repudiation of the great insights of human neuroscience: Mental life arises from brain activity. Both levels, the brain and the mind, are essential to a complete understanding of human experience and behavior. The field of addiction psychiatry provides a good example. Within the last decade, in particular, neurocentrism has been ascendant and not always for the better. As a consequence of heavy promotion by the National Institute on Drug Abuse (NIDA), part of the National Institutes of Health, addiction has been labeled a “brain disease” and, moreover, a chronic and relapsing disease. The logic for this designation, as explained by a former director of the NIDA, is that “addiction is tied to changes in brain structure and function.” It is certainly true that repeated use of drugs such as heroin, cocaine, and alcohol alters the neural circuits that mediate the experience of pleasure as well as motivation, memory, inhibition, and planning—modifications that are often visible on brain scans. The critical question, though, is whether this neural disruption renders the addict incapable of self-control. Evidence indicates that they retain substantial control.

The neurocentric model leaves the addicted person in the shadows. Yet, to treat addicts and guide policy, it is important to understand how addicts think. It is the *minds* of addicts that contain the stories of how addiction happens, why they continue to use, and, if they decide to stop, how they cope with life stressors. The answers cannot be divined alone from an examination of addicts’ brains alone, no matter how sophisticated the probe. Viewing addiction as a “chronic and relapsing” condition diverts attention from promising behavioral therapies that challenge the inevitability of relapse by holding patients accountable for their choices. At the same time, because the model implies that addicts cannot stop using drugs until their brain chemistry returns to normal, it overemphasizes the value of brain-level solutions, such as pharmaceutical intervention.

Pragmatically, psychiatrists should be open to using any treatment if there is persuasive evidence that it is effective. But according to some thoughtful critics, NIDA has overemphasized the importance of pharmacologic intervention in the care of addicts. In 1997, the head of NIDA ranked the search for a medication to treat methamphetamine addiction as a “top priority.” A decade later, another director told *Newsweek* magazine that psychiatrists will “treat addiction as a disease [by 2018], and that means with medicine.” The search for a magic bullet is

Telegram: @medical_k

www.konkur.in

at best dubious—and even NIDA eventually gave up hope of finding a wonder drug—but simplistic forms of the brain-disease narrative continue to inspire unrealistic goals. When British pop star Amy Winehouse succumbed to her high-profile alcoholism in the summer of 2011, a *Psychology Today* blogger asked rhetorically, “Could neuroscience have helped Amy Winehouse?” The author answered in the affirmative, suggesting a dopamine-altering medication of the future because addiction “may be a brain problem that science can eventually solve.” One neuroscientist goes even further, asserting that “addiction can be reasonably viewed as a neurological problem that allows for medical solutions, just as pneumonia can be viewed as a lung problem.” But the analogy is questionable at best. Changing a behavior such as addiction requires addicts to work hard to change their patterns of thought and behavior. And it must be recalled that addiction is a behavioral condition centrally characterized by persistent seeking and using of substances, which are quintessential human actions. Virtually no other disease includes actions as part of the definition of the disease, although actions can ameliorate or exacerbate many diseases.

In contrast, antibiotic cures for pneumonia work even if the patient is in a coma. The hope of a medical treatment is the logical outgrowth of placing the brain at the center of the addictive process. Overall, success to date has been genuine but modest. When motivated patients take medications—especially patients already armed with relapse-prevention strategies and the support of family and friends—they can sometimes vault into sustained recovery. Methadone, a long-acting synthetic opiate taken once a day to prevent opiate withdrawal, has played a major role in treating addiction to heroin and painkillers since the 1960s. Still, up to half the patients in methadone clinics also fortify themselves with heroin, cocaine, or benzodiazepines sold on the street.

Despite three decades of effort, there is still no medication therapy for cocaine dependence. Cocaine immunotherapy (popularly called a cocaine “vaccine”) to prevent cocaine molecules from entering the brain is now in development, but initial data do not look promising for wide-scale use. Other types of medications include blocking agents, such as naltrexone for opiate addiction, which occupy receptors for endorphins and blunt a drug’s effect. Aversive agents, such as Antabuse (disulfiram), cause people to feel nauseated and vomit when they ingest alcohol. They can be

Telegram: @medical_k

www.konkur.in

effective in some cases, although many individuals elect to stop taking them.

NEURAL CORRELATES AND VOLUNTARINESS COEXIST

To be critical of the neurocentric model of addiction is not to dismiss the reality and research the importance of biologic correlates but rather to put them in perspective. The reward circuit is intimately involved in "cue-induced" craving. Such craving is a special species of desire that manifests itself in a sudden, intrusive urge to use drugs brought on by cues associated with use. The mere clink of a whiskey bottle, a whiff of cigarette smoke, or a glimpse of an old drug dealer on the corner can set off an unbidden rush of yearning fueled by dopamine surges. For the addict who is trying to quit, this is typically a tense, not a pleasurable, feeling. Because the rush of desire typically seems to come out of the blue, users may feel blindsided, helpless, and confused.

In a typical demonstration of the biologic correlates of craving, researchers study addicts as they lie in a brain scanner and watch videos of people handling a crack pipe or needle. In response, their prefrontal cortices, amygdalae, and other brain structures typically bloom with activity. (Videos of neutral content, such as landscapes, usually induce no such response.) Even in users who quit several months previously, neuronal alterations may persist, leaving them vulnerable to sudden, strong urges to use drugs.

The familiar late-1980s slogan "This is your brain on drugs" still echoes but now manifests with the brain itself substituting for the fried egg. But that egg is not always sizzling. There is a surprising amount of lucid time in the daily life of addicts. In their classic 1969 study "Taking Care of Business: The Heroin User's Life on the Street," criminologists Edward Preble and John J. Casey found that addicts spend only a small fraction of their days getting high. Most of their time is spent either working or hustling. The same is true for many cocaine addicts, as work by ethnographer Philippe Bourgois reveals. Most people tend to think of them, at their worst, frantically gouging their skin with needles, jamming a new rock into a pipe every 15 minutes, or inhaling lines of powder. In the grip of such hunger, an addict cannot be expected blithely to get up and walk away.

Telegram: @medical_k

www.konkur.in

These tumultuous states—with neuronal function severely disrupted—is the closest drug use comes to being beyond the user's restraint. But in the days between binges, cocaine users worry about a host of everyday matters, such as whether to find a different job, enroll their children in school, or attend a Narcotics Anonymous meeting. It is during these stretches of relative calm that many addicts could make the decision to get help or quit on their own—and many of them do. But the decision to quit can be long in coming, far too long for those who destroy their health, families, or careers in the meantime.

The paradox at the heart of addiction is this: How can the capacity for choice coexist with self-destructiveness? "I've never come across a single person who was addicted who wanted to be addicted," is a common observation. The implication is that because the state was not desired, it must have been involuntary, that is, beyond the user's control. But how many have ever come across a heavy person who wanted to be overweight? Many undesirable outcomes in life arrive incrementally. "We can imagine an addict choosing to get high each day, though not choosing to be an addict," writes psychologist Gene Heyman. "Yet choosing to get high each day makes one an addict."

Imagine a typical trajectory to see how this dynamic unfolds. In the early phase of addiction, drugs or alcohol become ever more appealing, while once-rewarding activities, such as relationships, work, or family, decline in value. The attraction to the drug starts to fade as consequences accrue—spending too much money, disappointing loved ones, attracting suspicion at work—but the drug retains its allure because it blunts psychic pain, suppresses withdrawal symptoms, and douses intense craving. Addicts find themselves torn between the reasons to use and reasons not to.

Sometimes, a spasm of self-reproach or a flash of self-awareness tips the balance toward quitting. William S. Burroughs, an American novelist and heroin addict, calls this the "naked lunch" experience, "a frozen moment when everyone sees what is on the end of every fork." Christopher Kennedy Lawford, himself in recovery from drugs and alcohol, edited a 2009 collection of essays called *Moments of Clarity* in which the actor Alec Baldwin, singer Judy Collins, and others recounted the events that spurred their recoveries. Some quit on their own; others obtained professional help. A theme in each of their stories is a jolt to self-image: "This is not who I am, not who I want to be." One recovered alcoholic described the process: "You tear yourself apart, examine each individual

Telegram: @medical_k

www.konkur.in

piece, toss out the useless, rehabilitate the useful, and put your moral self back together again." These are not the sentiments of people in helpless thrall to their diseased brains. Nor are these sentiments the luxury of memoirists. Patients have described similar experiences: "My God, I almost robbed someone!" "What kind of mother am I?" or "I swore I would never switch to the needle."

Data consistently demonstrate that quitting is the rule, not the exception—a fact worth acknowledging, given that the official NIDA formulation is that "addiction is a *chronic and relapsing* [italics added] brain disease." The Epidemiologic Catchment Area Study, done in the early 1980s, surveyed 19,000 people. Among those who had become dependent on drugs by age 24, more than half later reported not a single drug-related symptom. By age 37, roughly 75% reported no drug symptoms. The National Comorbidity Survey, conducted between 1990 and 1992 and again between 2001 and 2003, and the National Epidemiologic Survey on Alcohol and Related Conditions, conducted between 2001 and 2002 with more than 43,000 subjects, found that 77% and 86% of people who said they had once been addicted to drugs or alcohol reported no substance problems during the year before the survey. By comparison, people who were addicted within the year before the survey were more likely to have concurrent ("comorbid") psychiatric disorders. The vast majority of those who quit received no professional services, although they often had the help of family or friends.

In addition, NIDA estimates that relapse rates of treated drug-addicted patients range from 40% to 60%. In other words, they are not representative of the universe of addicts. They are the challenging cases—the chronic and relapsing patients. They are also disproportionately comorbid. Yet these patients often make the biggest impressions on clinicians and shape their views of addiction, if only because clinicians are especially likely to encounter them. Falling prey to what psychologists term an "availability heuristic," researchers and medical professionals may err in generalizing from the sickest subset of people to the overall population of patients.

This caveat applies across the medical spectrum. Just as the clinician wrongly assumes that all addicts must be like the recalcitrant ones who keep stumbling through the clinic doors, psychiatrists and other mental health professionals sometimes view people with schizophrenia as doomed to a life of dysfunction on the basis of their frequent encounters

Telegram: @medical_k

www.konkur.in

with those whose delusions and hallucinations do not improve with treatment. The error of extrapolating liberally from these subsets of difficult patients is so common that statisticians Patricia and Jacob Cohen dubbed it the "clinician's illusion."

At this time, behavioral and psychological approaches have the research edge in treating addiction. In December 1966, Leroy Powell of Austin, Texas, was convicted of public intoxication and fined $20 in the lowest level court. Powell's lawyer argued that he suffered from "the disease of chronic alcoholism." Powell's public display of inebriation, therefore, was "not of his own volition," and the fine constituted cruel and unusual punishment. A psychiatrist concurred, testifying that Powell was "powerless not to drink."

Then Powell took the stand. On the morning of his trial, he had a drink at 8 AM that his lawyer gave to him, presumably to stave off morning tremors. Here is an excerpt from the cross-examination:

Q: You took that one [drink] at 8 o'clock [AM] because you wanted to drink?
A: Yes, sir.
Q: And you knew that if you drank it, you could keep on drinking and get drunk?
A: Well, I was supposed to be here on trial, and I didn't take but that one drink.
Q: You knew you had to be here this afternoon, but this morning you took one drink, and then you knew that you couldn't afford to drink anymore and come to court; is that right?
A: Yes, sir, that's right.
Q: Because you knew what you would do if you kept drinking that you would finally pass out or be picked up?
A: Yes, sir.
Q: And you didn't want that to happen to you today?
A: No, sir.
Q: Not today?
A: No, sir.
Q: So, you only had one drink today?
A: Yes, sir.

The judge let stand Powell's conviction for public intoxication. Powell appealed directly to the U.S. Supreme Court, the only appeal possible as a result of the procedural posture of the case. It, too, affirmed the constitutionality of punishment for public intoxication. "We are unable to conclude," said the court, "that chronic alcoholics in general, and Leroy Powell in particular, suffer from such an irresistible compulsion to drink and to get drunk in public that they are utterly unable to control their performance."

For people like Powell who are not otherwise motivated to quit, consequences can play a powerful role in modifying behavior. Powell took only a single drink on the morning of his trial because of foreseeable and meaningful consequences. Far from being unusual, his ability to curtail his drinking accords with a wealth of studies showing that people addicted to all kinds of drugs—nicotine, alcohol, cocaine, heroin, methamphetamines—can change their behavior in response to rewards or sanctions. Powell had surely experienced many alcohol-induced brain changes, but they did not keep him from making a choice that morning. If Powell came before a judge today, his lawyer might well

Telegram: @medical_k

www.konkur.in

introduce a scan of his brain “craving” alcohol as evidence of his helplessness. If so, the judge would be wise to reject the scan as proof. After all, a judge, or anyone, can ponder scans of “addicted” brains all day, but they would never consider someone an addict unless that person behaves like one.

Researchers have found that the brains of smokers reporting a strong desire to smoke commonly display enhanced activation of reward circuitry, as would be expected. But they also showed that subjects could reduce the brain’s telltale signs of craving by considering the long-term consequences of smoking, such as cancer or emphysema while observing videos depicting people smoking. When subjects did so, their brains displayed enhanced activity in areas of the prefrontal cortex associated with focusing, shifting attention, and controlling emotions. Simultaneously, activity in regions associated with reward, such as the ventral striatum, decreased. Investigators at NIDA observed the same pattern when they asked cocaine users to inhibit their craving in response to cues. Subjects underwent positron emission tomography (PET) scanning as they watched a video of people preparing drug paraphernalia and smoking crack cocaine. When researchers instructed the addicts to control their responses to the video, they observed inhibition of brain regions normally implicated in drug craving. When not deliberately suppressing their cravings, the addicts reported feeling their typical desire to use drugs, and the PET scans, accordingly, revealed enhanced activation in brain regions that mediate craving.

These powerful findings illuminate the capacity for self-control in addicts. They also underscore the idea that addicts persist not because of an inability to control the desire to use but at least in part because of a failure of motivation. Granted, summoning sustained motivation can be a great challenge: It takes considerable energy and vigilance to resist the craving, especially urges that ambush the addict unexpectedly. Studies on the regulation of craving also help distinguish behaviors that people do not control from behaviors that they cannot control. Imagine, by way of contrast, promising a reward to people with Alzheimer if they can keep their dementia from worsening. That would be both pointless and cruel because the kinds of brain changes intrinsic to dementia are immune to rewards or penalties.

What Powell’s case showed was that even though he sustained brain changes, those changes did not prevent his behavior from being shaped by consequences. Contingency management—the technical term for the

Telegram: @medical_k

www.konkur.in

behavior therapy technique of adjusting consequences, including incentives—often succeeds with people who face serious losses, such as their livelihood, professional identity, or reputation. When addicted physicians come under the surveillance of their state medical boards and are subject to random urine testing, unannounced workplace visits, and frequent employer evaluations, they fare well: 70% to 90% are employed with their licenses intact 5 years later. Likewise, scores of clinical trials show that addicts who know they will receive a reward, such as cash, gift certificates, or services, are nearly two to three times as likely to submit drug-free urine samples as addicts not offered rewards.

Unfortunately, treatment programs are rarely in a position to offer cash or costly rewards. But the criminal justice system has an ample supply of incentives at its disposal and has been using such leverage for years. One of the most promising demonstrations of contingency management comes from Honolulu in the form of Project HOPE, Hawaii's Opportunity Probation with Enforcement. Project HOPE includes frequent random drug testing of offenders on probation. Those who test positive are subject to an immediate and brief incarceration. Sanctions are fair and transparent: All offenders are treated equally, and participants know what will happen in case of an infraction. The judges expressed a heartfelt faith in offenders' ability to succeed. These basic elements of HOPE's contingency administration—swiftness, sureness, transparency, and fairness combined with the expectation for achievement—are a potent prescription for behavior change in just about anyone. Indeed, after 1 year of enrollment in Project HOPE, participants fared considerably better than probationers in a group who served as a comparison. They were 55% less likely to be arrested for a new crime and 53% less likely to have had their probation revoked. These results are even more impressive in light of the participants' criminal histories and their heavy, chronic exposure to methamphetamine, which can impair aspects of cognitive function.

These findings join a vast body of experimental data attesting to the power of incentives to override the lure of drugs. Yet, because the facts contradict the idea that addiction is analogous to Alzheimer disease, some HOPE personnel objected to incentives, arguing that addicts could not be accountable for their behavior. Indeed, the brain-disease narrative misappropriates language better used to describe such conditions as multiple sclerosis or schizophrenia—afflictions of the brain that are neither brought on by the sufferer nor modifiable by the desire to be well. It offers

Telegram: @medical_k

www.konkur.in

false hope that an addict's condition is completely amenable to a medical cure. Finally, it threatens to obscure the vast role of personal agency in perpetuating the cycle of use and relapse.

Addicts embarking on recovery often need to find new, clean, and sober friends, travel new routes home from work to avoid passing near their dealer's street or deposit their paycheck directly into a spouse's account to keep from squandering money on drugs. A teacher trying to quit cocaine switched from using a chalkboard—the powdery chalk was too similar to cocaine—and had a whiteboard installed instead. An investment banker who loved injecting speedballs—a cocktail of cocaine and heroin in the same syringe—made himself wear long-sleeved shirts to prevent glimpses of his bare and inviting arms. Former smokers who want to quit need to make many fine adjustments, from not lingering at the table after meals to ridding their homes of the ever present smell of smoke, removing car lighters, and so on.

Thomas Schelling, a 2005 Nobel laureate in economics, refers to these purposeful practices as self-binding. The great self-binder of myth was Odysseus. To keep himself from heeding the overpowering song of the sea sirens—the half-woman, half-bird creatures whose beautiful voices lured sailors to their deaths—Odysseus instructed his men to tie him to the mast of his ship. The famous Romantic English poet Samuel Taylor Coleridge, an opium addict, is said to have hired men to prevent him from entering a pharmacy to purchase opium. Today, one can hire a firm that will provide binding services. It imposes surprise urine tests on the client, collects evidence of attendance at Alcoholics Anonymous (AA) meetings or treatment sessions, and sends a monthly status report (with the good or bad news) to another person, such as a parent, spouse, or boss.

Some addicts devise their own self-binding strategies. Others need the help of therapists, who teach them to identify and anticipate cues that trigger craving. Beyond the classic triad of people, places, and things, addicts may come to realize that internal states, such as stress, bad moods, and boredom, can prompt drug urges. Managing craving matters mightily in recovery, but it usually is not enough. Another important truth is that an addict uses drugs or alcohol because they serve a purpose, or what behavioral psychologists term an operant function. Caroline Knapp, in her powerful 1996 memoir *Drinking: A Love Story,* recounted why she spent two decades of her life as an alcoholic: "You drank to drown out fear, to dilute anxiety and doubt and self-loathing and painful memories." Knapp doesn't describe an urge to drink so much as a need to drink. She was not manipulated by an alien desire but by something woven into her being. To say that Knapp's problem was merely the effect of heavy drinking on her brain is to miss the larger picture.

Telegram: @medical_k

www.konkur.in

Heroin and speed helped screenwriter Jerry Stahl, author of *Permanent Midnight,* attain "the soothing hiss of oblivion." But when the drugs wore off, his vulnerabilities throbbed like a fresh surgical incision. In surveying his life, Stahl wrote, "Everything, bad or good, boil[ed] back to the decade on the needle, and the years before that imbibing everything from cocaine to Romilar, pot to percs, LSD to liquid meth and a pharmacy in between: a lifetime spent altering the single niggling fact that to be alive means being conscious." Or take Lisa, a 37-year-old woman featured in a 2007 HBO documentary on addiction. When viewers meet her, Lisa is living in a rundown hotel room in Toronto and working as a prostitute. She sits on the bed and talks with the filmmaker behind the camera. Flipping her shiny brown hair and inspecting her well-kept nails, Lisa is animated as she boasts about how much she makes selling sex, how much she spends on cocaine, and the longed-for "oblivion" that drugs help her attain. When Lisa was filmed, she was healthy and engaging; she looked and talked like someone who had recently been abstinent but was back in the early stages of her next downward spiral. She had no interest in stopping things at this point. "Right now, I am in no position to go into recovery. [This way of life] is working for me…. I have money, drugs, business. I'm O.K." To say that Lisa's problem is the effect of cocaine on her brain distracts from the true threat to her well-being: Lisa herself. "I always use for a reason. It's repressing what needs to be repressed," she says.

These stories highlight one of the shortcomings of the strictly neurocentric view of addiction. This perspective ignores the fact that many people are drawn to drugs because the substances temporarily quell their pain: persistent self-loathing, anxiety, alienation, deep-seated intolerance of stress or boredom, and pervasive loneliness. The brain-disease model is of little use here because it does not accommodate the emotional logic—or illogic—that triggers and sustains addiction.

We conclude this chapter with a discussion of an important case that raises all the issues we have just discussed. For nearly 50 years, the holding in *Powell* that addicts should not be excused simply because they are addicts had scarcely been challenged. Then, in a 2017 Massachusetts case that received wide national attention and newspaper editorials, a full-fledged claim was mounted that, as a constitutional matter, addicts didn't deserve punishment because they could not control their seeking and using. Defendant Julie Eldred was a 28-year-old fentanyl addict who stole and fenced some jewelry to support her habit. It was her second such offense. She essentially pleaded guilty. The sympathetic trial judge placed her on probation after Eldred promised to stay clean and to submit to random drug tests. About 10 days after being released, she tested positive for fentanyl but denied using it. Eldred was returned to court for her probation violation. Again, the sympathetic judge tried to avoid imprisoning Eldred. Instead, the judge ordered inpatient treatment, but no

Telegram: @medical_k

www.konkur.in

appropriate inpatient beds were available in the state, so the judge reluctantly sent Eldred to prison where she would not be a danger to herself or others. After about 10 more days, a bed was found, and she was transferred to the inpatient facility.

Ms Eldred then sued the state, claiming that any prison based on her use of the drug constituted cruel and unusual punishment in violation of her 8th and 14th Amendment rights. She claimed that it could not be fair to punish her for behavior symptomatic of her disease that she was helpless to avoid. Rather than decide this claim on the merits, the trial court certified the question to the Massachusetts Supreme Judicial Court, which agreed to hear the case. Virtually all professional medical organizations in the state submitted friend of the court (amicus) advisory briefs on Eldred's behalf. They based their arguments heavily on the neuroscience of addiction. The editorial board of the New York Times urged that relapsing shouldn't be a crime because addiction was a disease. Only two amicus briefs were offered on behalf of the state. The National Association of Drug Court Professionals rejected Eldred's claim because they, the treating professionals, know that incentives matter and fear of negative consequences, such as potential incarceration, are a bedrock of their therapeutic armamentarium. The state's position was also supported by an informal group of addiction experts, including the authors of this chapter, who argued on the basis of the evidence this chapter just addressed that addicts do have sufficient choice to be held accountable for relapsing and for other criminal behaviors associated with their addictions. The neuroscience does not entail the necessity of an excuse. We took no position on what the state's best policy should be, but we were clear that the evidence did not support a one-size-fits-all addiction excuse.

In the event, the Supreme Judicial Court decided unanimously to reject Ms Eldred's claim. It did leave proponents of the excuse an out, however. It held that it could not uphold Ms Eldred's position based on the record before it but seemed willing to reconsider if there were a full airing of the issues in the trial court below. The case has not proceeded, however. Instead, advocates have introduced legislation in Massachusetts to prevent the imprisonment of addicts for relapsing. The legislation has stalled, which we think is a good thing. The legislature is the appropriate branch to decide such issues, but we believe the policy of preventing imprisonment is unwise.

Telegram: @medical_k

www.konkur.in

There have been very few such cases since Eldred was decided, but one seems worthy of brief mention. Manning v. Caldwell, a federal case (4th Cir. 2019), involved a constitutional attack on an exceptionally complex Virginia statute applied against homeless addicts. Essentially, the claim was the same as Ms Eldred's, and again neuroscience played a crucial role in the plaintiffs' argument. The bitterly divided court held that the record didn't support the plaintiffs' case, but the case was remanded to the trial court for a full hearing on the merits of the addiction claim. It was clear that the majority thought that a good case could be made and that there were grounds for overturning *Powell.* If there had been a remanded hearing and the case again reached the 4th Circuit and ruled in the plaintiffs' favor, a Supreme Court decision might have ensued. But the case settled, and there was no decision on the merits of the excuse. Nonetheless, the case does indicate that there is pressure to reconsider *Powell* based on the allegedly new scientific understanding of addiction. We expect more such cases to arise in the future. But as Justice Marshall, the author of *Powell*, wrote in that opinion, the petitioner was asking for too much based on too little knowledge. We think that is still true for the reasons given.

NEUROCENTRISM, FREE WILL, AND LEGAL RESPONSIBILITY

It is only natural that advances in knowledge about the brain make people think more mechanistically about themselves. But in one venue, in particular—the courtroom—this bias can be a prescription for confusion. The brain-based defense ("Look at this fMRI scan, your Honor. My client's brain made him do it.") is being used with increasing frequency in capital defenses. The problem with these claims is that, with rare exceptions, neuroscientists cannot yet translate aberrant brain functions into the legal requirements for criminal responsibility. The bedrock principles of criminal responsibility are that human beings are capable of acting intentionally and rationally, that mental states such as intentions play a partial causal role in explaining behavior, and that a reasonable degree of freedom of choice exists when the agent acts. More controversially, many believe that people must have an independent capacity for self-control to be responsible. More controversially, many believe that people must have an independent capacity for self-control to be responsible. For example, no

Telegram: @medical_k

www.konkur.in

one “blames” the weather or inanimate objects when they cause harm because these are not intentional and potentially rational agents. The severely mentally ill may be acting agents, but their rationality may be so compromised when they do harm that they do not deserve blame and punishment. The very young or the demented may also have their harmdoing mitigated or excused on rationality grounds; the former as a result of developmental immaturity, the latter as a result of brain disease.

What is known about many criminals is that they do not conform to the law and often say that they cannot control themselves. That is very different from being unable to do so. To date, brain science cannot distinguish these alternatives. Moreover, even abnormal-looking brains frequently have owners who are otherwise quite normal. Looking to the future, some neuroscientists envision a dramatic transformation of criminal law. David Eagleman of the Baylor College of Medicine’s Initiative on Neuroscience and Law hopes that “we may someday find that many types of bad behavior have a basic biological explanation [and] eventually think about bad decision making in the same way we think about any physical process, such as diabetes or lung disease.”

But is this the correct conclusion to draw from neuroscience? If every troublesome behavior is eventually traced to correlates of brain activity that can be detected and visualized, will society be able to excuse it on a don’t-blame-me-blame-my-brain theory? Will no one ever be judged responsible? Eagleman’s way of thinking may fall prey to what law professor Stephen Morse calls the “fundamental psycho-legal error,” the powerful temptation to equate cause with excuse. Morse notes that the law excuses criminal behavior only when a causal factor produces an impairment so severe that it deprives the defendant of their rationality. Bad genes, bad parents, or even bad stars are not an excuse.

Nothing less than the legal system’s authority to hold offenders accountable hinges on a clear grasp of the relationship of mental contents and mental capacity to ascriptions of responsibility. How can neuroscientific data assist the law in ascertaining guilt? To answer this question, it is important to understand how the law determines guilt. Some brief background: The criteria for legal (and moral responsibility) are the folk psychological concepts of acts and mental states. American criminal law would hold a person responsible for a crime if they intended to commit a prohibited act. This mental state is called *mens rea,* or guilty mind, which generally requires either intent, knowledge, recklessness

Telegram: @medical_k

www.konkur.in

(conscious awareness of a risk that one is doing wrong), or negligence (creating an unreasonable risk of doing wrong without awareness that one is doing so). In addition, the criminal law also provides for what are known as affirmative defenses. In these cases, the prohibited act and mental state may be proven, but the defendant claims that his act was right under the circumstances (a justification, such as self-defense) or claims that even if what he did was wrong, he was not responsible (an excuse, such as legal insanity).

Without evidence of *mens rea,* the law cannot hold a person criminally responsible. For example, hitting and killing a pedestrian when one's car goes out of control does not entail *mens rea,* whereas aiming one's car at a pedestrian, stepping on the gas, and running over that person does. Again, even if the defendant intentionally ran over the victim, the defendant may claim that he acted in self-defense (e.g., the victim was trying to shoot me) or acted because he had a delusional belief about the need to kill the victim.

The question for brain imaging is whether it is able to translate information about brain function into the legal requirements for criminal responsibility. Now, neuroscience is an utterly mechanical level of explanation. Neurons and the connectome do not have reasons, aspirations, or a sense of past, present, and future. These are properties of persons. The law, in contrast, is concerned with acts and mental states. The question is whether the mechanical language and concepts of neuroscience can be validly translated into the folk psychological language of the law. The answer is that brain scans cannot shed significant light on most criteria for responsibility. Thus, lawyers, jurors, and judges will still need to rely on traditional methods of assessing the defendant: interviews, observations, witness reports, psychiatric history, and well-established clinical assessments. It is from these methods that a subtler, necessary appreciation of the defendant's mental state can be inferred.

When defense attorneys want to convince the judge and jury that their clients are less worthy of blame or punishment, they try to make the case that the defendant's capacity to reason or to control himself is defective. And because his brain is defective, he made a bad choice, a choice that was unavoidable, and so he should not be held responsible. But what about the argument that no one is truly responsible? What are the implications of brain science for morality and law? Although individuals

Telegram: @medical_k

www.konkur.in

generally think of themselves as free agents who make choices, a number of prominent scholars claim that they are mistaken. “Our growing knowledge about the brain makes the notions of volition, culpability, and, ultimately, the very premise of the criminal justice system, deeply suspect,” contends Stanford biologist Robert Sapolsky. It should be recognized that critiques such as this are “external” because they reject the premises of the criminal justice system in their entirety. An internal critique, in contrast, accepts the basic validity of the system but attempts to change specific doctrines and practices to achieve greater justice. Often, this debate is framed in terms of whether humans have “free will.” This is an interesting metaphysical question that science cannot answer, but the question exerts its enduring hold, we contend, because so many people believe that having the God-like power to act uncaused by anything other than oneself is necessary for responsibility, and we care deeply about responsibility. The remainder of this section, therefore, explores the interlocking questions of free will and criminal responsibility.

If otherwise healthy individuals can think coherently, plan and change their minds in response to information, should not that render them free enough to be blamed (or praised, for that matter)? Philosophical “compatibilists,” who roughly adopt some version of physicalism (all phenomena start with matter, including immaterial things such as culture) and causal closure (the universe is a causal place; no spooky entities allowed), would say yes. The compatibilist view does not negate material explanations of the world. They concede that behavior and thoughts are the products of a vast array of influences—genes (and the evolutionary history they represent), brain mechanisms, personal upbringing, and the physical and social environments in which people live. They further acknowledge that these forces converge, presumably, to produce one and only one specific act, be it “choosing” soup over salad or murder over mercy. Yet, under this determined view of the universe, people who nonetheless possess the capacities to be guided by reason, to follow rules, deliberate, be deterred, and conform to norms are considered by philosophers to have the freedom to choose—and, thus, to be accountable and perhaps deserving of blame and punishment. Only if the bedrock premises of criminal responsibility are missing will we consider the agent not responsible.

Before continuing, it is important to point out a fundamental error that doctors, lawyers, judges, and others make all the time. It is the misguided

Telegram: @medical_k

www.konkur.in

belief that if we identify a cause for a particular behavior, especially an abnormal cause such as a mental disorder, then the behavior should be excused or at least mitigated. Because all behavior is caused, the implication of this view is that no one is responsible, but this is inconsistent with the moral and legal world we inhabit. Some harms are caused by neuromuscular spasms; others by intentional actions. Some criminals are severely mentally disordered when they commit their crimes; most are not. Yet all are fully caused even if we don't understand all the causes of the behavior. Yet we morally and legally distinguish these cases on grounds we have good reason to accept: the distinction between no action and action or between rationality and irrationality. Causation, whether by biologic, psychological, sociologic, or astrologic variables, is not per se an excusing condition.

Others, like Sapolsky, disagree. They insist that individuals' deliberations and decisions do not make them free to choose because they are dictated by neuronal circumstances. They say that, as people come to understand the mechanical workings of their brains, they will be compelled by logic to adopt a strictly utilitarian model of justice in which criminals are "punished" solely as a way to change their behavior, not because they deserve blame. Philosophers call this a "hard determinist" view of free will, and some believe that neuroscience can demonstrate that it is the correct understanding of free will.

Philosopher–neuroscientist Joshua Greene and neuroscientist Jonathan Cohen contend that neuroscience has a special role to play in giving the age-old argument about free will more rhetorical bite. "New neuroscience will affect the way we view the law, not by furnishing us with new ideas or arguments about the nature of human action, but by breathing new life into old ones," they write. The familiar argument, of course, is that mental states can be reductively explained mechanistically. The authors embrace the mechanistic conception, believing that neuroscience will accelerate the elucidation of "the mechanical processes that cause behaviour." After predicting that people will finally be convinced by the mechanical account, they make the following claim about the criminal law: "The law will continue to punish misdeeds, as it must for practical reasons, but the idea of distinguishing the truly, deeply guilty from those who are merely victims of neuronal circumstances will, we submit, seem pointless." The most natural reading of this passage in light of the argument about mechanism is that all behavior is mechanically

Telegram: @medical_k

www.konkur.in

caused in the same way. In short, although we may behave differently, at base, we are all “victims of neuronal circumstances,” or just a “pack of neurons,” as Francis Crick claims. The compatibilist view is most common among the public and even among philosophers. But so what if most people think that they and others have “free will”? Now comes the heart of the matter: The question of whether humans can live in a material world and yet be morally responsible is not empirically testable. It is not a scientific problem. It is a conceptual and ethical impasse that has bedeviled thinkers since antiquity and is still without a resolution.

What is important to establish is that neuroscience has not resolved it either. Those who believe that the absence of ultimate free will means that moral responsibility is an incoherent notion and that society should therefore abolish blame have already staked out a philosophical claim. Simply amassing more data on the workings of the brain may strengthen their conviction that determinism is correct, but it will not make their argument against the coexistence of determinism and moral agency any stronger. The vision of the hard determinist neurocentrist is inconsistent with what common sense, bolstered by scientific confirmation, has taught. But no science, including neuroscience, can prove a metaphysical thesis such as hard determinism. Thus, the neurocentrists are mounting a radical challenge to entrenched concepts and practices about how we should live together, a task in which law and criminal blame and punishment play a central role. In what follows, we suggest the wide range of data and considerations that indicate just how radical the neurocentrist view is. Because concepts and practices are accepted does not mean that they are scientifically or morally justified, but the burden of persuasion must surely be on the radical critics who wish to upend many millennia of human experience and practice based on an unprovable metaphysical thesis that would strip humans of responsibility and its consequences that provide much of the basis for human dignity and worth.

The hard determinist view—a world without “just desert”—raises a set of interesting questions regarding how the criminal justice system should work. Most momentously, are humans even capable of removing blame from the moral and legal domain? Could it somehow be pried loose from entrenched notions of how human beings operate? The prospect of a world without moral responsibility collides head-on with the innate sense that people can choose freely. By the age of 5, most children perceive

Telegram: @medical_k

www.konkur.in

others' actions in terms of their intentionality and agency. In one experiment, kindergartners observed an investigator sliding open the lid of a box, putting her hand in, and touching the bottom of the box. Asked by the experimenter if she had to touch the bottom or whether she "could have done something else instead," the vast majority of children believed that she could have done something else. But when the experimenter placed a ball on the lid and slid open the lid, and the ball fell to the bottom of the box, only a few of the children said that the ball itself could have "done something else instead."

The intuition that people can do something else persists with age. Adults across cultures, religions, and countries steadfastly reject the idea that the decisions are fixed in such a way that no other actions are possible. Just as consistently, human beings are highly attuned to notions of fairness. Communities buzz with gossip about who did what scandalous thing to whom; people keep score ("I did two favors for you, but you did only one for me") and punish cheaters who fail to reciprocate. Indigenous people in the Amazonian rain forest are as diligent about detecting free riders and are as ready to punish offenders as are college students in the United States, Europe, and Asia. In his 1991 book *Human Universals,* anthropologist Donald E. Brown presented a comprehensive survey of moral concepts shared across the globe. Among them are proscriptions against murder and rape, as well as redress of wrongs.

In an exhaustive review of anthropologic data, psychologists found that within all human cultures, individuals tend to react with quick, automatic feelings of anger, contempt, and indignation when they see people causing suffering. The universality of these responses raises the distinct possibility that intuitions about fairness, harm, and respect for authority are innate to the human mind. The behavioral economics laboratory is a showcase for fairness attitudes as well. Nobel Prize–winning psychologist and behavioral economist Daniel Kahneman and colleagues documented how study participants voluntarily incurred a penalty to punish others for unfair behavior. It is even more striking that they found evidence that people will pay to punish a third person even when participants are not directly involved in the transaction if they perceive that the third person's unfair behavior was intentional.

The stirrings of moral sentiment begin early on. In a series of studies, psychologists Karen Wynn and Paul Bloom of Yale University found that toddlers who watched a puppet show in which one puppet "stole" a ball

Telegram: @medical_k

www.konkur.in

and another puppet returned the ball to its rightful owner were far more likely to give candy to the helper puppet than to the “bad” puppet and preferentially take it away from the “bad” puppet. More generally, violations of fairness arouse emotions that trigger the urge to retaliate, especially when the violator intentionally injures an innocent person.

Social psychologist Philip Tetlock of the University of Pennsylvania and his collaborators presented subjects with a scenario involving a brutal assault that left the victim permanently brain damaged. No matter what happened to the aggressor—in one hypothetical scenario, he suffered a painful accident; in another, he was cured with medication—subjects’ desire for justice was unchanged. Merely rendering him harmless or causing pain accidentally was not sufficient. This is why certain nations, such as Israel, direct their law enforcement officials to pursue octogenarian Nazi war criminals living quietly in South America and elsewhere even though they no longer pose a danger. The deep-seated desire for justice compels that the moral ledger be balanced.

Intrinsic to the idea of retribution—which is not revenge; it is a theory of justice based on giving people what they deserve—is that people must suffer in proportion to the suffering they inflicted. Psychologist Jonathan Haidt of New York University and colleagues showed clips from Hollywood films that portrayed injustice (one involving the rape and murder of a child, and another in which a slave’s foot is mutilated by a slave catcher). They next gave subjects a variety of endings and asked which one was the most “satisfying.” Among the alternative endings was the “revenge” option: The grieving mother violently kills her daughter’s rapist; the hobbled slave chops off part of the foot of the man who mutilated him. In the “catharsis” option, the mother undergoes “primal-scream” therapy; the slave chops wood while visualizing the slave catcher’s foot.

In the “forgiveness” ending, the victims join a support group or become more active in church and learn to forgive the transgression that was committed. The viewers derived far less satisfaction from the scenarios in which the victims come to terms with their tragedies and forgive the transgressor. They wanted the perpetrators to pay. It was most satisfying when the punishment matched the crime. At the same time, viewers found gratuitous and less satisfying another ending in which the slave retaliated by murdering his catcher.

This result is consistent with the extensive work of psychologists the late Kevin M. Carlsmith and John M. Darley of Princeton University. In a

Telegram: @medical_k

www.konkur.in

series of experiments, they found that when it came to sentencing wrongdoers, subjects were exquisitely sensitive to the severity of the offense—say, the theft of $100 to feed a starving child versus using the money to create the world's largest margarita—and largely ignored the likelihood that the person would offend again. Subjects punished people exclusively in proportion to the harm done and not for the harm that might be done in the future. "People want punishment to incapacitate and to deter, but their sense of justice requires sentences proportional to the moral severity of the crime," they concluded. Punishment that violated proportionality offended people's intuitive sense of fairness.

Although hard determinists reject the concept of blameworthiness, they still accept the view that censure can have practical value. As any parent knows, well-calibrated disapproval, along with encouragement, is essential to raising children who are sensitive to the rights of others, behave kindly toward the injured and vulnerable, and reciprocate when they have been helped. No society, whether modern or preliterate, can function and cohere unless its citizens exist within a system of personal accountability that stigmatizes some actions and praises others. Punishment signals to the community who should not be trusted, and its severity reflects the enormity of the transgression. But none of these punishment-related functions requires that anyone be blamed. In utilitarian fashion, punishment could be meted out simply to shape future behavior.

Retribution, however, is a thoroughly different concept. In its pristine, theoretical form, retributive practices are triggered by the simple fact that someone who is mentally competent and uncoerced has committed an offense. The point of punishment is to make perpetrators suffer in proportion to the harm that they have already caused the victim and society. Any incidental benefit to the greater society that comes from reinforcing norms or protecting against future crime is irrelevant.

But when retribution is applied in the real world, it inescapably carries great practical value, too. For one thing, it strengthens people's shared norms of moral obligation to one another. One of those norms is that victims should be valued as human beings. Consider the following vignette: A serial rapist, John, attacks Mary, is found guilty, and is sent to prison. A few months later, John is treated with "Castrex," a fictional new antirape medication guaranteed to permanently eradicate sexually aggressive urges. Castrex works after just a few doses, and several weeks later, John is freed. He is no longer a danger to anyone. His

Telegram: @medical_k

www.konkur.in

rehabilitation was a success. But John's light punishment would almost surely have woeful repercussions for Mary, her family, and the community at large.

When society fails to condemn aggressors or simply slaps them on the wrist, victims often feel unavenged and therefore devalued and dishonored. If perpetrators die before they can be judged or are killed in prison before they can be adequately punished, victims and their families usually feel enraged. Criminals who do not "pay their debt" can spur victims and their families to contemplate private retaliation and sometimes even undertake it. Contrary to common perception, such feelings do not always arise out of a sense of white-hot rage or bloodlust vigilantism. The motivation to give wrongdoers what they deserve can instead be motivated by grief or by a solemn sense of duty to set things right.

Communities, too, resist what they perceive to be inadequate punishment. Consider the 2011 trial of Casey Anthony, the 25-year-old Florida woman who never reported her 2-year-old daughter missing. Widely believed to have killed her child or at least to have abetted in her death, Anthony received death threats after she was exonerated for the crime of murder. Likewise, jurists often speak of their moral duty to satisfy the victims and their families, but such satisfaction should not produce disproportionately long sentences.

Restoring the social standing of the victim is another vital function of just punishment. When the law imposes inadequate punishment on wrongdoers or allows them to escape penalties altogether, the demoralizing message to the community is clear: The victim is so inconsequential that their rights, security, and property can be breached with impunity. This is why proportionate punishment must be carried out in full view of the community after open trials, announced in the press, and preceded by a clear message of society's moral condemnation. Everyone in the community must be reminded that such mistreatment will not be tolerated. In a series of experiments, legal scholar Kenworthey Bilz, now of the Illinois University College of Law, asked subjects to evaluate the moral worth of a female victim whose attacker was punished for rape and a similar woman whose rapists pled guilty to a lesser offense. Both women were judged by participants before their rapists were punished. When participants learned that the rapists were convicted of rape, they rated the victim as more "respected," "valued," and "admired" than they were before punishment. When the rapists pled to a lesser nonsexual crime, subjects ranked the victim's social standing lower than in the prepunishment phase.

Telegram: @medical_k

www.konkur.in

What happens when the community is prevented from administering justice? In the mid-1960s, sociologist Melvin Lerner developed the “belief in a just world” hypothesis. According to this influential hypothesis, people harbor a strong need to believe that the world is a place where people get what they deserve and where actions have predictable consequences. A just-world belief is akin to a “contract” with the world regarding the outcomes of one’s conduct: do the right thing and be rewarded—or, at least, know largely what to expect. Lerner understood that the notion of a truly just world is illusory, yet he posited that it helps people to plan their lives and achieve their goals.

In one of his seminal experiments, Lerner asked subjects to observe a 10-minute video of a fellow student as she underwent a learning experiment involving memory. The student was strapped into an apparatus sprouting electrode leads and allegedly received a painful shock whenever she answered a question incorrectly (she was not receiving real shocks but believably feigned distress as if she were). Next, the researchers randomly assigned the observers into groups. One was to vote on whether to remove the victim from the apparatus and reward her with money for correct answers. All but one voted to rescue her. The experimenters told another group of observers that the victim would continue to receive painful shocks; there was no option for compensation. When asked to evaluate the victim at this point, participants in the victim-compensated condition rated her more favorably (e.g., more “attractive,” more “admirable”) than did subjects in the victim-uncompensated condition, in which the victim’s suffering was greater. Lerner’s conclusion is disturbing. “The sight of an innocent person suffering without the possibility of reward or compensation motivated people to devalue the attractiveness of the victim in order to bring about a more appropriate fit between her fate and her character,” he wrote. In other words, when subjects’ intuitions of justice are satisfied, their belief in a just world is supported. But when subjects (or society) are prevented from restoring justice, they typically blame the victim. Somehow, the reasoning goes, she must have asked for it.

Beyond the victims, the legal system itself suffers when criminals are not punished, although not just any punishment will do. The penalty must seem proportionate to the offense. If it is perceived as skewed in either direction—too lenient or too harsh—the law can lose its moral force. Recall Rodney King, the man who led California police on a high-speed

Telegram: @medical_k

www.konkur.in

chase before being caught and beaten severely. Shortly after the 1992 acquittal of the police officers involved in the assault, half of all Californians surveyed said that they had lost confidence in the court system. In a system perceived as unfair, juries may ignore judges' instructions, and police officers may impose their own judgment on whether to arrest, trump up charges, or abuse suspects.

For their part, witnesses may rebel by refusing to participate in investigations or to testify. Researchers have observed that subjects are more willing to commit minor offenses such as traffic violations, petty theft, and copyright violations when laws more generally do not conform to their sense of right and wrong. Jurors are more susceptible to nullification—that is, to acquit defendants who are legally guilty—when the verdict dictated by law is contrary to their sense of justice, morality, or fairness. Examples of perceived unfairness include suspicions of judges' failure to admit evidence, prosecutorial suppression of evidence, police misconduct, or police lying on the stand.

Finally, intuitions about justice are strong motivators for social change. The victims' rights movement grew out of a powerful sense of unfinished business. Unmet justice alienates juries, judges, and prosecutors, thereby undermining the authority of the law, an institution that depends for its smooth functioning on the good faith of its participants. Pragmatic efforts aimed solely at reducing future crime (and not at all at exacting retribution for past bad deeds) would leave many victims questioning the moral credibility of the law. Those victims do not necessarily seek harsh treatment for their violators, although they surely want judges to administer appropriate punishment. What they want most is for the law to acknowledge that what happened to them was wrong and morally offensive. Indeed, the idea of a victim impact statement was developed so that the sentencing judge could hear directly about the anguish that victims and their loved ones had suffered. Some victims want an apology from their violators—not in place of a penalty, but in addition to it.

In summary, some scientists say that they look forward to a day when neuroscience will explain the mechanical workings of the brain so thoroughly that it will be impossible for society to continue to ignore the "fact" that people do not choose their behavior and, therefore should be absolved of blame. This vision seems to be on a collision course with the psychological and social meanings that criminal justice in general and retribution in particular hold for victims, their loved ones, and societies.

Telegram: @medical_k

www.konkur.in

Victims of crime are exquisitely attuned to society's regard for the people who have violated their rights. Unless authorities mete out deserved punishment, victims feel devalued and suffer a loss of moral standing in their community. Society is also harmed when citizens do not see justice being served and thereby lose faith in the moral authority of the law.

Although cloaked in neuroscientific garb, this free will and responsibility question remains one of the great conceptual impasses of all time, far beyond the capacity of brain science alone to resolve. Unless, that is, investigators can show something truly spectacular: that people are *not* agents, not conscious beings whose actions flow from reasons and who are responsive to reason. True, people do not exert as much conscious control over their actions as they think they do. Every student of the mind, including William James and Sigmund Freud, has been aware of this important truism. But it does not mean humankind is powerless to act otherwise than it does. Neuroscience simply cannot prove that responsibility, which is at the heart of our conception of ourselves and others and gives so much meaning and worth to our lives, is an illusion.

CONCLUSION

The brain is said to be the final scientific frontier, and perhaps with some justification. Yet, in many quarters, brain-based explanations appear to be granted a kind of inherent superiority over all other ways of accounting for human behavior—they have exercised the "neurocentric" presumption or the view that human experience and behavior can be best explained from the predominant or even exclusive perspective of the brain. From this popular vantage point, the study of the brain is inherently more "scientific" than the study of human motives, thoughts, feelings, and actions. By making the hidden, allegedly but misleadingly visible, functional brain imaging has been a spectacular boon to neurocentrism. Such imaging has contributed substantially to the knowledge of the correlates of mental illness and personality. The risk is losing sight of the mind in the age of brain science. Although the scans are dazzling and the technology an unqualified marvel, it is important to remember that the brain and the mind, although not differing materially, are two complementary but different frameworks for conceptualizing human behavior.

The neurobiologic domain is one of brains and physical causes, the mechanisms behind one's thoughts and emotions. The psychological

Telegram: @medical_k

www.konkur.in

domain, the realm of the mind, is one of people—their desires, intentions, ideals, and anxieties. Both are essential to a full understanding of why people act as they do.

ACKNOWLEDGMENT

Scott O. Lilienfeld, who died on September 29, 2020, was a transformative leader in the field of clinical psychological science. An excellent teacher and adored mentor, his work was known for its clarity, astute critical frame, fairness, and intellectual courage.

4.2 Transcultural Psychiatry

Telegram: @medical_k

www.konkur.in

KENNETH FUNG, M.D., F.R.C.P.C., M.SC., AND ROBERT KOHN, M.D.

Culture, while often overlooked, is all around us and broadly refers to patterns of human activity among groups of people, giving rise to symbolic systems, shared meaning, and social structures. This includes languages, systems of knowledge, beliefs, norms, values, and other behavioral patterns that are socially acquired and may be transmitted within and across generations. Culture can shape our perception and understanding; thoughts and feelings and their expression; motivation and morality; rituals and other behavioral patterns and practices; identity and sense of belonging; verbal and nonverbal communication; social norms and relationships; social systems and structures including families, kinships, communities, and institutions; and technology and tools.

Culture has eight essential characteristics:

1. It is learned.
2. It is both an individual and group process.
3. It can be passed on from one generation to the next.
4. It involves a set of words, behaviors, events, and symbols whose meanings have been tacitly or explicitly agreed upon by the cultural group.
5. It acts as a template to shape and orient future behaviors and perspectives within and between generations and to take account of novel situations encountered by the group.
6. It exists and evolves in a constant state of change.
7. It includes patterns of both subjective and objective components of human behavior.
8. It is expressed in societal and structural elements, such as institutions and laws.

As cultural influences pervade all human activities, the aim of cultural psychiatry (transcultural psychiatry) includes developing scientific lines of inquiry and clinical approaches to examine and understand the influence of culture and sociocultural contexts on all aspects of mental health and psychopathology, including cultural influences on and interactions among different levels of analysis, including neurobiologic, cognitive-affective, interpersonal, and social systems.

Telegram: @medical_k

www.konkur.in

Cultural competence can be broadly defined as the capacity to function effectively taking cultural factors into consideration, including at the micro level of individual clinical care; meso level of programmatic and organizational activities; and macro level of systemic or societal structures and characteristics. Learning objectives in clinical cultural competence training include attitudes (affective), knowledge (cognitive), and skills (psychomotor) domains, as well as the interrogation of the impact of power differentials among cultural groups on the three domains, such as whose knowledge systems are being prioritized and valued. While the concept of cultural competence is useful for providing a framework for training and clinical care for mental health professionals and increasing accountability of the healthcare system to uphold a minimum standard of care for diverse populations, it has been criticized when it is narrowly conceptualized, defined, and taught, such as when it is misconstrued as about developing stereotypic knowledge of specific ethnocultural groups. Other concepts have been developed in view of this potential pitfall.

Cultural safety, arising from work of nurses with indigenous Mao_ ri population in New Zealand, emphasizes the need to recognize historical and ongoing processes of oppression; develop critical consciousness in reflecting on the potential harms in healthcare by the practitioner and health systems due to assumptions, biases, and structural issues; and prioritizing safety from the care recipients and their communities' perspectives.

Structural competence focuses on addressing the impact of social determinants of health on mental health, including promoting the capacity to recognize and address the impact of social structures, such as policies, economic systems, and institutions, on mental health problems, both clinically and in collaboration with other disciplines, communities, and organizations through advocacy and other actions. It is undergirded by developing structural humility to recognize the limitations of physicians to solve structural problems alone, and cultural humility to commit to self-reflection, self-critique, and lifelong learning from others.

Antioppressive practice focuses on disrupting all forms of oppression, such as racism, classism, genderism, heterosexism, and ableism, and addressing inequities. This includes developing a critical consciousness to identify, resist, and disrupt oppressive structures and forces; overcoming barriers to unlearn and relinquish power and privilege; and empowering oppressed individuals and communities to engage in advocacy and

Telegram: @medical_k

www.konkur.in

activism collaboratively through individual and collective actions, with the aim of promoting liberation of those being marginalized from oppression and systemic change.

The overlapping frameworks above, while varying in perspectives and emphases and each arising from a particular sociocultural and historical context, share foundational values of diversity, equity, and inclusion (DEI), increasingly acknowledged to be essential in medicine. Diversity refers to the recognition, valuing, and representation of differences that may exist among individuals and communities, including race, ethnicity, nationality, sex and gender identity, sexual orientation, (dis)ability, neurodiversity, and other social characteristics. Equity refers to the principle of fairness and that each person should have access to opportunities and resources to maximize their mental wellbeing in accordance with their needs. Equity is different from equality, where every person is treated the same without consideration of different needs caused by historical and ongoing systems of privilege and oppression. Inclusion refers to ensuring that each person is able to fully and meaningfully engage, participate, and have a voice in society, from receiving needed services to being involved in leadership and decision-making processes. These three interrelated values and principles need to be enacted and implemented together.

ETHNOCULTURAL DIVERSITY OF THE U.S. POPULATION

Defining Race, Ethnicity, and Immigration Status

Race has been variously defined and is a social construct that groups people together by superficial physical traits such as skin color and facial features. Some prefer the term racialized to emphasize the social process by which people become defined, which has been used throughout history as justification for exclusion, segregation, discrimination, racism, oppression, slavery, and other acts of violence and atrocities. Manifestations and sequelae of social and structural racism are often falsely misattributed to inherent racial differences, implying biologic differences without scientific evidence, furthering harm and perpetuating oppression. Instead, race-based data may be helpful when utilized to identify needs, inequities, and disparities.

Telegram: @medical_k

www.konkur.in

Ethnicity, similarly, is a socially constructed group identity used to define groups of people and communities, rooted in perceived or actual commonality in history, ancestry, geography, language, religion, or other shared social or cultural group characteristics. Ethnicity may be self-assigned or attributed by others. Social and cultural changes, mobility and migration, intermarriages, and intermixing of groups continuously give rise to newly defined, mixed, multiple, or hybrid ethnic identities.

Both race and ethnicity have been variously defined and operationalized in different countries and contexts. This differs significantly even among Western nations with diverse populations.

For the 2020 U.S. Census, race includes White; Black or African American; American Indian or Alaska Native; Asian (which has been broken down in the latest census to include Chinese, Vietnamese, Native Hawaiian, Filipino, Korean, Samoan, Asian Indian, Japanese, and Chamorro); Other Asian; Other Pacific Islander; or some other race. Respondents can identify with one race alone or endorse multiple and can fill in more specific details about their origin under each racial category. Separately, respondents can self-identify their ethnicity as being of Hispanic, Latino, or Spanish origin, defined as ethnic groups originating from Mexico, Puerto Rico, Cuba, and other Spanish-language cultures including those in Central and South America.

In neighboring Canada, another settler country and the only Western country among the top 20 most diverse countries in the world, the 2021 long-form census includes a question that asks for the ethnic or cultural origin of the respondent's ancestors linked to a list of over 500 examples. It has a separate question on whether the respondent identifies as First Nations, Métis, or Inuk (Inuit), and there is also a self-identification question with a list of selection based on the concept of visible minorities in Canada, including White, South Asian, Chinese, Black, Filipino, Arab, Latin American, Southeast Asian, West Asian, Korean, Japanese, and Other. While the concept of "visible minorities" has been used to promote employment equity in Canada, it has also been criticized, including by the United Nations, because the term's "lack of precision may pose a barrier to effectively addressing the socio-economic gaps of different ethnic groups."

As another comparison, in the 2021 Census of England and Wales, the list of ethnic groups included: Asian or Asian British (Indian, Pakistani, Bangladeshi, Chinese, or Any other Asian background); Black, Black

Telegram: @medical_k

www.konkur.in

British, Caribbean or African (Caribbean, African, Any other Black, Black British, or Caribbean background); Mixed or multiple ethnic groups (White and Black Caribbean, White and Black African, White and Asian, Any other Mixed or multiple ethnic background); White (English, Welsh, Scottish, Northern Irish or British, Irish, Gypsy or Irish Traveller, Roma, Any other White background); Other Ethnic group (Arab, Any other ethnic group). Scotland and Northern Ireland use different ethnicity classifications for their census.

Evidently, race and ethnicity are arbitrary sociocultural constructs with localized rather than universal applicability or utility. Using them to stereotype an individual is inaccurate and harmful. Nevertheless, they both remain relevant constructs. For some individuals and communities, they may be an important and meaningful aspect of their individual or collective identities. In the interpersonal and social context, these constructs often influence social interactions, such as in the form of racism, and become part of the fabric of social reality with real impacts. At a systems level, disaggregated data by race and ethnicity can surface disparities.

Migrants: Defined broadly as an umbrella term by the United Nations, a migrant refers to any person who is moving or has moved across an international border or within a State away from their habitual place of residence, regardless of the person's legal status, whether the movement is voluntary or involuntary, what the causes of the movements are, and what the length of stay is.

Immigrants: An immigrant can be defined as a person living in a country other than that of their birth. There are four categories of immigration status: naturalized citizens, permanent or conditional residents, nonimmigrants, and undocumented immigrants. People may also migrate to another country without the objective of permanent residence, but rather, for short-term purposes of study or work with the intention of returning to their home countries; these are often referenced as migrants as opposed to immigrants.

The Changing U.S. Population: Race, Ethnicity, and Migration

Racial and Ethnic Diversity. There has been increasing diversity in the U.S. population as captured by the latest census in 2020. Respondents can choose to indicate one race, reported as "alone" in the census report, or multiple races, reported as "in combination." The White alone

Telegram: @medical_k

www.konkur.in

population accounted for 204.3 million people (61.6% of population), decreased by 8.6% since 2010. The Hispanic or Latino population grew to 62.1 million (18.7%), increased from 16.3% of the population in 2010. The total Black or African American alone and in combination population accounted for 46.9 million people (14.2% of the population), with a growth of 88.7% for the Black or African American in combination population since 2010. The Asian alone or in combination population accounted for 24 million people (7.2% of population). The American Indian and Alaskan Native in combination population grew by 160%, with the alone and in combination population totaling 9.7 million people (2.9% of the population). The Native Hawaiian and Other Pacific Islander alone or in combination population totaled about 1.6 million people (0.5% of the population). The percentage of people reporting two or more races has increased from 2.9% to 10.2% of the population.

Immigration. The United States, like Canada, Australia, and South Africa, is a settler colonial society. Except for indigenous populations, Americans are either immigrants or descendants of immigrants. From the Chinese Exclusion Act of 1882 to the Immigration Act of 1924, early U.S. immigration policies and laws were exclusionary and discriminatory against non-European populations until the Immigration and Nationality Act of 1965, which marked the abolishment of the National Origins Formula. Current U.S. immigration laws are based on the principles of allowing the reunification of families; admitting immigrants with skills that are valuable to the U.S. economy; protecting refugees; and promoting diversity, with a ceiling that family and employment-based immigrants from any single country cannot exceed 7% of the total number of people immigrating to the United States in a year.

During the first half of the 20th century, the two world wars and immigration restrictions resulted in a steady decline in the number of foreign-born Americans, reaching the low point of 4.7% in 1970. During the last three decades of the 20th century and continuing through the beginning of the 21st century, there has been an increasing inflow of immigration. Currently, the United States has the largest immigrant population globally. In 2020, it is estimated that 14.8% of the U.S. population was foreign-born. By 2060, the immigrant population is expected to rise to over 69 million, comprising 17.1% of the projected U.S. population of over 404 million. Viewed from the perspective of how long

Telegram: @medical_k

www.konkur.in

ago they immigrated, 27% of the total foreign-born population came to the country since 2010, 25% between 2000 and 2009, 21% between 1990 and 1999, 13% between 1980 and 1989, and 13% before 1980.

The immigration rates from source countries to the United States have changed significantly since the 1960s, in part due to the changes in the immigration system, as well as other drivers of migration such as economic, political, demographic, environmental, and sociocultural forces. In 1960, 84% of immigrants were born in Europe, Canada, or other North American countries, while only 6% were from Mexico, 4% from Asia, 3% from the rest of Latin America, and 3% from other areas. From 2011 to 2020, the top five source countries of immigration included: Mexico (14.6%), China (7.0%), India (6.2%), Philippines (4.9%), and Dominican Republic (4.9%). Based on the 2021 American Community Survey, of the 45 million foreign-born U.S. population, about 50% is from Latin America, 30% from Asia, and 11% from Europe, with the top ten countries of origin being Mexico (23.6%), China (6.1%), India (6.0%), Philippines (4.4%), El Salvador (3.1%), Vietnam (3.0%), Cuba (2.8%), Dominican Republic (2.8%), Guatemala (2.4%), and Korea (2.2%).

Starting in the 1960s, opportunities for temporary migration increased steadily in many high-income countries (HICs), including the United States, for temporary workers, students, and technicians. The most significant numbers were for seasonal agricultural workers and factory workers, followed by temporary workers in the service industry, mainly hotels, restaurants, and building maintenance. Between 1997 and 2013, the annual inflow of foreign-born temporary migrants to the United States exceeded the number of permanent immigrants. In 2022, about 3 million temporary workers came to the United States. They are a vulnerable group, as they may experience stress from loss of social status, discrimination, separation from families, and precarious and sometimes dangerous and abusive working conditions.

Refugees and Asylum Seekers. Voluntary migrants are people from rural areas migrating to urban industrial areas in their own and neighboring countries, motivated mainly by job opportunities in the industrializing cities. Involuntary migrants are people who left the regions and countries of their upbringing because of discrimination, persecution, revolution, and war, but followed the same paths of migration to other

Telegram: @medical_k

www.konkur.in

countries as other migrants. Involuntary migrants are frequently considered refugees.

A refugee as defined by the United Nations High Commissioner for Refugees (UNHCR) is a person who “owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion, is outside the country of his nationality, and is unable to or, owing to such fear, is unwilling to avail himself of the protection of that country.” An internally displaced individual is not considered a refugee. Refugees have the right to international protection. An asylum seeker is a person who has left their country and is seeking protection from persecution and serious human rights violations in another country but is not yet legally recognized as a refugee and is waiting to receive a decision on their asylum claim.

Of the world’s population, 3.6% are international migrants. Europe has the largest proportion of international migrants, 30.9%, followed by Asia, 30.5%, and North America, 20.9%. Africa, Latin America and the Caribbean, and Oceania have 25.4%, 14.8%, and 9.4% of the international migrant population, respectively. There is great variation as to the types of international migrants in a country. In 2017 in the United States approximately 23% were unlawful migrants and 5% were lawful temporary workers. By the end of 2021, according to UNHCR there were 89.3 million displaced people in the world of whom 27.1 million were refugees and 53.2 million were internally displaced by conflict.

The United States admitted 25,465 refugees in 2022, a significant increase from 2021 when the United States admitted only 11,411 refugees, the lowest since the Refugee Act of 1980. The peak year was 1992, with 132,531 refugees admitted. The leading five countries for recent refugees to the United States were the Democratic Republic of the Congo (42.9%), Syria (10.9%), Afghanistan (7.6%), Ukraine (7.0%), and Burma (6.8%). In 2021, the United States granted asylum to only 8,349 individuals, half the number granted relief in 2020. Nevertheless, this number represents an increase in the proportion of successful applications: in 2020, 71% of applications were denied, compared to 63% in 2021. The small number reflects a continued partial court shutdown due to the COVID-19 pandemic–by comparison, the United States granted more than 20,000 applications in 2019 and took in over 120,000 refugees. Before 1983, the United States received waves of Cuban and Indochinese refugees. Between 1985 and 1991, many refugees came from the former

Telegram: @medical_k

www.konkur.in

Soviet Union, including Jews and evangelical Christians. From 1992 to 1998, refugees came from Bosnia, Kosovo, and other Balkan states due to the breakup of Yugoslavia. Liberians also were admitted as refugees until the end of their civil war. In 2019, the most common refugee home countries were Venezuela, China, Egypt, Turkey, and Russia.

RACISM AND MENTAL HEALTH

Racial and ethnic discrimination can cause both direct and indirect harm to mental health and can occur at the micro, meso, and macro level.

Interpersonal and Internalized Racism

At the individual micro level, interpersonal acts of racism include both overt actions, such as verbal and physical assaults, and covert acts or microaggressions, such as subtle acts of disrespect, slights, bias, misrecognition, or exclusion, which may or may not be intentional. Both types of racism have been shown to have adverse mental health impacts, and microaggressions are often denied and dismissed, with the victim being blamed as oversensitive, compounding a sense of shame and helplessness.

Based on data from the National Latino and Asian American Study (NLAAS) and the National Survey of American Life (NSAL), discrimination has been found to be associated with psychotic experiences among Latino, Asian, African American, and Afro Caribbean Americans, and Premenstrual Dysphoric Disorder among Asian, Latina, and Black premenopausal women. In the NLAAS, discrimination was associated with lifetime depression, anxiety, and any disorders among Asian Americans; 12-month depressive and anxiety disorders among Asian American women; and lifetime and 12-month depressive and anxiety disorders among Latino immigrants. The National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) study found that among Hispanics, discrimination was a risk factor for mood, anxiety, or substance use disorder. The study found a dose-response relationship, where experiencing discrimination across a greater number of domains was associated with an increased likelihood of being diagnosed with a mental disorder. Similarly, the Study of Women Across Nation (SWAN) assessed discrimination experienced by women at six-time points over 10 years and found that Black, Chinese, Hispanic, and non-Hispanic White women who

Telegram: @medical_k

www.konkur.in

experienced the highest accumulation of discrimination over time, domain, and attributes reported the highest level of depressive symptoms.

A 2015 meta-analysis of 293 studies from 1983 to 2013 found that racism was associated with poorer physical and mental health, including depression, anxiety, and psychological stress. The association between racism and negative mental health was significantly stronger for Asian Americans and U.S. Latinos compared with African Americans, while the association between racism and negative physical health was significantly stronger for Latinos compared with African Americans.

Allostatic load refers to the accumulation of physiologic perturbations from repeated or chronic stress in daily life and has been found to predict increased cardiovascular events and all-cause mortality and may partly account for the increased mortality in Blacks compared to Whites. In a study with African Americans, perceived discrimination was associated with higher allostatic load. In another study, African Americans had a higher allostatic load than Whites. Results of a pathway analysis found that racial group was associated with perceived discrimination, which was associated with increased anger and decreased sleep quality, which were associated with allostatic load; in combination, discrimination, anger, and decreased sleep fully mediated the relationship between race and allostatic load.

In a recent review of studies employing ecologic momentary assessments (EMA), which provide intensive and detailed longitudinal information, race-based discrimination was found to be associated with same-day anxiety for all racialized groups. Associations with discrimination also included somatic symptoms among Asians, same-day depressive symptoms in the days following among African Americans, and next-day depressive symptoms among Latinos. Individuals whose racial identification was more central to their self-concept experienced higher depressive symptoms on the same day compared to those with lower racial centrality. Racial identity exploration exacerbated next-day distress, while racial identity commitment buffered the effect of daily discrimination (see later section on racial identity). Consistent with this, having a strong ethnic identity, as noted in a study of Filipino Americans, helps reduce the stress of discrimination and is associated with fewer depressive symptoms. Having a sense of ethnic pride, involvement in ethnic and communal activities, and having an emotional commitment to one’s ethnic group may be protective factors for mental health.

Telegram: @medical_k

www.konkur.in

Racism may become internalized, impacting self-esteem as well as inducing negative perceptions about one's own racial or ethnic group. For example, colorism is the prejudicial treatment against dark-skinned individuals which can occur by in-group (i.e., by other Black people) or out-group (i.e., by Whites) individuals. Using NSAL data, a recent study found that in-group colorism among Black Americans was associated with greater odds of having lifetime psychiatric disorder, as well as substance use disorder, anxiety disorder, and eating disorder.

The myth of the model minority has been used to describe Asian Americans being stereotyped as a successful "intermediary minority" in the social hierarchy with the Whites at the top and the Blacks at the bottom. This has multiple deleterious effects, resulting in the negation of the long history and ongoing anti-Asian racism; ignoring the disparities faced by the diverse Asian populations; promoting a perpetual foreigner identity among Asians; becoming a source of stress and internalized racism for Asians; exacerbating anti-Black racism and perpetuating the denial of systemic racism by promoting a narrative of meritocracy and that hard work alone can lead to success; and promoting divisive intergroup racism.

The concept of intersectionality was first advanced by black feminist scholar Kimberlé Crenshaw. It provides a framework for understanding how multiple social identities, including race, gender, caste, ethnicity, sexuality, religion, disability, class, etc. can intersect and overlap in an individual, which can be empowering or oppressing depending on the social context. For many individuals, in addition to racism, they may encounter sexism, homophobia, classism, and ablism, finding themselves marginalized and oppressed in both the mainstream and their own cultural communities. A recent review of 40 studies on multiple forms of discrimination concluded that the current evidence suggests that multiple discriminated groups exhibit an increased risk of mental health problems, especially depressive symptoms.

Structural and Systemic Racism

At the meso level, or institutional or structural racism, racism is embedded in institutions and structures of the society, including laws, policies, institutional practices, and other norms that scaffold the society. At the macro level, or systemic racism, racism is embedded in the totality of the social system, including its political, legal, economic, health care, school,

Telegram: @medical_k

www.konkur.in

and criminal justice aspects, as well as all supporting structures, systems, cultural scripts, and peoples of the society. Inequitable structures and systems are mutually reinforcing and interconnected. Systemic racism is sometimes used as an overencompassing term for both meso and macro forms of racism (see Table 4.2–1).

Systemic racism is the result of the historical legacy of slavery and colonialism, as well as ongoing forms of systematized racism that continue to oppress and marginalize indigenous and minoritized ethnoracial groups, while privileging Whites. Examples include political disempowerment through gerrymandering and suppression of voting rights of people of color; segregation of neighborhoods resulting in concentrated economic disadvantages and limiting upward mobility through poorly resourced schools and limited employment opportunities; unfair financial practices, such as racially biased mortgage assessments and underfunded disproportionately segregated neighborhoods deemed hazardous for lending or investments (“redlining”); environmental injustice, such as locating coal-fired power plants and hazardous waste disposals in segregated communities; criminal justice system inequities, resulting in people of color representing about 39% of the general population but making up 60% of incarcerated individuals; police violence, leading to the death of 1 in every 1,000 Black men, with Black victims being more likely than White victims to have been unarmed; a “school-to-prison pipeline” education system, with harsher punishment for minorities in schools and higher involvement of police leading to expulsions and arrests.

Telegram: @medical_k

www.konkur.in

Table 4.2–1.
Pathways Between Racism and Mental Health

Telegram: @medical_k

www.konkur.in

Economic injustice and social deprivation

Examples include residential, educational, and occupational segregation of marginalized, racialized groups to low-quality neighborhoods, schools, and jobs (both historical de jure discrimination and contemporary de facto discrimination), reduced salary for the same work, and reduced rates of promotion despite similar performance evaluations

Environmental and occupational health inequities

Examples include strategic placement of bus garages and toxic waste sites in or close to neighborhoods where marginalized, racialized groups predominantly reside, selective government failure to prevent lead leaching into drinking water (as in Flint, MI, in 2015–2016), and disproportionate exposure of workers of color to occupational hazards

Psychosocial trauma

Examples include interpersonal racial discrimination, microaggressions (small, often unintentional racial slights and insults, such as a judge asking a black defence attorney “Can you wait outside until your attorney gets here?”), and exposure to racist media coverage, including social media

Targeted marketing of health-harming substances

Examples include legal substances such as cigarettes and sugar-sweetened beverages, and illegal substances such as heroin and illicit opioids

Inadequate health care

Examples include inadequate access to health insurance and healthcare facilities, and substandard medical treatment due to implicit or explicit racial bias or discrimination

State-sanctioned violence and alienation from property and traditional lands

Examples include police violence, forced so-called urban renewal (the use of eminent domain to force the relocation of urban communities of color), and the genocide and forced removal of Native Americans

Political exclusions

Examples include voter-restrictions (e.g., for former felons and through identification requirements)

Maladaptive coping behaviors

Telegram: @medical_k

www.konkur.in

Examples include increased tobacco and alcohol consumption on the part of marginalized, racialized groups

Stereotype threats

Examples include stigma of inferiority, leading to physiological arousal, and an impaired patient–provider relationship

Reprinted from Bailey ZD, Krieger N, Agénor M, et al. Structural racism and health inequities in the USA: evidence and interventions. *The Lancet.* 2017;389:1453–1463. © 2017, with permission from Elsevier.

Systemic racism is also embedded in the mental healthcare system from its historical roots to the present time. One of the signers of the Declaration of Independence and considered the "Father of Psychiatry," Benjamin Rush, taught medical students that black skin was a form of leprosy termed "negritude." Psychiatrist Samuel Cartwright believed that enslaved Africans wanting to run away from captivity were suffering from drapetomania; their supposed disease of "rascality" or laziness was caused by dyaesthesia aethiopica; and that the treatment for both was whipping. The structural issues continue to the present day, resulting in demonstrable disparities arising from misdiagnosis, decreased access to care, and decreased quality of care. Observed disparities may be misattributed to biologic differences, a form of biologic determinism, or cultural differences, a form of cultural determinism. To address the latter, cultural competence is important, as culture exists in all, not only in "the other." Rather than pathologizing the cultures of oppressed groups, psychiatrists need to identify and redress embedded cultural norms, assumptions, and biases that inherently perpetuate oppression and systemic racism, which need to be dismantled at the micro, meso, and macro levels. In addition to antiracism strategies, a cultural shift is needed in psychiatry, as "culture eats strategy for breakfast" in institutions.

Table 4.2–2.
Poverty and Ethnoracial Background

	All Ethnoracial Groups	White Alone, Non-Hispanic	Asian Alone	Hispanic[a]	Black Alone, Non-Hispanic	American Indian and Alaskan Native Alone	Two or More Races
2021	7.8	5.7	9.5	11.2	11.2	12.4	7.3
2020	9.2	6.5	8.8	14.0	14.8	15.5	9.0
2019	11.8	8.2	11.3	18.8	18.8	16.6	12.0
2018	12.8	8.7	13.9	20.3	20.4	20.0	13.6

[a]While data for White, Asian, Black, and American Indian and Alaskan Native only included individuals who did not report other racial backgrounds, the aggregate data used for Hispanics include those reporting other racial categories.

Data from United States Census Bureau. Number and Percentage of People in Poverty Using the Supplemental Poverty Measure by Age, Race, and Hispanic Origin: 2009 to 2021. https://www2.census.gov/programs-surveys/demo/tables/p60/277/tableB-2.xlsx. Accessed December 31, 2022.

Telegram: @medical_k

www.konkur.in

Psychiatrists and mental health practitioners can play a key role as allies to fight against systemic racism. Increased awareness through self-reflection and self-education will be the first step, including learning about historical oppression, implicit bias, and unearned privileges that we hold as professionals and through our sociocultural identities. The fundamental DEI principles need to be integrated into the entire mental healthcare system, including psychiatric research, education, and clinical care. This includes ensuring diversity representation and inclusion among clinicians, academics, and leadership; implementing DEI and cultural competence training; and taking steps to improve access to culturally competent mental health programs. Much more focus is needed to address the inequities that impact the social determinants of health and their role in precipitating and perpetuating psychopathology. Advocacy needs to be championed at the clinical level, at the healthcare programs and organizational level, and at the social and health policy level. This work needs to be guided by humility, non-defensiveness, and willingness to collaborate, including engaging and empowering patients and their communities.

Economic Disparities

There is substantial disparity in rates of poverty when race and ethnicity are considered (Table 4.2–2). In 2021, the poverty rate for the total U.S. population was 7.8%, compared with 12.4% for American Indians/American Natives, 11.2% for Blacks, 11.2% for Hispanics (any race), 9.5% for Asian Americans, and 5.7% for non-Hispanic Whites, using the Supplemental Poverty Measure, which takes into account family resources and expenses as well as geographic variation.

Among median household incomes in 2020, Asian Americans had the highest median income, followed by non-Hispanic Whites, Hispanics, and Blacks. A Pew Research Center report analyzed income changes from 1970 to 2016 and estimated an income inequality gap, the gap between the top 10% and bottom 10% of income within a group. In 2016, Asians had the highest income inequality gap at 10.7 times, compared to Blacks (9.8×), non-Hispanic Whites (7.8×), and Hispanics (7.8×). Comparing among the lower-income earners in 2016, defined as the bottom 10% of each group, the lowest income was found among Blacks at 54% of Whites, followed by Hispanics at 66% of Whites, and Asians at 83% of Whites. Among the bottom 10% of each group, percentage gains in

Telegram: @medical_k

www.konkur.in

income from 1970 to 2016 were lowest among Asians at 11%, followed by Hispanics (37%), Whites (45%), and Blacks (67%). Overall, Hispanics' incomes have increased the least among the groups, likely due to immigration. In another study using longitudinal data from 1989 to 2015 to examine intergenerational changes in income, Blacks and American Indians/American Natives were found to have much lower rates of upward mobility and higher rates of downward mobility than Whites, leading to persistent disparities across generations. The Black–White gap is not explained by parental marital status, education, or wealth, and persists even among boys growing up in the same neighborhood.

Migration and citizenship status are also related to poverty. In 2020, the proportion of foreign-born Americans with incomes below the poverty line was approximately 13.4% compared to U.S.-born Americans at 11.1%. Immigrants who were permanent residents but had not yet become citizens had an especially high poverty rate of about 17.8%. On average, it has been estimated that it may take 10 to 15 years for immigrant families to make the transition from economic dependence to independence.

Social Determinants of Mental Health

Some populations experience an increased risk of mental disorders due to unfavorable social, economic, and environmental factors. These disadvantages and disparities may begin at birth and continue through the life course. Social determinants may be considered risk factors for mental disorders, many of which may be modifiable at the neighborhood, country, or cultural group level. Examples of social determinants include safe housing, transportation, and neighborhoods; racism, discrimination, and violence; education, job opportunities, and income; access to nutritious foods and physical activity opportunities; polluted air and water; and language and literacy skills. Figure 4.2–1 provides an overview of the major social determinants of mental health.

At the individual level, gene-environment interactions may modify the role of social determinants. An inverse relationship between social class and many mental disorders has been found. Education can impact economic prospects. Poverty may initiate and perpetuate mental disorders. Unemployment is considered both a risk factor for and a potential consequence of mental disorders. Food and housing insecurity are associated with economic disadvantage, and may also be associated

Telegram: @medical_k

www.konkur.in

with climate change, disasters, and war. Food insecurity may affect childhood academic performance, social skills, and other markers of poor mental health. Children in food insecure environments have been found to have increased symptoms of depression, anxiety, and other behavioral problems.

The original ACE study has brought attention to the impact of adverse childhood experiences (ACEs) on lifelong physical and mental health as well as other social outcomes. ACEs include childhood psychological, physical, or sexual abuse, or living with household members who abuse substances, have mental illness, are incarcerated, or exhibit violence against mothers. The initial study conducted involved mainly a White sample (79.8%). A subsequent study done in Philadelphia included a more diverse sample in an inner-city setting and expanded ACEs to include bullying, community violence, low neighbor safety, racism, and living in foster care. The study found that 83.2% reported at least one ACE, with Blacks experiencing significantly higher urban ACE indicators than Whites in witnessed violence, discrimination, adverse neighborhood experiences, and living in foster care. ACEs are associated with mental disorders, substance use, multiple sexual partners, suicide attempts, and worse physical health. Children with higher ACE scores are at a higher risk of being trafficked.

Exposure to violence–whether due to domestic violence, crime, disasters, or war–increases the risk of developing mental disorders, in particular post-traumatic stress disorder (PTSD). Lives lost to natural disasters occur in low- and middle-income countries (LMICs) in part due to poverty, living in unsafe housing, and weak social safety and support systems. Exposure to trauma has been shown in some studies to have an intergenerational impact. Attitudes toward mental health care vary at the individual level and among cultural groups and governments. The WHO 2020 Mental Health Atlas found that 35% of countries do not have stand-alone mental health laws. Lower-income countries spend disproportionality less of their health care budget on mental health.

MENTAL HEALTH OF RACIAL, ETHNIC, AND MIGRANT POPULATIONS

Common Mental Disorders among Minoritized Ethnoracial Populations

Telegram: @medical_k

www.konkur.in

Multiple studies in the United States have examined the prevalence of mental disorders across ethnoracial groups. They have generally found lower prevalence of common nonpsychotic mental disorders among minoritized ethnoracial groups compared to White Americans. One of the largest sets of epidemiologic data comes from the Collaborative Psychiatric Epidemiology Surveys (CPES), which joins together three national representative surveys conducted from 2001 to 2003: the National Comorbidity Survey-Replication (NCS-R), The National Latino and Asian American Survey (NLAAS), and The National Survey of American Life (NSAL). The NCS-R is a nationally representative survey of a predominately non-Hispanic White sample (n = 9,282). The NLAAS is a survey of Asians (Chinese, Vietnamese, Filipino, and other Asians, n = 2,095) and Latinos (Mexicans, Cubans, Puerto Ricans, and other Latinos, n = 2,554). The NSAL included African American (n = 3,570), Afro-Caribbean (n = 1,623), non-Latino White (n = 1,006) adults, and Afro-Caribbean and African-American adolescents (n = 1,200).

In a 2019 analysis of the consolidated dataset of 21,024 Americans, combining CPES with the National Comorbidity Survey Reinterview (NCS-2), non-Latino Whites were found to have higher rates of mood, anxiety, and substance disorders (22.6%, 26.1%, 18.8%) than Asians (12.0%, 13.1%, 5.1%), Blacks (13.6%, 21.7%, 13.7%), and Latinos (17.3%, 19.8%, 16.2%), consistent with past analyses. These comparative differences remained significant after controlling for nativity, except for Latinos. However, analysis of the 2005 to 2012 U.S. National Health and Nutrition Examination Survey of 12,272 participants aged 40 to 79 years found a higher prevalence of depressive disorders among Latinos (11.3%) and African Americans (10.4%) than non-Latino Whites (7.1%). The more recent All of Us study, a national cross-sectional study collecting voluntary data from 214,206 Americans from 2018 to 2021, found lower prevalence of mood, anxiety, substance use, and personality disorder disorders among Asian, Black and African American, Hispanic/Latino populations compared to non-Hispanic Whites.

It has been proposed that the observed lower prevalence among minoritized ethnoracial groups may be due to the relative protective effects of non–majority-White cultural backgrounds, such as interdependence, familism, collectivism, or religious practices; the relative negative effects of mainstream U.S. society; or the “immigrant paradox” (see next section). Stronger minoritized ethnoracial identity, being foreign-

Telegram: @medical_k

www.konkur.in

born, and lower English proficiency as a proxy measure of lower acculturation were all negatively associated with mood disorders, while non-Latino White Americans with at least one parent born in the United States had a higher risk of mood disorder than non-Latino Whites who were foreign-born or both of whose parents were foreign-born. In addition, another sociocultural hypothesis is that non-Latino Whites with less education and limited job opportunities may have increased vulnerability compared to other minoritized ethnoracial groups in a system where there is a higher social expectation of success for Whites.

www.konkur.in

FIGURE 4.2–1. Social determinants of mental health. (Adapted and reprinted with permission Compton MT, Shim RS. The social determinants of mental health. *Focus*. 2015;13:420.)

Although there is a finding of lower prevalence, analysis of the combined CPES and NCS-2 dataset also found that Asian, Latino, and

Telegram: @medical_k

www.konkur.in

Black populations with mood disorders were more likely to be persistent compared to non-Latino Whites. While a longitudinal study of 423 African American and White women from 1996 to 2009 did not replicate this finding, it did find a higher number of women with seven or more depressive episodes among African Americans compared to Whites. These differences, suggesting higher severity or chronicity among racialized populations, may reflect differences in access to care and/or the impact of ongoing stressors due to structural factors.

The NLAAS compared the prevalence of mental disorders among Puerto Ricans, Cuban Americans, Mexican Americans, and other Latinos. Puerto Ricans had the highest overall prevalence of mental disorders among the Latino groups assessed. Increased rates among Puerto Ricans were noted for depressive, anxiety, and substance use disorders. Mexican Americans had the lowest risk among the Latino groups for depressive disorders. Cuban Americans were at the lowest risk for substance use disorders and, among men, for anxiety disorders. Differences among the Latino groups in overall risk for lifetime mental disorders were also noted, with Cuban American men, Mexican American men, and “Other” Latina women having significantly lower risk than their Puerto Rican counterparts. The increased risk for mental disorders among Puerto Ricans compared to other Latino groups has been noted in other studies. More detailed analysis of disaggregated data of the CPES also found African Americans, Puerto Ricans, and Mexicans to have significantly higher chronicity of mental disorders compared to non-Latino Whites. Disaggregated data can yield a finer understanding of health disparities.

Common Mental Disorders among Immigrants

Although immigrants are vulnerable to stressors related to migration, acculturation, discrimination, and other psychosocial predicaments, the healthy immigrant paradox or the healthy immigrant effect hypothesizes that immigrants may have better physical and mental health than native-born individuals because of several factors. These include the somewhat stringent criteria for immigration, as well as selection bias of relatively healthier and more resourced individuals who apply for immigration. Research from the United States, unlike some studies from Europe, is largely consistent with this hypothesis.

Telegram: @medical_k

www.konkur.in

The CPES studies generally found immigrants to have lower prevalence of mental disorders compared to U.S.-born individuals. The NCS-R found that immigrants, which included Hispanics (50.7%), non-Hispanic Whites (38.3%), and non-Hispanic Blacks (11%), had a lower lifetime risk of mental disorder than U.S.-born individuals (OR = 0.7), although immigrants who arrived in the United States at age 12 or younger had similar rates of mood and impulse control disorders as the U.S.-born. The NLAAS found that Asian immigrants had a lower risk of lifetime mood, substance, and any mental disorders compared to U.S.-born Asians, with U.S.-born Asian men being at greatest risk of substance use disorder and U.S.-born Asian women being at greatest risk of mood disorders. Among immigrant Asian men, low income and poor English proficiency were associated with a higher risk of mood disorders. The NLAAS found lower rates of most mental disorders among immigrant Latinos compared to U.S.-born Latinos. Disaggregated data found that the lower rates for depressive and anxiety disorders only applied to Mexicans, and lower substance use rates were observed among Mexicans, Cubans, and Other Latinos. No evidence for the immigrant paradox was found among Puerto Ricans. Puerto Ricans are U.S. citizens at birth and would not need to go through the U.S. immigration system. Scholars suggest that they should be classified as internal migrants rather than immigrants, and as noted in other studies, they may have relatively higher mental healthcare needs compared to other Latino immigrants. Data from the NESARC-II (2004 to 2005) confirmed these findings among Latino subgroups, adding that the risk of mental disorders among Mexican-origin respondents increased linearly with rising acculturation indices; these associations were in the same direction, but less consistent for Cuban Americans and other Latinos and no association with acculturation was found among Puerto Ricans. In the NSAL study, first-generation Caribbean Black immigrants had lower prevalence of mental disorders compared to the second- and third-generation U.S.-born Caribbean Blacks, with third-generation respondents having the highest rate. Among women, this difference was limited to substance use disorders.

The NESARC-III (2012 to 2013) found that DSM-5 lifetime mental disorders were significantly less prevalent among all immigrants compared to U.S.-born individuals: 20.3% and 34.9% respectively. The lower prevalence was found for generalized anxiety disorder, major depressive disorder, persistent depressive disorder, panic disorder, social

Telegram: @medical_k

www.konkur.in

phobia, specific phobia, and post-traumatic stress disorder, but not bipolar disorder. Immigrants who arrived as adolescents (ages 12 to 17) and as adults (age 18+) had significantly lower prevalence of mental disorders compared to the U.S.-born, but the difference was not significant for immigrants who arrived as children. Being in the United States for over ten years was associated with a higher risk of mental disorder compared to more recently arrived immigrants, although the risk for both immigrant groups was still lower than for the U.S.-born. Except for immigrants from Puerto Rico, immigrants from other countries in the study had lower rates of mental disorders compared to native-born, consistent with the NLAAS and NESARC-II findings; immigrants from Vietnam and South Korea also did not differ from their U.S.-born counterparts, which may be explained by smaller sample sizes.

Most recently, the All of Us study similarly found a lower prevalence of mood (OR 0.77), anxiety (OR 0.73), substance use (OR 0.41), stress-related (OR 0.80), schizophrenia (OR 0.57), and personality (OR 0.64) disorders among the non–U.S.-born populations compared to their U.S.-born counterparts.

As proposed by the healthy immigrant effect hypothesis, immigrants who arrive as children may not have an advantage over nonimmigrant children as they are not the main applicants for immigration. Further, child immigrants, as well as second-generation immigrants, are exposed to several adversities. Despite the potential advantages of better cultural adaptation and language skills than their parents, they may experience stress from encountering discrimination, such as being bullied at schools; experiencing social disadvantages such as poverty and growing up in disadvantaged neighborhoods; feeling caught between heritage and mainstream identities and cultures; erosion of protective aspects of their heritage culture or up-taking negative aspects of mainstream cultures, such as substance abuse; experiencing early parentification; or having higher parental pressures to succeed as immigrant families. A recent study using the NCS-R adolescent supplement found that compared to third-generation non-Hispanic White adolescents, there was a higher prevalence of mood and anxiety disorders among second-generation Asians (OR 2.51) and third-generation Hispanics (OR 1.28), but a lower prevalence among first-generation Asians (OR 0.27) and second-generation non-Hispanic Whites (OR 0.5). Behavioral disorders were lower among first-generation Asians (OR 0.26) and all generations of non-

Telegram: @medical_k

www.konkur.in

Hispanic Black adolescents compared to non-Hispanic White adolescents. Research has also found that the risk of substance use disorder among Asians and Latinos increases across generations, possibly due in part to the loss of the protective effects of stronger cultural sanctions against substance use reflected in the lower rates of their use in China and Mexico (Table 4.2–3).

Schizophrenia and Psychotic Symptoms. For psychotic disorders, the Alameda County Kaiser Permanente California birth cohort study of 19,044 people followed over 1981 to 1997 found a 3.27-times higher risk of a schizophrenia-spectrum diagnosis for African Americans compared to Whites. Epidemiologic data on 16,423 Americans from the CPES found a higher lifetime prevalence of psychotic symptoms among Blacks (15.3%) and Latinos (13.6%) compared to non-Latino Whites (9.7%) and Asians (9.6%). Low ethnic identity has been found to increase the risk of psychotic symptoms. In a review of empirical studies in the United States from 1989 to 2013, African Americans and Latinos had over three times higher odds of being diagnosed with schizophrenia compared to Whites; rates were also increased for other psychotic disorders.

Table 4.2–3.

[c]denotes $P < .05$.
The reference groups for nativity (OR = 1) are those born in the United States from the same ethnoracial group. The reference groups for generational status (OR = 1) are first-generation migrants to the United States from the same ethnoracial group.

A 2011 meta-analysis of 21 population-based studies on migration and psychotic disorders conducted between 1977 and 2008 found that first and second-generation immigrants overall had 2.3- and 2.1-times higher

Telegram: @medical_k

www.konkur.in

risk of developing psychosis, respectively, compared with nonimmigrants; first and second-generation Black immigrants had 4.0- and 5.4-times higher risk. Respondents were from Australia, Canada, Denmark, Israel, Netherlands, Sweden, and the United Kingdom, but not the United States.

Most recently, a 2019 meta-analysis of 24 studies examining the effect of both ethnicity and migration on psychosis in the general population found that ethnic minorities (defined as ethnic groups representing less than half of the total population) conferred a 1.44-times higher risk for reporting psychotic symptoms and 1.36-times higher risk for reporting psychotic experiences. The latter refers to the presentation of milder psychotic symptoms not reaching the threshold of clinical relevance, operationalized in the meta-analysis as studies that excluded people with psychotic disorders. Among ethnic groups studied, the greatest risk for psychotic symptoms was observed among populations from the Maghreb and the Middle East in Europe (OR 3.3), Hispanics in the United States (OR 1.98), and Black populations (OR 1.85), all of which are populations which are disadvantaged or discriminated against in their local context. The increased risk experienced by ethnic minorities also differed between countries, including the United States (OR 1.59), the United Kingdom (OR 1.38), and the Netherlands (OR 2.74). Studies from HICs (OR 1.55) were higher than low and middle-income countries (OR 1.03), which did not have an elevated risk. Migration was only associated with an increased risk of delusional symptoms.

One of the factors contributing to the observed elevated prevalence of schizophrenia among Black individuals is diagnostic bias, whereby psychotic disorders are overdiagnosed and affective disorders are underdiagnosed, a finding supported by multiple studies over the years. For example, in a study of admitted patients with psychotic symptoms and an expert-consensus diagnosis of a DSM-IV affective disorder, African-American patients were more likely than other patients to be diagnosed with a schizophrenia-spectrum disorder by clinical assessment or structured interviews. A similar pattern of overdiagnosis has been found in various other clinical settings. In a study of 610 in- and out-patients at academic medical centers, African Americans had a higher prevalence of schizophrenia diagnoses even after controlling for the rate of severe affective disorders. A recent study found that among patients with a diagnosis of schizophrenia at a community outpatient clinic, African Americans were 8.2 times more likely than non-Latino Whites to have

Telegram: @medical_k

www.konkur.in

moderately severe to severe depressive symptoms, suggesting possible misdiagnosis. The race of the clinician may also influence the diagnostic decision-making process. For example, in an inpatient study, clinician's race was not found to impact the prevalence of a schizophrenia diagnosis, but African American clinicians tended to associate positive symptoms with schizophrenia, while non-African American clinicians tended to associate negative symptoms with schizophrenia. In a 2018 meta-analysis of 55 studies from 1983 to 2017, Black Americans were found to be diagnosed with schizophrenia 2.42 times more frequently than White Americans. The use of structured (OR 1.59) over unstructured (OR 2.43) diagnostic assessments appeared to have a small though not statistically significant impact in decreasing this elevated risk. The study year was not a significant predictor of diagnostic disparities, suggesting that there has been no improvement over time despite research attention to this issue for years.

In addition to diagnostic bias, most researchers agree that the observed higher risk of psychosis among migrant and minoritized ethnoracial groups is related to the interrelated effect of social determinants of health and structural racism. In fact, many have argued that overemphasis on diagnostic biases in the literature may detract from a focus on structural causes for higher rates. The elevated risk for a schizophrenia-spectrum diagnosis among African Americans relative to Whites in the Kaiser Permanente California study was reduced to 1.92 after adjustment for socioeconomic status indicators at birth. In U.S. studies, perceived discrimination is associated with elevated psychotic symptoms in the general population, and police discrimination is associated with lifetime increases in psychotic experiences among Black individuals. A 2013 meta-analysis found that the prevalence of psychotic disorders was higher in low-ethnic density areas compared to high-ethnic density areas, implicating the deleterious effect of racism. Recently, a model was proposed to comprehensively examine and address the relationship between structural racism and psychosis in the U.S. context, noting especially the increased exposure to social risk factors in Black and Latino populations. Multiple exposures to neighborhood-level disadvantage, individual-level social disadvantage, collective trauma, and everyday discrimination may lead to cumulative stress, which, through genetic vulnerability, perinatal complications, and altered neurobiology, may result in various forms of psychosis.

MENTAL HEALTH CARE DISPARITIES FOR MIGRANT AND MINORITIZED ETHNORACIAL POPULATIONS

Mental Healthcare Utilization

Lower service utilization rates among U.S. racial and ethnic minorities compared to Whites have been the norm in research studies over several decades, with various access barriers and the lack of culturally competent services being implicated.

In the NLASS study, among Asians, only 8.6% of the sample and 34.1% of the subset with a probable DSM-IV diagnosis of mood, anxiety, or substance disorder in the past 12 months utilized mental health-related services, compared to 17.9% and 41.1% respectively in the total NCS-R sample. In the Latino sample, the utilization rates among Puerto Ricans, Cubans, and Mexicans were 19.9%, 11.5%, and 10.1%, respectively; these rates increased to 43.0%, 41.9%, 34.2% among respondents with probable DSM-IV diagnoses in the past 12 months.

Subanalyses of the Asian sample found that U.S.-born Asians were more likely to utilize services than foreign-born; for example, third-generation individuals with a probable diagnosis had a high utilization rate of 62.6%. Subanalyses of the Latino sample found that nativity, language, age of migration, years of residence in the United States, and generational status were associated with mental health care use only for those without a probable diagnosis; in this subgroup, Puerto Ricans were significantly more likely to use services than Cubans, Mexicans, and other Latinos. Another major factor determining mental healthcare use was insurance. For those with a probable psychiatric disorder, only 19.1% of uninsured Latinos used services, compared to 38.6% with private insurance and 51.6% with public insurance.

In the NSAL, most African Americans with major depression did not seek mental health care. Only 45.0% of African Americans and 24.3% of Caribbean Blacks received treatment of any type. In addition, mental health service utilization did not significantly increase as symptom severity increased. Only 48.5% of African Americans and 21.9% of Caribbean Blacks with severe or very severe symptoms received any psychiatric treatment.

A study using national representative data from the 2004 to 2012 Medical Expenditure Panel Survey (MEPS) found that access to any

Telegram: @medical_k

www.konkur.in

mental health care increased from 16% to 20% for non-Hispanic Whites, 8% to 9% for Hispanics, 7% to 10% for Blacks, and from 3% to 5% for Asians between 2004 and 2012. The Black/White and Hispanic/White disparities are widening in accessing mental health care and use of psychiatric medications; Asians consistently show the lowest mental healthcare utilization. Overall, the study found no reduction in disparities for any mental health care use, outpatient mental health care, or access to psychiatric medications after controlling for clinical needs.

A study on the impact of the 2008 Mental Health Parity and Addiction Equity Act (MHPAEA) and the 2010 Patient Protection and Affordable Care Act (ACA) examined changes in healthcare utilization patterns from 2006 to 2014, including ethnoracial and gender differences. The 2014 mental health visits for men and women respectively were: 6.7% and 9.2% for Whites; 4.7% and 6.3% for Hispanics; 5.7% and 7.5% for Blacks; and 1.6% and 3.5% for Asians, with no significant difference observed between 2006 and 2014. Subanalyses showed that utilization by Asian men significantly decreased from 2012 to 2014 by 2.4%.

Disparities in healthcare utilization have also been found in individuals with suicidal behaviors. In a study using the National Survey on Drug Use and Health from 2009 to 2016, among suicide attempters, outpatient care usage was lower among non-Hispanic Blacks, Hispanics, and multiracial individuals compared to non-Hispanic Whites, and Hispanics were also less likely to receive inpatient care. Among individuals with suicide ideation but no attempts, outpatient care usage was lower among non-Hispanic Blacks, Hispanics, and Asian, Hawaiian and Pacific Islanders compared to non-Hispanic Whites. The overall pattern suggests that ethnoracial minorities underutilize outpatient services until inpatient treatment is required.

Disparities in Mental Health Treatment

Many studies have consistently documented disparities in the quality of mental health care received by minoritized ethnoracial groups.

A 2016 systematic literature review summarized disparities in the diagnosis and treatment of major depressive disorder among ethnoracial minorities. Consistent with epidemiologic studies, clinical research generally found lower rates of diagnosis of depression, attributable in part to underdiagnosis by clinicians, differences in symptom presentation or help-seeking behaviors, and cultural insensitivity of some psychometric

Telegram: @medical_k

www.konkur.in

measures. In terms of treatments for depression received, African Americans and Hispanics were less likely to receive adequate care according to evidence-based guidelines compared to Whites. Undertreatment of depression was similarly found in various subpopulations including older adults, adolescents, and postpartum women, and in various healthcare settings, including primary care. African Americans and Hispanics were less likely to receive antidepressants, less likely to fill these prescriptions, and more likely to discontinue medications prematurely. There were similar findings of undertreatment among Asians. African American inpatients were less likely to receive ECT. Utilization of psychotherapy was more mixed; many minoritized ethnoracial groups reported preferring therapy over medications when given the choice and if language and insurance coverage were not barriers. The 2000 Medical Expenditure Panel Survey found that African Americans were more likely than Hispanics and Whites to receive adequate psychotherapy. Hispanics were less likely than Whites to receive counseling during primary care visits, and in another study, Hispanics without adequate insurance coverage to supplement Medicare were less likely to receive psychotherapy. In a depression study conducted in the Veterans Administration system, which would have mitigated against coverage differences, there were no differences in receipt of adequate psychotherapy by race or ethnicity.

A 2017 review of 131 studies summarized key findings on diagnostic, treatment, and outcome disparities affecting ethnoracial groups with severe mental illness (SMI), including schizophrenia, bipolar disorder, and recurrent depression. In medical settings, Black respondents received higher doses of antipsychotics, higher use of depot antipsychotics, and lower use of second-generation antipsychotics (SGA). In terms of outpatient treatment, Blacks in the Veterans Administration system were less likely than Whites to have follow-up visits after an index diagnosis of bipolar disorder or to receive regular follow-up visits after hospitalizations. Both Blacks and Hispanics/Latinos had lower use of case management services. Regarding the quality of care, Blacks, compared to Whites, were more likely to be involuntarily hospitalized, use crisis services, enter emergency treatment by means of law enforcement, receive higher doses of antipsychotic medications, and less likely to receive minimally adequate treatment for SMI, defined as medication management and at least four follow-up visits, or receive treatment for comorbid depression. In treatment

Telegram: @medical_k

www.konkur.in

engagement, racial and ethnic minorities were found to have a higher risk of premature treatment discontinuation. In terms of outcomes, Blacks showed less improvement in psychotic symptoms, were less likely to return to work, and experienced less improvement in functioning at 1-year post-discharge.

Several recommendations converge from various reviews to better address disparities in providing care for ethnoracial minorities. Upstream social determinants of health need to be addressed to prevent mental illness and enable ethnoracial minorities to receive care. Stigma and health literacy need to be addressed through community engagement strategies using culturally appropriate messaging. Increasing diversity representation in the healthcare system and cultural competency training may increase trust in the system over time. Service development and planning need to be inclusive of the voices of patients, families, and communities, including involving individuals with lived experience in the delivery of care. Treatment interventions, programs, and services need to be culturally competent, and more interventions need to be developed involving families and communities. Spiritual and religious values and practices need to be taken into consideration and integrated into care.

MENTAL HEALTH OF INDIGENOUS PEOPLES OF THE UNITED STATES

For thousands of years, millions of Indigenous Peoples lived as diverse Nations in North America until colonization around 600 years ago by European powers and later the United States government, which sanctioned massacres, forced removals, decimated traditional food systems, and introduced infectious diseases to the populations. From the 1950s to 1970s, policies promoting relocation and forced assimilation were imposed on American Indians/American Native (AI/AN) communities. This included forcibly removing children from their homes into residential schools and foster care services through child protection services to isolate them from their cultures, exposing many to various forms of physical, sexual, or emotional trauma. In 1978, the Indian Child Welfare Act prevented the federal government from continuing to take children away from their homes and the American Indian Religious Freedom Act prevented federal programs from further prohibiting AI/AN religions and cultures. By then, generations had been impacted.

Telegram: @medical_k

www.konkur.in

Currently, there are 9.7 million U.S. AI/AN people (i.e., people who report AI/AN background as their only identity or one of several identities) living in the United States, comprising 574 recognized tribes and representing about 2.9% of the total U.S. population. While there are up to 245 indigenous languages recognized in the United States, 65 are extinct and 75 are in jeopardy. Life expectancy at birth of AI/AN in 2021 was 65.2 years compared to 76.1 years for the general U.S. population. AI/AN people are five times more likely to die of alcoholism and liver disease, and twice as likely to have diabetes mellitus compared to Whites. The indigenous population also has higher rates of accidents, violence, suicide, and homicide than the majority U.S. population. Suicide rates are higher among AI/AN groups compared to Whites, with three times the rate of death by suicide among those under age 25. Among all ages and sexes, the death rate due to mental and behavioral disorders for AI/AN is 1.10 to 1.53 times higher than for Whites; between the ages of 15 to 24, AI/AN men have 2.38- to 2.69-times higher risk of death than African Americans. One-third of the Native American population does not receive regular health care.

Studies indicate that AI/AN are at a higher risk for mental disorders. A nationally representative psychiatric epidemiologic study, NESARC, which included a small sample of AI/AN (n = 701), found that they have higher rates of any psychiatric disorder, any mood disorder, and any substance use disorder compared to non-Hispanic Whites.

Several studies have focused on the prevalence of mental disorders among specific groups of AI/AN. The American Indian Service Utilization, Psychiatric Epidemiology, Risk and Protective Factors Project (AI-SUPERPFP) worked with Southwest Indian and Northern Plains Indian communities. Compared to other ethnoracial groups, AI/AN was at higher risk of alcohol use disorders and PTSD but at lower risk for major depressive disorder. Among individuals exposed to DSM-IV–defined traumatic events, 15.9% qualified for a lifetime diagnosis of PTSD, comparable to other U.S. studies, suggesting that the higher prevalence rate of PTSD among AI/AN may be due to higher traumatic exposure.

Studies of American Indian Vietnam Veterans from the Northern Plains and the Southwest also found very high rates of PTSD: 31% and 27% for current prevalence and 57% and 45% for lifetime prevalence, respectively. This rate was significantly higher than among Vietnam war veterans of other ethnoracial groups, including Whites, African Americans, and

Telegram: @medical_k

www.konkur.in

Japanese Americans. AI/AN veterans were more likely than other groups to have been exposed to war-zone stress in Vietnam, including combat exposure, being wounded, and having noncombat injuries. This higher exposure to war-zone stress accounted for the high rate of PTSD among AI/AN veterans compared to other ethnoracial groups. These veterans also had higher prevalence of alcohol use disorders: over 70% (current) and 80%% (lifetime), compared to much lower prevalence for other ethnoracial groups: 11% to 32% (current) and 33% to 50% (lifetime).

AI/AN children were more likely to receive mental health treatment through the juvenile justice system and inpatient facilities than non-AI/AN children. In 2017, 752 AI/AN youths lived in residential placement, which included detention centers, group homes, and boot camps, according to the National Center for Juvenile Justice. Among adults, AI/AN were more likely to seek help for substance use problems than Whites but less likely to seek help for depressive and anxiety disorders. Less than 30% of those with a mental disorder obtain help from mental health service providers.

Indigenous Historical Trauma (IHT), a synthesis of historical oppression and psychological trauma, is an important concept proposed to help understand the trauma experienced by AI/AN arising from colonization and oppression. Historical trauma is preferred over the term racial trauma as the indigenous identity is closely related to tribal identity, which is an ethnic rather than racial identity. The distinguishing core features of IHT are that it is colonial in origin, collective in impact, cumulative across adverse events, and crossgenerational in the transmission of risk and vulnerability.

A recent systematic review of IHT was conducted on research from the United States and Canada. Although AI/AN consist of diverse and distinct groups of people living throughout North America, they share similar experiences of colonial history and oppression, such as residential schools, with the notable difference that U.S. schools were substantially reformed in the 1930s while Canadian schools were unreformed until the 1970s. Most studies report IHT to be associated with adverse mental health outcomes, but the results are complex and specific, making it challenging to formulate definitive conclusions. Not all AI/AN attended residential schools, nor have family members who did. Among those who attended, including some who experienced abuse, not all reported being adversely impacted. While there can be further refinements in the methodology to conduct research into IHT, the concept should be used as

Telegram: @medical_k

www.konkur.in

a metaphorical understanding of the complex nature of the trauma experienced by AI/AN rather than as a literal and discrete psychological construct.

Another recent systematic review identified a dearth of empirical studies on mental health interventions that specifically address IHT, revealing mixed results. Findings suggest that sharing IHT memories might be cathartic; treatments integrating traditional healing and tribal practices might be helpful, and incorporating ceremonies into interventions might provide a culturally safe and affirming space for healing.

Clinicians should be aware of the potential role of IHT, the diversity among AI/AN communities and individuals, as well as the social determinants of health impacting AI/AN experiences, including poverty, lack of infrastructure, and ongoing racism. Individual treatment and service planning need to be attuned to their social, cultural, and spiritual needs. Possible interventions include promoting connections with extended families and cultural networks; collaborating with communities and elders including the incorporation of cultural and spiritual teachings as well as traditional knowledge and rituals; and doing advocacy work to address disparities in the social determinants of health and promote indigenous rights.

At a systems level, the Indian Health Services (IHS), established in 1955, currently provides healthcare to 2.6 million AI/AN through a combination of federal IHS programs, Tribally Operated Health Care Services, and Urban Indian healthcare services and resource centers. In many service areas, only about 7% of IHS federal funds are allocated to mental health. Compared to Whites, AI/AN report higher dissatisfaction with the quality of care received and poorer communications with their healthcare providers. Many AI/ANs who moved to the cities encouraged by various federal policies over decades have encountered difficulties accessing IHS. Surveys by AI/AN advocacy groups indicate that better care is received from tribally run programs than those under federal IHS management. The Substance Abuse and Mental Health Services Administration (SAMHSA) administers substance abuse prevention and mental health service grants, including grants to eligible AI/AN entities. SAMHSA has recently launched Circles of Care and Native Connections programs, which provide grant funding for AI/AN-focused services. Overall, key issues that still need to be addressed include underfunding,

Telegram: @medical_k

www.konkur.in

limited human resources, and lack of culturally and spiritually appropriate services.

A well-known example of a successful indigenous initiative is the Alkali Lake community in Canada, where alcoholism decreased from 95% to 5% over 10 years, and the story is captured in a film. Another example is the work of White Bison, a nonprofit grassroot organization in Colorado Springs, which published The Red Road to Wellbriety, a cultural competent text combining teachings of the Medicine Wheel and 12-step programs.

MENTAL HEALTH OF REFUGEES

Unlike those who emigrate voluntarily, often for primarily economic reasons, refugee populations have been highly traumatized prior to migration and are at a higher risk for mental disorders including depression and PTSD. For example, the NLAAS sample included 660 refugees. Premigration onset of PTSD was 4.86 times higher for refugees (3.5%) compared to voluntary migrants (1.2%), while there was no significant difference in the onset of PTSD postmigration.

Among Southeast Asian refugees, premigration trauma was a significant factor in predicting psychological distress even 5 years after migration to the United States. Some studies have suggested that up to 70% of Vietnamese, Cambodian, and Laotian refugees have PTSD. A community survey among Cambodian refugees found that 45% had PTSD and 51% suffered from depression. Adolescent Cambodian refugees also have high prevalence of depression; 41% had depression even ten years after their traumatic exposure. Among adult refugees arriving in the United States, Vietnamese refugees are at higher risk for depression than Chinese refugees. Even two decades after resettlement, Cambodian migrants have very high rates of PTSD (62%) and major depression (51%). Over 70% experienced violence after migration to the United States. A dose-response relationship has been observed between an increasing degree of exposure to trauma (both premigration and postmigration) and an increased likelihood of a current mental disorder. The most extensive study on Cambodian refugees using a structured diagnostic instrument found that women were no more likely than men to develop PTSD or depression.

The Bhutanese is one of the largest groups of South Asian refugees in the United States; about 90,000 arrived between 2008 and 2012. The prevalence of depression was reported by the CDC to be 21%, with a high suicide rate of 21.5 per 100,000. Being a family provider, self-reporting poor health, and being illiterate in their native language were risk factors for depression. In another recent study of 225 Bhutanese resettled in Massachusetts, 24% and 34.2% had moderate to severe symptoms of depression and anxiety, respectively. High resilience was associated with reduced symptoms of depression and anxiety, with personal competence accounting for most of the effects.

Approximately 91,000 Iraqis refugees arrived in the United States from 2008 to 2013. Most refugees prior to resettlement came from dispersed urban areas in Jordan, Syria, Iraq, Turkey, and Lebanon, rather than through refugee camps. Among Iraqi refugees living in the United States between 8 and 36 months, 27% were depressed and 31% had PTSD. In another study, among a sample of Iraqi refugees assessed 1 year after arrival, 9% reported having been kidnapped; on the SCID-1, 4% met PTSD criteria and 3% met MDD criteria. Those who experienced kidnapping had a higher prevalence of PTSD, but not MDD.

The Syrian conflict began in 2011, resulting in one of the largest refugee crises since World War II, with about 6 million having fled the country. Most have fled to neighboring Lebanon, Jordan, and Turkey, as well as Europe. The United States has taken in more than 23,000 Syrian refugees since 2011. Syrian refugees (n = 157) screened at primary care in Michigan a month after their arrival had a high risk of suspected PTSD (32%), depression (47.7%), and anxiety (40.3%). In a recent systematic review of 15 studies, including 8,176 Syrian refugees resettled in 10 countries, comparable prevalence was found for post-traumatic stress (43.0%; 23.4% to 83.4%), depression (40.9%; 20% to 44.1%), and anxiety (26.6%; 19.30% to 31.8%); the wide ranges were due to diverse research methodologies and country settings. Like Somali and Iraqi refugees, most Syrian refugees are Muslim, and they may be at risk of encountering discrimination due to Islamophobia and challenges with a healthcare system that is not culturally or religiously suitable for their needs.

A 2020 meta-analysis of 26 studies on refugees and asylum seekers around the world reported a prevalence of PTSD at 31.5%, depression at 31.5%, anxiety disorders at 11%, and psychosis at 1.5%. Similarly, in a 2022 meta-analysis of 40 studies on refugees and asylum seekers, the

Telegram: @medical_k

www.konkur.in

prevalence of PTSD was 31%, MDD 32%, bipolar disorder 5%, and psychosis 1%. Subgroup analyses showed a higher prevalence of MDD in studies conducted in LMICs compared to HICs.

The role of mental health professionals is frequently not well understood by refugees. For example, while Congolese refugees were found to have many mental health problems, including depressive, anxiety, and substance use disorders, as well as domestic violence, many declined mental health services. However, in a controlled trial of psychotherapy with Congolese survivors of sexual violence, group psychotherapy was more effective than individual support in decreasing depression and anxiety symptoms, PTSD symptoms, and functional impairment. This suggests that it may be challenging to build safety and trust in a traditional one-on-one approach with some refugees, while it may be more efficacious to facilitate the collective capacity to heal and develop resilience through group approaches.

Another study of refugees from Bhutan, Burma, Ethiopia, and Somalia found that refugees were willing to report their symptoms when these were described within their political context in focus groups; moreover, their PTSD symptoms varied across cultural settings. The study highlighted the need to ask refugees about their symptoms in context, including political history and struggles and the impact of symptoms on their functioning. Across groups, there were common reports of cognitive symptoms, described as “thinking too much,” and physical symptoms, such as head, stomach, and body pain. Expression of emotional experiences was culturally specific, such as Oromo refugees describing feeling “burning from the inside” and Somalis describing having “air in the brain” or feeling “not dead or alive.” These expressions highlight the combination of universal and culturally specific ways of experiencing and communicating distress.

The premigration life of refugees from war-torn developing countries ill prepares many for the difficulties encountered upon migration, due to limited occupational skills and educational attainment, barriers to cultural integration including language, and significant premigration health and mental health problems. These difficulties often place them in a continuing position of psychosocial vulnerability and at risk for chronic mental illness. Premigration traumatic experiences and postmigration stress are associated with PTSD and depressive or anxiety disorders.

Telegram: @medical_k

www.konkur.in

Postmigration factors may mediate the negative impacts of premigration stressors and may have even greater impact on mental health than premigration stressors. These include detention, harsh living conditions, financial stress, length of the asylum process, legal status, sense of belonging, family separation, social isolation, discrimination, and cultural adaptation. Though often studied together with refugees, asylum seekers appear to be at an increased risk of developing mental disorders compared to refugees due to their precarious legal status. In a systematic review of postmigration social and environmental factors facing asylum seekers, discrimination and postmigration stress were linked with increased risk of mental disorders, underscoring the need to provide support for the postmigration settlement process.

For premigration trauma, studies have found empirical support for cognitive behavior therapy, narrative exposure therapy, eye movement desensitization and reprocessing, and other forms of psychotherapy. There have also been a few studies describing the effectiveness of community-based psychosocial programs. Clearly, there is a need to develop an effective and integrated approach to refugee care that takes into consideration their complex needs beyond narrowly focusing on individual psychopathology. A Multitier Mental Health and Psychosocial Support (MHPSS) model has been adapted for humanitarian settings, which provides mental health care for resettled refugees. The model includes four tiers: (1) social adjustment and integration to provide basic services through resettlement programs; (2) family and community support through community-based psychosocial interventions; (3) bereavement and trauma healing through trauma-focused interventions; and (4) specialized mental health treatment through psychiatric services. Being culture-informed and trauma-informed are the two central pillars of the model across tiers, highlighting their critical importance to refugee care. This approach also emphasizes the need to breakdown silos between tiers and between services and the need to engage families and communities in collective empowerment and healing.

CULTURE AND MENTAL HEALTH

Although culture impacts the daily mental functioning of every person, it is often dismissed as irrelevant or only pertaining to racialized or minoritized groups. This presumption has led to the development of theory and

Telegram: @medical_k

www.konkur.in

knowledge about normal mental functioning that is largely defined by and founded on Western Eurocentric cultural frames of reference and norms. Joseph Henrich has argued that most basic psychological research is based on Western, Educated, Industrialized, Rich, Democratic ("WEIRD") populations, often from White college samples, despite the fact that many of their basic psychological measures such as visual perception, spatial reasoning, categorization, inferential induction, moral reasoning, and self-concepts are outliers when compared to data from most other world populations. Recognition and systematic study of sociocultural differences are key steps toward advancing scientific, clinical, and structural work in mental health.

When exploring group-level cultural differences, a key principle of cultural psychiatry is to avoid stereotyping, which can give a false sense of expertise. Every individual is unique, and their mental wellbeing is affected by their own life experiences as well as particular biologic, psychological, social, cultural, spiritual, and other environmental factors, interacting across time and contexts. Thus, culture should neither be ignored nor used as a simplistic categorical tool to label, stereotype, or stigmatize individual or groups but, rather, as an important lens to promote deeper understanding of the complexity of human suffering and aid the development of more effective approaches to address it.

Cultural Dimensions

Hofstede Cultural Dimensions. One approach to examining sociocultural group differences is the use of cultural dimensions. Geert Hofstede pioneered this in studying IBM employees across different countries, and the model elaborated by him and others consists of six dimensions: individualism-collectivism, defined as the strength of the ties between community members, with individualism focusing more on individual goal attainment and collectivism focusing more on group goals and wellbeing; power distance, the degree to which differences between those with and without power exist and are accepted; uncertainty avoidance, the level of tolerance to ambiguity; masculinity-femininity, the degree of overlap of gendered roles and expectations and the valuing of assertiveness versus modesty; long-term versus short-term orientation (LTO), the relative emphasis on pragmatism, adaptation, perseverance, and thrift (long-term) versus adherence to traditions and principles and focus on short-term gains (short-term); and indulgence versus restraint,

Telegram: @medical_k

www.konkur.in

the degree of permissiveness to satisfy individuals' desires versus regulation by social norms. This model remains one of the most influential and empirically tested models in crosscultural studies.

At the country level, the U.S. profile on Hofstede's model scores highest on the individualism (91/100) and indulgence (68/100) dimensions and lowest on the LTO dimension (26/100). This stands in contrast to China, where the lowest two dimensions are individualism (20/100) and indulgence (24/100) and the highest dimension is LTO (87/100). The LTO dimension is a concept originally derived from Confucian values to counterbalance the Western bias in the initial model and later became incorporated into it. Caveats of characterizing national cultural profiles include intranational variations, which can account for more variance than across countries, and supranational clusters, which can account for similarity in regions across countries, for example, a Latin American cultural zone. The degree of intranational variations is influenced partly by the looseness-tightness characteristics of the cultural setting, which refers to the relative strength of social pressures and enforcements of cultural norms and behaviors. In general, individualistic cultural areas tend to be looser than collectivistic cultural areas with some notable exceptions. Latin American countries and ex-Soviet countries are considered "loose" though they are collectivistic; Germany is considered "tight" despite the fact that they are relatively individualistic. A country's historical exposure to social and other ecologic challenges may be associated with the tightness of the cultural area as a protective response. For the COVID-19 pandemic, a study has shown that loose cultural settings have 4.99 times the case rate and 8.71 times the death rate compared to tight cultural settings. Another challenge to using cultural models is that culture is fluid and changes over time. A cohort analysis using the World Values Survey (1981 to 2008) suggests that contemporary societies tend to demonstrate increases in individualism and indulgence and decreases in power distance over time with modernization, but the crossnational differences relative to each other were found to remain generally stable across time.

Individualism-Collectivism. At the individual level, among Hofstede's most studied dimension is individualism-collectivism. This has spawned a wealth of crosscultural psychological research, including representation of the self, cognition, emotions, communication, and moral appraisal. Studies often contrasted Western American and European cultural

Telegram: @medical_k

www.konkur.in

regions, relatively high on individualism, versus Eastern Asian cultural regions, relatively high on collectivism. In a collectivist society, in addition to an independent self, an interdependent self-construal is proposed, where the self is fundamentally defined in relation to others. Western compared to Eastern individuals tend to have a stronger positive bias about themselves. Western individuals tend to reason linearly, analytically, and in a focused manner, while Eastern individuals tend to exhibit more cyclical reasoning and attend to the broader picture, as reflected in differences in relative cognitive strengths in attending to foreground versus background objects. Western individuals tend to demonstrate a greater spontaneous trait inference (i.e., attributing the cause of observed behaviors to an individual person's trait) compared to Eastern individuals.

Research on basic emotions based on facial expressions and cognitive appraisal of emotions has largely found them to be universal, although there are cultural differences demonstrated in in-group cultural advantage in the recognition of emotions. Emotional suppression appears to be maladaptive in Western cultural settings, while valued in Eastern ones. Western individuals tend to both experience and value high-arousal positive motions (e.g., happiness) over low-arousal positive emotions (e.g., calmness), while the reverse has been found for Eastern individuals.

There are limitations to crosscultural psychological findings given that a lot of research only compared United States and European individuals as the Western cultural group versus Japanese and Chinese as the East Asian cultural group, although increasingly more studies are available on Latinx populations. While some studies are limited by the use of self-report instruments, many findings demonstrate convergent results using different psychological experimental paradigms, most recently including neuroscience techniques such as differences in evoked response potential (ERP) and brain imaging. For example, in a meta-analysis, functional imaging suggests that the dorsal medial prefrontal cortex, lateral frontal cortex, and temporoparietal junction are more strongly activated among East Asians during social processing, while anterior cingulate, ventral medial prefrontal cortex, and bilateral insulae are more strongly activated among Westerners, implying that the former is more focused on inferring others' emotional states, while the latter has a relatively greater focus on self-referential processing.

There is emerging research into gene x culture interactions, including a line of research on the DRD4 gene, with the 7- or 2-repeat allele (7R/2R)

Telegram: @medical_k

www.konkur.in

hypothesized to be associated with increased sensitivity to environmental influences and hence greater capacity to internalize cultural norms. For example, as predicted, East Asians carrying the 7R/2R allele in one study scored higher on an interdependent self than European Americans while noncarriers did not. Similarly, in another study, East-Asian 7R/2R allele carriers experienced greater emotional balance (i.e., weak emotional positivity bias) than noncarriers; among Euro-Americans there was a nonsignificant trend toward the opposite, with positivity bias being stronger among carriers than noncarriers.

In sum, complex gene × environment interactions occur in every individual, highlighting the need not to stereotype. Western individuals may be collectivistic and Eastern individuals may be individualistic. In fact, some Western cultural groups are known to be collectivistic. Adding to the complexity are emerging studies on the health impacts of different types of individualism and collectivism based on differences along another dimension, horizontal, emphasizing equality, versus vertical, emphasizing hierarchy. In a recent study of 1906 university students in the United States (ethnicity not specified), individualism was negatively related to wellbeing, while collectivism was positively correlated to wellbeing, with horizontal collectivism having a more robust positive association with wellbeing than vertical collectivism. This body of research alerts us to potential individualistic biases that may impact clinical care. It also underscores the importance of becoming aware of non-Western cultural concepts that may influence the patient's behaviors, motivations, or value system, such as collectivistic cultural concepts of filial piety among Confucius cultures or familismo (familism) among Latinx groups.

Cultural Values. Values, which guide and motivate actions and transcend specific activities and situations, differ across cultural settings. To provide basic dimensions to study values differences crossculturally, Schwartz's theory of basic values has been studied using data from over 80 countries and is an alternative to Hofstede's dimensions, which also reflect cultural values. Schwartz argues that the existence of values is universal as they help meet the needs of individuals as biologic organisms, coordinate social interactions, and benefits group survival and welfare. He lists 10 basic values: power, achievement, hedonism, stimulation, self-direction, universalism, benevolence, tradition, conformity, and security. His model proposes that values, in general, fall along two

Telegram: @medical_k

www.konkur.in

orthogonal dimensions: openness to change versus conservatism and self-enhancement versus self-transcendence. Assigning high importance to universalism and openness to change and low importance to conservation values has been found to predict tolerance to immigrants and other minority groups, such as LGBTQ+ individuals. In some studies, immigrants' personal values are shown to change after migration. Across 29 countries, person-country and person-region value congruence predicted six wellbeing measures, including emotional wellbeing, and this was moderated by value types, such that some types of value fit have a positive effect on wellbeing, while others have negative effects.

Racial and Ethnic Identity Development

William Cross Jr., developed the Nigrescence Theory in 1971, which has become an influential model in understanding Black and ethnoracial identity development. His initial model includes five stages for a Black individual: pre-encounter, marked by a neutral stance that race does not matter or by internalized anti-Black sentiments; encounter, the occurrence of an event that challenges a previous identity, ideology, and worldview, such as experiencing a racist incident; immersion-emersion, the person participates in Black culture exclusively, experiencing emotions such as anger and guilt, and then emerges with a more nuanced and balanced view of Blackness; internalization, the new Black identity is accepted, resolving internal conflicts; and internalization-commitment, the person develops a balanced relationship with their own Black identity and with other ethnoracial groups, with a long-term commitment to Blackness, including social activism. The last two stages have later been combined by Cross.

Influenced by Cross, a White Racial Identity Model has been developed by Janet Helms, describing the developmental journey of White individuals toward a nonracist identity. The contact status is marked by a denial of systemic racism and profession of being color-blind while being unaware of internal biases. In the disintegration status, the person becomes conflicted over racial dilemmas, such as believing that one is not a racist, while becoming aware of discomfort about their children marrying a minority group member. The person may experience guilt, depression, or anxiety, and respond by avoiding contact with persons of color, not thinking about race, or seeking reassurance that racism is not the fault of White individuals. Influenced by societal ideology, the reintegration status

Telegram: @medical_k

www.konkur.in

is marked by a retreat into affirming White superiority and blaming minority groups for their problems. After a painful or insightful event, the individual may enter the pseudo-independence status, learning more about racism cognitively, outreaching to minorities that are most like themselves, and trying to help them conform to White standards. In the immersion-emersion status, there is a deeper experiential and affective understanding of oppression and racism, with a shift in focus from trying to change people of color to changing oneself and other Whites. In the autonomy status, there is awareness of one's Whiteness, acceptance of one's role in perpetuating racism, renewed determination to abandon White entitlement, and the capacity to explore issues of racism without defensiveness.
