
FIGURE 1.20–2. A: The nucleosome as a basic folding unit of chromatin. **B:** Chromatin can transition from a "beads on a string" 10-nm filament to a more compact 30-nm filament structure that is stabilized by the presence of histone H1 (*light ovals*). Histone tails (in *gray*) make contacts between neighboring nucleosomes known as internucleosomal contacts (*top arrows*) and with the underlying DNA (*bottom arrow*).

Histone Acetylation. Acetylation neutralizes lysine residues, rendering the N-terminal tails on histones less positively charged. This decrease in positive charge is thought to disrupt contacts with the negatively charged DNA and with neighboring nucleosomes. Histone acetylation is associated with transcriptional activation and other cellular processes that require access to the underlying DNA, such as DNA replication and repair (Table 1.20–4). Histone acetyltransferases (HATs) acetylate lysine residues on the tails of histones H3 and H4, while histone deacetylases (HDACs) remove these acetylations (Fig. 1.20–4). Acetylation modifies lysines (K) that are systematically spaced on Histone 3 (e.g., 9, 14,18, and 23) and Histone 4 (e.g., 5, 8, 12, and 16). Different HATs and HDACs are responsible for acetylating and deacetylating specific residues. On histone H3, for example, K14 and K18 are acetylated by cAMP response element-binding protein (CREB)-binding protein (CBP/P300), while K9, K14, and K18 are acetylated by a different HAT, PCAF/GCN5.

www.konkur.in

This enzyme specificity provides an opportunity to develop more selective and targeted pharmacotherapies to act on this system. Recent work using reconstituted purified histones found that a single acetylation at lysine 14 in histone 4 (H4K14-Ac) was sufficient to maintain chromatin in the “beads on a string” state by preventing interactions between neighboring nucleosomes. Interestingly, the H4K14-Ac modification inhibited the ability of the chromatin-remodeling enzyme ACF to slide nucleosomes, suggesting that this modification “locks” chromatin into an open state.

Consistent with histone acetylation opening chromatin, deacetylation of histones leads to chromatin compaction and transcriptional repression (Fig. 1.20–4). HDACs fall into three classes, Class I, Class II, and the NAD-dependent Class III of the SIR family. These classes are based on structural similarities and are therefore inhibited by different pharmacologic agents. In general, HDACs seem to have less specificity than HATs with regard to the lysine resides they deacetylate. Different HDACs are targeted and bind to different compartments within the nucleus, allowing them to conduct somewhat distinct functions. For example, HDAC1 seems to play a general role in chromatin condensation and repression, while HDAC3 is tethered to the nuclear periphery, where it forms highly repressive null chromatin (see Chromatin Domains section below).

www.konkur.in

FIGURE 1.20–3. "Permissive chromatin" (**top left**) is acetylated (*gray squares*), methylated (*open ovals*) and phosphorylated (*gray triangle*). These histone modifications open up the chromatin by disrupting internucleosomal contacts and DNA–nucleosome contacts and recruit ATP-dependent chromatin-remodeling enzymes (not shown) that further open up the chromatin to form "active chromatin" (**top right**). Permissive chromatin can be modified to form "inactive chromatin" (**bottom left**) by removing activating histone modifications and the addition of inhibitory histone methylations (windowpane-patterned hexagon). These repressive modifications compact chromatin by promoting internucleosome and DNA–nucleosome contacts. Inactive chromatin can be further condensed to form "repressed chromatin" (**bottom right**) by recruiting ATP-dependent chromatin-remodeling enzymes and other structural proteins (not shown).

Table 1.20–4. Enzymatic Activities That Modify Chromatin

Modification	Residues Modified	Impact on Chromatin	Modifying Enzyme	Demodifying Enzyme
Histone acetylation	H3K9, H3K14, H3K18, H3K23, H4K5, H4K8, H4K12, H4K16	Opens chromatin/transcriptional activation	HAT (GCN5, SRC-1, CBP)	HDAC (HDAC1, HDAC2, HDAC5)
Histone methylation (activating)	H3K4, H3K36, H3K79	Opens chromatin/transcriptional activation	HMT (Set7/9, MLL, SUV39H/H2)	HDMT (LSD1, JMJD2A)
Histone methylation (repressing)	H3K9, H3K27, H4K20	Condensed chromatin/ transcriptional repression	HMT (GLP, G9A, EZH2	HDMT (KDM3A/JMJD1A, JMJD2A, JMJD3)
Histone phosphorylation	H3S10, H3S28	Opens chromatin/transcriptional activation (immediate early genes)	HK (AURORA/IP1, MSK1/MSK2)	HP (DUSP1)
Chromatin-remodeling enzymes	NA	Open or condense chromatin	NA	NA
DNA methylation	Cytidine within the CpG dinucleotide	Condensed chromatin/ transcriptional repression (mainly)	DNMT1, DMT3a, DNTM3b	Tet family, Gadd45 family, AID, SMUG1/TDG

Proteins that have a bromodomain-folding motif are able to bind acetylated histones in order to maintain open chromatin. Mutations in the HAT domain of CBP cause Rubinstein–Taybi syndrome, which is associated with mental retardation and cardiac abnormalities (Table 1.20–3). Interestingly, a mouse model of this condition

Telegram: @medical_k

www.konkur.in

showed that the cognitive deficits associated with low levels of CBP could be reversed by administrating HDAC2 inhibitors to adult mice. These findings suggest that the relative activities of HATs and HDACs in postmitotic neurons play an important role in neuroplasticity with broad implications for neurodevelopmental disorders, aging, and drug addiction (see Epigenetics in Preclinical Work). Indeed, increased HDAC2 has been shown to silence genes that are necessary for learning and memory, and HDAC2 activity was found to be elevated in Alzheimer's disease. Clinical work is currently underway to test whether specific HDAC inhibitors can be used to improve cognition in conditions such as early Alzheimer's disease, schizophrenia, and traumatic brain injury.

FIGURE 1.20–4. Histone tails are reversibly modified at specific residues. HAT-Histone acetyltransferases, HDAC-histone deacetylase, HMT-histone methyltransferase, HDMT-histone demethyltransferase, HK-histone kinase, HP-histone phosphatase.

Histone Methylation. Histone methylation is more complex than acetylation because both lysines (K) and arginines (R) can be methylated. Moreover, each lysine can be methylated once, twice, or three times, providing another layer of complexity. Lysine methyltransferases are more selective compared to acetylating enzymes, targeting specific lysine residues within the histone tail. Methylation on three sites is associated with transcriptional activation (H3K4, H3K36, H3K79), whereas methylation on 3 other lysine resides is associated with repression (H3K9, H3K27, H4K20), see Table 1.20–3 for a summary. In addition to transcriptional regulation, histone methylation also plays a role in DNA repair.

As with other chromatin modifications, methylated lysines can be demethylated by histone demethylases, allowing for dynamic and reversible chromatin changes (Fig. 1.20–4). Proteins that contain chromo-like domains (e.g., chromo, tudor, MBT) or the structurally unrelated PHD motif are able to bind methylated histones. Such proteins form large complexes that contain chromatin-remodeling enzymes and other

Telegram: @medical_k

www.konkur.in

histone modifiers. These complexes are recruited to methylated histones and, depending on the exact composition of the complex, are able to efficiently open or close the chromatin. For example, appropriate activation of the HOXC8 gene is essential for normal axis development in all vertebrates. Activation of the HOXC8 gene requires histone methylation during a specific period in development. This methylation step is required to recruit the nucleosome-remodeling factor (NURF) via the bromodomain PHD finger transcription factor (BPTF). The NURF complex contains a chromatin-remodeling enzyme (SNF2L) that removes nucleosomes from the HOXC8 promoter allowing for transcriptional activation. Mutations that interfere with the ability of BPTF to bind the methylated promoter cause abnormal expression of HOXC8 and abnormal axis formation in tadpoles. This sequence of events illustrates the multilayered coordination of chromatin regulation in which histone modification recruits additional machinery making the chromatin more accessible and allowing for the expression of genes necessary for normal axis development (Fig. 1.20–5).

Methylation at lysine 9 in histone 3 (H3K9-me2/ H3K9-me3) plays a critical role in maintaining a specialized form of chromatin known as *pericentric/constitutive heterochromatin*. One of the main functions of the pericentric chromatin is to support the formation of centromeres that are used to align and segregate chromosomes during cell division (see also Table 1.20–4). H3K9 is methylated by a specific histone methyltransferase (Suv39h1/h2), which in turn triggers the binding of the repressor protein HP1 via its chromodomain. HP1 then associates with several other proteins to form a complex that extends this specialized repressed chromatin structure through large sections of the underlying DNA. This is accomplished by the ability of HP1 to recruit additional Suv39h1/h2, allowing further histone methylation and HP1 recruitment to propagate down the DNA (Fig. 1.20–6). HP1 is also associated with DNA methyltransferases, DNMT1 and DNMT3a, allowing for DNA methylation and further chromatin compaction. Finally, during replication, HP1 is associated with chromatin factor 1 (CAF1) protein, which deposits histones at the replication fork. The presence of a complex containing HP1, Suv39h1/h2, DNMT1, and CAF1 at the replication fork provides a possible mechanism by which pericentric chromatin is inherited in daughter cells and a good example of how DNA methylation and histone modification activities are coordinated (see DNA Methylation section below).

www.konkur.in

FIGURE 1.20–5. Histone methylation recruits BPTF via its PHD domain bringing with it the chromatin-remodeling enzyme SNFL2 as part of the NuRF complex. Binding of SNFL2 allows for ATP-dependent removal of nucleosomes from the promoter, HOXC8 expression, and normal axis development in vertebrates.

Histone methylation is also critical for the creation of repressive polycomb chromatin structures, which are instrumental in maintaining the pluripotency of embryonic stem cells, regulating cell cycle progression, cell differentiation, and chromosome-X inactivation. In this process, histone methylation at H3K27 is catalyzed by the Polycomb Repressive Complex (PRC2), a highly evolutionarily conserved protein complex. PRC2 is recruited to specific regions of DNA via interactions with other DNA-binding proteins and noncoding RNA. Once recruited, PRC2 methylates H3K27 to form the di, and the tri methylated states (H3K27-me3), which then serve as tethering sites for the entire complex. H3K27-me3 also recruits the chromatin-remodeling machinery (PRC1) that further condenses chromatin into the highly repressive polycomb conformation (see Fig. 1.20–7 and Table 1.20–4). Interestingly, the PRC2 complex maintains its binding to DNA during DNA synthesis, providing a mechanism by which H3K27-me3 and polycomb chromatin repression are maintained in daughter cells. Mutations in the histone methylase activity of PRC2

Telegram: @medical_k

www.konkur.in

prevent the stable propagation of polycomb repression into daughter cells, suggesting an essential role for methylation in this epigenetic form of inheritance, with critical implications for many developmental programs, including X-inactivation and the transition from cellular pluripotency to differentiation.

FIGURE 1.20–6. The HMT Suv39h1/h2 methylates H3K9 (**top**), recruiting HP1 via its chromodomain (**middle**). HP1 binds Suv39h1/h2 allowing for the propagation of this repressive pericentric/constitutive heterochromatin (**bottom**).

Histone Phosphorylation. Phosphorylation of histones plays a role in chromosome segregation during mitosis, induction of early response genes, and DNA repair. Histone kinases such as Aurora/Ip1 and the mitogen and stress-activated protein kinases 1 and 2 (MSK1/MSK2) phosphorylate serines (S) 10 and 28 on histone 3. The proximity of these serine residues to lysines 9 and 27 influences the decision as to whether these lysines will be acetylated or methylated. This influence is critical because acetylation at lysines 9 and 27 tends to activate transcription, whereas methylation at these same sites represses transcription (Fig. 1.20–4). Several environmental stimuli, such as stress, cocaine, changes in neurotransmission, and UV light, induce H3S10 phosphorylation by activating MSK1

Telegram: @medical_k

www.konkur.in

and MSK2. Activated MSK1 is recruited to the promoters of immediate early genes, such as c-fos and Jun, in a complex containing 14-3-3 proteins, chromatin-remodeling machinery, and a HAT. This complex efficiently activates the expression of immediate early genes that provide appropriate cellular responses depending on the type of cells and the environmental context. In the dentate gyrus, this response facilitates helplessness behavior, while in the striatum, this response modifies drug-seeking behavior (see Epigenetics in Preclinical Work section below).

FIGURE 1.20–7. The PRC2 complex has an HMT activity that generates H3K27-me3, which further stabilizes PRC2 binding to chromatin (**top**). PRC2 recruits the PRC1 complex that further compacts chromatin by increasing nucleosome density (**middle**). These newly recruited nucleosomes are methylated by PRC2, allowing for the propagation of this polycomb repressive chromatin (**bottom**).

ATP-Dependent Chromatin Remodeling

Telegram: @medical_k

www.konkur.in

Nucleosomes are distributed in a stereotypical pattern along actively transcribed housekeeping genes. This pattern is highly conserved from yeasts to mammals and is characterized by a 250 bp nucleosome-free region (NFR) that is flanked by two positioned nucleosomes in the promoter of housekeeping genes (Fig. 1.20–8). Similar NFRs are also found at the 3' end of the gene and in enhancer regions. This pattern allows the transcriptional machinery to bind and constitutively express housekeeping genes. Nucleosome positioning is accomplished in vivo by two mechanisms. First, specific DNA sequences within the promoter region can guide the nucleosome's position, providing an important example of how the genetic code influences the epigenetic code. However, this arrangement is static and does not allow for the rapid reorganization of chromatin in response to environmental demands. The second and perhaps more important mechanism is mediated by chromatin-remodeling enzymes. These enzymes are equipped with chromatin binding motifs and use ATP to remove, add, or slide nucleosomes along the DNA strand. In some cases, chromatin-remodeling enzymes maintain NFR by removing nucleosomes from specific promoter sequences. This, in turn, allows transcription factors to bind DNA and activate transcription (Fig. 1.20–8). Alternatively, nucleosomes can be pushed by chromatin-remodeling enzymes into NFRs, where they block transcription and form higher-order chromatin structures (Fig. 1.20–8). Recruitment of chromatin-remodeling enzymes has been implicated in the development of addictive-like behaviors after chronic cocaine exposure in mice via modification of the promoters of late-onset addiction-related genes, such as cyclin-dependent kinase 5 (CDK5) (see Epigenetic Mechanisms of Cocaine Addiction section).

FIGURE 1.20–8. Top: Nucleosome-free region (NFR) can be passively maintained by DNA sequences that position nucleosomes on both sides of the NFR (shown in *dark gray*). This, in turn, allows transcription factors to bind and activate gene expression. In many cases, NFR is actively maintained by ATP-dependent removal of nucleosomes (depicted as CRE1 on the **lower-left panel**). ATP-remodeling activities (CRE2, on the **right lower panel**) use ATP to deposit nucleosomes making the NFR inaccessible and therefore turning transcription off.

DNA Methylation

Unlike histone modifications that do not alter the chemical structure of the genetic code, DNA methylation directly changes the molecular structure of cytosines. This is accomplished by transferring a methyl group from a donor molecule to the 5′ position on the cytosine ring to generate 5-methylcytidine (5mc). In vertebrates, DNA methyltransferase (DNMT) enzymes methylate cytosines in a dinucleotide (CpG) palindromic sequence. Cytosine methylation does not affect its ability to form correct Watson-Crick pairing with a guanosine on the antiparallel DNA strand and thus does not affect the underlying genetic information. Instead, DNA methylation marks the DNA at specific locations in a manner that can be inherited and allows the recruitment of histone and nucleosome-remodeling machinery to do the heavy lifting of opening or compressing chromatin.

Within the mammalian genome, CpG dinucleotides are either clustered in a high-density region known as CpG islands (CGIs) or found sporadically across the genome. CGIs usually mark promoters of active housekeeping genes and are thus generally unmethylated. In rare cases, when CGIs are methylated, they form a highly repressive chromatin structure that inhibits gene expression and, in many cases, is inherited. Some well-known examples include X-inactivation and imprinted genes. The observation that abnormal regulation of imprinted genes leads to several forms of intellectual disability demonstrates the importance of correct methylation of these CGIs for normal neurodevelopment (see Table 1.20–3 and Rescuing Prader–Willi Syndrome section below).

FIGURE 1.20–9. Top: In the absence of DNA methylation, a generic transcription factor (TF) binds a specific DNA sequence within the promoter and activates gene expression. **Middle:** DNA methylation (*black* no entry signs) prevents the TF from binding its binding site and therefore prevents gene expression. **Bottom:** The NuRD complex is recruited to methylated DNA via methyl-binding proteins (MBPs). These MBPs are complexed with enzymatic activities such as HDACs and the chromatin-remodeling protein CHD3 to compact DNA and terminate gene expression.

Methylation of CpG in sporadic regions usually down-regulates gene expression. This downregulation is achieved in one of two ways. First, DNA methylation can prevent the binding of a transcription factor to its binding site (Fig. 1.20–9). A second mechanism involves the direct binding of a methyl-binding protein (MBP) to methylated cytosines. Docking of MBP to methylated DNA recruits enzymes that further compress chromatin and inhibit gene expression. A good example of this repressive cascade is the nucleosome-remodeling deacetylases (NuRD) repressive complex. NuRD is a highly conserved multisubunit complex that synergistically represses chromatin. The NuRD complex includes two HDACs (HDAC1 and HDAC2), a chromatin-remodeling subunit (CHD3 or CHD4), and several MBPs (MBD2 and MBD3). The MBPs recruit the NuRD complex to methylated cytosines where CHD3/CHD4-mediated ATP hydrolysis compacts nucleosomes and stimulates deacetylation by HDACs. This synergism between ATP hydrolysis and histone deacetylation is thought to be due to the ability of chromatin-remodeling enzymes to make histone tails more accessible for deacetylation. The result is a highly repressive chromatin structure around methylated sites (Fig. 1.20–9). DNA methylation can therefore be thought of as a “molecular bridge” between the genetic code (i.e., CpG within specific binding sites) and the other chromatin-modifying machinery (e.g., Figs. 1.20–9, 1.20–13, and 1.20–14). The clinical section of this chapter provides an example of this concept, showing how the genetic code and

Telegram: @medical_k

www.konkur.in

changes in DNA methylation induced by early life stress interact to modify the expression of the FKBP5 gene and subsequent vulnerability to PTSD.

FIGURE 1.20–10. Unmethylated DNA is methylated by the de novo DNMTs, DNMT3a and DNMT3b, to form hemimethylated DNA. Hemimethylated DNA is methylated further by the maintenance DNMT, DNMT1. DNA methylation is lost after each round of DNA replication. The CpG dinucleotide is shown in gray, and the DNA methylation is shown as *black* "no entry" signs.

Two de novo DNMTs enzymes (DNMT3a and DNT3b) are able to methylate CpG sequences on naked or unmethylated DNA, whereas the maintenance DNMT (DNMT1) methylates only hemimethylated sequences (Fig. 1.20–10). De novo DNMTs are responsible for remethylating chromatin after two global demethylation events that occur during normal development. The first global demethylation occurs in the embryonic gametes in order to reprogram these cells to become sperm or an oocyte. The second global demethylation occurs immediately after fertilization and is necessary to establish a pluripotent state in the zygote. Deletion of either DNMT3a or DNMT3b is embryonic lethal, underscoring the importance of de novo methylation for normal development. De novo DNMTs are also expressed in postmitotic neurons, where they methylate promoter elements that regulate the expression of genes implicated in synaptic plasticity, learning, and the response to cocaine.

In contrast to the two de novo DNMTs (e.g., DNMT3a, DNMT3b), DNMT1 does not efficiently methylate naked DNA (i.e., unmethylated DNA). Instead, DNMT1 efficiently methylates DNA in which only one strand is methylated (Fig. 1.20–10). This hemimethylated DNA is commonly formed after DNA replication of a fully methylated CpG site. The presence of DNMT1 at the replication fork allows it to faithfully copy the DNA methylation pattern present on the maternal strand onto the newly formed daughter strand. This mechanism is responsible for the heritability of DNA methylation across mitosis. Deletion of DNMT1 in neural stem cells (NSCs) causes premature induction of gliogenesis (i.e., the production of glial cells) during embryogenesis and multiple defects in neuronal differentiation and synaptogenesis. In addition, exposure of rodents to early life stress increases the expression of DNMT1 in NSCs, which is associated with increased methylation in promoter regions of the retinoic acid receptor. This promoter methylation results in decreased expression of the retinoic acid receptor, which leads to defects in the ability of NCSs to differentiate into neurons. In summary, appropriate DNMT1 activity is required for normal differentiation of NSCs.

Telegram: @medical_k

www.konkur.in

The prevailing dogma for many years has been that DNA methylation is a stable epigenetic marker that can be removed only by DNA replication coupled with the inactivation of DNMT1 (see Fig. 1.20–10), a process known as passive demethylation. Therefore, the presence of DNA methylation in postmitotic neurons was thought to be a stable marker that caused long-term suppression of gene expression. This assertion was based on the observations that the carbon-carbon covalent bond formed between the methyl group, and the cytosine ring is highly stable, and no enzymatic activities have been conclusively shown to cleave this bond *in vivo*. However, a growing body of work has consistently shown that demethylation of some CpG sites can occur rapidly in postmitotic neurons. For example, from a total of 219,000 CpG sites examined in postmitotic neurons in the dentate gyrus of the hippocampus, roughly 3000 sites showed a change in DNA methylation four hours after the administration of a single ECS. About two-thirds of these sites showed an increase in DNA methylation, while the remaining third showed a decrease in DNA methylation, indicating rapid and active demethylation. DNA methylation and demethylation modified the expression of genes involved in synaptogenesis, providing a possible mechanism to explain how ECS modifies neuroplasticity in the hippocampus. Interestingly, similar changes in DNA methylation were observed after 3 days of voluntary running, suggesting that ECS and exercise share similar epigenetic mechanisms for modifying synaptogenesis in the hippocampus.

The observation that DNA can be rapidly demethylated in neurons has led to an intense search for the responsible mechanisms. Different models have been proposed, and additional work is needed to further clarify this issue, especially given that several pathways are likely to be involved. Nevertheless, compelling evidence has emerged to support the role of the ten-eleven translocation (TET) family of proteins, especially Tet1, in this process. This family of Fe(II)/2-oxoglutarate-dependent dioxygenases catalyzes the hydroxylation of methylated cytosine (5mC) to 5-hydroxymethyl-cytosine (5hmc). 5mhc is poorly recognized by DNMT1, providing a mechanism by which passive DNA demethylation can occur in mitotic cells (see also above). In neurons, 5mhc is recognized by deaminases, which catalyze the formation of 5-hydroxyuracil (5mhU). This alteration is recognized as a U:G mismatch that is repaired by the base excision repair (BER) machinery (Fig. 1.20–11). The BER complex consists of a DNA glycosylase that hydrolyzes the N-glycosidic bond creating an apyrimidinic/apurinic (AP) site that is removed by an AP endonuclease, and the resulting gap is filled by DNA polymerases. The growth arrest and DNA damage 45 protein family (Gadd45a, Gadd45b, Gadd45c) facilitate this process by recruiting deaminases or glycosylating enzymes to 5mhc sites (Fig. 1.20–11). Interestingly, the C to T transition in a CpG dinucleotide is the most common mutation in human disease, suggesting that this convoluted DNA demethylation/repair mechanism is associated with a significant cost for the organism. This observation further highlights the intimate relationship between the epigenetic and the genetic code.

Chromatin Domains

Chromatin has been traditionally divided into euchromatin (active chromatin) and heterochromatin (repressed chromatin). However, recent advances in chromatin precipitation and high throughput sequencing allow for more precise chromatin mapping. This work has shown that in the mammalian cell, chromatin is organized in topologically associating domains (TAD) that divide each chromosome into roughly 1Mb segments. TADs can be grouped into four major categories of chromatin: active chromatin (equivalent to euchromatin) and three distinct subtypes of heterochromatin known as polycomb-repressed chromatin, null chromatin, and constitutive heterochromatin (see Table 1.20–5). The boundaries between different TADs are fairly well delineated by CGIs of actively transcribed housekeeping genes and binding sites for insulator proteins. However, some flexibility and shift within these boundaries can occur in response to environmental cues. The positions and boundaries of TADs are programmed by the genetic code and are therefore similar in all cells in the body. However, the exact chromatin content within each TAD is different in different cell types (Fig. 1.20–12). These changes in TAD content are induced by histone modifications, chromatin-remodeling enzymes, and DNA methylation allowing cells to alter gene expression in response to different environmental conditions and to use the same genetic code to form different cell types (Fig. 1.20–1). This segmented organization further illustrates how genetic information and the epigenetic machinery interact with each other.

FIGURE 1.20–11. Pathways for DNA demethylation (methylation site is highlighted with an *arrow*).

Active Chromatin. Active chromatin is characterized by the presence of specific histone acetylations (H3K9-ac) and methylations (H3meK4) that are associated with open chromatin and active transcription (see Table 1.20–4). Genes within an active TAD are usually co-expressed and are functionally related. Active TADs are mainly

Telegram: @medical_k

www.konkur.in

found in the interior of the nucleus and, in some cases, are aggregated together in specific sub-regions of the nucleus to form efficient “assembly lines” (Fig. 1.20–12). Perhaps the most well-characterized example is the nucleolus, where ribosomal RNAs (rRNAs) are synthesized and assembled with ribosomal proteins to form ribozymes. The rRNA transcriptional unit is arranged in a tandem series of about 100 such units clustered on different chromosomes in regions known as nucleolus organizer regions (NORs). Not all NORs are active, and the activation process is at least partly dependent on the ability of the UBF transcription factor to recruit NORs into the nucleolus. This recruitment process helps maintain the rRNA chromatin in an active state, creating a more efficient assembly of ribosomes. This ability of chromatin to loop enhancer elements, some of which are hundreds of kbs away from each other, in and out of contact with each other, and the transcriptional machinery represents an important mechanism by which chromatin regulates gene expression in response to environmental cues (Fig. 1.20–12). The effect of such looping on the risk of developing PTSD is discussed in the clinical section.

Table 1.20–5.
Chromatin Can Be Categorized into Four Different Topologically Associated Domains

TAD Chromatin	Histone Modifications and Associated Proteins	Nuclear/Chromosomal Position	Chromatin Structure and Transcription Activation
Active	H3K9-ac, H3meK4	Interior of the nucleus	Open chromatin, active transcription
Polycomb	H3K27-me3, PRC1, PRC2	Peripheral in differentiated cells	Compact chromatin, transcriptional repression
Null	H3K9me2, nuclear laminin, H1 histones	Nuclear envelope	Compact chromatin, transcriptional repression
Constitutive/Pericentric	H4K20me3, H3K9me2/me3, HP1, H1 histones	Chromocenters, centromeres, telomeres, tandem repeats	Compacted chromatin with intermediate transcriptional repression

Telegram: @medical_k

www.konkur.in

FIGURE 1.20–12. Chromatin in the nucleus is organized into TADs that are separated by house-keeping genes or insulator proteins (not shown). TADs can be categorized as active, polycomb, null, or constitutive/heterochromatin. The chromatin identity of each TAD may be different between different cell types or across the cell cycle within the same cell. Long-distance loops of chromatin bring DNA regions that are far apart in the genetic code into close proximity in the epigenetic code, allowing the formation of assembly lines (*black dots*). These chromatin loops are dynamic and can change in response to environmental cues (*black arrow*).

Polycomb-repressed Chromatin. Polycomb TADs are characterized by polycomb-group response elements (PREs). These sequences are bound by specific transcription factors that recruit the PRC1 and PRC2 complexes to these TADs (Fig. 1.20–7). Polycomb TADs are therefore characterized by the presence of H3K27-me3, polycomb proteins, and repressed chromatin. Polycomb TADs regulate many important cellular processes such as X-inactivation, imprinting, neural stem cell differentiation and cortical development.

Null Chromatin. In mammals, null chromatin is characterized by H3K9me2 histone methylation. This modification is required to tether TAD null chromatin to the nuclear envelope via laminin proteins (Fig. 1.20–12). Null TADs can be significantly larger than other TADs extending up to 10 Mb in humans. They consist of highly repressive, late replicating chromatin that is characterized by high levels of H1 histones and laminin. HDAC1 is required for the general silencing of null chromatin, whereas HDAC3 seems to play an important role in maintaining null chromatin tethered to the nuclear envelope. Mutations in laminin cause the movement of null

Telegram: @medical_k

www.konkur.in

chromatin from the nuclear envelope to the central part of the nucleus and are associated with chromatin decompaction, gene activation, and severe developmental defects such as Hutchinson–Gilford progeria syndrome.

Constitutive Heterochromatin. Constitutive heterochromatin is compacted during the entire cell cycle and is usually located around centromeres, telomeres, and regions that are enriched with tandem repeats. About 30% of the human chromatin is constitutive chromatin and is characterized by the presence of methylated histones, such as H4K20me3 and H3K9me2/me3, specialized histone variants, and high density of the HP1 protein (see also Fig. 1.20–6). Constitutive heterochromatin provides a more repressive chromatin than active chromatin but is less repressive compared to polycomb or null chromatins (Fig. 1.20–12).

EPIGENETICS IN PRECLINICAL WORK

Several lines of animal research elegantly demonstrate how epigenetic changes cause stable alteration of neuronal circuitry and psychiatrically relevant phenotypes such as stress reactivity, drug-seeking behaviors, and helplessness behavior. Four examples are discussed to illustrate how epigenetic changes modify complex behaviors in animals and the potential therapeutic implications of these findings.

Epigenetic Transmission of Stress Reactivity and Maternal Behavior

The importance of early life experience for the development of the organism has long been appreciated from both psychodynamic and biologic perspectives. Cases of early life abuse and neglect often fit into a transgenerational pattern in which individuals that were maltreatment as children will frequently display maladaptive parenting styles later in life. Exposure to early life stress (ELS) is linked with enhanced endocrine and autonomic responses to stress that persist into adulthood. This enhanced stress reactivity is closely related to an increased risk of developing several psychopathologies, including affective disorders, PTSD, and substance abuse (see Epigenetics Mechanisms in Psychiatric Illness). Animal models taking advantage of the normal heterogeneity in “parenting styles” in rats have allowed investigation of the biologic mechanisms by which parental neglect increases stress reactivity in a manner that persists into adulthood and can be transmitted across generations.

The frequency by which rats lick and groom (LG) their pups during the first week of life differs significantly between individuals, with some mothers LG their pups almost three times compared to others. Despite the fact that differences in the frequency of LG are seen only during the first postpartum week, they have profound effects on many behavioral phenotypes in the offspring (summarized in Table 1.20–6). For example, offspring raised by high LG mothers perform better in several memory tests, are less fearful, and show decreased corticosterone secretion in response to stress compared to “neglected” offspring raised by low LG mothers. Several observations suggest that these behavioral changes are due to the frequency of LG

Telegram: @medical_k

www.konkur.in

during the first week of life and not to genetic differences between the high and low LG mothers. First, cross-fostering studies show that offspring born to low LG mothers but raised by high LG dams are behaviorally indistinguishable from pups born and raised by high LG mothers. Similarly, offspring born to high LG dams but raised by low LG mothers resemble the biologic offspring of low LG mothers. Second, mimicking maternal behavior by providing rat pups with different amounts of paintbrush strokes during the first weeks of life can induce similar behavioral changes. These distinct phenotypes persist into adulthood, indicating that exposure to different levels of tactile stimulation during the first week of life in some way programs adult behavior and physiology. Importantly, female offspring raised by high LG dams become high LG mothers themselves, while those born to low LG mothers become low LG mothers (Table 1.20–6). As a result, the low and high LG phenotypes are propagated transgenerationally by maintaining specific levels of tactile stimulation within a lineage early in life.

Table 1.20–6.
Differences between Offspring Exposed to High and Low LG Mothers

Behavioral Phenotype in Adulthood	High LG Offspring	Low LG Offspring
Hypothalamic pituitary axis (HPA) reactivity (GR resistance)	Low	High
Anxiety	High	Low
Hippocampal dependent learning	Intact	Impaired
Maternal behavior (LG)	High	Low

These observational studies beg the question of how seven days of early life experience determine stress reactivity and maternal behavior in adulthood. The emerging answer is that the frequency of LG during the first week of life causes stable changes in DNA methylation in promoter elements that regulate the expression of genes in neuronal circuits that control stress- reactivity and maternal behavior. For example, the promoter of the glucocorticoid receptor (GR) is heavily methylated at birth, leading to low GR levels in the hippocampus of newborn pups. Exposure to high LG during the first week of life induces several transient changes in the hippocampus that ultimately lead to extensive demethylation of the GR promoter. Demethylation of the GR promoter allows the transcription activator nerve growth factor inducible protein A (NGFI-A) to bind to the GR promoter. The binding of NGFI-A recruits the HAT, and CBP, to acetylate nearby histones, which further opens chromatin and enhances GR expression in the hippocampus of high LG offspring (Fig. 1.20–13). High levels of GR persist in the hippocampus of adult high LG offspring and exert an inhibitory influence on neurons in the paraventricular nucleus of the hypothalamus (PVN) that secrete corticotropin-releasing hormone (CRH) in response to stress. The promoter of the GR in offspring of low LG mothers is kept

Telegram: @medical_k

www.konkur.in

hypermethylated. This hypermethylation prevents NGFI-A from binding to the GR promoter, leading to reduced GR levels in the hippocampus of low LG offspring (Fig. 1.20–13). In sum, exposure to high LG during the first week of life decreases stress reactivity in adulthood by demethylating the GR promoter during a critical period of development.

FIGURE 1.20–13. Top: The promoter of the GR is maintained in a methylated state in the offspring of low LG mothers, leading to low levels of GR expression in the hippocampus and high-stress reactivity. **Bottom:** High LG during the first week of life leads to demethylation of the GR promoter, allowing the NGFI-A transcription factor to bind and activate GR expression by recruiting the HAT, CBP. Elevated levels of GR in the hippocampus decrease stress reactivity in the offspring of high LG mothers.

Exposure to high LG behavior also decreases DNA methylation at the estrogen receptor alpha (Erα) promoter in the medial preoptic area (MPOA) of the hypothalamus. Demethylation of this promoter recruits the transcription factor Stat5 to the Erα promoter allowing for increased Erα levels in the MPOA of high LG female offspring. Offspring raised by low LG mothers maintain low levels of Erα in the MPOA due to the persistence of DNA methylation at the Erα promoter. Differences in Erα levels in the MPOA persist into adulthood, regulate oxytocin expression, and are thought to program subsequent LG behavior in adult female offspring.

An important clinical question regarding the capacity of LG to cause stable alterations in DNA methylation, gene expression, and behavioral phenotype is whether these changes can be reversed pharmacologically in adulthood. The answer to this question seems to be yes. For example, intraventricular infusion of an HDAC inhibitor decreases DNA methylation at the GR promoter, increases GR levels in the hippocampus, and decreases stress reactivity in adult low LG offspring. While HDAC inhibitors do not change DNA methylation directly, they increase chromatin accessibility, a process that may facilitate the demethylation of DNA. Conversely,

Telegram: @medical_k

www.konkur.in

intraventricular infusion of methionine (a donor for methylation reactions) increases DNA methylation at the GR promoter, reduces hippocampal GR expression, and increases stress reactivity in adult high LG offspring. These findings suggest that the epigenetic landscape at the GR promoter can be modified pharmacologically in adulthood by tilting the balance between activities that promote open chromatin (histone acetylation, DNA demethylation) and activities that compact chromatin (methylating agents). It is currently unclear whether the developmental phenotypes induced by LG at the GR promoter will be reestablished after a prolonged washout of the HDAC inhibitors or methionine. Addressing this question will have important implications regarding the true reversibility of these developmentally sensitive epigenetic changes.

The relevance of these findings to human psychopathology has been examined in postmortem studies by assessing the brains of suicide victims with documented histories of childhood abuse or neglect compared to suicide victims with no childhood trauma. Similar to the preclinical work in rats, childhood maltreatment was associated with increased DNA methylation at the GR promoter and reduced GR levels in the hippocampus. While the challenges of assessing epigenetic signatures in living patients remain (see Epigenetics Mechanisms of Psychiatric Illness section below), these studies suggest that preclinical work in rodents can provide important insights into the mechanisms by which epigenetics contribute to psychiatric conditions in humans.

Rescuing Prader–Willi Syndrome in the Mouse

Prader–Willi syndrome (PWS) is an imprinting disorder affecting roughly 1/15,000 to 30,000 individuals. The core features of this variable syndrome include neonatal hypotonia and a failure to thrive, followed by hyperphagia, childhood obesity, hypogonadism and mild intellectual disability (Table 1.20–3). PWS is caused by a lack of expression of a group of genes located on the paternal 15 chromosome (e.g., 15q11-q13). This region contains several protein-coding genes such as Necdin (NDN), Small Nuclear Ribonucleoprotein Polypeptide N (SNPRN), Ubiquitin Protein Ligase E3A (UBE3A) and noncoding RNAs such as SNORD116 and UBE3A-ATS whose expression is regulated by the PWS imprinting center (*PWS-IC*). In males, the DNA at the PWS-IC is unmethylated and is maintained in an open chromatin state, allowing for the expression of PWS genes (Fig. 1.20–14, top). The expression of UBE3A-ATS in males causes local suppression of its neighboring UBE3A gene (Fig. 1.20–14-, top). On the maternal chromosome, the PWS-IC DNA is highly methylated, leading to the recruitment of the histone methylase G9A. G9A methylates histone 3 on lysine 9 (H3K9-Me2 and H3K9-Me3), resulting in the expansion of compacted chromatin over the entire PWS locus and the blockade of gene expression from the maternal chromosome (Fig. 1.20–2, middle). The absence of UBE3A-ATS expression on the maternal chromosome allows for the transcription of the UBE3A gene. This is important because conditions that impair the expression of functional UBE3A from the maternal chromosome cause Angelman syndrome (Table 1.20–3).

Telegram: @medical_k

www.konkur.in

Deletion of the paternal 15q11-q13 locus eliminates the only genomic source for these genes and is the most common cause of the PWS. The exact contribution of each of these genes to the PWS is yet to be clarified, but a growing body of work has implicated the noncoding, highly conserved RNA SNORD116 as an important contributor to the pathology. The presence of an intact yet highly compacted chromatin over the maternal chromosome raised the possibility that “forcing” the maternal chromatin to open may eliminate or at least mitigate the clinical features of PWS. To accomplish this, embryonic fibroblasts were harvested from transgenic mice that express the green fluorescence protein (GFP) from the maternal PWS-IC. Since the maternal PWS-IC is inactive (Fig. 1.20–14, middle), no GFP expression is seen in this cell line. However, when exposed to a large library of over 9000 small compounds, two compounds (UNC0638 and UNC0642) were able to induce the expression of GFP in this cell line. Both compounds were known inhibitors of the HMT G9A, suggesting that blocking histone methylation might be the key to opening the compacted chromatin structure on the maternal chromosome. Further analysis confirmed that UNC0638 and UNC0642 opened up the chromatin structure at the maternal locus and restored expression of PWS genes in mouse embryonic fibroblasts, with similar results seen when fibroblasts obtained from PWS patients were exposed to UNC0638 and UNC0642. What is particularly promising about this approach is that, unlike agents that block DNA methylation (such as 5-Aza-dc), UNC0638 and UNC0642 increased the expression of most of the genes found in the PWS locus, including SNORD116. Further, treatment of a mouse model of PWS showed no evidence of toxicity and led to a significant reduction in mortality caused by a failure to thrive in this model. In vivo and in vitro treatment with UNC0638 and UNC0642 did not activate the expression of more downstream genes such as UBE3A-ATS which would block the expression of UBE3A and lead to Angelman syndrome (Fig. 1.20–14, bottom). UNC0638 and UNC0642 blocked histone methylation but did not reduce DNA methylation or interfere with G9A binding at the maternal PWS-IC region, suggesting that blocking histone methylation is able to restore some gene expression and reduce lethality even in the presence of high levels of DNA methylation. Expression of genes from the maternal chromosome reached only 30-50% of levels expressed from the parental locus, indicating that DNA methylation and histone methylation are both necessary for full repression and that reversing one layer of regulation within this system is likely to provide only a partial rescue of the PWS. Nevertheless, the use of a reporter-mediated cell line coupled with a high throughput screen of small molecules to induce localized changes in chromatin structure provides an exciting new frontier in epigenetic drug discovery.

Telegram: @medical_k

www.konkur.in

FIGURE 1.20–14. Top: The paternal DNA at the Prader Willis imprinting center (PWS-IC, shown in *dark gray*) is unmethylated, allowing the formation of open chromatin and the expression of genes such as NDN, SNPRN, SNORD116 that are necessary for normal neurodevelopment. Expression of UBE3A-ATS prevents UBE3A transcription from the parental chromosome. **Middle:** The maternal DNA at the PWS-IC is methylated, recruiting the HMT G9A and leading to histone methylation and chromatin compaction across the entire PWS locus. Compacted chromatin prevents gene expression, including UBE3-ATS, while restoring transcription of UBE3A from the maternal chromosome. **Bottom:** UNC0642 inhibits G9A HMT activity allowing for partial expression of genes such as NDN, SNPRN, SNORD116 (but not UBE3-ATS) from the maternal PWS locus and reducing pup mortality in a mouse model of PWS.

The Epigenetic Mechanisms of Depressive Behavior and Antidepressant Action

Rodent models of depression and PTSD typically employ some form of chronic, unpredictable, or severe stress that leads to despair, avoidance, or anhedonic-like behaviors. One such paradigm involves chronic social defeat in which a mouse is briefly exposed to an aggressive intruder over the course of 10 days. Defeated mice show a decrease in sucrose consumption, suggesting an anhedonic-like state and increased helplessness in the forced-swim and the tail-suspension tests. Like human depression, many of these behavioral changes are reversed by chronic but not acute antidepressant treatment.

Several observations suggest that the behavioral consequences of social defeat and the rescue of depressive phenotypes by antidepressant medications are due to epigenetic changes in the expression of genes implicated in neuroplasticity. One of the best examples of epigenetic regulation of neuroplasticity genes is the opposing effects of stress and antidepressants on the expression of brain-derived neurotrophic factor (BDNF) in limbic brain areas. BDNF expression in the hippocampus is downregulated in defeated mice in a manner that persists for many weeks after terminating the stress, an effect that can be reversed with chronic treatment with the tricyclic antidepressant, imipramine. The ability of social defeat to decrease hippocampal BDNF levels appears to be mediated by increasing H3K27 methylation at the BDNF promoter. These histone modifications lead to a repressive chromatin state that inhibits BDNF expression (see Fig. 1.20–15). These findings are consistent with human postmortem studies showing that depressed individuals have increased H3K27 dimethylation (H3K27-me2) at the BDNF promoter and reduced BDNF levels. Treatment with imipramine rescued the depressive phenotype and increased BDNF levels in the hippocampus of defeated mice but did not alter H3K27-me2 levels. Instead, imipramine treatment increased acetylation at H3K9 residues at the BDNF promoter, a modification that is associated with open chromatin and transcriptional activation (Fig. 1.20–15). These results underscore the combinatorial nature of the histone code, in which acetylation can override the repressive nature of H3K27-me2. Treatment with imipramine decreased HDAC5 expression in defeated but not control mice, raising the possibility that reduced HDAC5 in defeated mice might promote H3K9 acetylation and therefore mediate the therapeutic effects of imipramine (Fig. 1.20–15). This assertion is supported by data showing that overexpression of HDAC5 in the hippocampus blocks imipramine's antidepressant effects in defeated animals. These preclinical findings have suggested that treatment with HDAC inhibitors may provide a novel therapeutic strategy to increase BDNF and treat depression. However, despite significant effort, no such treatment is currently available, highlighting the complexity and the challenges of using epigenetic-modifying agents to treat psychiatric conditions (see more on this issue below)

Epigenetic Mechanisms of Cocaine Addiction

Telegram: @medical_k

www.konkur.in

While the prior sections have addressed how negative life experiences (fear conditioning, chronic social defeat, or maternal neglect) cause long-lasting changes in chromatin structure, intensely rewarding experiences can also be coded epigenetically. A classic example is drug addiction, in which the natural reward system is hijacked by highly rewarding exogenous substances, resulting in maladaptive, compulsive drug-seeking behavior.

The transition from the initial experimentation phase of drug consumption, driven by the rewarding experience, to the addictive phase, characterized by compulsive maladaptive behavior, is a gradual process that is seen across diverse species, from humans to rodents. In rodents, the transition to addictive behavior is mediated by epigenetic changes in the expression of genes that modify synaptic plasticity in neurons located within the reward system. This section provides a brief summary of some of the main lessons learned about this process by focusing on the role that histone acetylation in the nucleus accumbens (NAc) plays in the development of drug-seeking behaviors.

Telegram: @medical_k

www.konkur.in

FIGURE 1.20–15. Top: Control mice show normal BDNF levels and euthymic-like phenotype. Middle. Exposure to repeated social defeat leads to an increase in repressive HK27-me2 methylation (windowpane-patterned hexagons), leading to condensed chromatin, decreased BDNF levels, and a depressive-like phenotype. **Bottom:** Treatment of socially defeated mice with imipramine does not alter HK27-me2 levels but instead decreases HDAC5 levels. Reduced HDAC5 levels contribute to the increase in histone acetylation (*gray squares*), chromatin decondensation, increased BDNF levels, and restoration of euthymic phenotype.

The immediate rewarding effects of cocaine are closely associated with an increase in dopamine levels in several brain circuits, with the Nac being one of the most important and well-studied targets. The initial rewarding effects of cocaine are experienced within minutes and lead to the transient expression of immediate early genes such as c-fos. Chronic, but not acute, administration of cocaine is necessary to increase the expression of an additional group of late-onset genes such as FosB/

Telegram: @medical_k

www.konkur.in

ΔfosB, CDK5, and BDNF. The expression of many of these late-onset genes can persist for many weeks even in the absence of cocaine and is necessary to elicit robust drug-seeking behaviors in rodents. This effect has been extensively studied for the highly stable transcription factor ΔfosB. Repeated activation of c-fos leads to the accumulation of ΔfosB in a subset of Nac neurons. High levels of ΔfosB are necessary to express synaptic proteins that enhance synaptic plasticity in Nac neurons, which results in the stable changes that are necessary for drug-seeking behavior. Accumulation of ΔfosB is also seen in other compulsively consumptive behaviors such as exercise and feeding, consistent with the notion that cocaine is able to hijack endogenous reward pathways.

Histone acetylation plays a critical role in coordinating the transition from inducing immediate early genes to the stable expression of late-onset genes such as ΔfosB. Acute cocaine administration induces c-fos expression by increasing H4 acetylation and H3 phosphorylation. With repeated cocaine use, these chromatin changes are no longer present at the c-fos promoter leading to a decline in c-fos levels. Instead, repeated cocaine administration leads to an increase in H3 acetylation at promoters of late-onset genes (e.g., FosB, ΔfosB, Cdk5, and BDNF). Manipulations that inhibit histone acetylation, such as viral knockdown of the HAT CBP or the overexpression of different HDACs in the Nac, block the ability of chronic cocaine to induce late-onset genes and reduce compulsive drug-seeking behaviors. These findings suggest a model in which the transition to drug addiction is mediated by an epigenetic switch from an initial rapid H4 acetylation to a slower wave of H3 acetylation that is necessary to induce late-onset genes.

It is important to note, however, that this is a highly simplified model and that the epigenetic effects of chronic cocaine are far more complex. For example, prolonged inhibition of HDAC1 in the Nac reduces cocaine locomotor sensitization, which is inconsistent with the “expected” increase in histone acetylation and the promotion of drug-seeking behavior. This unexpected result is likely due to the ability of chronic HDAC1 inhibition to maintain the repressive H3K9-me2 marker at the promoters of GABA receptor genes even after chronic cocaine exposure. Thus, the retention of the H3K9-me2 repressive marker prevents the expression of these genes even in the presence of high levels of acetylation. This example underscores the complexity by which different histone modifications interact with one another to modify chromatin structure and gene expression (see also Fig. 1.20–15, above).

Chronic cocaine also down-regulates the expression of DNMT3a in the Nac, and manipulations that decrease DNMT3a enhance addictive phenotypes. These findings suggest that some of the behavioral consequences of cocaine addiction are mediated by the demethylation of DNA in the Nac. Finally, some of the epigenetic changes seen after cocaine administration appear to be cell-type specific. For example, knockout of the HMT (G9A) in D1 neurons decreases the behavioral consequences of cocaine, but the opposite phenotype is seen when the same enzyme is knocked out in D2 neurons. This cell-type specificity is not surprising, given that different cell types possess very different chromatin structures and functions (see the introduction and Fig. 1.20–1). Nevertheless, this cell-type

Telegram: @medical_k

www.konkur.in

specificity represents a challenge for pharmacologic interventions that target specific chromatin activities (e.g., the HMT G9A) and for interpreting chromatin changes seen in heterogeneous brain regions such as the Nac.

EPIGENETIC MECHANISMS IN PSYCHIATRIC ILLNESS

While epigenetics in psychiatric research holds significant promise for addressing several fundamental unanswered questions in psychiatric research (Table 1.20–2), significant challenges in its clinical implementation have also emerged in recent years. This final section provides three clinical examples that illustrate the promise and challenges that epigenetic research holds for revolutionizing psychiatric care.

The Epigenetic Etiology of Fragile X Syndrome

Fragile X syndrome (FXS) is the leading cause of inherited intellectual disability in the world, with an estimated prevalence of 1:2,500 males. It is an X-linked monogenetic neurodevelopmental psychiatric disorder characterized by moderate intellectual disability, social deficits, a high incidence of ADHD, and multiple physical abnormalities (Table 1.20–3). Fragile X syndrome is caused by the loss of function of the fragile X mental retardation gene 1 (FRM1). The FMR1 gene codes for an RNA-binding protein that regulates levels of synaptic and chromatin-modifying genes that are critical for normal synaptic development and cognition. While the term “monogenetic” implies mutated genetic code, the actual disease-causing mechanism involves epigenetic changes that silence the promoter of this gene.

The number of CGG repeats in FXS can be categorized into three groups: normal, premutated, and fully mutated alleles. The normal allele consists of 5-55 CGG repeats allowing for normal expression of the gene. The premutated allele has 56-200 repeats and maintains normal expression of the FRM1 protein. However, the premutated allele is associated with increased risk for further expansion, pushing it into the fully mutated range, defined as greater than 200 repeats. Since each CGG repeat contains a CpG dinucleotide, this expanded repeat is recognized as an unstable genomic region that becomes heavily methylated. As in the case of other heavily methylated CpG islands (see The Epigenetic Machinery, DNA Methylation section), this methylated region recruits additional remodeling enzymes that form a highly repressive chromatin structure that prevents the expression of the FRM1 gene (Fig. 1.20–16).

In a subset of rare cases, individuals with fully mutated alleles (i.e., >200 repeats) do not develop clinical symptoms of FXS. In these rare cases, the expanded repeats somehow escape DNA methylation providing compelling evidence that DNA methylation is necessary to induce the clinical syndrome in individuals with the full mutation. Therefore, therapies that prevent DNA methylation could potentially rescue the neurodevelopmental sequelae of individuals with the fully mutated allele. Indeed, treatment with DNA demethylating agents such as 5-azacytidine of cell lines and iPSCs obtained from individuals with FXS were able to partially demethylate and express FMR1protein. However, the clinical utility of these compounds is limited due

Telegram: @medical_k

www.konkur.in

to their high degree of cytotoxicity and risk for mutagenesis, and there is a need to develop nontoxic, stable, and highly specific epigenetic interventions. Indeed, a recent proof of concept study has successfully used crisper technology to meticulously excise the CGG repeat from iPSCs derived from an FXS patient leading to full activation of the FMR1 gene and restoring normal electrophysiologic properties in neurons generated from these iPSCs. Although far in the future in terms of clinical utility, this work demonstrates the utility of iPSCs in testing outcomes of novel epigenetic interventions in humans.

Gene-by-Environment Interaction Modulates FKBP5 Expression and the Risk for PTSD

In many cases, the effects of stress on complex behaviors are mediated by genetic vulnerability. Several examples of this type of gene by environment interaction have been described in the psychiatric literature. However, the molecular details by which these interactions take place have only just started to emerge. This was recently illustrated in a series of studies showing how childhood trauma preferentially interacts with a specific genetic predisposition to increase the expression of the FK506-binding protein 5 (FKBP5) and the vulnerability to PTSD and depression.

Telegram: @medical_k

www.konkur.in

FIGURE 1.20–16. In normal individuals, the FRM1 gene contains 5–55 CGG repeats (each gray box represents 10 CGG repeats). Individuals with the premutation have 56–200 repeats and are phenotypically normal. However, they are at increased risk for repeat expansion during meiosis resulting in a fully mutated phenotype in their offspring. The DNA promoter of fully mutated individuals (>200 CGG repeats) becomes highly methylated (black no entry signs), leading to abnormally reduced FMR1 expression and the Fragile-X phenotype. Rarely individuals have been identified who possess the full mutation yet lack epigenetic silencing. These children are phenotypically normal, suggesting that DNA methylation is necessary to induce the clinical syndrome.

FKBP5 is a stress-related gene that exerts its effects via interaction with the GR. Under basal conditions, the GR is maintained in the cytoplasm by the heat shock 90 (Hsp90) and FKBP5 proteins, which bind GR and mask its nuclear localization signal. High levels of cortisol induced by stress dissociate Hsp90 and FKBP5 from GR, allowing it to enter the nucleus and induce two transcriptional programs. The first transcriptional program is essential for terminating further release of cortisol from the adrenal gland (see Epigenetic Transmission of Stress Reactivity and Maternal Behavior section). The second task involves the induction of FKBP5, a negative feedback loop that prevents further entry of GR into the nucleus. Retaining GR in the cytoplasm is thought to reset the stress response so it can be reactivated in response to additional threats (Fig. 1.20–17).

Conditions in which FKBP5 is overexpressed prevent normal activation of the GR, leading to inefficient termination of the stress response. This inability to terminate HPA activity leads to prolonged exposure to high levels of cortisol and is referred to as "*GR resistance*." GR resistance is associated with an increased risk for depression, PTSD and several other medical complications (Fig. 1.20–17). This disease model is similar to that described for insulin resistance, in which ineffective

Telegram: @medical_k

www.konkur.in

insulin signaling causes end-organ toxicity by maintaining high levels of glucose in the circulation.

The rs1360780 haplotype of the FKBP5 gene has an A/T and a C/G allele. At baseline, the A/T allele is associated with higher levels of GR-induced FKBP5 expression, leading to more robust HPA activation compared to the protective C/G allele (Fig. 1.20–18). While the A/T allele alone is not associated with increased risk for stress-related psychiatric disorders, the risk allele interacts with early life trauma in a dose-dependent manner to increase the risk for PTSD. In other words, individuals with the A/T allele that were exposed to more severe childhood maltreatment are more likely to develop PTSD and depression. This is not the case for individuals with the protective C/G allele in which exposure to childhood trauma is not associated with an increased risk for PTSD or depression.

The mechanistic explanation for these clinical observations points to a synergy between genetic and epigenetic regulation of FKBP5 levels and GR resistance. At the genetic level, A/T susceptible individuals show a more efficient GR-mediated FKBP5, producing higher levels of FKBP5 than C/G individuals. The FKBP5 gene has two glucocorticoid response elements (GREs) that are occupied by GR in response to stress. One GRE is found in intron 2 (GRE-2) is roughly 50 kb from the transcriptional start site (TSS), while a second GRE is found in intron 7 (GRE-7), about 100 kb from the TSS of FKBP5. Despite these long distances, both GREs are able to contact the TSS via long-distance loops. These chromatin-mediated loops recruit these GREs to the vicinity of the TSS, driving FKBP5 expression. When GR is activated, the GRE-7 site is recruited to the TSS regardless of the genotype. In contrast, GRE-2 is recruited to the TSS only in AT individuals. The presence of GRE-2 in the vicinity of the TSS results in a more robust expression of FKBP5 in response to stress and hence greater HPA activation in individuals with the A/T allele (Fig. 1.20–18). It is currently unclear how these genetic changes contribute to these differential looping configurations, but the presence of these loops is an important function of chromatin (see Active Chromatin section).

As a result of these genetic differences, A/T individuals exposed to childhood abuse are predicted to secrete higher levels of cortisol compared to C/G individuals. Greater cortisol levels are thought to decrease DNA methylation at the GRE-7–binding site in individuals with the risk allele. Decreased DNA methylation at GRE-7 leads to more efficient recruitment of GR, further augmenting FKBP5 expression and GR resistance in A/T individuals that were exposed to childhood trauma (Fig. 1.20–18). GRE-7 continues to be methylated in G/C individuals that were abused or neglected, demonstrating specific gene-by-environment interactions for this epigenetic marker. *Ex vivo* experiments with patient-derived monocytes show a strong negative correlation between GRE-7 methylation and glucocorticoid potency, supporting a functional role for this epigenetic biomarker in mediating GR resistance.

The ability of trauma to induce these epigenetic changes appears to be confined to a sensitive period, as exposure to trauma in adulthood does not lead to a decrease in the GRE-7 methylation rate. These clinical findings are supported by cell culture experiments in which dexamethasone decreases GRE-7 methylation in proliferating

Telegram: @medical_k

www.konkur.in

NSCs, but not in fully differentiated postmitotic neurons. When exposed during proliferation, this decrease in methylation is maintained after the NSCs differentiate into neurons, even once the dexamethasone stimulus is removed, suggesting stable propagation of demethylated GRE-7 into differentiated neurons. These observations suggest that exposure to stress during childhood, when high levels of neurogenesis are present, is responsible for this gene by early life stress interaction. Therefore, interventions that are aimed at decreasing stress early in life are likely to be more effective in reducing vulnerability to PTSD compared to interventions that eliminate stress in adulthood.

Telegram: @medical_k

www.konkur.in

FIGURE 1.20–17. A: In the absence of stress, when cortisol levels ("C" triangles) are low, the glucocorticoid receptor (GR) is bound to the chaperone proteins FKBP5 and HSP90. In this bound state, the GR is prevented from entering the nucleus and activating transcription. **B:** Exposure to stress increases cortisol levels allowing GR to enter the nucleus by displacing the FKBP5/HSP90 complex. Inside the nucleus, GR activates transcription of genes that terminate further cortisol release and activates transcription of FKBP5. Increased FKBP5 levels prevent further GR entry into the nucleus, resetting the system so it can respond to subsequent waves of stress. **C:** Overexpression of FKBP5 leads to GR Resistance by preventing high levels of cortisol from driving GR into the nucleus. As a result, additional levels of cortisol are being released, leading to high levels of circulating cortisol.

Epigenetic Suicide Signatures: Advance Toward a Biomarker

Telegram: @medical_k

www.konkur.in

Suicide is the 11th most common cause of death in the United States. The importance of accurate risk assessment is highlighted by the observation that roughly half of the individuals who commit suicide are seen by a mental health worker prior to their death. In the absence of reliable biomarkers to predict suicide, psychiatric evaluation relies on a long list of risk factors to assess the likelihood of lethal self-harm. These population-risk factors have poor predictive value, as most people who have these risks do not commit suicide, and some individuals who ultimately take their own life may not share these risks. Therefore, the recent findings that certain peripheral epigenetic markers can predict suicide with more than 80% accuracy provide a possible breakthrough for preventing these tragedies.

To search for epigenetic markers of suicide, DNA methylation patterns from the prefrontal cortex of depressed individuals who committed suicide were compared to depressed individuals who died of other causes. DNA methylation is amenable to study in postmortem tissue because of its relative stability and its ability to predict gene expression (see DNA methylation). Only one gene, coding for the spindle and kinetochore associated complex subunit 2 (SKA2), was found to be differentially methylated in neurons of suicide completers compared to the control group. SKA2 is a scaffolding protein that chaperones the GR into the nucleus and therefore helps terminate HPA activation in response to stress. Increased DNA methylation at the 3′ untranslated region (3′-UTR) of SKA2 was replicated in a separate postmortem cohort, suggesting that it represents a reliable retrospective biomarker of suicide. Methylation of SKA2 was associated with a decrease in SKA2 protein levels, suggesting that this epigenetic modification regulates SKA2 activity in suicide victims. Interestingly, the CpG methylation site at the 3′-UTR of SKA2 contains an alternative single-nucleotide polymorphism allele in which the cytidine is replaced with thymidine. This T allele cannot be methylated and is therefore considered to be the protective allele.

While postmortem replication is an important first step, the more important question is whether the presence of this epigenetic biomarker in peripheral tissue can predict future suicidal behavior in living patients. This was assessed by first comparing gene expression in prefrontal cortex neurons and glial cells obtained from the postmortem analysis and peripheral immune cells obtained from a different cohort of individuals with depression. This analysis showed a high correlation between gene expression in neurons, but not glia, and peripheral immune cells, suggesting that the two cell populations share similar epigenetic signatures, which is a critical feature in establishing a peripheral biomarker. Next, the relationship between SKA2 methylation state in peripheral immune cells, genetic makeup (T vs. C alleles), and suicidal ideation were assessed prospectively in three separate cohorts. The remarkable findings were a significant interaction between genetic disposition (T vs. C alleles) and epigenetic status (low vs. high methylation) in predicting suicidal ideation. In addition, levels of SKA2 methylation in immune cells were highly correlated with morning (waking) cortisol levels suggesting a possible functional link between SKA2 methylation and stress levels. In some cases, high levels of methylation at SKA2 were detected months before the reported onset of

Telegram: @medical_k

www.konkur.in

suicidal ideation, raising the possibility that this biomarker was present in these individuals before they developed suicidal thoughts.

The inclusion of additional variables such as cortisol levels and anxiety further improved the predictive value of the model. This revised model was tested in another prospective cohort using genotype (T vs. C alleles), methylation rate of SKA2, and anxiety scores. This model was able to predict suicidal behavior with 71% accuracy, which was increased to 82% when levels of salivary cortisol were added. Further refinement of the stringency of categorizing suicidal ideation improved the predictive value to 97%, successfully predicting all 4 eventual suicide attempts in this particular cohort.

These provocative findings have now been replicated by other groups providing one of the most tangible examples linking epigenetic markers with complex and devastating human behaviors such as suicide. The challenges of relating peripheral biomarkers to human psychopathology and behavior were elegantly addressed in this study by showing that the transcriptional and the epigenetic programs in the peripheral cells resemble those seen in postmortem neuronal tissue and by relating the methylation rate of SKA2 in the periphery with morning cortisol levels and suicidal ideation. It will be interesting to see if the peripheral methylation rate of SKA2 could be modified by treatment with ketamine, which has recently emerged as a rapid and promising treatment for suicidal ideation.

FIGURE 1.20–18. A: The FKBP5 gene has two GREs located in introns 2 (GRE-2) and intron 7 (GRE-7). **B:** The top two panels demonstrate the impact of the *genetic risk* on FKPB5 expression and GR resistance. On the left, GRE-2 containing the protective C/G allele is not recruited to the promoter/GRE-7 complex producing relatively low levels of FKBP5 and low cortisol **levels** in response to mild stress. The presence of the GRE-2 at the promoter/GRE-7 complex in the A/T allele (**top right**) produces higher levels of FKBP5 and hence higher levels of cortisol in response to mild stress. The bottom panels demonstrate the *epigenetic* contribution of early life stress to FKPB5 expression. Early life stress results in relatively low levels of cortisol and normal methylation at the GRE-7 in individuals with the C/G protective allele (**lower left panel**). In contrast, early life stress leads to higher cortisol levels and a decrease in the DNA methylation at the GRE-7 of

Telegram: @medical_k

www.konkur.in

individuals with the A/T risk allele. Demethylation at GRE-7 leads to more efficient GR binding to this site and, therefore, higher FKBP5 levels and GR resistance (**lower right panel**).

1.21 Pharmacogenetics

JULIO LICINIO, M.D., PH.D., M.B.A., M.S., AND MA-LI WONG, M.D., PH.D.

Why do some individuals respond so well to drugs–pharmacologic treatment and others do not? This fundamental question underlies the heterogeneity of treatment responses, which is one of the biggest challenges in the pharmacologic treatment of psychiatric disorders. While some respond exceptionally well to psychopharmacologic interventions, others do not. Likewise, some, but not others, have clinically meaningful side effects. Treatment outcomes consist of multiple combinations of positive and negative treatment responses. Those combinations can be broadly grouped into six categories as follows:

1. Fully positive clinical response, that is, remission or cure with minimal or occasional side effects.
2. Fully positive clinical response, but with clinically impactful side effects.
3. Partial clinical response with minimal side effects.
4. Partial clinical response with significant side effects.
5. Limited clinical response with minimal side effects.
6. Limited clinical response with substantial side effects.

The pharmacotherapy of psychiatric disorders is a process of shared decision making with patients, as both parties must balance risks and benefits. Choices may involve compromising efficacy to improve the tolerability of treatment. The better that physicians can predict risks and benefits for patients, the more likely treatment can be optimized to achieve the shared objectives of both physician and patient. A significant challenge for this process is the limited ability of physicians to predict clinical efficacy or medication tolerability before initiating treatment.

THE SEARCH FOR INDIVIDUALIZED PSYCHOPHARMACOLOGY

For decades, clinicians have sought markers that identify the likelihood of favorable outcomes before pharmacologic treatment is administered. These markers would move clinical practice into a situation where treatments would be personalized (personalized medicine) or given with precision (precision medicine). In current

Telegram: @medical_k

www.konkur.in

routine clinical practice, when considering medication targets, the choice focuses more on the issue of adverse drug reactions (ADRs). For example, as a first line of treatment, one would avoid giving a medication with potential cardiac side effects to someone with impaired cardiac function and heart disease.

The cost of our limited ability to predict clinical response is that many patients drop out of treatment before achieving a meaningful clinical response. This point was illustrated by the National Institute of Mental Health (NIMH)-funded Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study, the largest and longest study ever conducted to evaluate depression treatment. The overall goal of the STAR*D trial was to assess the effectiveness of depression treatments in patients diagnosed with major depressive disorder (MDD) in primary and specialty care settings. The study had four levels, each testing a different medication or combination. The primary goal of each level was to determine if the treatment used during that level could adequately treat participants' MDD. Those who did not remit (i.e., no symptom more than mild) could proceed to the next level of treatment. In level 1, about one-third of the participants reached remission, and about 10% to 15% more responded but did not reach remission. It is noteworthy and clinically crucial that almost 70% is remitted. However, the rate at which participants withdrew from the trial was meaningful and rose with each level—21% withdrew after level 1, 30% withdrew after level 2, and 42% withdrew after level 3.

A paradigm shift that would transform psychopharmacology from the mostly imprecise effort that it is today into a precision effort would be truly transformational for clinical psychiatry.

Pharmacogenetics' tremendous appeal comes from the promise of real-life clinical pharmacologic treatment guided by science and given to patients with precision based on their genetic makeup. Patients with similar clinical presentations treated with the same drug and dosage may have different outcomes. The underlying central hypothesis of pharmacogenetics is that one's genetic and epigenetic makeup is a significant determinant of treatment response. Thus, if we identify the genetic sequences that correlate with treatment outcomes with a specific drug, these sequences can serve as biomarkers to guide matching particular patients to specific treatments. Conversely, genetic or epigenetic biomarkers that predict adverse outcomes to particular medications could be used to guide patients to alternative medications and to prevent these bad outcomes.

PHARMACOGENETICS AND PHARMACOGENOMICS

There are two historical phases in pharmacogenetics: Before and after 2000, when the rough draft of the entire human genome was finished. Before 2000, genetic sequencing was expensive and limited as we needed the human genome blueprint. Until then, we could test for particular genetic variants at a high cost. In contrast, after 2000, technology grew at a vertiginous pace, and we can now sequence a person's entire genome at a moderate cost. As a reference, the total cost of the Human Genome Project is reported to have been USD 3 billion. Today, whole

Telegram: @medical_k

www.konkur.in

genome sequencing is offered at a direct-to-consumer price range of USD 300 to 800, depending on the level of DNA sequencing depth.

As we look at genome-wide data in some circles, a distinction was created between pharmacogenetics, based on testing specific sequences, and pharmacogenomics, based on whole genome sequence data. However, in many settings, including this chapter, the terms pharmacogenetics and pharmacogenomics are used interchangeably.

PHARMACOKINETICS AND PHARMACODYNAMICS

As we seek to optimize treatment response, it is essential to understand the two critical aspects of pharmacology with direct relevance to pharmacogenetics: pharmacokinetics and pharmacodynamics. Different proteins and their encoding genes mediate each of them. Therefore, some pharmacogenetic targets will map to pharmacokinetic pathways, while others will be related to pharmacodynamics (Fig. 1.21–1).

PHARMACOGENETICS OF PHARMACOKINETICS

Pharmacokinetics refers to all the factors that regulate drug availability. Drugs enter the body and are metabolized. Their bioavailability reflects the balance between drug administration, metabolism, and excretion. Drug metabolism occurs primarily in the liver, particularly as drugs enter the liver from the portal venous blood before reaching the systemic bloodstream in the “hepatic first pass.” Drug excretion happens principally through the kidney.

Telegram: @medical_k

www.konkur.in

FIGURE 1.21–1. The trajectory of an antidepressant drug from ingestion through pharmacokinetics (*left-hand column*) to pharmacodynamics (*right-hand column*). Boxes show representative pharmacogenetic targets. CYP2D6, cytochrome P450 family 2 subfamily D member 6; MDR1, multidrug resistance protein 1, also known as adenosine triphosphate (ATP)-binding cassette subfamily B member 1, ABCB1; SERT, serotonin transporter, also known as solute carrier family 6 member 4, SLC6A4; NET, norepinephrine transporter, also known as solute carrier family 6 member 2, SLC6A2; DAT, dopamine active transporter, also known as solute carrier family 6 member 3, SLC6A3; CREB, cyclic adenosine monophosphate (cAMP) response element-binding protein; BNDF, brain-derived neurotrophic factor, and trkB, tyrosine receptor kinase B, the receptor for BDNF. (See eBook for color images.)

The drug-metabolizing enzymes belong to the cytochrome P450 (CYP) superfamily. Data from the Human Genome Project show 57 human genes coding for the various CYP enzymes. Of those, a small but highly significant subset is particularly relevant for psychiatry because they metabolize many of the drugs we use in our field. Furthermore, they have multiple genetic variants of functional relevance and are prime targets for treatment optimization based on pharmacogenetics. Specifically, six CYPs metabolize 90% of drugs; the two most significant enzymes are CYP3A4 and CYP2D6.

Note that there are complex relationships between multiple drugs and CYP enzymes. On the one hand, a drug can be metabolized by more than one CYP. On the other hand, when different drugs are taken together, the effect of one drug on the function CYP450 enzyme can affect the metabolism of another drug by that same enzyme. Specifically, some drugs are solely substrates for CYP enzymes, but other drugs or herbal products can either induce or inhibit the activity of a CYPP450 enzyme. Therefore, taking one drug that either induces (e.g., haloperidol) or inhibits (e.g., bupropion, methylphenidate, sertraline, or escitalopram) the activity of CYP2D6 will affect the metabolism of drugs that are substrates for CYP2D6, such as

Telegram: @medical_k

www.konkur.in

imipramine, fluoxetine, venlafaxine, duloxetine, mirtazapine, or oxycodone. It is a relatively common situation clinically that someone will have attention deficit hyperactivity disorder (ADHD) and depression and may be treated with a combination of the CYP2D6 inhibitor methylphenidate and an antidepressant that is a CYP2D6 substrate, such as fluoxetine, venlafaxine, duloxetine, or mirtazapine. In these cases, patients may better respond to lower doses of the (CYP2D6 substrate) antidepressant.

CYP3A4

This enzyme metabolizes about 50% of all drugs on the market, including tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), some other antidepressants, buspirone, multiple antipsychotics, opioids (mainly analgesics), methadone, benzodiazepines, anticonvulsants, mood stabilizers, and barbiturates. Over 38 single-nucleotide polymorphisms (SNPs) have been identified in the *CYP3A4* gene, which is part of a cluster of CYP450 genes on chromosome 7q22.1, some resulting in decreased and others increased catalytic activity with certain ligand drugs, compared to wild-type CYP3A4 metabolism. Of note, CYP3A4 can be induced on exposure to substrates. CYP3A4 activity levels have also been linked to diets and environmental factors, such as duration of exposure to xenobiotic substances and nutritional status, given the enzyme's extensive presence in the intestinal mucosa. Therefore, directly translating pharmacogenetics into significant interindividual variability *in vivo* is not straightforward.

CYP2C19

CYP2C19 is a member of the CYP2C subfamily of the mixed-function oxidase system, which includes enzymes responsible for metabolizing xenobiotics such as proton pump inhibitors and antiepileptic drugs. In humans, the *CYP2C19* gene, located on chromosome 10q24, encodes the CYP2C19 protein, which is primarily found in the liver and responsible for metabolizing at least 10% of drugs currently used in clinical practice. These include clopidogrel (Plavix), which is used as an antiplatelet treatment, pain medications such as omeprazole, antiseizure drugs like mephenytoin, and diazepam, as well as some barbiturates. CYP2C19 is also involved in epoxygenase activity and plays a crucial role in the formation of signaling agents through the attack of double bonds in long-chain polyunsaturated fatty acids.

Also known as loss-of-function alleles, *CYP2C19*2* and *3* have been linked to a reduction in enzyme activity, while *CYP2C19*17*, a gain-of-function allele, leads to increased activity. These three variant alleles are recommended to be included in the minimal clinical pharmacogenomic testing panel.

CYP2C19 is also involved in the metabolism of several TCAs such as imipramine, amitriptyline, trimipramine, and clomipramine, as well as the secondary amine TCA nortriptyline. In CYP2C19 poor metabolizers (PMs), these TCAs have been found to lead to greater plasma concentrations and active metabolite levels, resulting in a higher risk of adverse effects. CYP2C19 is also involved in the metabolism of SSRIs,

Telegram: @medical_k

www.konkur.in

including citalopram, sertraline, fluoxetine, and venlafaxine, as well as the reversible monoamine oxidase inhibitor moclobemide. CYP2C19 genotype has been found to affect citalopram serum concentration, while patients with one or two loss-of-function alleles have higher dose-adjusted serum concentrations of sertraline than normal metabolizers, which can predict outcomes.

The clinical relevance of CYP2C19 ultrarapid metabolizers (UMs) is still under investigation, and *CYP2C19*17* has been found to be linked to lower serum concentrations of several antidepressants in comparison to normal metabolizers. However, further research is required to ascertain the clinical importance of UM genotypes in antidepressant therapy.

CYP2D6

CYP2D6 constitutes up to 2% of hepatic CYP content and it is responsible for the metabolism and elimination of approximately 25% of clinically used drugs by adding or removing specific functional groups, such as hydroxylation, demethylation, and dealkylation. CYP2D6 is encoded by genes on human chromosome 22. *CYP2D6* has multiple functional alleles, some of them providing standard effects, while others have either low or high activity. *The CYP2D6*1* allele is commonly used as a reference allele and is assumed when no variant is detected by a genotyping test. Individuals with a normal enzyme activity and no variants detected are often associated with the *CYP2D6*1* allele, which is known as the extensive metabolizer phenotype. Some groups use this term to refer to individuals with this phenotype. The *CYP2D6* gene may also be duplicated or multiduplicated in some individuals who then have very high CYP2D6 enzymatic activity. Please refer to Figure 1.21–2 for further details. Those drugs are among the most widely used in medicine and psychiatry. Please refer to Figure 1.21–3 for a diagram showing recognized pharmacogenes according to their association with drugs used in different therapeutic areas.

Telegram: @medical_k

www.konkur.in

FIGURE 1.21–2. Selected CYP2D6 genetic polymorphisms, with functional implications. Genetic variability is the primary cause of interindividual phenotypic diversity in CYP2D6. The genetic spectrum of CYP2D6 comprises several hundred well-defined allelic variants, such as null alleles, functional variants, splice variants, and structural variants including complete gene loss, gene amplifications, and hybrid genes. When compared to extensive metabolizers (EMs), who have at least one fully functional allele, individuals classified as poor metabolizers (PMs) carry two nonfunctional alleles and have a significantly reduced ability to eliminate CYP2D6 drug substrates. The intermediate metabolizer (IM) phenotype is another genetically determined trait that results from the presence of reduced-function alleles, while the ultrarapid metabolizer (UM) phenotype is caused by CYP2D6 gene duplications of functional alleles. (See eBook for color images.) (With permission from Zanger UM. Genetic variability of CYP2D6: basic and clinical aspects. In: Baumann P, ed. *CYP2D6: Genetics, Pharmacology and Clinical Relevance*. Future Medicine Ltd, Future Science Group; 2014:28–41. https://doi.org/10.2217/fmeb2013.14.16.)

Even though CYP3A4 metabolizes more drugs, CYP2D6 may be clinically more critical as it metabolizes more of the most widely used drugs. CYP2D6 is particularly relevant to psychiatry, as it metabolizes all TCAs, most selective serotonin receptor reuptake inhibitors—such as fluoxetine, paroxetine, fluvoxamine—as well as venlafaxine, duloxetine, mianserin, mirtazapine, minaprine, opioids, codeine, oxycodone, hydrocodone, antipsychotics—such as haloperidol, risperidone, perphenazine, thioridazine, aripiprazole, chlorpromazine, levomepromazine, and remoxipride—cocaine, amphetamine, methoxyamphetamine, dextromethamphetamine, lisdexamfetamine, and atomoxetine. CYP2D6 also metabolizes widely used drugs, such as beta-blockers, antiarrhythmics, calcium channel blockers, H3 receptor antagonists, antihistamines, and multiple other therapeutically essential drugs, such as tamoxifen.

Telegram: @medical_k

www.konkur.in

Based on one's combination of *CYP2D6* genetic alleles, individuals can be functionally classified as PMs (little or no CYP2D6 function), intermediate metabolizers (IMs) (metabolize drugs at a rate somewhere between the poor and extensive metabolizers), extensive metabolizers (standard CYP2D6 function), and UMs, who have multiple copies of the *CYP2D6* gene, resulting in greater than normal function. CYP allele frequencies and metabolizer status vary across populations worldwide. Therefore, normative data from one population may not be applicable across the board.

FIGURE 1.21–3. Venn Diagram showing recognized (non-HLA) pharmacogenes according to their association with drugs used in different therapeutic areas. CYP2D6 overlaps with four distinct therapeutic areas. BCHE, butyrylcholinesterase; CFTR, cystic fibrosis transmembrane conductance regulator; CYP2B6, CYP2C9, CYP2C19, CYP3A5, CYP4F2, members of cytochrome P450 superfamily; DPYD, dihydropyrimidine dehydrogenase; F5, factor 5; G6PD, glucose-6-phosphate dehydrogenase; IFNL3, Interferon lambda 3; ITPA, inosine triphosphate pyrophosphohydrolase; NAT2, N-acetyltransferase 2; NUDT15, nudix hydrolase 15; POLG, DNA polymerase subunit gamma; RARG, retinoic acid receptor gamma; SLCO1B1, solute carrier organic anion transporter family member 1B1; SLC28A3, solute carrier family 28 member 3; TPMT, thiopurine S-methyltransferase; UGT1A1, UDP-glucuronosyltransferases; VKORC1, vitamin K epoxide reductase complex. (See eBook for color images.) (With permission from Taylor C, Crosby I, Yip V, Maguire P, Pirmohamed M, Turner RM. A review of the important role of CYP2D6 in pharmacogenomics. *Genes*. 2020;11:1295. doi:10.3390/genes11111295. License: https://creativecommons.org/licenses/by/4.0/)

The more active CYP2D6 is, the faster the drugs metabolized by this enzyme will be cleared. Therefore, standard doses may be insufficient for UM, and higher doses are required. CYP2D6 UMs may not respond to a psychiatric drug simply because their standard dose is too low. They are then inappropriately labeled as nonresponders when they have yet to receive an adequate dosage of a drug that might be excellent for them. Conversely, poor and IMs will break down prescribed

Telegram: @medical_k

www.konkur.in

drugs more slowly than those with standard CYP2D6 function. At least 15 allelic variants of *CYP2D6* can cause PM phenotype, but 75% of PMs are *CYP2D6*4* homozygotes. Therefore, by taking standard dosages, they accumulate bioactive drugs that may rapidly result in serious side effects. The patients are then incorrectly labeled as intolerant to a drug that was actually given to them in doses that far exceeded their metabolic capacity. In this case, the doses should be lowered to offset the slow metabolism, and individuals may respond well to the individually tailored dosage.

Multiple reports have shown that individuals who appear to be treatment refractory were either UM or PM. The UM did not receive enough medication dosage, and the PM received doses that exceeded their capacity to metabolize the drug. Therefore, they involuntarily and rapidly overdosed and experienced ADRs that led them to drop out of treatment before a clinical effect could be achieved.

CYP2D6 Phenocopying and Autophenocopying. The use of CYP2D6 substrates in therapy can be complicated, not only due to genetic variability but also due to drug–drug interactions. Several drugs, such as statins, are CYP2D6 inhibitors, and co-administration with a CYP2D6 substrate can alter the apparent phenotype of a patient. This occurrence is referred to as phenocopying. In such situations, an individual with a standard metabolizer phenotype may appear to be an IM or a PM because most of the available enzyme is being inhibited by the confounding drug. Another related phenotype that can arise with chronic administration of a CYP2D6 drug is called autophenocopying, in which the substrate inhibits its own metabolism as the drug concentration reaches a steady state. Consequently, the pharmacokinetic profile of a single dose and of repeated dosing for drugs that exhibit phenocopying can vary significantly.

PHARMACOKINETICS BEYOND DRUG LEVELS OF THE PARENT DRUG

The effects of P450 genotypes on drug bioavailability go beyond the simple pharmacologic prediction of the levels of the parent compound. In many cases, drug development takes drug metabolism into action, and the drug that is prescribed and ingested is a prodrug that requires metabolism for bioactivity. In these cases, we have the reverse situation of what was described above. PM may have insufficient active drugs as they do not metabolize the parent drug well, and UM may then have excessive bursts of the active drug as they metabolize the parent compound very rapidly.

Drugs may be formulated as prodrugs for a variety of reasons. These include improved stability during manufacture and storage, enhanced absorption by the body, or superior pharmacokinetics. All of these advantages of prodrugs make them attractive for use in drug formulations. Since its inception in 1958, the concept of prodrugs, proposed by Albert, has been used to alter the physical and chemical

Telegram: @medical_k

www.konkur.in

properties of drugs to render them pharmacologically inactive until metabolized in the body.

Lisdexamphetamine

Lisdexamphetamine (LDX) is a unique type of long-acting stimulant prodrug that was the first of its kind for treating ADHD and binge-eating disorder. It also has similar off-label uses as other pharmaceutical amphetamines. LDX is inactive and requires hydrolysis to convert it into the potent central nervous system (CNS) stimulant dextroamphetamine. The chemical structure of LDX consists of the amino acid L-lysine attached to dextroamphetamine. Although drug efficacy may not be directly related to pharmacokinetic characteristics, LDX's significant impact on symptoms could be linked to the predictable bioavailability of the active ingredient, d-amphetamine, upon hydrolysis from the inactive prodrug. The United States approved LDX for medical use in 2007, and in 2020, it was the 85th most commonly prescribed medication in the country, with over 8 million prescriptions. LDX is classified as a Class B controlled substance in the United Kingdom and a Schedule II controlled substance in the United States.

Codeine

Codeine is a prodrug that is converted to morphine, a potent mu-opioid receptor agonist, by the CYP2D6 enzyme, as illustrated in Figure 1.21–4. Ultrarapid metabolizers (UM), who produces higher levels of active metabolites such as morphine and morphine-6-glucuronides, are at an increased risk for opioid-related side effects, including respiratory depression. Several case reports have documented severe and even life-threatening opioid intoxication in patients with UM due to functional duplication of the CYP2D6 gene. In addition, a clinical study showed that breastfeeding newborns whose mothers had an ultrarapid metabolism genotype were at a higher risk of respiratory depression. As a result, the Clinical Pharmacogenetics Implementation Consortium has published guidelines recommending genotyping before prescribing codeine. Moreover, an observational study on postpartum analgesia revealed that patients with poor metabolism genotypes received no analgesic effect from codeine, whereas those with ultrarapid metabolism genotypes experienced sedation.

Telegram: @medical_k

www.konkur.in

FIGURE 1.21–4. Codeine Metabolism Pathway. The activity of codeine depends on its conversion to morphine by CYP2D6. Morphine is subsequently metabolized to the active morphine-6-glucuronide by means of UDP-glucuronosyltransferase 2B7. The gene encoding CYP2D6 has many genetic variations that affect the amount of codeine that is converted to an active form and that results in the drug's variable effect. (From Racoosin JA, Roberson DW, Pacanowski MA, Nielsen DR. New evidence about an old drug–risk with codeine after adenotonsillectomy. *N Engl J Med*. 368;23:2155–2157.)

Tramadol

Similarly, tramadol, another prodrug, is metabolized by CYP2D6 to O-desmethyltramadol, also known as (+)-M1, which has mu-opioid receptor activity. Patients with UM genotypes have been found to have higher levels of tramadol metabolites and a reduced experience of discomfort from experimental pain. In contrast, those with PM genotypes showed minimal clinical effects with low levels of detectable metabolites. Case reports have also highlighted the potential risk of respiratory depression in patients with UM genotypes.

THE PHARMACOKINETICS OF ONE DRUG MAY GENERATE MULTIPLE ACTIVE COMPOUNDS

In other, more complex cases, both the parent drug and its metabolite(s) are bioactive. There are several examples where the pharmacokinetics of administered

Telegram: @medical_k

www.konkur.in

drugs results in active metabolites with properties that may differ from that of the parent compound. The pharmacogenetics of CYP enzymes may determine final therapeutic effects based on the different combinations of parent compounds versus metabolites that are generated due to the bioactivity of CYP enzyme isoforms. There are several such cases in psychopharmacology. We provide here some illustrative examples.

Clozapine and Desmethylclozapine

Clozapine and its active metabolite, N-desmethylclozapine (NDMC), are metabolized by several CYP enzymes, including CYP1A2, CYP2D6, CYP3A4, and CYP2C19. The activity of CYP1A2 is particularly relevant in determining the required dose of clozapine. While clozapine is an atypical antipsychotic that acts as an antagonist at the D2/D3 receptors, NDMC has intrinsic activity at these receptors and acts as a weak partial agonist, similar to aripiprazole and bifeprunox. Moreover, NDMC has been shown to be a potent agonist at the M1 and delta-opioid receptors, unlike clozapine. These unique actions of NDMC led to the hypothesis that it might be responsible for the clinical superiority of clozapine over other antipsychotics. However, clinical trials have demonstrated that NDMC alone is ineffective in treating schizophrenia, specifically in managing positive symptoms. Nevertheless, it remains possible that NDMC could contribute to the efficacy of clozapine in treating cognitive and negative symptoms of the disease. Targeting M1 receptor agonism could be a promising avenue for developing drugs that can address cognitive deficits in schizophrenia and other neuropsychiatric disorders.

Clomipramine and Desmethyl Clomipramine

Clomipramine, a TCA, undergoes significant biotransformation before excretion. One of the primary routes of hepatic first-pass metabolism is demethylation into desmethyl clomipramine by several CYP enzymes, including CYP2C19, CYP3A4, and CYP1A2. In-vivo studies have shown that CYP2C19 is involved in this process, while in-vitro studies have demonstrated the involvement of CYP3A4 and CYP1A2. Notably, smokers exhibit lower plasma concentrations of clomipramine than nonsmokers, suggesting a role for smoking-induced CYP1A2. Desmethyl clomipramine is an active metabolite that is a more potent inhibitor of norepinephrine reuptake and a weaker serotonin reuptake inhibitor than the parent drug. Both the parent drug and the active metabolite undergo hydroxylation, catalyzed by CYP2D6, to form several metabolites, including 8-hydroxy desmethyl clomipramine, 8-hydroxy clomipramine, 2-hydroxy clomipramine, and 2-hydroxy desmethyl clomipramine. The 2- and 8-hydroxylated metabolites are primarily excreted through the kidneys as glucuronide conjugates. Desmethyl clomipramine can also be further demethylated to produce didesmethyl clomipramine. The elimination half-life is approximately 24 hours for clomipramine and 96 hours for desmethyl clomipramine. Typically, it takes around 3 weeks to reach steady-state concentration.

Dextromethorphan and Dextrorphan

Dextromethorphan (DM) and its active metabolite, dextrorphan (DXO), share pharmacodynamic similarities with the antidepressant ketamine and have been suggested to possess rapid-acting, conventional, and treatment-resistant antidepressant properties. DM is primarily metabolized to DXO by CYP2D6. DXO is an N-methyl-D-aspartate (NMDA) antagonist and contributes to the psychoactive effects of DM, producing phencyclidine-like behavioral effects in animals. In addition, DXO exhibits anticonvulsant and neuroprotective properties in various experimental models.

Diazepam and Oxazepam

Diazepam is metabolized to either nordiazepam by CYP 2C19 or temazepam by CYP3A4. Nordiazepam and temazepam are hydroxylated and demethylated to oxazepam. Oxazepam is then glucuronidated and excreted in the urine. Therefore, due to its pharmacokinetics, those who take diazepam have a combination of multiple active metabolites, including nordiazepam, temazepam, and oxazepam. Diazepam treats anxiety, but it is more likely to cause dependence. Oxazepam treats short-term anxiety and insomnia and is also used as a first-line treatment to prevent alcohol withdrawal symptoms.

PHARMACOKINETICS AND ALCOHOLISM

Drug metabolism (pharmacokinetics) can determine the susceptibility to alcohol use disorder (AUD). The effects of alcohol on various organs, including the brain, are influenced by the amount of ethanol and the duration of exposure. These factors are impacted by how quickly the ethanol is absorbed into the bloodstream and tissues and how efficiently it is metabolized. The liver is the primary site of ethanol metabolism, and the main process for ethanol metabolism involves converting it into acetaldehyde through alcohol dehydrogenases (ADHs) enzymes and then into acetate by aldehyde dehydrogenase (ALDH) enzymes. Other enzymes, such as CYP2E1, metabolize a small portion of ingested ethanol.

Multiple genes encode ADH and ALDH enzymes, and the variants of these enzymes differ in their rates of ethanol and acetaldehyde metabolism and production levels. These variations can impact an individual's drinking patterns and the likelihood of developing alcohol dependence. Certain ADH and ALDH alleles have been shown to reduce the risk of becoming alcohol dependent, and these gene associations are widely recognized and significant. However, the frequency of ADH and ALDH variants varies among ethnic groups.

The mechanism by which ADH and ALDH variants influence the risk of alcoholism involves an increase in acetaldehyde levels. This may be due to either more rapid oxidation of ethanol (in cases with more active ADH variants) or slower oxidation of acetaldehyde (in cases with less active ALDH variants).

Telegram: @medical_k

www.konkur.in

Acetaldehyde is a toxic substance that can produce an unpleasant reaction, including facial flushing, nausea, and tachycardia. The ADH1B2 allele, associated with fast ethanol oxidation, protects against alcohol dependence in various populations.

In East Asians, carrying one ADH1B2 allele reduces the odds ratio of developing alcoholism to 0.19, and carrying two ADH1B2 alleles reduces it to 0.12, compared to a person carrying two ADH1B1 alleles. The ADH1B2 allele is less prevalent in European and African populations but still offers protection against alcoholism. Among people of Jewish ancestry, the ADH1B2 allele occurs with moderate frequency and reduces binge drinking and the risk of alcoholism. However, the protective effect of ADH1B2 is weaker in European populations than in Asian populations, possibly due to varying social and environmental factors. It could also be co-inherited with other unidentified ADH variations that affect the risk of alcoholism, which could differ among Europeans and Asians.

PHARMACOKINETICS, PHARMACOGENETICS, AND DRUG ENTRY INTO THE BRAIN

In addition to liver enzymes, the pharmacokinetics of drugs acting in the brain, such as those used to treat psychiatric disorders, depend on proteins that regulate drug entry into the CNS. As an example, adenosine triphosphate (ATP)-binding cassette (ABC) subfamily B member 1 (*ABCB1*), also known as multidrug resistance protein 1 (*MDR1*), is 1 of 49 putative members in the superfamily of human ABC transporters, encoding transporter and channel proteins that function as efflux pumps. *ABCB1/MDR1* appears to modulate the brain concentrations of several antidepressants.

GEOGRAPHIC AND ETHNIC PHARMACOKINETIC VARIABILITY

The CYP enzymes are highly polymorphic, with immense genetic variability. That variability is deposited and freely available in two federally funded and connected databases, the Pharmacogene Variation Consortium or PharmVar (https://www.pharmvar.org) and the Pharmacogenomics Knowledgebase or PharmGKB (https://www.pharmgkb.org). As an example, PharmVar shows 171 CYP2D6 alleles, most with multiple variants, demonstrating the existence of several hundred CYP2D6 allele variants. For CYP2C19, PharmVar shows 39 alleles, some of them with several variants, while for CYP2C19, PharmVar shows 38 alleles, some of them also having several variants. Those allele frequencies vary substantially worldwide, across different regions and ethnic groups. Therefore, therapeutic ranges for specific drugs can vary widely depending on the genetic makeup of diverse populations worldwide.

Telegram: @medical_k

www.konkur.in

Using CYP2D6 UMs as an example, considerable variability in allele frequency is found in UM. This is because those individuals tend to be undertreated, as standard doses of medications metabolized by CYD2D6 are rapidly cleared from their bodies. It is, therefore, not surprising to see that UMs have higher hospital admission rates, presumably, because their underlying diseases are undertreated. To show the very drastic variations in rates of UM across populations, a large study conducted in Kentucky, United States, showed that the overall prevalence of CYP2D6 UMs was 1.5% in Caucasians and 2.0% in African Americans. This is consistent with other studies. In contrast, other work by Aklillu et al. (2006) has shown that 29% of the population in Ethiopia carried alleles with duplicated or multiduplicated CYP2D6 genes. In Saudi Arabia, 21% of subjects studied had genetic profiles indicative of CYP2D6 gene duplication, as documented by McLellan RA et al. (1997).

FIGURE 1.21–5. Worldwide CYP2D6 nonnormal metabolizer probability estimates. (From Koopmans AB, Braakman MH, Vinkers DJ, Hoek HW, van Harten PN. Meta-analysis of probability estimates of worldwide variation of CYP2D6 and CYP2C19. *Transl Psychiatry.* 2021;11:141. doi:10.1038/s41398-020-01129-1. License: https://creativecommons.org/licenses/by/4.0/)

Koopmans et al. conducted a meta-analysis of probability estimates of worldwide variation of CYP2D6 and CYP2C19. Due to the high frequency of allele duplications, high percentages of CYP2D6 UM were found in the Mozabite people, a Berber ethnic group in the Sahara, North Africa (39.5%), in non-Austronesian Melanesians (21.5%), and the ethnoreligious Druze from the Middle East (21.4%). On the other hand, high percentages of CYP2D6 PM were found in Europeans, for example, in the British (12.1%), the Danish (10.6%), and Basque (French) people (9.7%) due to the high frequency of *CYP2D6*4*. Frequencies of CYP2D6 predicted phenotypes by ethnicity worldwide are summarized in Figure 1.21–5.

Telegram: @medical_k

www.konkur.in

Such evidence covers UM as an illustration. Substantial cross-population variability also exists for CYP2D6 PMs. Bertilsson et al. described that among Swedish Caucasians, 6.3% were PM. This incidence is very similar to that in other European Caucasian populations (7% to 10%). In collaboration with Lou and associates in Beijing, they showed that the incidence of PM among the Chinese was only 1%. A similar low incidence of PM has been shown in Japanese and Koreans. As they assessed PM in various communities, they discussed the genetic heterogeneity of different black populations of Africa. Looking at CYP2D6 phenotype from genotype across world populations, Gaedigk and colleagues showed that allele frequencies vary considerably across the major ethnic groups predicting PM status (activity score, AS = 0) between 0.4% and 5.4% across world populations. The prevalence of genotypic intermediate (AS = 0.5) and standard (AS = 1, 1.5, or 2) metabolizers ranges between 0.4% and 11% and between 67% and 90%, respectively. Finally, 1% to 21% of subjects (AS >2) are predicted to have UM status. The ranges of 0.4% to 5.4% and 1% to 21% are extensive and demonstrate that standard doses are not standard across populations worldwide.

CULTURE OR ETHNICITY-RELATED PHARMACOGENETICS?

Another point to consider is that both cultures and allele frequencies vary across populations, and sometimes pharmacogenetic variants may be mistaken for cultural factors. For example, in Hispanic women, depressive symptoms and ADRs frequently present as somatic symptoms. These symptoms may include fatigue, headaches, backaches, insomnia, and loss of appetite, which in Hispanics may be misattributed to cultural factors when they could be due to genetic background. In our pharmacogenetic studies, we reported on Hispanic patients who were homozygous for *CYP2D6*4* and were consequently PM. While receiving low doses of antidepressants, the blood levels of the treatment drug were substantially above the therapeutic range, with concomitant ADRs, namely worsened anxiety and physical symptoms including palpitations, hyperventilation, and myalgias. They were appropriately managed because they were in a prospective antidepressant pharmacogenetic study. Their genetically determined somatic symptoms might have been easily attributed to cultural factors in other settings.

PHARMACOGENETICS OF PHARMACODYNAMICS

Pharmacodynamics refers to the interactions of drugs with their targets, in our case, the CNS, as well as all downstream effects relevant to a drug's effects and mechanisms of action. Drugs can fail because they must achieve sufficient concentrations at the targets in the context of pharmacokinetic factors. On the other hand, even at sufficient or even high levels at the target cells, some individuals may not respond sufficiently to a drug because of genetic variants with functional relevance at the level of drug targets, such as receptors and transporters, or at the level of downstream second messenger pathways. While clinical pharmacology has

Telegram: @medical_k

www.konkur.in

evolved substantially to identify the enzymes involved in drug metabolism and their genetically based functional variability, we still need to fully identify the ultimate mechanisms of action and therapeutic pathways for most psychotropic drugs. With few exceptions, such as drugs used to treat anxiety and ADHD, most drugs used in psychiatry take a long time to exert their therapeutic effects, despite rapidly reaching immediate targets. Those targets include the human serotonin transporter encoded by the *SLC6A4* gene, the target for SSRIs, and the dopamine receptor D_2, also known as D2R, encoded by the *DRD2* gene, the target for antipsychotics. Clinical effects require many days to weeks of continuous drug treatment; therefore, drug action mechanisms are beyond the initial targets, and the final therapeutic aims have not yet been identified. It is challenging to develop pharmacogenetic biomarkers of therapeutic response at the pharmacodynamic level without fully elucidating the mechanisms of action for most drugs used in psychiatry. As that knowledge basis grows, the number of potential pharmacodynamic pharmacogenetic targets increases exponentially. For example, in 2011, we published a paper covering 29 pharmacodynamic targets in the pharmacogenetics of antidepressants (Licinio & Wong, 2011). In 2023, when searching PharmGKB.org for antidepressant pharmacogenomics, we find 1,300 variant annotations and 334 clinical annotations.

On a positive note, as new pharmacodynamic pathways of treatment responses are identified, not only will the genes related to those pathways be natural aims for future pharmacogenetic testing, but they will also have the potential to become therapeutic targets for conceptually novel treatments.

PHARMACOGENETICS OF SPECIFIC PSYCHIATRIC DISORDERS

This evolving field has been expertly reviewed elsewhere. We have edited one of the first books on this topic (Licinio & Wong, 2009). We would refer readers to relevant recent papers on each disorder that are listed in our reference section, including the pharmacogenetics of major depression and bipolar disorder, exciting work on the pharmacogenetics of lithium treatment response, as well as advances on the pharmacogenetics of ketamine. In schizophrenia, a particular area of interest has been the use of pharmacogenetics to identify those most likely to gain substantial weight and develop metabolic complications following antipsychotic use, particularly, but exclusively restricted clozapine. Other areas of emerging pharmacogenetic interest include, but are not restricted to, ADHD, obsessive-compulsive disorder (OCD), and anorexia nervosa.

Using antidepressants as an example, Figure 1.21–1 depicts the steps from drug intake to action, with representative pharmacogenetic targets along the way. With antidepressants and antipsychotics as case examples, Figures 1.21–6 and 1.21–7 depict CYP2D6-mediated quantitative influences on the pharmacokinetics of antidepressant (see Fig. 1.21–6) and antipsychotic (see Fig. 1.21–7) drugs.

PHARMACOGENETIC TESTING: A BRIEF OVERVIEW

Optimizing drug dosage based on genetic profiles related to CYP enzymes is the constituent element of pharmacogenetics that is most available for immediate translation to clinical settings. As an example of emerging translation, there are now various Medicare-funded pharmacogenetic tests that inform the optimal prescribing of antidepressants by taking CYP enzyme genotypes and their predicted functional capacity into consideration to adjust drugs and dosages.

FIGURE 1.21–6. CYP2D6-mediated quantitative influences on the pharmacokinetics of antidepressant drugs expressed as percent dose adjustments: CYP2D6 PM (*white*), IM (*gray*), EM (*dark gray*), UM (*black*). If data on active drug moiety (consisting of active principle metabolite plus parent drug of active enantiomers of a racemic drug) were given, dose recommendations were based on these data only (other studies not providing such detailed information were not incorporated). If more than one study was integrated, the weighted mean for the dose adjustment was taken according to the number of poor metabolizers in each study. Data on mirtazapine, moclobemide, fluoxetine, and maprotiline were not shown in the figure since no dose adjustment based on CYP2D6 can be recommended at present. (With permission from Kirchheiner J, Nickchen K, Bauer M, et al. Pharmacogenetics of antidepressants and antipsychotics: the contribution of allelic variations to the phenotype of drug response. *Mol Psychiatry.* 2004;9:442–473. doi: 10.1038/sj.mp.4001494.)

Pharmacogenetics of antidepressants and antipsychotics: the contribution of allelic variations to the phenotype of drug response. *Mol Psychiatry.* 2004;9:442–473. doi: 10.1038/sj.mp.4001494.)

Despite the potential ease of translational pharmacogenetics related to pharmacokinetics, it must be highlighted that this pharmacology component primarily addresses bioavailability. Accordingly, we only ensure that adequate drug amounts reach their therapeutic targets by optimizing pharmacokinetics through pharmacogenetics. However, that does not ensure therapeutic outcomes that will be dependent on pharmacodynamics.

Limitations of our knowledge of pharmacodynamic targets hamper the full translation of pharmacogenetics to clinical settings. As illustrative examples based on information currently provided at their websites, Medicare-funded Castle's IDgenetix Pharmacogenetic Testing supports psychiatric pharmacology practice by covering 15 genes, as follows: on the pharmacokinetic side: *ABCB1*, *CYP1A2*, *CYP2C9*, *CYP2C19*, *CYP2D6*, *CYP3A4*, and *CYP3A5*. In contrast, on the pharmacodynamic side, the genes tested are *ADRA2A*, *COMT*, *HTR2A*, *HTR2C*, *MTHFR*, *NAT2*, *OPRM1*, and *SLC6A4*. Myriad's GeneSight covers variants across 8 genes (pharmacokinetics: *CYP1A2*, *CYP2C9*, *CYP2C19*, *CYP3A4*, *CYP2B6*, and *CYP2D6*, and pharmacodynamics: *HTR2A* and *SLC6A4*). The Invitae Mental Health Pharmacogenomics Panel tests for variants in the following 15 genes, seven of them encoding for CYP enzymes, namely *CYP1A2, CYP2B6, CYP2C19, CYP2C9, CYP2D6, CYP3A4, CYP3A5, COMT, GRIK4, HLA-A, HLA-B, HTR2A, HTR2C, MTHFR,* and *UGT2B15*.

www.konkur.in

Commercially Available Pharmacogenetic Testing: Significant Translational Limitations

Before commercially available tests can predict actual treatment responses, much more knowledge is needed on the mechanisms of action and related pharmacogenetics of drugs commonly used to treat psychiatric disorders. As described by Hicks et al. (2020), in 2018, the Food and Drug Administration (FDA) cautioned that there might be a lack of clinical evidence supporting the utility of clinical pharmacogenetic testing. Moreover, the FDA also issued a warning letter to a laboratory regarding the marketing and gene content of their clinical pharmacogenetic tests. However, in a press release of February 20, 2020, entitled "FDA Announces Collaborative Review of Scientific Evidence to Support Associations Between Genetic Information," the FDA recognizes that "genetic testing can enhance patient management by improving the selection of medications or the dosage of a medication, tailoring the therapy to the patient—but only when it is based on sound science. That is why [they introduced] a collaboration between the FDA's Center for Devices and Radiological Health and Center for Drug Evaluation and Research intended to provide the agency's view of the state of the current science in pharmacogenetics." This "new web-based resource includes a table that describes some of the gene–drug interactions for which we believe there is sufficient scientific evidence to support the described associations between certain genetic variants, or genetic variant-inferred phenotypes and altered drug metabolism, and in certain cases, differential therapeutic effects, including differences in risks of adverse events." As promised in that statement, the FDA now maintains and constantly updates a Table of Pharmacogenetic Associations—for reference, see Rubinstein and Pacanowski, 2021. In this chapter, Table 1.21–1 summarizes the large FDA table focused only on drugs relevant to psychiatry and neurology. It can be seen in Table 1.21–1 that all genes highlighted are involved only in pharmacokinetics or in ADRs. No pharmacodynamic targets are identified in that table.

It is self-evident that the mechanisms of action of antidepressants, for example, will, at the pharmacodynamic level, involve many more genes and their variants than those tested by current commercially available pharmacogenetic tests. Therefore, that type of testing may be helpful for dose adjustment (pharmacokinetics); however, a high percentage of patients will not respond well to a given drug (pharmacodynamics), despite the dosage.

In a 2020 editorial Smith and Nemeroff stated that "the field of PGx [pharmacogenetics] is advancing quickly, but evidence of its utility is meager. Clearly, insufficient evidence supports the universal use of PGx testing to guide antidepressant treatment decisions. Of course, gene structure is only one piece of the puzzle that contributes to the inter-individuality of antidepressant response. Personal or environmental variables, such as concomitant medications, ethnicity, gender, smoking status, and comorbidities, are also important."

A fundamental limitation for the clinical applicability of pharmacogenetics in psychiatry is the insufficient availability of rigorously peer-reviewed, prospective,

Telegram: @medical_k

www.konkur.in

multicenter studies on the effectiveness of psychiatric treatment that are federally or foundation funded, and therefore without pharmaceutical or testing company bias. For example, over a 20-year stretch, there were no new drugs for treating acute lymphoblastic leukemia (ALL) in children. However, clinical outcomes continued to improve substantially during that period due to the better use of existing drugs, guided by rigorous multicenter studies. Those types of extensive, rigorous, prospective, multicenter, peer-reviewed studies, possibly with pharmacogenetics as an integral part of the study design, have been carried out in various therapeutic areas such as cancer, heart disease, diabetes, and neurologic diseases. However, they have not been conducted as needed for psychiatric disorders. While STAR*D, cited above, was an important step forward, it was a contract by the National Institutes of Health (NIH), not a peer-reviewed multicenter R01 or similar research grant study. A significant limitation of STAR*D was that pharmacogenetics was not part of the study design and was included later as an afterthought. The study was already underway when it was added, and blood was collected for that purpose. Participants who dropped out early on for multiple reasons, including pharmacogenetics related to ADRs, were lost, and their DNA was not sequenced. There are significant limitations to the growth of evidence-based pharmacogenetic testing in psychiatry in the absence of extensive (and costly), national, peer-reviewed, multicenter, rigorously controlled clinical research studies to assess the prediction of clinical outcomes prospectively.

Table 1.21–1.
Representative Gene–Drug Combinations Relevant to Psychiatry and Neurology Extracted from the FDA Table of Pharmacogenetic Associations in February 2023

Telegram: @medical_k

www.konkur.in

Section 1: Pharmacogenetic Associations for Which the Data Support Therapeutic Management Recommendations

Drug	Gene	Affected Subgroups+	Description of Gene–Drug Interaction
Amphetamine	CYP2D6	Poor metabolizers	May affect systemic concentrations and adverse reaction risk. Consider lower starting dosage or use alternative agent.
Aripiprazole	CYP2D6	Poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk. Dosage adjustment is recommended. Refer to FDA labeling for specific dosing recommendations.
Aripiprazole lauroxil	CYP2D6	Poor metabolizers	Results in higher systemic concentrations. Dosage adjustment is recommended. Refer to FDA labeling for specific dosing recommendations.
Atomoxetine	CYP2D6	Poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk. Adjust titration interval and increase dosage if tolerated. Refer to FDA labeling for specific dosing recommendations.
Carbamazepine	HLA-B	*15:02 allele positive	Results in higher adverse reaction risk (severe skin reactions). Avoid use unless potential benefits outweigh risks and consider risks of alternative therapies. Patients positive for HLA-B*15:02 may be at increased risk of severe skin reactions with other drugs that are associated with a risk of Stevens–Johnson Syndrome/Toxic Epidermal necrolysis (SJS/TEN). Genotyping is not a substitute for clinical vigilance.
Citalopram	CYP2C19	Poor metabolizers	Results in higher systemic concentrations and adverse reaction risk (QT prolongation). The maximum recommended dose is 20 mg.
Phenytoin	CYP2C9	Intermediate or poor	May result in higher systemic concentrations and higher adverse

Telegram: @medical_k

www.konkur.in

		metabolizers	reaction risk (central nervous system toxicity). Refer to FDA labeling for specific dosing recommendations. Carriers of CYP2C9*3 alleles may be at increased risk of severe cutaneous adverse reactions. Consider avoiding phenytoin as an alternative to carbamazepine in patients who are CYP2C9*3 carriers. Genotyping is not a substitute for clinical vigilance and patient management.
Phenytoin	HLA-B	*15:02 allele positive	May result in higher adverse reaction risk (severe cutaneous reactions). Patients positive for HLA-B*15:02 may be at increased risk of Stevens-Johnson Syndrome/Toxic Epidermal necrolysis (SJS/TEN). Consider avoiding phenytoin as an alternative to carbamazepine in patients who are positive for HLA-B*15:02. Genotyping is not a substitute for clinical vigilance and patient management.
Thioridazine	CYP2D6	Poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk (QT prolongation). Predicted effect based on experience with CYP2D6 inhibitors. Contraindicated in poor metabolizers.
Venlafaxine	CYP2D6	Poor metabolizers	Alters systemic parent drug and metabolite concentrations. Consider dosage reductions.
Vortioxetine	CYP2D6	Poor metabolizers	Results in higher systemic concentrations. The maximum recommended dose is 10 mg.

Section 2: Pharmacogenetic Associations for which the Data Indicate a Potential Impact on Safety or Response

Drug	Gene	Affected Subgroups+	Description of Gene–Drug Interaction
Carbamazepine	HLA-A	*31:01 allele positive	Results in higher adverse reaction risk (severe skin reactions). Consider risk and benefit of carbamazepine use in

			patients positive for HLA-A*31:01. Genotyping is not a substitute for clinical vigilance.
Oxcarbazepine	HLA-B	*15:02 allele positive	Results in higher adverse reaction risk (severe skin reactions). Patients positive for HLA-B*15:02 may be at increased risk of severe skin reactions with other drugs that are associated with a risk of Stevens–Johnson Syndrome/Toxic Epidermal necrolysis (SJS/TEN). Genotyping is not a substitute for clinical vigilance.
Perphenazine	CYP2D6	Poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk.

Section 3: Pharmacogenetic Associations for which the Data Demonstrate a Potential Impact on Pharmacokinetic Properties Only

Drug	Gene	Affected Subgroups+	Description of Gene–Drug Interaction
Amitriptyline	CYP2D6	Ultrarapid, intermediate, or poor metabolizers	May alter systemic concentrations.
Amoxapine	CYP2D6	Ultrarapid, intermediate, or poor metabolizers	May alter systemic concentrations.
Clomipramine	CYP2D6	Ultrarapid, intermediate, or poor metabolizers	May alter systemic concentrations.
Desipramine	CYP2D6	Ultrarapid, intermediate, or poor metabolizers	May alter systemic concentrations.
Diazepam	CYP2C19	Poor metabolizers	May affect systemic concentrations.
Donepezil	CYP2D6	Ultrarapid or poor metabolizers	Alters systemic concentrations.

Telegram: @medical_k

www.konkur.in

Doxepin	CYP2C19	Intermediate or poor metabolizers	Results in higher systemic concentrations.
Doxepin	CYP2D6	Ultrarapid, intermediate, or poor metabolizers	May alter systemic concentrations.
Escitalopram	CYP2C19	Ultrarapid, intermediate, or poor metabolizers	May alter systemic concentrations.
Fluvoxamine	CYP2D6	Poor metabolizers	Results in higher systemic concentrations. Use with caution.
Galantamine	CYP2D6	Poor metabolizers	Results in higher systemic concentrations. Titrate dosage based on tolerability.
Imipramine	CYP2D6	Ultrarapid, intermediate, or poor metabolizers	May alter systemic concentrations.
Nortriptyline	CYP2D6	Ultrarapid, intermediate, or poor metabolizers	May alter systemic concentrations.
Paroxetine	CYP2D6	Ultrarapid, intermediate, or poor metabolizers	May alter systemic concentrations.
Propranolol	CYP2D6	Poor metabolizers	May affect systemic concentrations.
Protriptyline	CYP2D6	Poor metabolizers	Results in higher systemic concentrations.
Risperidone	CYP2D6	Poor metabolizers	Alters systemic parent drug and metabolite concentrations.
Trimipramine	CYP2D6	Ultrarapid, intermediate, or poor metabolizers	May alter systemic concentrations.
Viloxazine	CYP2D6	Poor metabolizers	May result in higher systemic concentrations.

Note: This table includes select examples and does not represent all gene–drug combinations of potential interest to family physicians and may not include all interactions within the drug class. For a complete list that is periodically updated, go to https://www.fda.gov/medical-devices/precision-medicine/table-pharmacogenetic-associations. Table appears as published by the FDA.

FDA, U.S. Food and Drug Administration; INR, international normalized ratio; NAT, arylamine N-acetyltransferases.

+The table describes gene–drug interactions and indicates specific affected subgroup(s) to which the interaction applies. The affected subgroup(s) may be carriers of a specific genetic variant (e.g., *HLA-B**15:02) or a genotype-inferred phenotype, ultrarapid, normal, intermediate, or poor metabolizers/function transporters of a drug-metabolizing enzyme/drug transporter. Normal metabolizers or normal transporters do not have genetic variants that are expected to impact metabolism or transport function. In general, ultrarapid metabolizers have two or more copies of a genetic variant that increases metabolic function; intermediate metabolizers or reduced function transporters are individuals who have one or two copies of a genetic variant that reduces the ability to metabolize or transport a drug; and poor metabolizers or poor function transporters are individuals who generally have two copies of a genetic variant that results in little to no ability to metabolize or transport a drug.

From Food and Drug Administration. Table of pharmacogenetic associations. 2022. https://www.fda.gov/medical-devices/precision-medicine/table-pharmacogenetic-associations.

While the promise of pharmacogenetics-driven personalized and precision medicine is exciting and appealing to patients and physicians, our current scientific knowledge is still insufficient to predict, based on pharmacogenetic testing alone, who will respond particularly well to specific psychotropic medications, despite the marketing claims of various testing companies.

CONCLUSIONS

Those who practice medicine know that patients respond differently to identical treatments. In general, the best predictor of drug response is the patient's personal or familial treatment response history, which suggests an inherited, hence genetic, basis for treatment response. However, that type of information is only sometimes available. The clinician often observes that certain patients following the same dose of the same drugs will show complete symptoms remission. In contrast, others may report only severe side effects or no response. Physicians need to balance a patient's health with adverse drug interactions when prescribing various antidepressants; however, this may fail to predict drug response.

Work by our group and others on the translational and clinical pharmacogenomics of psychiatric disorders has been focused on identifying genetic markers as predictors of positive and negative treatment outcomes. Rigorous clinical studies must continue to be performed to closely examine the relation between genotype and the drug response phenotype. In well-conducted clinical trials, positive clinical responses and adverse events can be related to specific genetic polymorphisms. Such research is designed to identify markers significantly linked with treatment responses. This line of investigation offers enormous promise for the individualization of drug therapy.

Telegram: @medical_k

www.konkur.in

It would be highly beneficial to public health if the likelihood of favorable or adverse responses were known before administering a drug. Despite the potential for enormous returns, a myriad of problems emerges in conducting such work. Problematic clinical factors include the placebo response, sample size issues, genetic background, ethnic stratification, continual versus categorical outcome measures, drug choice and treatment strategy, treatment regime adherence, and the impact of the environment on treatment outcome. The dilemmas raised by this line of work's genetic components are also substantial and discussed elsewhere. A significant difficulty is choosing the appropriate genetic polymorphisms associated with drug response. A statistical conundrum is created by the need to assess multiple variables that are partially related to one another (without a priori knowledge of the exact nature of such interactions) and that contribute to minor effects in sample sizes that require standardized clinical research treatment and that therefore are highly costly and often cannot be as large as desired. Despite these limitations, pharmacogenetic testing has been translated from the bench to the bedside, with utility for tailoring specific treatments, such as those for major depression.

Neither the biology of psychiatric disorders nor the mechanisms of action of psychotropic drugs are entirely known to date, and knowledge continues to accumulate progressively. The pharmacogenetic perspective contributes considerably to developing customized treatments and presents a good starting point for understanding the pathophysiologic mechanisms underlying psychiatric disorders. All pharmacogenetic studies are based on the neurobiologic research theories for these disorders.

Pharmacogenomics is a new area of medical science based on novel databases that have been emerging since the completion of the Human Genome Project. High throughput technologies have been developed to enable researchers to harness the overwhelming amount of genomic data to improve therapeutics. In addition, genomics now gives us the tools to search for new biomarkers and therapeutic targets by providing new avenues of treatment optimization and research. Finally, applying advanced molecular biology techniques and a complete understanding of human genomic sequences relevant to treatment responses will facilitate searching for conceptually novel therapeutic target sites for psychiatric disorders.

1.22 Animal Models in Psychiatry

Janna K. Moen, B.A., Ph.D., and Paul J. Kenny, Ph.D.

THE USE OF ANIMAL MODELS IN PSYCHIATRIC RESEARCH

Animal research allows experimenters to manipulate and measure behavioral and biologic processes that are relevant to psychiatry. Animal research in psychiatry falls into two broad categories. First, basic research aims to improve our understanding of psychological and neural processes in their species-specific context using established and novel technical approaches. Second, in applied research, animal experiments are used to model specific aspects of human psychiatric conditions, either to help identify novel targets for therapeutic drug development, or to provide a preclinical test of the effectiveness of a compound on behavior considered relevant to a particular disorder. As the usefulness of the latter type of research depends on the degree to which findings can be translated between species, it is constrained by how effectively aspects of psychiatric conditions can be modeled in animals.

There are clearly substantial differences between humans and nonhuman primates (NHPs) and rodents, which are the species most often used in animal research. Abstract thought in humans allows for self-regulation while self-reflection can lead to rumination, which may play a role in human susceptibility to depression or anxiety. Language allows humans to engage in uniquely complex communication, and insights gained during therapy may be instrumental in coping with psychiatric

Telegram: @medical_k

www.konkur.in

disorders. Biologic differences probably underlie these differences between humans and other species, including a more developed cortex and prefrontal cortex compared to rodents and even NHPs. In addition, although the vast majority of human brain regions and genes have homologous versions in NHPs and rodents, there are substantial differences at the level of cell structure, connectivity, and gene regulation. These differences notwithstanding, there are many similarities between humans and experimental animals in both functional and biologic terms. Thus, basic psychological processes such as stress, fear, anxiety, motivation, attention, and reward are present in species-specific manners in rodents and NHPs. In addition, subcortical structures are quite well conserved, with a common brain design and substantial homologies for most neural structures.

Table 1.22–1.
Implication of Class of Symptoms in Major Psychiatric Conditions

Domain	Autism Spectrum Disorders	ADHD	Schizophrenia	Bipolar Disorder	Depression	Anxiety	PTSD	OCD	Eating Disorders	Impulse Control	Substance Use Disorders	Sleep Disorders
Negative valence	++	+	++	+++	+++	+++	+++	++	++	+	++	++
Positive valence	++	+++	++	+++	+	+	++	+++	+++	+++	+++	+
Cognitive	+++	+++	+++	+	+	+	+	+++	+	+++	++	++
Social	+++	+	++	++	++	++	+	+	+	++	+	+
Sleep and arousal	++	++	+	+++	++	++	+++	+	++	+	+	+++

+++ strongly impacted, ++ moderately implicated, + slightly implicated.
ADHD, attention deficit hyperactivity disorder; OCD, obsessive-compulsive disorder; PTSD, post-traumatic stress disorder.

Based on these considerations, and on the limited success in using animal models to develop new therapeutics for psychiatric disorders, it has been suggested that animals should be used to model particular symptoms instead of entire human psychiatric disorders. In particular, productive animal research in psychiatry should focus on well-defined phenotypes that have a known biologic basis which can be measured to facilitate experimentation, and preferentially focus on brain substrates that have reasonable homologies between humans and the animal model of choice. In addition, when genetic models are used in animals, it is useful to focus on highly penetrant genetic variants to ensure relevance to human disease. In a general sense, the usefulness of animal models in modeling aspects of human psychiatric disorders can be assessed by three criteria:

- *Face validity* refers to the extent to which a behavior that is studied in animals resembles the behavior in humans it is intended to model.
- *Predictive validity* refers to the extent to which manipulations in animal models predict clinical effectiveness in psychiatric patients, and an ideal model would have low false-positive and false-negative rates.
- *Construct validity* refers to the extent to which an animal model reproduces the etiology of the human psychiatric disorder.

Following recent guidelines from the National Institute of Mental Health, this chapter is organized by a description of available animal models in five broad classes of symptoms, which may be observed across psychiatric disorders (Table 1.22–1).

www.konkur.in

NEGATIVE VALENCE

In psychology, “valence” refers to the intrinsic value of an internal feeling or emotional state. In psychiatric disorders, “negative valence” typically indicates a level of aversiveness or discomfort. Behaviors associated with negative valence that can be studied in animal models include the following:

Defensive Behaviors

Ethologic studies of defensive behavior in rodents have shown that threatening situations evoke defensive behaviors that depend on the proximity of the threat. When a threat is very near and acute, panic responses consisting of flight or defensive attack are elicited, while fear responses consisting of concealment and freezing occur when a threat is present but more distal. Finally, potential threats elicit lower-intensity anxiety-like behavior, with risk assessment and reduction of exploratory behaviors for extended periods of time. In general, animal models of defensive behavior are focused on acute normal defensive responses, while only a few models involve chronic stress manipulations.

Panic-Like Behavior. Panic is often defined as a sudden and sometimes uncontrollable episode of intense fear or anxiety provoked by a real or perceived threat. Panic responses can be studied in rats and mice in its ethologic context in defensive tests that use a predator (human, rat, or in some recent studies, robotic) closing in on subjects in a circular runway. In this test, called the defense test battery, the predator approaches the subject on a long oval runway, and flight responses can be quantified. If the runway is blocked, the imminent approach of the predator elicits flight or defensive threat and attack responses. In addition to good face validity, pharmacologic agents that are clinically effective at reducing panic attacks, such as benzodiazepines, have been shown to reduce flight in this model, while anxiolytic agents that are less effective in reducing panic attacks do not have a strong effect on flight, suggesting good predictive validity. However, the main drawback of this model is its relative complexity, and it has not been widely adopted to date. Panic responses can also be evoked artificially in rats by electrical stimulation of the dorsal periaqueductal grey matter (dPAG). As the dPAG harbors a hypoxia-sensitive alarm system, this model is most relevant to the putative respiratory subtype of panic disorder.

Fear-Like Behavior. Fear can be broadly defined as a noxious behavioral state provoked by exposure to potentially threatening stimuli. Fear responses are typically studied in the context of an aversive stimuli being presented at random (unconditioned) or following association with a predictive cue (conditioned). Unconditioned fear responses to predators can also be measured in the defense battery tests for rats or mice. In both cases, freezing behavior is observed in the blocked runway when the predator approaches up to a certain point. Further approach is followed by active defensive attack. Conditioned fear responses have

Telegram: @medical_k

www.konkur.in

traditionally been studied to elucidate the neural basis of learning and memory but are increasingly used to study normal and pathologic defensive behaviors. In the basic fear conditioning setup, experimenters consistently present a conditioned stimulus (typically a tone or a light) before an aversive unconditioned stimulus (typically a mild foot shock). After repeated pairings, the subject will be able to predict presentation of the aversive stimulus when the conditioned stimulus is presented. Conditioned fear can be measured in the fear-potentiated startle paradigm, where presentation of the conditioned stimulus potentiates the locomotor response to a loud startle tone. This procedure can be used in both rodents and humans with minor adaptations. Alternatively, conditioned fear is often measured in rodents in enclosed environments as a freezing response. Although both tests can be confounded by manipulations that affect locomotion, when a pharmacologic manipulation reduces fear-potentiated startle and increases locomotion by reducing freezing, the results can be interpreted as fear reducing with confidence.

Generalization of conditioned fear is a learning phenomenon that refers to the transfer of conditioned fear responses from the proper conditioned stimulus that predicts an aversive outcome to stimuli that are related, but distinct. Theoretically, putative abnormal generalization of conditioned fear to related stimuli is an attractive explanation for the pervasiveness of defensive responses in panic disorder and post-traumatic stress disorder. Operationally, rodents, NHPs, or humans can be tested for generalization of conditioned fear by measuring fear responses following the presentation of stimuli similar to but distinct from the original conditioned stimulus.

Extinction of conditioned fear is another learning phenomenon that has clear relevance to clinical psychiatry. In this procedure, after fear conditioning in rodents, NHPs, or humans, the conditioned stimulus is presented repeatedly in the absence of the unconditioned stimulus. Over time, subjects will gradually reduce, or extinguish, their conditioned fear responses until the stimuli no longer elicits an aversive response. This procedure has a clear parallel in exposure therapy that is used to successfully treat generalized anxiety disorder, specific phobias, and post-traumatic stress disorder. Pharmacologic treatments that expedite development of extinction in animals can enhance the beneficial effect of exposure therapy in human patients. The drug D-cycloserine has been shown to improve outcomes of exposure-based therapy in the treatment of anxiety disorders and phobias, but may not be an effective option for treating post-traumatic stress disorder.

While fear is often discussed as a different emotional state from anxiety distinguished by the presence or absence of an active threat, respectively, there is considerable debate among behavioral neuroscientists regarding whether fear and anxiety involve different neurobiologic mechanisms or instead encompass different aspects of a shared internal state. For example, stress-induced fear learning in rodents elicits anxiety-like responses in the elevated plus maze in addition to conditioned fear responses (i.e., freezing) following extensive pairing of foot shock with conditioned stimuli, indicating that the anxiety response in this model serves to increase fear behaviors. Further study is necessary to distinguish the difference between fear and anxiety.

Telegram: @medical_k

www.konkur.in

Anxiety-Like Behavior. Anxiety is typically considered to be a more generalized emotional state than fear, with anxiety corresponding to intense uneasiness or apprehension regarding something with an uncertain outcome in the absence of an imminent threat. The most common way to measure anxiety-like behavior in rodents is based on approach-avoidance conflicts. Rats and mice are naturally cautious in open, elevated, and brightly lit environments because of the risk of predation, and the avoidance of such places can be a measure of anxiety-like behavior. Typically, animals are allowed to explore an apparatus with two parts: one enclosed or dark compartment, and a second more open or brightly lit or elevated compartment. The elevated plus maze, light–dark box, and open field tests are the most popular tests in this category. In addition, the elevated plus maze has been adapted to measure stretch-attend postures, reflecting risk assessment. There is also a human version of the open field test, called the human behavioral pattern monitor, which combines free exploration of a novel environment with presentation of novel objects, thus allowing for translational studies of anxiety-like behavior. Tests of approach-avoidance behavior have been criticized as a test of anxiety-like behavior, as drugs may affect the drive to explore independently of anxiety, which could be misinterpreted as an anxiolytic effect. In addition, these behavioral tests were developed primarily to measure the anxiolytic effect of benzodiazepine drugs, and might therefore not be very effective at detecting novel anxiolytics that work through alternative mechanisms. Indeed, selective serotonin reuptake inhibitor (SSRIs) that are clinically effective at reducing anxiety in human patients generally do not have strong anxiolytic effects in approach-avoidance tests.

A second approach to study anxiety-like behavior is through conflict tests, in which food- or water-restricted animals are punished with a mild electric shock for lever pressing for food (Geller–Seifter conflict test) or licking a spout for water (Vogel conflict test). The resulting suppression of appetitive behavior is interpreted as anxiety-like behavior and is sensitive to anxiolytic drugs.

A third approach for studying anxiety-like behavior involves measuring responses to novel objects. A classic example is the marble-burying test, in which rodents are placed in a cage with plentiful bedding and unfamiliar marbles. Rodents will typically bury these novel objects in bedding, which can be interpreted as a defensive anxiety-like behavior. Importantly, the marble-burying test is controversial in the field of behavioral neuropharmacology. It is difficult to ascribe a rodent's anxiety toward an object like a novel marble, and drugs that are effective at reducing marble burying may instead serve to increase freezing or object avoidance, which can also be interpreted as anxiety-like responses. A model with more face validity is the shock probe burying test for rats, in which animals are confronted with an electrified probe that delivers aversive shocks on contact. Defensive burying of the probe with bedding material serves as the measure of anxiety-like effects.

Finally, there are tests for anxiety-like responses that do not measure anxiety-like responses as behavioral inhibition, as general sedative effects might be mistaken for anxiolytic effects in the tests described above. In the stress-induced hyperthermia test, animals are stressed with rectal placement of a thermometer, and the gradual

Telegram: @medical_k

www.konkur.in

increase in body temperature is measured as an index of the effect of stress. In addition, light-enhanced startle is a test that uses a continuous bright light in the startle chamber, which gradually potentiates the startle response. As all of the acute models described in this section have both benefits and pitfalls, the general consensus when testing potential anxiolytic drugs is to perform a battery of behavioral tests before drawing conclusions.

Social Anxiety-Like Behavior. Several tests of social anxiety have been developed in rodents and NHPs. In the social interaction test for rats and mice, two animals are either allowed to interact freely, or through a wire bar enclosure. Time spent interacting with this conspecific (animal of the same species) is quantified, and treatments that increase interaction time are considered anxiolytic. In addition, ultrasonic distress vocalizations, particularly in rats, are social signals that serve to indicate distress. Such signals in pups separated from mothers, or in mature animals in distressing conditions, can be taken as a measure of anxiety.

Although the most common animal models of anxiety are based on rat or mouse studies, the human intruder test for primates is well validated and offers particularly good face and construct validity as a model of human social anxiety. In this test, confined macaque or marmoset primates are confronted with the presence of a human who does not look at them directly. The mere presence of the human intruder causes behavioral inhibition, aggression, and displacement stress responses such as scratching and autogrooming. The behavior of animals in this test has been shown to be sensitive to clinically effective anxiolytic drugs and correlates well with fear responses in other paradigms, but can vary significantly between facilities and between different human intruders. A more recent primate model of anxiety and fearful temperament has been developed in which NHPs are rewarded for touching visual stimuli on a touch screen device. During test trials, the face of an unknown male conspecific with direct gaze is presented on the touch screen, and behavioral inhibition can be observed in subjects who hesitate or fail to touch the screen for a juice reward. This touch screen paradigm may be less sensitive to facility and experimenter variability, and offers a more ethologic approach compared with the human intruder test.

Depressive Behaviors

Reduced Effort to Escape Aversive Stimuli. Hopelessness is critical symptom of depression, and the rodent forced swim test is one of the most widely used acute behavioral screens for antidepressant activity. In this test, rodents are placed in a cylinder filled with water. While the animals will initially try to escape the cylinder with vigorous escape movements, eventually the animals will show immobility, which is interpreted as learned helplessness. Antidepressant effects are inferred by an increase in the time spent in escape movements. Importantly, immobility time in the forced swim test may be influenced by other factors, such as adaptive floating for energy conservation. As such, these acute models are often performed as part of a

Telegram: @medical_k

www.konkur.in

battery of behavioral tests to further characterize a putative antidepressant-like response. A related task for mice is the tail-suspension test, in which mice are hung by the end of their tails and a similar transition from active escape movements to immobility occurs. Various classes of clinically effective antidepressants produce acute reductions in immobility in these tests, suggesting good predictive validity. In addition, lower doses of antidepressants show an effect after chronic but not acute treatment, in line with the delayed effectiveness of antidepressants for humans. In the learned helplessness paradigm, uncontrollable stress can lead to reductions in escape attempts in subsequent situations where the stressor can actually be evaded. Such escape deficits are also reversible by antidepressant drugs. Notably, these tests have been developed explicitly to detect the effects of monoamine-targeted antidepressants, although recent studies have shown other drugs like psilocybin and ketamine can produce similar antidepressant-like behavioral phenotypes in a rat model.

Reduced Effort to Obtain Rewards. Anhedonia, or the loss of interest in otherwise pleasurable activities, is also a key symptom of depression which can be modeled in rodents. Preference for palatable sucrose over water, or the maximum number of lever presses an animal is willing to expand to obtain food in the progressive ratio test, can both provide measures of anhedonia. In addition, chronic implantation of intracranial self-stimulating electrodes in reward centers of the brain can allow for repeated measures of the threshold current at which animals are willing to self-stimulate, thus allowing for a more robust measure of reward function.

Chronic Stress Models. Finally, antidepressant activity can also be measured in rodent tests that use chronic stress manipulations. In the chronic mild stress paradigm, experimenters administer various mild unpredictable stressors for prolonged periods. Common stressors include restraint, damp bedding material, and disrupted light–dark cycles. The effects of chronic stress can be measured as reduced sucrose preference and reduced grooming behavior in mice. Although the chronic mild stress model has good face and predictive validity, it has received criticism for its high level of variability.

In the chronic social defeat model, subject mice are introduced in the home environment of a large aggressive mouse each day for 10 days. The sequential defeat experience leads to a relative avoidance of a novel nonaggressive mouse in the social interaction test, as well as reduced sucrose preference. The study of susceptible versus resilient animals in the chronic social defeat stress model has yielded interesting insights into the molecular biology underlying this behavior. An important drawback of the traditional chronic social defeat model is that the test can only be performed using male mice, as female mice typically do not display or elicit the same aggression when confronted with a novel conspecific. As women have higher rates of depression and distinct transcriptomic profiles when depressed compared with men, it is necessary to adapt this model for use in female animal subjects. In one adaptation, male odorants are applied to female subjects who are

Telegram: @medical_k

www.konkur.in

then confronted with a male aggressor. Another model involves housing intact female subjects with castrated males. These females will readily attack another female intruder, presumably as an adaptive defensive mechanism to protect potential offspring. These models allow for the study of both biologic sexes in chronic social defeat paradigms, and have resulted in the discovery of important sex differences in the development and manifestation of chronic stress-induced adaptations.

POSITIVE VALENCE

"Positive valence" refers to an emotional state that is intrinsically attractive, rewarding, or valuable. In psychiatric disorders, symptoms that fall under the category of positive valence include, for example, excess energy and impulsive behavior. Behaviors associated with positive valence that can be studied in animal models include the following:

Mania

Sleep disturbance often triggers manic episodes in bipolar patients, and sleep deprivation paradigms in rodents can produce short-term effects that resemble some aspects of mania such as hyperactivity, stereotypy, insomnia, aggressive behavior, and hypersexuality. Typically, rats or mice are placed in a small platform surrounded by water that does not allow for sleep without falling into the water. Seventy-two hours of sleep deprivation is sufficient to produce a brief manic-like state evidenced by increased frequency of the behavioral patterns mentioned above. Interestingly, these behaviors are sensitive to chronic treatment of mood-stabilizing drugs such as lithium. In addition, acute amphetamine injections in rats have been used to induce hyperactivity.

Impulsivity

Impulsivity can broadly be divided into actions that are initiated prematurely or without appropriate cognitive control, and actions that favor options with short-term payoff without taking longer-term consequences into consideration.

Impulsive Action. Behavioral inhibition can be measured in rodents, NHPs, and humans in the stop signal reaction time task. In the rat version, animals are trained to respond to a go stimulus, unless a no-go stimulus is concurrently presented. The no-go stimulus is presented at various time delays after the go stimulus, enabling a quantification of the maximal delay time at which a prepotent response can still be stopped. Clinically effective anti-impulsive drugs such as methylphenidate and atomoxetine decrease reaction time in both rodents and humans. Another test for impulsive action is embedded in the 5-choice serial reaction time task for rats. In this visuospatial attention task, after trial initiation, animals are faced with a standard intertrial interval before a visual stimulus prompts the correct response. When this intertrial interval is lengthened, rats tend to show premature responses, indicative of motor impulsivity. Clinically effective anti-impulsive medications tend to reduce

Telegram: @medical_k

www.konkur.in

premature responses in this task. Thus, both measures of motor impulsivity have good face and predictive validity. However, their operation requires substantial training, particularly for rodents and NHPs.

Impulsive Choice. Impulsive choices can be measured in delayed discounting paradigms in rodents, NHPs, and humans. Typically, subjects can choose between one option that results in an immediate small reward, and another option that results in a delayed larger reward. The relative discounting of future rewards can be deduced from choice behavior and can serve as an index of impulsivity. In animals, delayed reinforcement can only be delivered through experience and prior training. In contrast, human studies can use either experience of actual delayed rewards inside the timeframe of the experiment, or description of future rewards (outside of the timeframe of the lab visit). As such, animal experiments can best be compared to human studies using experience of delayed outcomes. Clinically effective anti-impulsivity drugs such as atomoxetine and methylphenidate have been shown to reduce choice of smaller immediate rewards.

Compulsive Behaviors

Repetitive invariant behavior with no apparent function or goal can easily be measured in its natural context. For example, excessive grooming in mice, circling behaviors in dogs, acral licking in dogs, or rocking, scratching, and head banging in NHPs occur naturally in stressful situations. Experimentally induced forms of compulsive behaviors include burying of unfamiliar marble objects, and the exaggerated drinking behavior that is observed in rats that respond for food under a fixed time schedule of reinforcement (schedule-induced polydipsia). Both types of compulsive behaviors respond well to clinically effective SSRI treatment for obsessive-compulsive disorder (OCD) patients. However, outcomes in the marble burying task also respond to antianxiety drugs like benzodiazepines, which are not clinically effective for reducing OCD symptoms in humans. In addition, other drugs that can effectively decrease marble burying have not been effective in the clinic for treating either anxiety or OCD. As such, results from the marble burying task alone are not considered sufficient evidence of reduced compulsivity.

In addition, more complex cognitive measure of perseverative responding can be obtained in operant tasks for rodents and primates. In a reversal learning paradigm, the ability of the animal to suppress lever pressing following previously reinforced stimuli is measured, in which continued responding despite the loss of the reinforcement reward can be interpreted as perseverative or compulsive responding. An analogous measure in the 5-choice serial reaction time task is based on repeated responding to a previously rewarded stimuli. Signal attenuation is a similar but more complex task that involves lever pressing rats that are presented with a sensory signal to mark reward delivery. When that cue is then presented without reward delivery (cue extinction), subsequent lever pressing under extinction conditions is not always accompanied by magazine entries to check for food rewards. The resulting

Telegram: @medical_k

www.konkur.in

lever pressing is considered to be perseverative. Of these three cognitive tasks, signal attenuation is most responsive to clinically effective SSRIs.

Abnormal Eating

The combination of undereating, compulsive or excessive exercise, and severe weight loss that is often seen in anorexia nervosa patients can be modeled in rodents. In the activity-based anorexia model, rats or mice are allowed to exercise on a running wheel, while food is only available for a limited amount of time per day. Paradoxically, access to the running wheel decreases food intake, which combines to produce severe weight loss that can lead to self-starvation. To date, no pharmacotherapies have been approved for the treatment of anorexia nervosa, so it is not clear what the predictive validity of this model is.

Excessive calorie intake can be measured by feeding rats or mice high-fat and carbohydrate food in the so-called cafeteria diet, which induces gradual weight gain and various metabolic changes. Binge-eating models restrict access to highly palatable food, such as chocolate- or fruit-flavored pellets, to short periods of time. Rats and mice show considerable increases in intake of the restricted highly palatable food over time, while intake of normal chow food decreases. These paradigms are useful for modeling aspects of binge eating disorder in humans, and recent studies have shown that such binge eating behaviors may be correlated with a dysregulated reward system similar to what is seen in addictive disorders. The etiology of binge eating disorder is still poorly understood with no clinically approved pharmacologic interventions.

Substance Use Disorders

Substance use disorders (SUDs) are chronic, relapsing conditions characterized by compulsive drug intake despite negative consequences. Patients with SUD frequently present with a genuine desire to decrease or eliminate their drug intake but typically experience great difficulty in achieving and maintaining abstinence. The prevailing framework considers SUD to be an acquired brain disease revolving around a dysregulated reward system, in which prolonged use of addictive drugs results in the overvaluation of drug reward at the expense of naturally rewarding stimuli. As these maladaptive changes make drug abstinence extremely challenging, preclinical research in addictive disorders typically focuses on methods to reduce drug craving/reward and withdrawal symptoms in order to assist a patient's attempt to quit.

Drug Reward. In its simplest form, drug reward can be measured by administering a compound to rodents and measuring the behavioral consequences. In the conditioned place preference test, drugs are repeatedly injected when the animal is confined to one of two compartments, while control injections are paired with the alternative compartment. Subsequently, in a free exploration test, animals tend to spend more time in the drug-paired environment, which is taken as an index of drug

Telegram: @medical_k

www.konkur.in

reward. The conditioned preference test can also be carried out in humans, in which human subjects are exposed to two rooms, one of which contains free palatable food. After repeated exposure, subjects in this test will prefer to spend time in the food-paired room even when the reward is absent. Although this test is relatively simple to administer it has limited construct validity due to the lack of animal-driven behavior, whereas patients with SUD actively seek out and control drug consumption. Another way to quantify the rewarding effects of drugs of abuse is to combine drug administration with threshold intracranial self-stimulation testing, where a rewarding effect is measured as a decrease in intracranial self-stimulation threshold.

Drug Self-Administration

Both rodents and NHPs can be trained to self-administer drugs of abuse, with drug delivery occurring either orally or through intravenous infusion via indwelling catheters. Animals will self-administer almost all drugs with abuse potential, with the exception of hallucinogens like lysergic acid diethylamide and psilocybin. In the simplest form, stable self-administration can be established, and the effect of environmental, pharmacologic, or genetic manipulations on self-administration can be studied. In these experiments, a dose–response function for earned rewards can be established to assess changes in sensitivity to drug dosing (leftward or rightward shift in preferred dose) or the reinforcing effect of the drug (upward or downward shift in the number of rewards earned). There are numerous more specific behavioral manipulations that are based on self-administration. The progressive ratio is a related test in which the number of operant responses required to earn a drug reward increases over training, allowing for measurement of the maximum effort (i.e., maximum lever presses) animals are willing to perform to obtain a fixed dose of the drug. Although intake of drugs of abuse tends to be well controlled and stable in short daily sessions, extended access to many drugs of abuse leads to a progressive escalation of drug intake over days. Finally, after prolonged drug self-administration, animals can be challenged with an aversive punishment such as foot shock alongside drug administration. The willingness of some animals to continue earning drug rewards despite an aversive punishment is thought to model compulsive drug seeking, much in line with human patients who continue to seek out drugs despite negative consequences.

Patients with SUDs typically attempt to quit drug consumption but often fail to do so, and many models of addiction involve an abstinence phase after chronic self-administration. Immediately after the cessation of self-administration, animals may undergo psychological or physical withdrawal symptoms. After a period of abstinence or extinction of the drug-seeking response, reinstatement of drug-seeking can be precipitated by the drug-seeking context, response-contingent presentation of the drug-paired cue, stressors like mild foot shock, or noncontingent administration of the drug by the experimenter. Incubation of craving refers to the finding that the magnitude of reinstatement tends to increase with the duration of abstinence. Finally, although most drug self-administration tests are based on free operant procedures,

Telegram: @medical_k

www.konkur.in

discrete trial procedures allow for a discrete choice between drugs of abuse and natural rewards.

There are few effective and approved medications for various SUDs, and it remains difficult to evaluate the predictive validity of drug self-administration procedures for screening potential pharmacotherapies to treat SUDs. However, chronic drug self-administration procedures have many commonalities with SUD presentation in humans, including prolonged and self-driven drug consumption, lending these models excellent face and construct validity compared with noncontingent drug exposure paradigms.

COGNITION

Preattentive Processing

Prior to conscious processing, sensory information is selected and processed in the brain to facilitate further analysis. One measure of preattentive processing in rodents, NHPs, and humans is prepulse inhibition. In this test, a loud startle tone is preceded by a quieter pretone with a specific latency. The presentation of the quieter pretone reduces or inhibits the startle response to the loud tone, with the reduced loud tone response representing the degree of prepulse inhibition. Prepulse inhibition is disrupted in schizophrenia patients with psychosis, but also in many other psychiatric patients. The antipsychotic activity of therapeutic agents can be measured in combination with the administration of dopaminergic agents that impair prepulse inhibition, such as apomorphine. The P50 response is a similar measure of preattentive processing in rodents and humans. In this test, two identical auditory stimuli are presented approximately 50 ms apart, and the second stimulus normally produces a less strong event-related potential than the first.

Attention

Attention, or the process of selectively focusing on specific information, is typically tested by training subjects to report the presence of discrete signals over prolonged periods of time. There are several sustained attention tasks for rodents based on analogous continuous performance tasks for humans. These tasks differ somewhat in that humans typically do not undergo training before testing. In the aforementioned 5-choice serial reaction time task, rats are trained to report the presentation of a stimulus light in one of five locations. In the behavioral vigilance task, rats are required to report the presence or absence of a visual stimulus by different responses, and background noise is used to increase the difficulty of the task.

Working Memory

The capacity to transiently hold and process new and already stored information can be tested in rodents, NHPs, and humans. Behavioral models of working memory depend on a delay between information that informs the correct response and the opportunity to execute the response. In delayed alternation tasks, rats are trained to

Telegram: @medical_k

www.konkur.in

select alternating arms in a T-maze, either based on sequential free choice or with alternating forced choices and free choice trials. In the radial arm maze, eight arms are baited with a food reward, and the frequency of reentry in already visited arms serves as an index of working memory function. Operant delayed nonmatching to place is another rodent task that has a direct primate analog. In this task, rats or mice are presented with a stimulus lever (right or left) that is subsequently retracted, and after a variable delay, the animals have to press the alternative lever in order to earn a reward.

Rodent models can provide valuable information on the neural basis of working memory and can serve as a first screen for potential pharmacotherapies to treat working memory deficits in humans. However, evolutionary differences in cognitive capacity and prefrontal cortex architecture suggest that NHP models of working memory provide a closer approximation of human working memory. Primate tests of working memory focus on spatial or object working memory, which depends on dissociable parts of the prefrontal cortex. In the spatial task, a reward is presented in one of several locations, after which a screen is lowered for various delays. When the screen is lifted up, the animal can find a reward if it looks in the same location. In the delayed match to sample object task, primates are presented with multiple objects, and they have to select the matching object after a delay in order to receive a reward. Critically, the objects have to be reused frequently for the same animals so that they cannot solve the task based on recognition memory. An analogous system for humans is the Cambridge Neuropsychological Test Automated Battery (CANTAB) cognitive assessment system.

Declarative Memory

Animal models of declarative memories have been developed for rodents and NHPs. In the Morris water maze, rodents are introduced to a large swimming pool with cool opaque water and a hidden submerged platform. Over multiple trials, rodents will learn the location of the platform in the pool and will quickly swim to the platform location regardless of their starting position. Spatial memory can then be tested by removing the platform and measuring the amount of time the rodent spends swimming in the location where the platform was previously located, with more time spent in the platform's previous location being interpreted as good spatial memory. The Morris water maze has been criticized by some researchers because of a rodent's natural tendency to spend time at the edges of a container, which may influence outcome measures. In addition, other factors, such as stress induced by swimming or sensitivity to water temperature, can alter the responses in this assay independent of memory formation. Another similar model is the Barnes maze, in which rodents are placed in the center of a circular open field with up to 20 circular holes around the edges of the field, with 1 hole leading to an escape tunnel. Over time, the animal will learn to head directly to the escape hole with few errors or entries into incorrect holes. This behavioral paradigm takes advantage of the rodent's natural aversion to open and brightly lit spaces, offering an ethologic advantage over

Telegram: @medical_k

www.konkur.in

the Morris water maze. Both the Barnes and Morris water maze have strong spatial memory components that are heavily reliant on hippocampal function.

The spontaneous object recognition task for rats is based on a sampling phase with two identical and novel objects at two ends of a y-maze. After a variable retention delay, one of the objects is replaced by a new object, and rats with intact memory tend to spend more time exploring the novel object. The most popular NHP model of object recognition is the delayed nonmatch to sample task. The basic setup of the task is similar to the object working memory task described above, except that the objects are new to the animal at the time of testing, so the task can be solved based on recognition memory.

SOCIAL FUNCTIONING

There are many rodent tests of social functioning. In addition to the social anxiety-like behavior described above, there are specific models of social attachment, dominance, and aggression.

Social Attachment

Mother–infant attachment is often studied in rodents in the homing test, where pups at postnatal days 8 to 10 are separated from their mothers and allowed to choose between bedding from their own nest and bedding from another age-matched litter. The pups will prefer bedding from their own nest, which is interpreted as normal social function. Similarly, isolated rat pups will emit specific ultrasonic vocalizations upon separation from the mother. Further in development, the social functioning of mice can be assessed in the social preference test, in which time spent near a confined conspecific versus a nonsocial stimulus (social preference) or familiar conspecific versus novel conspecific (novelty preference) can be measured. In addition, social interactions can also be studied in freely interacting conspecifics. Social play in young animals can be quantified in rats by placing two unfamiliar young rats together and observing the frequency of species-specific playful behavior. In addition, the rewarding qualities of social play can be quantified in an adaptation of the place preference procedure, where play behavior is confined to one chamber of a two-chambered apparatus. Finally, the formation of monogamous pair bonds between partners is often studied in another rodent species, the prairie vole. Unlike most rodent species, prairie voles are monogamous and form strong lifelong partner bonds with their mate, even to the extent that males will not seek a new mate after their female partner dies.

Social Hierarchy and Aggression

Both mice and rats tend to form stable hierarchies and engage in aggressive behaviors under particular circumstances. Aggression in males tends to occur between cagemates in order to establish dominance hierarchies and toward intruders in order to protect reproductive success. Female aggression in rodents tends to

Telegram: @medical_k

www.konkur.in

occur specifically postpartum to protect offspring, although sexually naive female cage mates still form stable social hierarchies similar to males. Dominance and aggression can be observed in natural and seminatural settings using a deep, clear structure such as the visible burrow system. Dominance hierarchies can also be studied in mice in the tube test, in which pairs of mice are placed opposite of each other at the ends of a tube, and the mouse that does not retreat is considered the dominant mouse. Further, aggression is often provoked by the resident intruder test, sometimes after social isolation, which enhances resident aggression.

SLEEP AND AROUSAL

Arousal

Arousal and hyperactivity can be measured in rats and mice, typically through automated analysis of locomotor behavior in the home cage or in testing equipment like the open field test. Such tests can quantify overall movement and the relative occurrence of rest and activity.

Sleep

Natural Sleep. Natural sleeping behaviors are most often studied in rats and mice. Rodent models of sleep have been informative for human sleep regulation. Similarly to humans, sleep parameters can be quantified on the basis of behavioral observation or electroencephalographic (EEG) measures. More detailed analyses focus on the amount of sleep per day and the temporal distribution of sleep. However, unlike humans, rodents are nocturnal and typically sleep during the light phase. In addition, rodents show highly fragmented sleep episodes with several activity bouts during their normal sleeping hours. As such, results from rodent experiments on sleep disturbances should be interpreted with some caution.

Insomnia. The inability to sleep has been modeled in rats and mice through the effects of stress manipulations on sleep architecture. Stressors may include immobilization, social stress, or fear conditioning. These manipulations generally prolong the latency to fall asleep, reduce sleep duration, and increase the fragmentation of sleep. Most of these changes are reversible by medications used to treat insomnia and other sleep disorders.

Narcolepsy. Drowsiness during normal waking hours and sudden attacks of sleep have been modeled successfully in dogs and rodents. There are several strains of dogs that have naturally occurring narcolepsy, and the investigation of the genetic determinants of narcolepsy in dogs led to the identification of the orexin 2 receptor and its natural peptide ligand orexin as critical for normal arousal and wakefulness. The sudden arrest of movement, or cataplexy, is a hallmark of narcolepsy and can be measured in dogs with a loss of function mutation in the hypocretin/orexin gene in the food-elicited cataplexy test, in which bits of food are placed along a semicircle,

Telegram: @medical_k

www.konkur.in

and sudden arrests in the movement are taken as partial or complete cataplexy. Analogous mouse models of cataplexy have been developed to investigate the effect of genetic manipulations on arousal and sleep systems. In susceptible mice, cataplexy can be elicited by various manipulations, including anticipation of food, wheel running, and social interactions. Rodent cataplexy can be measured as brief episodes of behavioral immobility, in particular atonia of muscles in the back of the neck, and a sleep-like EEG signature.

Sexual Function

Normal Sexual Behavior. Normal and dysfunctional sexual behavior have most often been studied in rodents. Although sexual interaction in rodents has important species-specific components, such as a strong role for olfaction and a series of approaches and withdrawals, many aspects of sexual behavior are preserved between rodents and humans. Normal sexual function can be characterized in rodents by observation studies, and male ultrasonic vocalizations toward females can be measured. Mice and rats both undergo a dynamic copulatory sequence in which female rodents will display solicitation behaviors such as darting and ear wiggling to entice a male partner. These behaviors, alongside the female rodent's sexual posture (lordosis), mounting, intromission, and ejaculation, can be measured as a readout of sexual function. Another rodent species used to study sexual behavior is the Syrian hamster. This species does not engage in solicitation behaviors or locomotor activity during the copulation sequence, and as such, these animals can be used for experiments in which a relatively fixed posture is ideal, such as measuring neurotransmitter release or cellular activity.

Sexual Dysfunction. Although not often studied, stress can have detrimental effects on male sexual behaviors in rats, leading to longer latencies to mounting and intromission but shorter latencies to ejaculation. In addition, there are many models of male erectile dysfunction that are based on physiologic manipulations, such as cavernous nerve damage.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Preclinical studies using animal models, including those described above, have undoubtedly provided critical information on both the etiology and treatment of psychiatric disorders. Medications to treat psychiatric conditions are typically required to undergo extensive preclinical testing using rodents and NHPs before proceeding to human clinical trials, with the majority of effective pharmacotherapies having relied on preclinical testing during their development. In this way, preclinical animal models have led to an improved quality of life in countless patients that benefit from current psychiatric medications. In the past decade, rodents, in particular, have become critical model organisms to study psychiatric conditions due to the wide availability of genetically modified mice that allow for targeted manipulations of specific cell types

Telegram: @medical_k

www.konkur.in

or brain areas, shedding light on the biologic mechanisms underlying complex behavioral phenotypes. The recent discovery and implementation of CRISPR/Cas9 gene editing tools has rapidly accelerated the ability to generate these specialized mouse lines, while technologies like RNA sequencing and proteomic screens can provide a wealth of information about the molecular and cellular adaptations present in abnormal behaviors. Many would argue that we are closer than ever to both understanding and treating psychiatric conditions.

Even with the advent of advanced methods to study psychiatric conditions in animal models, significant barriers remain that will require careful consideration by researchers. Most of the models described in this chapter were developed with the intention of screening potential therapeutic agents for treating specific behavioral abnormalities, with construct validity being tied to the predictive validity of pharmacologic agents being effective in both humans and animal models. However, the vast majority of drugs that show promise in preclinical studies have no or only modest success in clinical trials. In addition, most pharmacotherapies that are approved for treating psychiatric conditions in humans show success in only a subset of patients, with prominent examples including SSRI antidepressants and smoking cessation medications. As psychiatric disorders are still classified and diagnosed almost exclusively through behavioral symptoms, it is likely that common behavioral symptoms occur through a variety of distinct biologic mechanisms. Animal studies, by nature, tend to have high levels of variability, and the careful consideration of individual differences in the preclinical setting may help address these barriers. In addition, the majority of classical studies that inform the development and utilization of animal models utilized only male animals, a trend that unfortunately persists in neuroscience research despite growing evidence that sex as a biologic variable influences psychiatric conditions and treatment outcomes. Moving forward, a more complete understanding of psychiatric conditions at the preclinical level will require the integration of advanced scientific technology with the investigation of individual, population-based, and species-specific differences in behavioral models.

1.23 Basic Systems Neuroscience

André A. Fenton, Ph.D., and Dino Dvorak, Ph.D.

Systems neuroscientists study how neural circuits represent, analyze, and compute information by generating internal neural representations of variables in the external world to create knowledge, make decisions, and execute actions. Systems neuroscience aims to understand the causal relationships between the molecular and cellular levels of understanding brain structure and function, including the high-level mental functions that systems of neural circuits implement. For the basic systems neuroscientist, schizophrenia is at once a fascinating and frustrating subject to contemplate. Schizophrenia is fascinating because the core symptoms are of such substantial consequence. As such, schizophrenic symptomology is a profound reminder that thoughts and neural representations are neurobiologically mechanistic constructions that should be within our abilities to understand and decode, despite the apparently immense complexity. However, the absence of a mechanistic understanding of schizophrenia is a fundamental challenge to the effort to develop model organisms and model systems that could greatly accelerate scientific progress toward more effective treatments. The pendulum is decidedly on an optimistic swing as we enjoy the present era of advanced research tools that embrace the fact that the problem of schizophrenia, like that of understanding any mental phenomena, is fundamentally a systems problem that engages and demands integration across all the levels of biologic function and understanding from genes and molecules to cells and circuits and brain-regional specializations to individual and social behaviors (Fig. 1.23–1).

Telegram: @medical_k

www.konkur.in

FIGURE 1.23–1. Circle of Being. This cartoon illustrates distinct levels of biologic organization, each of which has a direct mechanistic influence on the adjacent levels of biologic function and thus, an indirect influence on any other level. If we start arbitrarily at the level of an individual's behavior (**A**), the schematic illustrates that individual behavior both influences and is influenced by social behavior (**H**) as well as brain activity (**B**). Brain activity influences and is influenced by neural circuit operations (**C**), and that activity influences and is influenced by the activity and properties of single cells (**D**). Single-cell activity influences and is influenced by synaptic function (**E**). Synaptic properties and function are determined by membrane and channel properties (**F**), and those in turn influence and are influenced by genetic function, depicted here as DNA, RNA, and peptides (**G**). While genetic function is not known to directly influence social behavior, the effects are indirect via the other levels of biologic function depicted here. Nonetheless, much of what is known about the genetics of mental illness derives from studies that seek to correlate gene function with social and individual behavior, and this extends to attempts to use this genetic knowledge for therapeutic interventions.

Telegram: @medical_k

www.konkur.in

This chapter will review the fundamentals of the basic systems neuroscience of cognitive circuit function in rodent models as may be relevant to concepts in schizophrenia. We will focus on the hippocampus, not merely because it is specifically abnormal in schizophrenia, but because the hippocampus circuit is a particularly well-characterized model system within which the systems neuroscience perspective on neural computation has been developed. This point invites the opportunity to clarify what can be productively expected of an animal model of schizophrenia in particular and any neuropsychiatric illness in general, at least from the systems perspective.

THE IMPORTANCE AND UTILITY OF ANIMAL MODELS

The importance of animal research for translating basic science to understanding mental illnesses like schizophrenia is highlighted by the fact that knowledge of basic neural and pharmacologic mechanisms has grown enormously while the expansion of treatment options has been much more modest. A central difficulty is the wide separation of biologic levels between the behavioral and mental spheres of the clinical manifestations and the biochemical domain of therapies and potential interventions. This separation is known as the “problem of the missing middle”; whereas research tools are optimized for studies at the microscopic levels of biologic function (genes, proteins, and cells), as well as the large systems level like the functional magnetic resonance imaging (fMRI) and electroencephalography (EEG) methodologies; the technologies and concepts for investigating the middle levels of biologic function are far less developed or possible to implement in people. These missing levels include the temporally organized action potential discharge within ensembles, that is, subpopulations of single neurons and the temporally activated subpopulations of activated synapses and the consequences of the patterns of intracellular and extracellular current flow. Without this middle level, it has proven rather difficult to connect the nitty-gritty of receptors and transmitters to the clinical observables that drive treatment decisions. Though crucial, this middle level of investigation is only practical in animal research and is especially well developed for rodent preparations where it is feasible to record the extracellular electrical discharge from several tens to thousands of single neurons,

Telegram: @medical_k

www.konkur.in

concurrent with the population-level summation of synaptic currents that manifest as oscillations in the local field potential (LFP).

Since much of this chapter will be concerned with animal research that is conducted in the effort to understand schizophrenia-related issues, it is necessary to clarify what is and is not meant by the term “animal model.” Although the term is commonly used to indicate that the animal is being used to mimic some aspect of the clinical disorder, this is unlikely to be a valid or productive conceptualization. The mental phenomena that are the foundation of a schizophrenia diagnosis are hardly applicable to animals. There is great uncertainty about whether animals have the corresponding mental capacities, and if they do, it is highly unlikely that they will manifest as they do in people. There has been considerable discussion over the validity of the current DSM-based diagnostic criteria and whether there should be greater emphasis on objective biologic criteria as proposed by the National Institute of Mental Health’s Research Domain Criteria (RDoC) project. A consequence from the vantage of animal research is that uncertainty in defining the disease translates into making it impossible to mimic something that is poorly defined. But even basing diagnosis on objective criteria like measurements of functions like attention, working memory, and long-term memory, one has to be aware and careful that such functions can manifest in species-specific ways. Consider, for example, the Stroop test as a tool to assess cognitive control. Surely rodents also use cognitive control, but effectively assessing cognitive control in the rodent certainly does not resemble a Stroop test. There is substantial overlap in the genetic abnormalities that predispose to the diverse conditions that are classified as autism spectrum disorder, attention deficit hyperactivity disorder (ADHD), bipolar disorder, major depressive disorder, and schizophrenia. Which disorder would be modeled by the genetic abnormality in a mouse? Even though it is clearly practical and advantageous to mimic genetic alterations associated with schizophrenia in mutant mice, one must also be wary that pleiotropy has species-specific outcomes. A gene expressed in one species may confer considerably different phenotypes in different species, making it challenging to even interpret how a human genetic alteration might be mimicked in a model organism. Finally, the penetrance of genetic variants is typically a few percent, which from the perspective of mimicry, should mean that there is a low probability of detecting that a specific genetic modification leads to an abnormal phenotype. There are a multitude of

Telegram: @medical_k

www.konkur.in

reasons not to seriously consider that animal models of neuropsychiatric disorders mimic the disorder. Yet, beyond the problem of the missing middle, animal models are among our most powerful tools to test hypotheses about schizophrenia and other neuropsychiatric disorders. We do not consider any of the rodent models reviewed here to be models of schizophrenia itself. The animals are themselves tools, somewhat akin to a reagent, which can be used to effectively evaluate the key hypotheses that drive understanding of schizophrenia.

NEURAL ELECTRICAL ACTIVITY AND NEURAL CODES

A major general challenge in neuroscience that may, in particular, provide an opportunity for progress toward a systems-level understanding of schizophrenia is to determine how information is represented in the electrical activity of neurons. The standard textbook treatment of this fundamental question is the “dedicated coding” hypothesis in which the action potential discharge of single neurons is interpreted to signal the presence (or absence) of a complex stimulus like an object or the occurrence of a complex event like a movement or being in a particular location of space, as is the case for hippocampus place cells (see Fig. 1.23–2). There is ample cardinal cell evidence for the dedicated coding hypothesis. These are neurons dedicated to signaling high-order stimuli and concepts, like “face” or “grandmother.” Especially dramatic, well-studied examples are the place cells, head direction cells, border cells, and grid cells in the rodent hippocampus and related structures that signal location, direction, environmental boundaries, and distance in external space. Another dramatic example recorded from the same brain regions of human epilepsy-surgery candidates is the cells with firing that are tuned to well-known individuals like the actresses Jennifer Aniston and Halle Berry. A problem with dedicated coding is that the capacity of a dedicated code is limited to the number of functional cell types, but a major attraction of the hypothesis is that it is conceptually straightforward to conceive of how it is possible for neurons to read and transform the information in the firing of such cardinal cells by, for example, higher-order representations like of a place emerging from the integration of converging connections from neurons representing lower-order concepts like the direction and distance to borders.

Telegram: @medical_k

www.konkur.in

Much of the contemporary research into the neural activity correlates of information representation in animal models that are relevant to schizophrenia has been conducted and interpreted within the framework of the alternative “ensemble-coding” hypothesis. The hypothesis asserts that information is encoded by the pattern of activity across many neurons. An ensemble code is analogous to a stadium jumbotron display that uses many light bulbs to represent a message. There is ample evidence of ensemble coding, even from the same spatially tuned cells in the hippocampal and related neocortical areas, which are interpreted as evidence of dedicated coding (Figs. 1.23–2 and 1.23–3). Analogous to the jumbotron bulbs, the activity of a given neuron contributes to multiple representations, yet, no particular neuron is essential to a representation; many more representations can be encoded than there are neurons, and crucially, the same neuron can only represent one message at a single moment. Like the jumbotron, these properties require that the activity within the system of neurons (or light bulbs) is temporally coordinated so that the proper subsets of cells are coactive at the proper time intervals to represent and transmit information, perhaps at multiple time scales. Hebb’s idea of the cell assembly, a set of cells that fire together to represent information by the pattern of active and inactive cells, is an example of an ensemble code. While there is substantial evidence of ensemble codes operating in the mammalian and invertebrate brains, there is a major issue with the hypothesis. Unlike a dedicated code, it is unclear how neurons might detect, read, and transform information from an ensemble code. The difficulty arises from the fact that (a) the information in an ensemble code is distributed across time and space (i.e., diverse locations of cells) and (b) single neurons tend not to possess the necessary connectivity to collect an overview of all the cellular activity that defines the representational patterns carrying information. How might we fare, either individually or collectively, to read messages on a jumbotron display if each person could only see a subset of the light bulbs?

A 2-s example of the location-specific LFP has been superimposed such that the start of the LFP corresponds to the location where it was recorded. **B:** Photos of the two familiar environments in which place cells were recorded, a 76-cm diameter cylinder and a 1.8 × 1.4 m box. **C:** Blue-to-red color-coded average firing rate maps document the spatial

Telegram: @medical_k

www.konkur.in

tuning of place cells recorded as a rat foraged for scattered food in the cylinder and box. Each set of five cells was recorded simultaneously from the same anatomical subdivision of the hippocampus circuit. Notice that in the cylinder, most place cells only discharge robustly in a single location, called the cell's place field, which suggests that the discharge provides a dedicated neural code for location. However, the fundamental nature of the place code is actually an ensemble code because, in the larger environment of the box, the same cells typically discharge in multiple place fields. If each cell's discharge in the box is interpreted as a dedicated code, the activity of each cell provides an ambiguous indication of location that cannot be reliably disambiguated within the dedicated coding framework. If, however, the discharge is interpreted as an ensemble code, the pattern of activity across the set of cells provides an accurate indication of location because the across-cell pattern of activity is unique at each location. The minimum firing rate (measured as spikes/s) in the *red* color (highest firing rate) category is given below each firing rate map. The *blue* color indicates a firing rate of 0 spikes/s. (See eBook for color images.) (B&C, reprinted from Park E, Dvorak D, Fenton AA. Ensemble place codes in hippocampus: CA1, CA3, and dentate gyrus place cells have multiple place fields in large environments. *PLoS ONE.* 2011;6(7):e22349. doi: 10.1371/journal.pone.0022349.)

The ensemble coding hypothesis offers a natural systems-level account for the cognitive and perceptual abnormalities that are observed in schizophrenia. Like the jumbotron, a neural network operating to represent information in an ensemble code must avoid the total loss of information resulting from simultaneously activating multiple representations with the same cells. A jumbotron can display two messages with the same lights, but only one message after the other as a temporally coordinated series of patterns, not simultaneously. Similarly, two cell assemblies that share neurons and are each defined as the subset of coactive neurons can represent multiple items so long as the two-coactivation patterns are separated in time. But there is a catastrophic loss of information if the two cell assembly patterns coactivate, because the coactivity merges all the active cells into a distinct, coactivity-defined cell assembly that represents something other than what is present or intended. Like any system that uses an ensemble code, a neural system can only operate effectively if mechanisms are in place to coordinate that cells within a single assembly coactivate and that multiple coactivity-defined assemblies do not coactivate. We will presently examine neural oscillations as one class of these coordinating mechanisms, but let us first consider what kind of conditions present a challenge to the ability to coordinate multiple neuronal ensemble representations of information.

FIGURE 1.23–3. The psychotomimetic phencyclidine (PCP) discoordinates neural discharge with minimal effects on the spatial tuning of individual place cells. **A:** The blue-to-red color-coded firing rate maps of an ensemble of 9 CA1 place cells that were recorded as a rat foraged for scattered food in a familiar cylinder before and after systemic injection of 5 mg/kg of PCP. The PCP had no discernable effect on the spatial firing of the individual place cells. **B:** In contrast, when the same data are investigated as a time-varying across-cell pattern of discharge, it is obvious that the PCP radically changed the ensemble firing of the cells (PCP was administered at 30 minutes). To generate the correlation matrix that is shown, every minute, the number of

Telegram: @medical_k

www.konkur.in

spikes that each cell discharged was counted and organized as an activity vector that described the temporal pattern of discharge across the population. Each activity vector was correlated with every other activity vector, and the correlation is represented using the color code. The correlation at any point in the matrix represents the activity at time x correlated with the activity at time y. The correlations along the x = y line are exactly 1 because it is the activity vector correlated with itself. The activity vectors under PCP immediately changed relative to the preinjection vectors (independent or negative correlations), but the PCP activity formed a stable pattern indicated by the correlations of approximately 1. Thirty to 40 minutes after PCP, the place cell ensemble activity switched back and forth between the preinjection and the PCP patterns until it settled back to the preinjection pattern. Notice that at 3 and 11 minutes during the preinjection period, the PCP pattern was expressed (in the absence of PCP). Not only do these data demonstrate discoordination of neural activity without affecting the information tuning of individual neurons, but also they indicate that ensemble activity is multistable. The system prefers to exist in one effectively stable activity pattern, and PCP radically changes the probability of observing the distinct patterns. (See eBook for color images.) (Data from Kao HY, Dvorak D, Park E, Kenney J, Kelemen E, Fenton AA. Phencyclidine discoordinates hippocampal network activity but not place fields. *J Neurosci.* 2017;37(49):12031–12049.)

A hypothesis for the information processing, perceptual, and cognitive impairments in schizophrenia falls out of the foregoing discussion of ensemble coding. Loss or aberrant coordination of neural activity will generate information processing failures in a network of neurons, and such failures are more likely when multiple sources of conflicting information compete for the same neural resources. Such ideas have been put forth in a number of ways. In essence, the notion asserts that discoordinated patterns of electrical neural activity are the core deficit in schizophrenia from which other deficits derive. This “discoordination” hypothesis is a systems-level attempt to account for the cognitive deficits in schizophrenia. It asserts that, by and large, cognitive and perceptual deficits of the disease are caused by the aberrant coordination of the many individually “normal” neurons that comprise a neural network or circuit. This discoordination is asserted to occur both within and between neural networks. Note that the coordination and discoordination of neural activity can only really be investigated and assessed directly by measuring the timing relationships of neural discharge among two or more neurons or other measures of neural activity, such as the EEG that reflects spatiotemporal patterns of synaptic currents.

Telegram: @medical_k

www.konkur.in

An instructive example of the neural discoordination that is hypothesized to underlie the cognitive deficits in schizophrenia is demonstrated by the effect of the psychotomimetic phencyclidine (PCP) on rat hippocampus place cells. The drug selectively increases the power of gamma oscillations (30 to 100 Hz) in the hippocampal LFP (Fig. 1.23–3A), but it does not cause a detectible change in the spatial tuning of hippocampal place cells (Fig. 1.23–3B). Interpreting the effect on place cells from the dedicated coding perspective, one must conclude that PCP has a minimal effect on the discharge of these cognition-related cells. Remarkably, the conclusion is rather different if the same data are interpreted from the ensemble-coding perspective and evaluated as an across-cell pattern of discharge (Fig. 1.23–3C). The correlation matrix shows that PCP has a large and immediate effect on the temporally organized pattern of discharge across the sample of hippocampal place cells. PCP causes the familiar, stable pattern of discharge to change to a new, different stable pattern of discharge that does not correspond to the familiar representation of this familiar environment. As the PCP effect begins to wear off, about 30 minutes after administration, the neural activity pattern alternates between the preinjection and the PCP patterns before it settles into the familiar preinjection pattern. It is notable that the PCP discharge pattern had been transiently expressed at minutes 3 and 11 of the recording before PCP was administered. These data indicate that hippocampal neural activity is multistable and reveals that PCP changed the probabilities of the system being in the familiar preinjection and the aberrant PCP states, where the network state is defined by the coordinated temporally defined ensemble pattern of discharge and not on the basis of a measure of the discharge properties of the individual cells. Ensemble disruptions have also been measured in neocortical ensembles in genetic and chronic ketamine mouse models that are relevant to schizophrenia.

The discoordination hypothesis conceptualizes the coordinating processes as distinct or, at least, dissociable from the more unitary processes that characterize neural activity like the firing rate and the tuning curves of individual neurons, and the frequency of oscillations in the field potentials that can be recorded as EEG from the scalp or as an LFP when it can be localized to a specific location of a neural circuit. However, since both the unitary physiologic properties of cells and their coordinating processes result from the deployment and operation of the

Telegram: @medical_k

www.konkur.in

cellular machinery, including protein channels, at some sufficiently detailed level, alterations of the coordinating activity also influence these unitary properties. As currently conceived, the discoordination hypothesis predicts that basic properties and neural network functions like the tuning of neural responses to stimuli, the behavioral responses to simple, unitary stimuli, and the expression and use of memory will be relatively normal when conflicting information is minimal. Whereas, functional and discoordination abnormalities will be prominent with increasing likelihood under complex conditions that require ignoring and selectively using the accessible information to manage and meet competing demands. A canonical example of such a situation has been formalized as the Stroop test. The basic form of the test presents stimuli to the subject that provide two distinct forms of information, such as the words of colors, for example, “blue” and “red” written in either a congruent (“blue” written in blue) or incongruent color (“blue” written in red). Because the subject is instructed to report the color and thus ignore the meaning of the word, to be effective, the subject’s relevant brain circuits must selectively represent the color and not the meaning. Using tasks that present a cognitive control challenge like this, one can observe the discharge across an ensemble of neurons in rodents coalesce into coactivity-defined groups or assemblies of cells that represent one class of information, but the activity toggles between distinct patterns of coactive cells, each representing one or the other class of information. At any moment, the network of cells prefers to represent the information with the greater behavioral relevance.

Origins of Local Field Potentials and Neural Oscillations

Whether it is a single-neuron action potential or an ensemble of synaptic potentials, neural electrical activity derives from changes in the transmembrane potentials of excitable cells like neurons. The extracellular currents emanate through the conductive extracellular medium and are recorded as field potentials, the origins of which can be localized to the vicinity of an intracranial electrode and are hence called an LFP, or in the case of the EEG recorded with a scalp electrode. The spatial localization of the neural origins of the EEG potentials is much reduced. There are, however, developments in the ability to do source localization computations that have allowed fMRI-like imaging of functional brain activity from the EEG collected at sufficiently dense scalp electrode sites.

Telegram: @medical_k

www.konkur.in

Extracellular fields are generated by the flow of positively or negatively charged ions through the semipermeable membranes of neurons. When positively charged ions (e.g., Na^+ or Ca^{2+}) leave the extracellular space in the cell, they cause local electrical sinks, which appear as a negative deflection in the LFP, measured at the proximity of the active membrane. Passive current in the opposite direction balances the current influx and is termed the return current. Excitatory neurons, such as those that release the neurotransmitter glutamate, cause a current influx in postsynaptic cells and, therefore, a depolarization of the postsynaptic membrane from its resting potential and an increased probability of a postsynaptic action potential. Inhibitory cells typically release gamma-aminobutyric acid (GABA), which in the postsynaptic cell causes hyperpolarizing and/or shunting inhibition where negative chloride ions can enter or leave the cell through chloride ion channels associated with the GABA receptors. This hyperpolarizes or stabilizes at rest the membrane potential of the postsynaptic cell, both of which make postsynaptic action potentials less likely. Currents through the membrane are extremely small, and, therefore, any measurable changes in the LFP are a result of many spatially uniform and temporally synchronized events. The largest contribution to the LFP comes from slow and synchronized currents activated by inhibitory neurons. While fast Na^+ and K^+ conductance-based action potentials generate the largest extracellular currents (an extracellular action potential or spike), they only have a limited contribution to the LFP spectrum below 100 Hz because of the short duration of the action potential events (<1 ms).

Neuronal oscillations are periodic fluctuations in neural activity in the central nervous system. Oscillations can be observed across multiple spatial scales. At the level of a single neuron, they either have a form of rhythmic, subthreshold changes of the membrane potential or rhythmic changes in action potential activity. The synchronized activity of large numbers of neurons gives rise to macroscopic oscillatory electric fields that can be observed in the LFP, invasively, using extracellular electrodes, or in the EEG, noninvasively, using scalp electrodes. Oscillations differ in several aspects, such as the typical frequency, anatomical localization, generating mechanism, relative power, and relationship to the ongoing brain state. Here, we will stress the importance of theta (5 to 12 Hz) and gamma (30 to 100 Hz) oscillations because their biophysical origins are well understood, and their interactions provide a functional coordinating

Telegram: @medical_k

www.konkur.in

infrastructure within which information-carrying action potentials are organized and controlled.

Theta oscillations can be detected in brain structures such as the hippocampus, entorhinal cortex, amygdala, sensory cortex, and prefrontal cortex. The theta rhythm has been associated with encoding and retrieval of memory, synaptic plasticity, long-range synchronization, and top-down control of cognitive functions such as attention and cognitive control. The hippocampal theta rhythm is the most prominent oscillation associated with the online state of the hippocampus; it is most notable during the intake of sensory information such as active locomotion, whisking, and sniffing, although it is also consistently present in the rapid eye movement (REM) stage of sleep. Theta rhythmicity is generated by pacemaker cells located in the medial septum-diagonal band of Broca, which provides GABAergic and cholinergic drive to hippocampal CA1 interneurons. On the other hand, excitatory CA3 hippocampal subfield and entorhinal cortical inputs to the dendrites of the CA1 hippocampal subfield may also produce stronger and higher frequency theta oscillations. The presence of multiple, weakly coupled theta oscillators might allow the necessary flexibility in the selection of appropriate cell assemblies for various cognitive tasks. One of the most important features of the theta rhythm is its ability to modulate the discharge of interneurons that generate local gamma oscillations by the postsynaptic inhibitory effects of their release of GABA. This mechanism was proposed as a general mechanism for chunking information throughout the brain. The result of such bias or so-called “nesting of oscillations” reflects the observation that the phase of the slower (theta) rhythm modulates the amplitude of the faster (gamma) rhythm (Fig. 1.23–4).

Gamma oscillations have the most ubiquitous rhythm; they have been localized in all brain structures where fast GABA-mediated inhibition is provided by soma-targeting interneurons. It is not surprising that something so widespread has been associated with perception, attention, memory, synaptic plasticity, and consciousness. In contrast to the theta rhythm, gamma oscillations are more locally generated, faster oscillations that cover a wide range of frequencies from 30 Hz to approximately 150 Hz. The upper limit of the gamma band has been a subject of intensive discussions. While the gamma rhythm was originally defined as the 35- to 85-Hz band, in more recent work, authors have subdivided the hippocampal gamma band into slow (<50 Hz), midfrequency (60 to 90

Telegram: @medical_k

www.konkur.in

Hz), and “high” or “fast” (>100 Hz) components. However, caution is necessary for oscillatory activity above 100 Hz because of their possible contamination by the wideband spectral content of action potentials and associated after potentials. Gamma oscillations are generated by the interplay of excitatory and inhibitory neurons. GABAergic interneurons, especially interneurons that express the Ca^{2+}-binding protein parvalbumin, have been shown to be a particularly important part of the pacemaker system that generates gamma frequency oscillations. These interneurons receive glutamate receptor-mediated excitatory inputs. Transient excitation of the network of parvalbumin-expressing interneurons, which are mutually interconnected through electrical gap junctions and GABAergic synapses, generates rhythmic inhibitory postsynaptic potentials which can synchronize the firing of large populations of pyramidal neurons (Fig. 1.23–5).

FIGURE 1.23–4. Phase-amplitude coupling of distinct neural oscillations. This LFP example illustrates the “nesting” of fast (60 to 100 Hz) gamma oscillations within theta (~8 Hz) oscillations. There are approximately 6.5 theta cycles depicted here. Notice that the largest gamma oscillations tend to occur preferentially following the peak of the concurrent theta oscillation.

Canonical pattern generating networks are shown in Figure 1.23–6. Feed-forward inhibition (Fig. 1.23–6 left) provides a mechanism for attenuation of the afferent excitation, where a distant excitatory cell activates a local interneuron or a group of local interneurons connected via gap junctions, which in turn inhibits multiple principal cells in the local network. This mechanism increases the temporal precision of firing by narrowing temporal windows of discharge probability of the principal neurons. Because the periodic repetition of the “window of opportunity” of the principal neuron discharge is defined by the time constant of the inhibitory neuron, this pairing of excitatory and inhibitory neurons is proposed as one of the generating mechanisms of gamma and other types of oscillations. In feedback inhibition (Fig. 1.23–6 middle), the interneuron receives excitatory glutamatergic input from the local principal cell and, in turn, provides inhibition to a specific compartment of the principal cells in the same network. Feedback inhibition provides a

Telegram: @medical_k

www.konkur.in

mechanism for reducing the excitability of principal cells and a mechanism for inhibition of a specific dendritic segment of the principal cell. Lateral inhibition (Fig. 1.23–6 right) provides an effective "winner-take-all" mechanism for selective activation of distinct ensemble patterns by increased activation of selected principal neurons (left population), which in turn inhibits other networks of neurons, therefore reducing their chance to fire (right population).

FIGURE 1.23–5. Theta-paced gamma frequency discharge of a parvalbumin-expressing basket cell type interneuron. A potential source of theta and gamma oscillations in the field potential is illustrated in this pair of simultaneous records from an intracellular recording of a parvalbumin-expressing basket cell and an extracellular recording of the LFP. (Adapted from Ylinen A, Soltesz I, Bragin A, Penttonen M, Sik A, Buzsaki G. Intracellular correlates of hippocampal theta rhythm in identified pyramidal cells, granule cells and basket cells. *Hippocampus*. 1995;5(1):78–90. doi: 10.1002/hipo.450050110.)

FIGURE 1.23–6. Basic mechanisms of network excitation-inhibition coordination. In these schemes, each cell type that is depicted, principal cell (PC) and inhibitory interneuron (IN), represents a population of the cell type, not an individual neuron. Circuitry for feed-forward inhibition (**left**) provides a mechanism for attenuation of the afferent excitation. Feedback inhibition circuitry (**middle**) provides a mechanism for reducing the excitability of principal cells and a mechanism for inhibition of a specific dendritic segment of the principal cell. Lateral inhibition circuitry (**right**) provides an effective "winner-take-all" competitive network mechanism for selective activation of distinct ensemble patterns according to relative effective input strength. The stronger of the momentary excitatory inputs will dominate and suppress the cells that are experiencing the weaker inputs, such that the network activity will exaggerate and sustain differences in input. Note that each of these functionally distinct schemes can be realized in the same circuitry based on the coordinated timing and levels of activity in the relevant neural elements.

Gamma activity is not actively propagated; instead, its role in neural coordination is to synchronize the spiking of neurons. From the perspective of the dedicated-coding hypothesis, it may not seem intuitive that inhibition would be synchronizing. However, from the perspective of the ensemble-coding hypothesis, inhibition synchronizes by defining narrow windows of opportunity for principal cells to discharge. The coupling between spiking activity and gamma oscillations could arise because local inhibitory neurons (crucial for generating gamma) fire preferably at the trough of the local gamma cycle. This mechanism makes the spiking of excitatory projection neurons more likely at the offset phase when inhibition is weaker. This feature of coupling between gamma and spiking has been hypothesized as a central aspect of cortical processing. Several hypotheses have also been proposed for the role of the gamma rhythm. According to one hypothesis, the phase of firing relative to gamma encodes the stimulus strength because stronger afferent

Telegram: @medical_k

www.konkur.in

excitation will permit firing to occur earlier in the window of opportunity that is set by ongoing gamma oscillations. Another idea is that gamma influences the communication between neuronal populations so that communication can entrain and increase when there is gamma phase-coherent spiking in the two populations.

Neural Coordination – Measuring the Varieties of Synchrony in Neural Oscillations. Various forms of neural synchrony, the coordinated, synchronized activation of same-function cells, and the active desynchronization of different-function cells have been proposed as a fundamental mechanism of neural computation. Neural synchrony appears across multiple scales. On the cellular (microscopic) scale, neural synchrony mediated by action potential and synaptic activity manifests as a transient coupling between functionally distinct neuronal subpopulations. This coupling of neural subpopulations creates a form of synchrony that manifests as oscillations in the LFP and the synchrony we observe on a mesoscopic scale of neural networks. The synchronized activity of a large number of neural networks, in turn, gives rise to the signals we observe at the macroscopic level, such as the scalp EEG.

An important aspect of neural synchrony is its cross-scale nature. For example, neural oscillations such as gamma synchronize action potentials within and between networks of neurons. Furthermore, slow oscillations, such as theta, synchronize transient bursts of fast oscillations such as gamma (Figs. 1.23–5 and 1.23–6). Coordinated neural interactions, therefore, appear across scales and across frequency bands. Although it is an extremely important and well-studied area, because of the difficulty of recording spiking data in clinical settings, we will not discuss spike-field synchrony further and instead focus on synchrony within and among the oscillations in field potentials.

Oscillations can be observed at multiple temporal and spatial scales. Cortical oscillations can be recorded noninvasively by conventional EEG. Circular cup electrodes of approximately 10 mm in diameter are placed on the scalp with a small amount of conductive gel between the scalp and the electrode. To facilitate fixing the electrode to a specific location of the head, electrodes are sometimes embedded in a fabric cap, which stabilizes their location during the recording. The location of electrodes has been standardized, as in the international 10 to 20 systems. Signals from electrodes are usually recorded using differential amplifiers where

Telegram: @medical_k

www.konkur.in

the common reference can be one of the electrodes (typically the *CZ* electrode at the center of the 10 to 20 system) or linked mastoid electrodes. Scalp EEG has several important limitations. The tissue between the cortex and the electrode is formed by the cerebrospinal fluid, pia mater, arachnoid, dura mater, skull, periosteum, and scalp. The tissue is highly heterogeneous, most importantly in terms of its conductance. The presence of the low-conductance bone causes signal smearing that decreases spatial resolution and source localization. Another problem is related to the distance between the electrode and the recorded neural tissue. Because the intensity of the electric field falls with the square of the distance, the measurable voltage change on the electrode (several tens of microvolts) corresponds to the synchronized activity of approximately 6 cm^2 of cortical gyri tissue corresponding to 60 million neurons forming the electrical dipole layer. The last important limitation of the scalp EEG is its frequency range. Because the spectral magnitudes of brain oscillations are inversely related to their frequency, according to a power law, it is progressively more difficult to record higher frequencies on the scalp because of the progressively worse signal/noise ratio. This fact limits the upper bandwidth of the EEG to approximately 70 Hz, although several techniques have been used to circumvent this limitation, such as trial-based averaging (event-related potentials, ERPs).

Higher spatial and frequency resolution than the EEG can be achieved by electrocorticography (ECoG) by using subdural electrodes which come into direct contact with brain tissue. In humans, this technique is limited to presurgery monitoring of epilepsy patients, where epileptogenic source localization provides the justification for this highly invasive technique. Compared to standard EEG electrodes, subdural electrodes are usually implemented in the form of grids or strips with typical electrode diameters of 2 to 3 mm and spacing of 10 mm between the electrodes. The close contact between the electrode and the neural tissue allows recording of LFPs up to 500 Hz.

The highest spatial and frequency resolution can be obtained by using penetrating high-impedance microelectrodes placed directly into the neuronal dipole sheet to record the electric signal of small groups of neurons. Microelectrodes come in several different forms, such as high-density microelectrode arrays used primarily in nonhuman primate research or micromachined multicontact silicon probes used primarily with rodents. When a microelectrode is placed in the CA1 region of the

Telegram: @medical_k

www.konkur.in

hippocampus, it can record the summed activity of up to 1,000 neurons within a radius of 140 μm.

The remaining parts of the recording system are principally the same, no matter if scalp EEG or LFPs are acquired. Conventionally, the signal is first routed into a signal follower, an operational amplifier with unity gain, although new low-power digital electronics can skip this step. The goal is to reduce the signal impedance to minimize additional electric noise caused by the signal passing through the cable that connects the subject to the main amplifier and digitization stages, and this can be avoided if the digitization occurs at the electrode site. After this stage, the signal is amplified using one or multiple operational amplifiers, so the signal's voltage is increased from tens to hundreds of microvolts to several volts. At this point, the signal is high-pass filtered to avoid saturation of the analog-to-digital converter (ADC) and then low-pass filtered to avoid aliasing effects in the ADC stage and finally routed to the ADC for digital conversion. The output of the ADC is a 16- or 24-bit binary number corresponding to the voltage between the active electrode and the reference electrode. The binary number is stored in computer memory for further processing. Recent advances in the use of metal-oxide-semiconductor silicon fabrication technology have made it possible to design dense arrays of electrodes with the electrode contacts integrated with the amplifier and digitization circuits. Instead of placing a limited number of electrodes at specific targets, this technology allows a large, excess number of electrodes to be placed such that only the subset that are in regions of interest will be recorded. For example, Neuropixels 2.0, that were designed with this technology, have 5,120 15-μm square recording sites distributed over four shanks such that using computer-controlled electronic switches, a user can select to record the electrical activity from any 384 of the sites. The 384 digital signals are multiplexed into a single digital data stream and transmitted on a single wire, allowing for the electrical activity from thousands of cells to be recorded with a recording system that weighs 1.1 g. This electronics technology advance is especially important because, although it has been possible to record the electrical activity of thousands of neurons by transducing the calcium transients that are associated with action potentials into a fluorescent signal using genetically encoded calcium indicators (GECIs), the time resolution (~10's ms) of even the latest GCaMP8 GECI is too slow to resolve individual action potentials or relate them to ongoing oscillations in

Telegram: @medical_k

www.konkur.in

the LFP. Nontoxic genetically encoded voltage sensors that are now being developed promise another revolution in recording technology. Such voltage sensors will enable the recording of the subthreshold transmembrane fluctuations as well as the action potentials from many tens to hundreds of individual cells in awake-behaving brains, all with high-temporal fidelity and μm spatial resolution. These unprecedented possibilities are sure to bring novel insights and permit novel questions and specific biophysical hypotheses to be evaluated, but in the meantime, analysis of neural oscillations is the state of the art for patient recordings.

Analysis of Oscillations. The most basic approach for the analysis of oscillations is based on Fourier analysis, where the time representation of the voltage signal is transformed into the frequency domain using the fast Fourier transform (FFT). The result of this transformation is a power spectrum, which defines the original voltage time series as a function of oscillations of different frequencies. Specifically, the power spectrum is the amount (power) of each frequency-defined sine function from which the original voltage time series signal is composed. Importantly, computing the FFT requires a sufficiently long time series of data, and it is assumed that the frequency content of the signal did not vary in any meaningful way in time. Consequently, appropriate analysis using the power spectra assumes stationarity of the signal and, as such, cannot provide any information about the dynamics of oscillations, should the stationarity assumption be invalid. Given that neural signals are time varying, especially those that might contribute to cognitive processes, it is important to recognize that several methods that have been developed for digital signal processing engineering applications are now available and are growing in their use and utility for systems neuroscience applications. One such development is called the short-time Fourier transform (STFT), an extension of the Fourier transform. The STFT adds the time dimension to the power spectra, which allows analysis of the dynamical changes of the power at individual frequencies over time. Limitations of the time-frequency resolution of the STFT had been partially overcome by wavelet analysis, which enables time-frequency analysis at various levels of detail or so-called scales. When a complex wavelet is used, one can also estimate the instantaneous phase and amplitude information from the signal. This concept is similar to the application of a pass-band filter followed by the Hilbert transform, which will also yield a time series of the

Telegram: @medical_k

www.konkur.in

phase and amplitude of a frequency-defined signal. The ability to measure the time-varying spectral content of EEG and LFP signals has made it possible to study the interactions of distinct oscillations, like that of the theta and gamma oscillations that can be seen in the LFP fragment in Figures 1.23–3 and 1.23–4. Interactions of oscillations can be studied by methods of bivariate data analysis. In general, these methods analyze the relationships between various aspects of signals, such as their amplitudes in time (cross-correlation), their phase relationship (coherence, phase locking), or the relationship between amplitude and phase (cross-frequency coupling [CFC]). The most advanced methods, such as phase locking and CFC, are based on a similar scheme. First, both signals under analysis are band-pass filtered. After that, the Hilbert transform separates the phase and amplitude information of both signals. In the next step, the phase and/or the amplitude information is compared using indicators such as circular variance or mutual entropy. The last important step is testing the statistical significance of any phase and/or amplitude relationships, for example, by using surrogate data techniques.

There are several types of synchrony that can be readily measured. Amplitude synchrony (Fig. 1.23–7 left) is maximal when the amplitudes of two signals covary and coincide in time. This form of synchrony can be detected by linear cross-correlation. Phase synchrony (Fig. 1.23–7, middle) is maximal when the difference between the instantaneous phases of two signals is constant. Phase synchrony can be detected by measures such as the phase-locking value (PLV) or coherence, although amplitude synchrony also contributes to coherence. Phase-amplitude synchrony (Fig. 1.23–7, right) is maximal when the amplitude of a fast signal like gamma is modulated by the phase of a slow signal, like theta. That coordination is called phase-amplitude coupling (PAC), but because such interactions also happen between different frequency bands, it is also known as CFC. The term “nesting” has also been used to describe PAC, and it emphasizes the fact that the phase of the slow oscillation modulates the amplitude of the fast oscillation within the cycle of the slow oscillation. While all forms of neural synchrony have a role in neural circuit and brain function, the present goal is to be illustrative rather than comprehensive, so we will expand the discussion of PAC to illustrate key principles of how neural oscillations participate in neural circuit computation.

Telegram: @medical_k

www.konkur.in

FIGURE 1.23–7. Types of synchrony. In amplitude synchrony (**left**), the amplitudes of two signals (depicted as *blue* and *black*) follow similar temporal patterns. In phase synchrony (**middle**), the phases of two signals maintain a constant phase offset over time. In phase-amplitude synchrony (**right**), the amplitude of the fast oscillation appears at a specific phase of the slower oscillation.

Phase-Amplitude Coupling. PAC has been observed across a variety of brain regions as well as across different animal species. We will not consider here how PAC is computed but refer the reader to a review of the methods and their limitations. The power of fast gamma oscillations (80 to 150 Hz) is phase-locked to ~8 Hz theta oscillations in the human neocortex, and different behavioral tasks evoke distinct patterns of theta–gamma coupling across the cortex. The properties of theta-slow gamma (25 to 50 Hz) coupling in the human neocortex reflect the number of items stored in working memory. Increasing memory load is associated with a reduction in the frequency of the slow oscillation, consistent with the idea that longer oscillation cycles are required to accommodate an increased number of information representations, each of which is paced by a gamma cycle.

PAC is thought to coordinate and route information flow into computationally different compartments of a neural circuit. In the rat CA1 region of the hippocampus, the theta phase of local oscillations is demonstrated to modulate the amplitude of two somewhat overlapping gamma frequency bands, slow and fast gamma. A role of the slow delta (1 to 4 Hz) rhythm in the sensory selection of the task-relevant input stream has also been demonstrated. Although the physiologic mechanisms of PAC are not well understood, it is hypothesized that perisomatic inhibitory basket cells in the hippocampus play a role in the spatiotemporal organization of cell assemblies by firing theta rhythmic trains of action potentials at gamma frequency, and therefore, this activity contributes to both rhythms and their phase–amplitude and phase–phase relationships (Fig. 1.23–5).

Several conceptual frameworks were also proposed for the computational role of PAC. The concept of a cross-scale organization of neural activity offers a possible neural mechanism for integrating

Telegram: @medical_k

www.konkur.in

information between several functionally distinct networks to accomplish perceptual binding, selective attention, cognitive control, and the recruitment of specific computational cell assemblies. Neural activity in macroscopic (slow oscillations), mesoscopic (high-frequency oscillations), and microscopic (single-neuron activity) scales are braided together such that a progressively faster activity occurs within a short time window of slower activity. A particularly clear example is seen in the hippocampus LFP of the freely behaving rat. The phase of the hippocampal theta rhythm modulates the amplitude of hippocampal gamma oscillations (see Fig. 1.23–4). In turn, gamma oscillations provide millisecond-scale "windows of opportunity" when the discharge probability of hippocampal pyramidal cells is the greatest. It has been suggested that because of conduction delays, slow oscillations such as theta are particularly suitable for the synchronization of functional networks over longer distances. On the contrary, fast oscillations such as gamma might transiently synchronize neuronal action potential discharge into same-function assemblies over relatively short spatial scales that can be as long as a few hundred microns. The interplay between the two oscillations might then provide a mechanism for spatial integration from a local to a global scale. In this scheme, the faster gamma oscillations that emerge at the specific phase of the slower theta oscillations might recruit subsets of cells that signal the same information into a cell assembly of coactive cells for neuronal information processing. Theta might then serve as an integration mechanism between several functional networks, each associated with a particular gamma episode across longer periods of time. Another conceptual framework for the functional significance of PAC is based on the idea of phase coding, where PAC is a mechanism for encoding different information at different phases of the theta cycle. In this scenario, faster gamma oscillations appearing at specific phases of slower theta oscillations are hypothesized to activate distinct neural ensembles, which encode distinct representations by the across-cell pattern of discharge as illustrated in Figure 1.23–4.

Discoordination of Neural Discharge and Oscillations

Disturbances of neural synchrony are proposed to underlie the cognitive deficits that associate with diverse brain disorders that include schizophrenia, autism, Alzheimer disease, Parkinson disease, and epilepsy. It is not a simple matter that dysfunction emerges from too little

Telegram: @medical_k

www.konkur.in

synchrony. Rather, the idea is that neural synchrony is optimized for cognitive function and either too much or too little manifests as abnormal cognition. Gestalt perception of Mooney faces (black and white contour pictures of human faces) is impaired in schizophrenia patients, and the impairment is associated with reduced phase synchrony in the gamma band. It has also been reported there is a selective alteration of theta-frequency oscillations, suggesting deficits in the large-scale synchronization while local synchrony in the gamma band is largely intact. Several studies have found that the positive symptoms, specifically visual and auditory hallucinations and delusions, are correlated with enhanced amplitude and phase synchronization of evoked and induced beta- and gamma-band activity. On the other hand, negative symptoms have been associated with both enhanced and reduced high-frequency oscillations. In fact, there is substantial evidence that resting, baseline (i.e., unprovoked) gamma power is elevated in schizophrenia. This might, in part, explain why stimulus-evoked gamma elevations appear to be attenuated in schizophrenia patients. While exact mechanisms are not known to explain these diverse findings of neural discoordination in schizophrenia, it is hypothesized that reduced parvalbumin expression in the cortical GABAergic interneuron population indicates GABAergic dysfunction, and this results in impaired gamma-band synchronization, which is crucial for the local synchronized firing of large populations of pyramidal neurons and may lead to deficits in the temporal coordination of distributed neural activity.

Neural Discoordination in Neurodevelopmental Models of Mental Disorders. An important development in understanding mental illness in general and schizophrenia, in particular, is the recognition that these are neurodevelopmental disorders. The effect of disturbing neurodevelopment has been investigated using animal models, which provide some of the most compelling support for the assertion that disorders like schizophrenia have a neurodevelopmental origin. In the MAM-E17 rat model, the mitotoxin methylazoxymethanol acetate (MAM) is administered to pregnant dams on embryonic day 17 to preferentially disrupt the ongoing embryogenesis of the hippocampus and prefrontal cortex. Adult MAM rats exhibit deficits in cognitive flexibility and hyperresponsiveness to dopaminergic agonists, hippocampal glutamatergic dysfunction, and reduced parvalbumin-positive interneuron expression. These

Telegram: @medical_k

www.konkur.in

abnormalities accompany reduced cortical up- and down-state transitions that underlie state-selective neural responses and slow oscillations in sleep. The coupling of hippocampal (150 to 250 Hz) ripple oscillations and sleep thalamocortical spindles in the prefrontal cortex is also disrupted in adult MAM rats. Thus, the MAM neurodevelopmental insult causes a wide variety of abnormalities with general relevance to schizophrenia and clear evidence of discoordination of neural network function.

The neonatal ventral hippocampus lesion (NVHL) rat is one of the most studied neurodevelopmental models in schizophrenia research. It was developed on the hypothesis that an early-life brain insult causes aberrant development of neural circuits. The excitotoxic lesion of the ventral hippocampus occurs on postnatal day 7, corresponding to the third trimester of pregnancy in human brain development. NVHL studies provide some of the strongest evidence that early brain insults can disturb neural circuits and cognitive functions relevant to schizophrenia. Adult NVHL rats demonstrate abnormalities that are relevant to mental illness, especially schizophrenia. These include abnormal cortical dendritic morphology, reduced GABAergic metabolism, excessive dopaminergic signaling, hyperresponsive behavior to dopaminergic agonists, and various behavioral abnormalities that emerge in adulthood. There is an increased prevalence of seizures in schizophrenia, and the incidence of epileptiform activity is increased in adult NVHL rats. Making the lesion in adulthood does not produce the same NVHL abnormalities, consistent with a developmental component to the consequences.

Single neuron responses in the prefrontal cortex and nucleus accumbens are aberrant in adult NVHL rats. Prefrontal firing normally decreases in response to dopamine from stimulation of the ventral tegmental area, but prefrontal activity increases in NVHL adults. Such disruptions of excitation–inhibition coordination occur, in part, because of impaired interneuron activation by dopamine. Disinhibition of the adult NVHL neocortex is associated with cognitive impairments, such as in decision tasks. In control rats, the adolescent prefrontal network is also disinhibited and less coordinated than in adults, suggesting that NVHL information processing networks are functionally immature.

NVHL cortical network activity patterns are discoordinated within and between the hippocampus and prefrontal cortices during cognitively challenging behaviors. During an odor discrimination task, rats generate behavioral sampling event-related increases in low-frequency (1 to 30 Hz)

Telegram: @medical_k

www.konkur.in

prefrontal oscillations. These increases are weak in NVHL rats. Consistent with reduced oscillations being an indicator of reduced excitation—inhibition organization, prefrontal neurons in NVHL rats are hyperresponsive when the animals sample odors and this was exacerbated on large reward trials when dopamine levels are expected to increase. These abnormalities were not evident during baseline behavior when differences in oscillatory power are hard to detect, indicating that network activity patterns are sensitive to what the subject is doing and presumably also thinking. It follows that group and treatment differences tend to emerge during cognitive effort, but it is also the case that physiologic differences may be irrelevant to cognitive performance, and this is difficult to know unless the behavior and physiology are assessed concurrently.

The interdependence of cognitive behavior and network activity is evident in studies of NVHL adults performing an active place avoidance task on a slowly rotating arena. The task requires intact hippocampus function and maintained hippocampal long-term potentiation (LTP) as well as cognitive control to use stationary spatial cues and ignore irrelevant rotating olfactory cues. NVHL adults are impaired at place avoidance, but with extended training, they can approach the performance of controls. NVHL rats are not impaired in adolescence, nor are they impaired if the cognitive control demand is reduced, indicating that an increased incidence of epileptiform activity is not sufficient to cause basic performance learning and memory deficits. Hippocampal and prefrontal LFPs are reduced across a wide band of frequencies during walking, but this is insufficient to explain the cognitive deficits which depend on experience and the availability of cues. Compared to during the task, interhippocampal and interprefrontal phase and amplitude synchrony of oscillations are reduced during home-cage behaviors such as quiet rest, grooming, and eating, except in the gamma range, which is similar in NVHL and controls in all conditions. Interhemispheric phase synchrony increases during place avoidance compared to home cage behaviors, but prefrontal synchrony is not different between NVHL and control groups during place avoidance. Theta-phase synchrony between the hippocampi is weaker in NVHL adults, even when the NVHL rats are performing as well as controls. These differences in adulthood were prevented by cognitive training in adolescence, presumably because of persistent changes in neural network function. The neural discoordination and

Telegram: @medical_k

www.konkur.in

cognitive abnormalities are also partly attenuated by reducing excitability with the antiepileptic ethosuximide, consistent with the notion that excitation–inhibition disbalance causes discoordination in NVHL adults and the possibility that this discoordination may be sufficient to explain the cognitive abnormalities.

Substantial advances in identifying genetic deletions and syndromes that confer risk for schizophrenia have allowed these genetic alterations to be modeled in mice. One basic observation is that such genetic deletions tend to confer risk for multiple disorders, including major depression, bipolar, ADHD, and autism, in addition to schizophrenia. This apparent pleiotropy highlights the value of understanding the mechanistic consequences of the genetic alterations and the fact that changes in cell biologic fundamentals like synaptic proteins and receptors can have diverse consequences depending on them when they are expressed and the specific cell types in which they are expressed. The *Df(16)A(+/−)* mutant mouse is emerging as an important genetic model because it models the 22q11.2 microdeletion syndrome with increased risk for a broad spectrum of neuropsychiatric diseases, including schizophrenia. These mutant mice express synaptic, cellular, neurocircuit, and behavioral abnormalities that include discoordinated neural activity in both the neocortex and hippocampus, including their interactions that predict cognitive dysfunction. Perhaps the most popular genetic model is the *Fmr1*-null mouse, which lacks the gene to make the RNA-binding protein named fragile X mental retardation protein (FMRP). The *Fmr1*-null mouse models the genetic defect in fragile X syndrome that results from silencing of the FMR1 gene due to an excessive (>200) CGG nucleotide repeat expansion. Lacking FMRP, *Fmr1*-null mice express a variety of synaptic, cellular, and neurophysiologic abnormalities, many of which can be restored by restoring FMRP or the molecular signaling for translation of mRNA to protein or even countering levels of dysregulated cAMP metabolism and protein expression resulting from FMRP loss. Consistent with the possibility of attenuating cognitive deficits and the discoordination hypothesis, despite the diverse cellular abnormalities, *Fmr1*-null mice can express normal hippocampus place cells and single-cell electrophysiologic characteristics, but discoordinated action potential timing among these cells and their relationship to ongoing oscillations in the LFP. These findings suggest fundamental excitation–inhibition discoordination in *Fmr1*-null as well as the *Cntnap2(−/−)*, *16p11.2(del/+)*,

Telegram: @medical_k

www.konkur.in

Tsc2(+/−) genetic models of defects observed in autism spectrum disorders. Such dissection and elucidation of the complex multilevel consequences of even a single-gene defect illustrate the power and promise of animal models for identifying novel therapeutic options. While these and other findings in *Df(16)A(+/−)*, *Fmr1*-null and other mutant mice with relevance for neuropsychiatric disorders are consistent with the discoordination hypothesis, understanding how these deficits of neural dysfunction emerge and how they can be normalized remains a daunting challenge. Consequently, the field is focusing on powerful new neurobiologic technologies that utilize animal models to identify elusive mechanisms.

SUMMARY

The systems neuroscience perspective embraces the diverse levels of biologic organization, and when this is practiced in an integrative framework, the goal is to make measurements at the different biologic levels from the same subject to look for cross-scale relationships and principles. This systems approach can be especially powerful when it is applied to testing hypotheses using animal models that are associated with mental illness, such as models that are relevant to schizophrenia, because it is extremely difficult, if not impossible, to perform the requisite multiscale systems-level analyses in a clinical population. As a closing example, let's consider the loss of GABAergic tone that is associated with schizophrenia and manifests as a reduction of parvalbumin immunoreactivity that is associated with GABAergic interneurons like the one depicted in Figure 1.23–5. Such compromised GABAergic function is consistent with the systems-level discoordination hypothesis that asserts that cognitive dysfunction is a result of multiscale disturbances that impact the different levels of biologic organization (Fig. 1.23–1). According to this viewpoint, genetic abnormalities and altered developmental programs cause, at the level of synapses and cells, impaired molecular interactions due to inefficient calcium binding, which is the normal function of parvalbumin. This can have diverse consequences, including abnormal synaptic signaling and the dysregulation of synthesis of synaptic proteins, all of which would contribute to disbalancing excitation and inhibition at the level of neural circuits. Because these circuits are dynamic and nonlinear, at least in part because of the network mechanisms depicted in

Telegram: @medical_k

www.konkur.in

Figure 1.23–6, the consequence of reduced parvalbumin expression in GABAergic neurons is a time-varying excitation–inhibition discoordination. The excitation–inhibition discoordination results in discoordinated neural activity that manifests as aberrant temporal patterns of discharge in neural ensembles as depicted in Figure 1.23–3, disruptions of the kind of spike-field synchrony that is illustrated in Figure 1.23–4, and the discoordination of the various forms of synchrony between oscillations in the field potentials that reflect population synaptic activity. According to the hypothesis, these diverse forms of discoordination cause cognitive impairments exemplified by failures of cognitive control and the disorganization of purposeful goal-directed behavior.

From the systems perspective, it is not obvious that standard pharmacologic interventions could be effective for improving cognitive deficits, at least because the systems view is often that interventions are needed at specific brain locations at specific times, depending on the particular ongoing cognitive effort. More optimistically, as exemplified by the research on the NVHL rat neurodevelopmental model, the systems neuroscience perspective suggests that there is an opportunity to harness experience itself to aid in the location- and time-specific correction and adjustment of dysfunctional neural circuit function. The hope and promise are that as we develop and elaborate knowledge of the detailed recruitment and input-specific activation and suppression of neural circuit operations, it will be possible to design and implement specific experience-based therapies, like cognitive behavioral therapy and computer-based cognitive training programs that harness the mechanisms of synaptic plasticity to tune and adjust dysfunctional neural circuits and in so doing, compensate and perhaps even correct impaired cognitive behavior. Although it is still a hypothesis, there is substantial optimism that if pharmaceutical or brain simulation-based interventions to regulate neuroplasticity can be coupled with the cognition-driven exercise of specific neural circuits, then this combination can be a powerful strategy to use the self-organizing neural consequences of experience to improve or normalize abnormal brain operations. There is much work to do but also reason for considerable optimism because basic systems neuroscience has never had such a powerful and vast toolbox to deploy.

1.24 Computational Modeling Approaches to Psychiatry

JOHN D. MURRAY, PH.D., AND ALAN ANTICEVIC, PH.D.

A primary goal of psychiatry is to understand the neural bases and mechanisms underlying mental disorders. Mechanistic understanding is integral to the development of new diagnostic and therapeutic approaches. A great challenge faced by the field of psychiatry is bridging the vast explanatory gaps across levels of analysis: from neurons to circuits to complex human behavior. At present, there is a lack of unifying understanding across this computational hierarchy for any psychiatric symptom. This profoundly limits the field's capacity to develop novel and rationally guided therapies that are grounded in well-established neural mechanisms.

It is no longer controversial to conceptualize severe mental illness as brain-based disease. The explosion of research in neuroscience has established that the brain is essentially a massively complex, nonlinear computational device that governs the expression of an organism's behavior. This perspective is also captured by the ongoing paradigm shift within the field of psychiatry, from categorical behavioral psychiatric diagnoses toward an understanding of dimensional disruptions in complex behaviors that map onto well-defined neural substrates. This perspective is not intended to argue for a reductionist model of complex mental illness. Critically, this view does not posit that psychiatric disorders cannot emerge as a result of external causal factors or perturbations (e.g., long-term stress or extreme trauma) that affect the brain. Nevertheless, such perturbations ultimately impact a set of neural processes and computations that govern a behavioral response (e.g., fear expression). Put simply, there is an organ that psychiatrists are attempting to treat—namely, the central nervous system.

Given the complexity of the brain and the vast number of possible disruptions across distinct levels of analysis, the field of psychiatry should attempt to harness all available tools to mechanistically understand abnormal behavior, regardless of whether the upstream cause lies in

Telegram: @medical_k

www.konkur.in

genes or external stressors. One promising way to link these levels is to combine empirical findings from clinical neuroscience with approaches from computational and theoretical neuroscience in an emerging field often called “computational psychiatry.” The key logic here is to use mathematical principles and formalism to generate consistent, rigorous, and testable hypotheses that can lead to a better understanding of mechanisms across levels of analyses.

In that sense, computational psychiatry offers the opportunity to interface with experimental and treatment studies at the level of neurons, neural systems, and, ultimately, abnormal behavior (Fig. 1.24–1). Put differently, disrupted mechanisms that contribute to a particular psychiatric disease can occur at the level of neurons and synapses, whereas psychiatric symptoms express at the level of behavior, which involves large-scale brain networks. Linking these disparate levels is vital for gaining mechanistic insight into mental illness and for the rational development of pharmacologic treatments, which act at the synaptic level. The primary objective of computational psychiatry is to help bridge this existing gap and to mathematically formalize computations across noted levels of analysis.

To date, mathematical models of neural systems have contributed greatly to our understanding of how neural dynamics and behavior arise from underlying mechanisms. Building on this mechanistic understanding, disruptions in the underlying elements of the model can then be linked to neural and behavioral dysfunction. In particular, researchers can evaluate which models or model parameters better describe empirical findings in a disease state compared to controls. By examining these disruptions within the models, we can describe key differences in underlying processes in a mathematically precise way. This approach can also test hypotheses about lower-level phenomena (e.g., specific synaptic disruptions) with experimentally accessible noninvasive measures at higher levels in humans (e.g., functional magnetic resonance imaging [fMRI] or psychophysical behavior).

Indeed, in the past several decades, the field of psychiatry has profited tremendously from the ongoing development of noninvasive neuroimaging technology, more sophisticated human cognitive neuroscience, as well as advances in basic neuroscience. The combination of these approaches has directly impacted the broad evidence base in psychiatry, providing support for neural alterations across psychiatric conditions. Such evidence

Telegram: @medical_k

www.konkur.in

for neural alterations in psychiatric disease has emerged from a wide range of experimental modalities. Analysis of postmortem brain tissue reveals differences in neuronal and synaptic structure across psychiatric disorders. Genetic analyses implicate specific neuronal and synaptic alterations. Neurochemical alterations can be assessed *in vivo* using noninvasive methods such as positron emission tomography (PET) and magnetic resonance spectroscopy (MRS). The spatiotemporal properties of brain activity during various tasks and at rest can be measured with noninvasive neuroimaging, such as fMRI, electroencephalography (EEG), and magnetoencephalography (MEG). Neuroimaging can also reveal structural differences in grey matter distribution and long-range white-matter pathways. As noted, these neural measurements are complemented by rapid and parallel advances in cognitive neuroscience that allow us to quantitatively characterize, at the behavioral level, cognitive, affective, and perceptual impairments in patients.

Telegram: @medical_k

www.konkur.in

FIGURE 1.24–1. Conceptual illustration of the computational modeling and experimental interplay across levels of analysis. The utility of computational modeling, particularly in the study of schizophrenia, is its ability to inform a given level of experimental study. Because we study abnormalities in schizophrenia from the cellular level at the neural system level, and ultimately at the level of behavior, we have to utilize our modeling approaches to best fit the experimental framework. For instance, cellular-level experiments use techniques and produce measurements that are best captured using models that contain the necessary level of biophysical realism (**bottom panels**). Such models can, for instance, inform synaptic processes that may govern the microcircuit phenomena under study such as neural oscillations. In turn, a number of neuroimaging studies have focused on characterizing system-level disturbances in schizophrenia both using task-based paradigms and resting-state functional connectivity approaches. To best inform such system-level cognitive neuroscience experiments, models should capture the relevant detail and complexity of larger-scale neural systems (**middle panel**). Such models can perhaps better inform the role of systemic pharmacologic manipulations on BOLD fMRI or can be used to predict results of functional connectivity studies in schizophrenia. Finally, schizophrenia produces complex and devastating behavioral symptoms, which can be measured via increasingly sophisticated behavioral paradigms. Here, the use of models that formalize complex behavior can provide a powerful tool to quantitatively examine a given behavioral process in patients (e.g., reinforcement learning).

Telegram: @medical_k

www.konkur.in

Despite this explosive technologic and experimental progress, the field of psychiatry has yet to produce systematic and mechanistic disease models that are amenable to the rational development of therapies. As noted, to achieve such a multilevel understanding of psychiatric diseases, the field of psychiatry must ultimately link these levels of analysis: from synapses to cells, to neural circuits, to large-scale systems, and to behavioral disturbances. The emerging field of computational psychiatry is in a unique position to help provide the theoretical foundation needed to close these gaps. computational psychiatry benefits from the diverse range of complementary modeling approaches within the broader field of computational neuroscience. Different types of models are best suited to address different questions and different types of experimental data. In that sense, the level of computational modeling is matched to the appropriate levels of experimental inquiry, enabling the interplay between experiment and theory. A multilevel understanding of complex abnormalities in behavior (i.e., psychiatric symptoms) directly benefits from these complementary modeling approaches (Fig. 1.24–2).

This chapter describes three broadly defined levels of computational modeling. (1) Biophysically based models, which are constrained by realistic physiologic properties of synapses, neurons, and circuits. These models are well suited for testing synapse-level hypotheses and allowing comparison to physiologic and pharmacologic studies in psychiatry. This type of modeling is also well suited to study neurophysiologic biomarkers of disease states. (2) Connectionist models use more abstract neural elements but incorporate a systems-level neural architecture. These models can be applied to more complex behaviors and are also well suited to interface with task-based neuroimaging and behavior—namely cognitive neuroscience approaches. (3) Mathematical models of behavior formalize the algorithms underlying cognitive computations, which can, in turn, formalize behavioral symptoms and cognitive deficits. These models are well suited to quantitatively fit behavior and symptoms. Collectively, this chapter provides a conceptual overview of the current state of the art in computational psychiatry, spanning from local neuronal circuits to complex behavior such as reinforcement learning (RL). Finally, ongoing challenges and future directions in computational psychiatry are discussed.

BIOPHYSICALLY BASED CIRCUIT MODELS

Telegram: @medical_k

www.konkur.in

Biophysically based circuit modeling refers to a computational framework for modeling neural systems that are grounded in neurobiologic mechanisms. These models can simulate neural circuit activity and computation at the levels of neurons and synapses, constrained by detailed physiologic characterization of neuronal and synaptic dynamics. These models can be further constrained with systems-level experimental measurements of circuit architectures, neural activity, and behavior in tasks. In these models, dynamic activity is typically simulated through systems of differential equations governing the biophysical properties of neurons, synapses, and ion channels. Patterns of activity across neurons are shaped by connectivity within the circuit along with external inputs, which are also grounded in basic anatomy principles. This allows such models to be tested with empirical measures of neural activity. In certain models, behavioral responses can be read out from the patterns of activity, allowing comparison with behavioral data from various task paradigms.

FIGURE 1.24–2. Multilevel analysis of hypothesized disruption informed by computational psychiatry. While current noninvasive neuroimaging methods offer major insights into neural system dysfunction in neuropsychiatric conditions, they cannot reveal synaptic or neuronal-level mechanisms. This leaves important explanatory gaps between neuroimaging systems-level observations and cellular-level hypotheses, such as those proposing cellular alterations on specific receptor subtypes. Computational psychiatry aims to help close these gaps by generating testable and translatable hypotheses across distinct levels of inquiry.

Telegram: @medical_k

www.konkur.in

In computational psychiatry, the biophysical basis of circuit models provides opportunities to probe how synapse-level disruptions produce aberrant neural activity and deficits in cognition and behavior. For instance, one can perturb specific synaptic parameters in the model that are physiologically interpretable and implicated in hypothesized disease mechanisms. This allows the direct implementation of hypothesized perturbations related to disease mechanisms and pharmacologic manipulations. One can then characterize the impact of these perturbations on emergent neural activity and behavior. Therefore, the model results can be related to human neuroimaging and psychophysics in healthy and clinical populations, as well as in animal models of disease states. Biophysically based circuit models have the specific potential to inform our understanding and design of pharmacologic therapies because they incorporate details of synaptic and neuronal properties that are altered by psychiatric medications.

Despite these inherent advantages, due to the level of detail in biophysically based modeling, it remains a challenge to relate circuit models to specific complex cognitive functions. For some core cognitive computations, we have knowledge of the neural circuit basis underlying these processes, which typically involve contributions from preclinical animal studies. For these cases, detailed circuit models can be developed rigorously to provide the link from synaptic disruptions to behavior (e.g., cognitive deficits discussed below). However, due to the large number of physiologic parameters, these models are more difficult to fit quantitatively to behavioral performance. In other cases, psychiatric symptoms relate to complex functions for which we lack understanding of the underlying neural circuit processes. At present, these circuit models are limited and cannot be applied to complex behavioral tasks, for which we lack understanding of neural circuit correlates.

Biophysically based circuit models can also provide insight into the mechanisms underlying neurophysiologic biomarkers of disease states (see section below). These biomarkers can include electrophysiologic measurements of aberrant neural oscillatory dynamics, and neuroimaging characterization of large-scale dysconnectivity in resting-state activity. Put differently, some neural measures are directly translatable from cells, to neural systems and from animals to humans (e.g., electrophysiologic signatures measured via single electrodes, electrode arrays or via electroencephalography in humans). In such cases, biophysically based

Telegram: @medical_k

www.konkur.in

models can provide testable predictions that can be readily translated from animal to human experiments.

Linking Synapses to Cognition: Working Memory

An important application of biophysically based neural circuit models to cognitive processing has been in the topic of working memory. Working memory refers to the ability to encode and transiently maintain or manipulate information internally, in the absence of sensory stimulation (e.g., remembering a phone number for a few seconds). This neural computation is fundamental for normal expression of behavior and relies on the delicate balance of local microcircuit neurons. Impairment in working memory is a prominent cognitive deficit in a number of psychiatric and neurologic disorders, including schizophrenia and attention deficit hyperactivity disorder.

Working memory function is also a promising candidate in clinical neuroscience as an endophenotype, a quantitatively measurable core trait that is intermediate between genetic risk factors and a psychiatric disorder. Such transdiagnostic endophenotypes may be more tractable for research into mechanistic underpinnings of symptom dimensions. In that sense, working memory is a useful test bed for applying biophysically based modeling to cognitive function, because there are experimental paradigms that provide multilevel data that can constrain and test models.

Neural Circuit Basis of Working Memory. Neuroscientific studies in animals and humans have revealed important neural circuits and systems involved in working memory. Working memory engages a distributed network of cortical and subcortical areas, with prefrontal cortex as a key node in this network. Single-neuron recording experiments in monkeys have found that a neural correlate of working memory in the prefrontal cortex is stimulus-selective persistent activity, in which neurons show elevated firing rates during the mnemonic delay. For instance, in one well-studied experimental paradigm, the oculomotor delayed response task, the subject must maintain in working memory the spatial location of a visual cue across a delay period to guide a saccadic eye movement toward that location. During the mnemonic delay, a subset of prefrontal neurons exhibits tuned persistent activity patterns, with single neurons firing at elevated rates for a preferred spatial location. This paradigm has been successfully extended to human studies and extensively tested via

Telegram: @medical_k

www.konkur.in

functional neuroimaging, confirming the neural correlates of working memory in humans. In that sense, this complex cognitive behavior is an ideal example where the synaptic, neuronal, system-level, and behavioral mechanisms are well linked in both animal and human studies. We focus here on biophysically based models of working memory that can offer specific insights into the circuit mechanisms causing disruptions in this complex behavior.

Attractor Network Models. A class of circuit models called *attractor networks* provides a leading framework for understanding the neural circuit basis of persistent activity supporting working memory. The term *attractor* comes from the mathematical formalism of dynamical systems: an attractor state is an activity pattern that is stable in time so that after a small perturbation to the state of the system, the system converges back to the attractor state. In attractor network models, these dynamics are typically formalized by a set of differential equations that capture the neuronal dynamics over time. An attractor network model of working memory typically possesses multiple attractor states: a low-activity baseline state and multiple stimulus-selective memory states in which a subset of neurons are persistently active. Because the memory state is a stable attractor state, it is self-reinforcing and resistant to noise or perturbation, allowing the memory to be maintained over time. This critical property of such models has been shown to rely on the slow currents mediated via the N-methyl-D-aspartate receptors (NMDARs) on excitatory pyramidal cells. It is important to highlight here that it is precisely this level of detail in biophysically based models (i.e., NMDAR conductance) that allows for perturbing and testing of specific synaptic contributions to the neural circuit or, ultimately, behavior (i.e., working memory performance).

In a typical attractor network, subpopulations of neurons are selective to different stimuli. Neurons of similar selectivity show a Hebbian pattern of strong recurrent excitatory connections between them. When the strength of recurrent excitatory connections is strong enough, they can support a persistent-activity memory state. Strong, structured recurrent excitation sustains the persistent activity. Inhibitory GABAergic interneurons mediate strong feedback inhibition that serves two roles. First, it stabilizes the low-activity baseline state. Second, during persistent activity, they provide lateral inhibition that enforces selectivity of the working memory representation, preventing the spread of excitation to the entire population

Telegram: @medical_k

www.konkur.in

of neurons in the network. The stability of attractor dynamics, which depends on excitation and inhibition, provides the network with a natural resistance against noise and distractors that intervene during the delay (i.e., a stable attractor state). This robustness of working memory against distraction is a key cognitive property that supports cognitive processing.

Detailed biophysically based models have revealed important constraints on circuit function and made specific predictions that are experimentally testable. Strongly recurrent networks are prone to oscillations, which can destabilize persistent activity patterns and destroy working memory function. As noted, a decade of computational modeling work has predicted that persistent activity can be stabilized if recurrent excitation is mediated primarily by slow NMDAR rather than by fast alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors to provide temporal stability of the delay activity. A number of model predictions have been tested through studies that record the activity of single neurons while focally applying pharmacologic agents localized to the cortical tissue surrounding that neuron. In line with model predictions, it was experimentally established that locally blocking NMDA receptors can abolish delay-period persistent activity and that locally blocking gamma aminobutyric acid receptors leads to decreased stimulus selectivity during the delay through elevated firing. These experimental tests support the critical roles of balanced excitation and inhibition in the prefrontal cortex in supporting working memory function, a neural property that is hypothesized to be affected by severe psychiatric conditions (e.g., schizophrenia).

Dysfunction in Attractor Models. A number of computational modeling studies have analyzed how attractor network function is impacted by alterations of synaptic and neuronal properties. Optimal cortical function depends on the proper balance of excitation and inhibition (E/I balance). Disruption of E/I balance in the cortex is implicated in the neuropathology of a number of psychiatric disorders, including schizophrenia, autism, and attention deficit hyperactivity disorder. As described above, attractor models require strong recurrent interactions between pyramidal neurons and interneurons and are, therefore, sensitive to perturbations of E/I balance. Because these models also implement the core cognitive process of working memory, which is known to be disrupted in psychiatric disorders, attractor models provide a useful test bed to link

Telegram: @medical_k

www.konkur.in

disrupted E/I balance to cognitive deficits and generate critical experimental predictions across levels of analysis (see Fig. 1.24–2).

These models have been most often applied to circuit disruptions implicated in schizophrenia, for which a number of cortical alterations are proposed. Although neuronal microcircuit alterations in schizophrenia are complex, many studies have converged on interneuron dysfunction as a key component of its pathophysiology. Impaired interneuron function can result in weakened recruitment of feedback inhibition, causing disinhibition of pyramidal neurons and an elevated E/I balance in the circuit. Computational models have explored the neural and cognitive effects of disinhibition in working memory circuits. A mild disinhibition can induce a broadening of working memory representations, which can be understood from the role of inhibition in maintaining the selectivity of persistent activity patterns. A strong disinhibition can destabilize the baseline state, causing working memory patterns to spontaneously appear (e.g., false memory representations). Importantly, these distinct regimes make dissociable predictions for performance in working memory tasks, which allows testing of these hypotheses with behavior. In addition to inhibitory deficits, there is also strong evidence that recurrent excitation is compromised in the prefrontal cortex in schizophrenia. In the attractor models, reductions in recurrent excitation can abolish persistent activity, preventing the circuit from implementing working memory. This regime again makes specific testable predictions for behavior and patterns of neural activity in the context of working memory tasks.

Attractor models have also been applied to study the effects of neuromodulation on working memory. Neuromodulators are known to alter the effective conductances of a number of synaptic receptor and neuronal channels. Dopamine (DA) has diverse effects on prefrontal cortical circuits, modulating multiple cellular and synaptic sites on both pyramidal cells and interneurons. DA also modulates working memory function, and DA signaling is found to be dysregulated in a number of psychiatric disorders. Numerous lines of evidence support the hypothesis that in schizophrenia, there is impairment of DA signaling, via the D1 receptor, in the prefrontal cortex. One circuit modeling study found that D1 stimulation increases the stability of both baseline and memory states in the network, which would be functionally beneficial during working memory maintenance. This, in turn, predicts that a hypodopaminergic state in the prefrontal cortex impairs working memory by weakening persistent activity

Telegram: @medical_k

www.konkur.in

and thereby rendering it vulnerable to disruption by noise or distraction. In contrast, an aberrantly hyperdopaminergic state could cause attractor states to be too strong, rendering the network inflexible to signals that should normally induce transitions between internal states.

In turn, biophysically based models can also be scaled to the level of neural systems. Extending biophysically based models in this way can generate experimental predictions for neuroimaging experiments that can be tested via causal pharmacologic manipulations in humans or during cognitive tasks in psychiatric populations. More specifically, one of the most established findings coming out of human neuroimaging experiments implicates an “anticorrelated” neural architecture. There are brain regions specifically involved in orienting to an externally demanding cognitive task (i.e., task-positive areas) or areas that are more active when engaged in internal mental states but suppressed during cognitive demand (i.e., task-negative areas or sometimes referred to as the default mode network, DMN). Studies have found that during demanding cognitive tasks, patients with schizophrenia typically cannot suppress task-negative areas and concomitantly cannot activate task-positive regions—a process also shown to occur following NMDAR antagonist administration in healthy individuals during working memory. Biophysically based microcircuit computational models have been expanded to capture the putative reciprocal antagonism between task-positive and task-negative neural systems in a biologically plausible fashion by incorporating mutual synaptic inhibition. In this way, such models can generate system-level predictions for task-based neuroimaging experiments in humans while still capturing the relevant synaptic detail. Nevertheless, as noted previously, these models are still limited in the repertoire of complex behaviors they are able to capture due to the inherent constraint placed by biologic realism in such models. Therefore, this branch of computational psychiatry is not yet positioned to address the range of complex cognitive and affective computations that can be represented in humans. This is, at present, much better accomplished by another type of modeling—namely connections models—which we turn to next.

COGNITIVE PSYCHIATRIC NEUROSCIENCE AND CONNECTIONIST MODELS

Telegram: @medical_k

www.konkur.in

The sections above introduce the interface between biophysically based computational modeling and clinical neuroscience. As noted, this branch of modeling is distinguished by building on the physical properties of real neurons and synapses, producing realistic cellular-level dynamics. This level of detail is ultimately vital to generate mechanistic predictions at the level of treatments or to elucidate synaptic mechanisms governing complex behaviors in psychiatric patients. Nevertheless, a parallel line of computational psychiatry research has emerged in lockstep with the cognitive neuroscience revolution, building on the rapid and productive advances in noninvasive neuroimaging technology. Specifically, this branch of modeling can be broadly referred to as *connectionist models* that are designed to capture the function of large-scale neural networks and generate behavioral predictions in conjunction with human cognitive neuroscience experiments.

Emergence of Cognitive Neuroscience in Psychiatry

Before detailing the contributions that connectionist modeling has made for psychiatry, it is important to set the stage for the type of research questions these models are best suited for—namely cognitive neuropsychiatry. The past two decades have witnessed an explosive growth of knowledge regarding the neural correlates of various cognitive and affective processes in healthy individuals. This burgeoning field of cognitive neuroscience has generated an increasingly robust platform for interpreting clinical neuropsychiatric phenomena. This is primarily accomplished by garnering an increased understanding of neural systems known to be involved in various cognitive operations in healthy individuals. This understanding, in turn, constrains our search space for what aspects of brain circuitry may be abnormal in clinical populations exhibiting deficits in these same cognitive operations. Therefore, using a cognitive neuroscience framework with a specific application toward understanding computational mechanisms offers a promising tool for elucidating and ultimately treating psychiatric symptoms by delineating abnormalities in neural circuits whose functions are increasingly understood in healthy populations.

This cognitive neuroscience framework has emerged in parallel with the development of computational modeling in psychiatry. Historically, the types of computational psychiatry models that first appeared were most directly aligned with the neural systems and behavioral levels of analyses.

Telegram: @medical_k

www.konkur.in

Therefore, there exists a productive and ongoing interplay between cognitive neuroscience in psychiatry and connectionist modeling approaches.

Connectionist and Parallel Distributed Processing Models

There is a long history of using models to understand central nervous system function. Such a review is beyond the scope of this chapter, and we refer the reader to one of the references at the end of the chapter. However, briefly, it is worth considering the long-standing analogy of the brain as a "computer." The growing sophistication of algorithms and principles in basic computer science has cross-fertilized the emerging application of such approaches in neuroscience. One particular framework that has emerged out of this effort is the modeling of neural networks. More formally, models of this class are called parallel distributed processing (PDP) or connectionist models. This broad class of models has emerged in an effort to elucidate the neural correlates of complex psychological functions, including cognitive control, language, and fear processing.

Importantly, these models are distinct in their flavor, architecture, and algorithmic implementation from the biophysically based (or behavioral) models reviewed in this chapter. The key distinction is represented in their ability to incorporate some level of abstraction beyond strict biologic realism. A major objective of PDP models is to develop a deeper understanding of the mechanisms driving cognition from a psychological perspective, but using principles thought to capture aspects of computations as they might be carried out in the brain. Put differently, such models do not necessarily build in explicit neurobiologic constraints or assumptions.

A typical PDP model architecture is conceptualized as a series of "units" that are interconnected in some fashion and that represent some computational process. Each unit implements a simple transfer function that summates its inputs from other model units and transforms that into an output activity level. The state of the network is described by the graded activity patterns over populations of these simple units, and information processing occurs through the transformation of activity patterns from one set, or layer, of units to another. To achieve the desired information processing, the connection strengths between units are modified through a learning algorithm, such as *back propagation*. This

Telegram: @medical_k

www.konkur.in

training of connection weights is meant to capture some elements of the type of Hebbian learning known to govern changes in connection strength between neurons.

In the back-propagation learning algorithm, the network is presented with an input pattern, and the output layer is allowed to generate its response. At each layer of the network, an error signal is computed as the difference between the response generated by the network and the desired target response. These error signals are propagated back through the network toward the input layer, used to modify the connection weights between units. The implementation of back-propagation learning provides an example of how connectionist models, while capturing complex neural phenomena, may not map onto specific neurobiologic mechanisms (in contrast to biophysically based models described above). Nevertheless, this approach captures the idea that learning occurs through an incremental minimization of error by small changes in the connections between units (a phenomenon referred to as *gradient descent*).

In typical PDP models, the units are abstracted, without a direct correspondence to individual neurons or explicit neurobiologic assumptions. Units instead represent processing accomplished by neuronal assemblies and capture the general principles of neural information processing. However, some modeling studies have incorporated neuroanatomical constraints and specific neurotransmitter modifications, at varying levels of resolution.

Connectionist models help to build bridges between understanding of low-level properties of neural systems, and their participation in higher-level (systems) behavior. They are able to capture a wide range of complex behaviors and neural systems interactions, which cannot at present be modeled as effectively by biophysically based models. Therefore, PDP models continue to be successfully applied in computational psychiatry to address questions and scenarios in which the field lacks firm empirical evidence to inform strong biologic assumptions.

Applications of Connectionist Models in Psychiatry

This section presents three example areas of research where PDP models have provided novel insights and established a vital interplay between basic neuroscience and psychiatric questions. First, the focus is placed on how PDP models have been used to understand the formations of hallucinations and delusions in schizophrenia. In turn, we review the

Telegram: @medical_k

www.konkur.in

role of PDP models in understanding cognitive control deficits, which cut across many psychiatric conditions. Third, we discuss the use of connectionist models in the context of fear conditioning, specifically from a systems neuroscience perspective, with possible implications for understanding posttraumatic stress disorder (PTSD).

Connectionist Modeling of Hallucinations in Schizophrenia. Some of the seminal models using the PDP framework were developed to examine the impact of abnormal synaptic pruning in cortex and its possible consequences on symptoms observed in schizophrenia, specifically formation of hallucinations, which are abnormal internal sensory experiences in the absence of external sensory input. This mechanism is based on the neurobiologic conceptualization of schizophrenia as a neurodevelopmental illness associated with abnormalities of synaptic pruning over the course of development, which in turn impacts the functioning of large-scale neural systems.

PDP models implemented this mechanism by eliminating the connections between units thought to represent synaptic connections. This line of research showed that if a sufficient number of connections were removed, then the model would repeatedly return to an abnormal state referred to as “parasitic foci.” That is, researchers observed patterns of activity across units in the model that did not correspond to any learned memory, but to the “state” to which the model kept returning—perhaps capturing an abnormal internally generated state that could occur during hallucinations. Researchers in this area hypothesized that these parasitic foci may behaviorally map onto delusions and hallucinations. A concrete example of how PDP models may help explain hallucinations came from applications to understanding language processing. Using the PDP-style architecture, the research found that language could be represented within an “Elman” network—namely, a sequential recurrent network that consists of an input and an output layer connected by a “hidden layer” that computed internal processing. This architecture included an additional layer connected to the hidden layer that could temporarily store information, thought to support working memory functions (temporary storage of information) during speech perception. In this architecture, it was shown that the elimination of connections between units (i.e., “synapses”) in the working memory subnetwork of the model initially improved speech perception. However, as the severity of the elimination

Telegram: @medical_k

www.konkur.in

increased, the model started to fail to detect words correctly and started to generate “hallucinations.” In this PDP model, this was computationally captured as patterns of activity across the output layer that corresponded to words even when there was no structured input into the model. In contrast to synapse elimination, a small amount of “cell” removal (e.g., elimination of units) also initially improved speech perception, but greater cell loss did not generate hallucinations. Critically, these early PDP models provided an important “proof of concept” for how various neurobiologic changes might affect connectionist networks.

In turn, such PDP models can also incorporate some aspects of broad neuromodulation. For instance, researchers that extended the PDP models of hallucinations in schizophrenia also captured the potential influence of increased DA in the model. This is concretely accomplished as a gain function within the model by abstracting a neurobiologically plausible broad ”neuromodulatory” influence on the entire PDP network. In schizophrenia, the role of DA is hypothesized to play a key role in cortical “tuning.” Based on this hypothesis, PDP models incorporated increased DA by changing the bias onto the units in the working memory module, effectively requiring them to accumulate greater information to maintain information. This manipulation only relates to one aspect of the influence of DA on neuronal information processing and by itself, it did not fully capture clinical observations. However, a combination of increased DA and synaptic pruning more successfully captured the performance of those patients who experienced hallucinations.

These types of models incorporate aspects of brain-style computational principles, but did not make strong commitments to key aspects of neurobiology during model development. Nonetheless, they provided critical steps and a mathematical formalism to understand how neurobiologic or neural network deficits might contribute to the formation of core symptoms of psychosis, such as hallucinations. Although the models themselves did not produce behaviors with the same format and content as shown by human patients, the “in principle” examples provided conceptual leverage to bridge the gap between biology and behavior and even extend to treatment recommendations (e.g., work in the area of transcranial magnetic stimulation that explicitly leveraged insights from these models). Therefore, despite not explicitly committing to biologic realism, PDP models can provide useful predictions for treatment development.

Telegram: @medical_k

www.konkur.in

Connectionist Modeling of Cognitive Control Deficits. A parallel line of research leveraged PDP models to understand cognitive control deficits that emerge across psychiatric conditions but are particularly prominent in schizophrenia. These models developed a more neurobiologically plausible architecture by postulating that “cognitive control” in the central nervous system arises from interactions between the DA neurotransmitter system and the PFC. These models suggested that goal-related information, or context information, was maintained in PFC and used to bias stimulus–response mappings represented in the posterior cortex, serving as a source of top-down support for controlling behavior. In these models, the “context” module was associated with the functions of the dorsolateral prefrontal cortex (DLPFC). Active maintenance in the absence of external inputs was assumed to occur via recurrent excitation, as suggested by neurobiologic data that was reviewed in the sections above. This branch of models assumed that feedback projections from the context/DLPFC module biased processing in posterior systems via direct excitation but that competition between representations within a processing stream occurred via lateral inhibition. Further, the effects of DA were assumed to be modulatory rather than purely inhibitory, such that changes in DA activity could either increase or decrease activity depending on the nature of inputs that DA was modulating. Put differently, increases in DA were assumed to increase the signal-to-noise ratio of a unit’s activation value in relation to its input.

Concretely, these models have been successfully used to generate predictions about a specific pattern of complex behavioral errors that are observed during cognitive paradigms evaluating context processing deficits in schizophrenia. Specifically, the models were used to test the hypothesis that reductions in DA input into lateral PFC lead to impairments in the ability to represent and maintain context information in lateral PFC, and that this impairment in the representation of context leads to deficits in a range of cognitive tasks among individuals with schizophrenia. Behaviorally, the model predicted that individuals with cognitive deficits should exhibit a specific pattern of behavioral errors when context information needed to be maintained. This pattern of errors was largely confirmed across a series of studies in schizophrenia patients. In turn, this type of PDP model was also successfully leveraged to generate predictions about patterns of lateral PFC signals found during task-based cognitive activation neuroimaging paradigms. The specific

Telegram: @medical_k

www.konkur.in

prediction from these models suggested that individuals with schizophrenia should show reduced lateral PFC activity in conditions with a strong demand for context maintenance. Again, a number of empirical reports confirmed this prediction, showing that patients with schizophrenia exhibited deficits in recruitment of lateral PFC specifically in line with model predictions. Subsequent work in this area suggested that deficits in DA signaling may contribute to abnormal context maintenance and information gating in lateral PFC, which in part contributes to cognitive processing deficits seen in this patient population.

Collectively, this line of research illustrates how PDP models can be used to make both behavioral and neural predictions of a given behavioral symptom (i.e., cognitive deficits) which can in turn be explicitly tested via cognitive neuroscience paradigms in patients. This line of research has also been successfully leveraged to understand the neural underpinnings of specific affective deficits in psychiatric populations—namely fear conditioning.

Connectionist Modeling of Fear Conditioning. It is well established that severe deficits in emotion processing cut across different diagnostic categories, including schizophrenia, bipolar illness, and anxiety disorders to name a few. Here, we specifically focus on computational modeling studies in a specific area of affect processing—namely fear expression. Abnormal fear expression provides a powerful translational target that can be understood computationally across mammalian species given the well-preserved neurobiologic mechanisms underlying basic fear expression. At the basic preclinical level, the role of the amygdala in fear generation is perhaps one of the best-studied neural computational mechanisms, having been translated across levels of analysis, including human studies. Clinically, abnormal fear expression can be found across a host of anxiety disorders, including generalized anxiety, social anxiety, specific phobias, and PTSD. Therefore, computationally formalizing abnormal fear circuits represents a particularly broad and important challenge for computational psychiatry.

Computational studies in this area have used the amygdala as a central starting point. The amygdala is a small structure comprised of several nuclei located anterior to the hippocampal formation, and is critical for the normal expression of fear and learning of fear-related associations (i.e., classical fear conditioning). In that sense, PDP models in this area build

Telegram: @medical_k

www.konkur.in

on both well-understood biophysical principles of this neural structure as well as its well-established large-scale anatomical connectivity. This is a good example of how PDP-style models can at times incorporate more explicit commitments to biologically plausible circuits and instantiate biophysical realism while maintaining a system-level architecture with useful behavioral predictions (e.g., fear learning). Specifically, such anatomically constrained PDP models of fear circuitry have been used to generate predictions for how multiple interacting neural structures could work jointly to accomplish a pairing between the unconditioned stimulus (US, nociceptive stimulus) and the conditioned stimulus (CS, auditory input) (see Fig. 1.24–3). Using this model architecture, it was found that fear learning can be established via the joint pattern of activation across specific unit pairs that map the CS and UC. Furthermore, the model provided a powerful way to generate predictions for how focal lesions may affect fear learning—a specific advantage of PDP models that are developed based and constrained via neuroanatomically plausible principles. This line of work in particular can help generate useful predictions for abnormalities in fear expressions that may result from neuropathology to one or more key components of the fear circuit.

Collectively, this work demonstrates how connectionist models can be used creatively and flexibly to generate behavioral and neuroimaging predictions across a wide range of neural systems and behaviors. As noted, this flexible repertoire of PDP-style models is possible because their architecture is not always explicitly developed or constrained based on neurophysiology or neuroanatomy. That said, these models still make a number of strong commitments to represent neural computations. For this reason, PDP models are not always capable of formalizing even more complex behaviors that may occur in psychiatric patients (e.g., formation of complex and abnormal belief patterns such as delusions, or deficits in motivation and reward learning). In such cases where neither PDP models nor biophysically based models can provide the final links to behavior, we turn to mathematical models of behavior that are explicitly developed to formalize the patterns of complex psychiatric symptoms.

Telegram: @medical_k

www.konkur.in

FIGURE 1.24–3. Illustrative example of a connectionist PDP-style model in the context of fear conditioning. In the case of fear learning, PDP models have successfully merged both connectionist-level architecture across distinct "modules" that represent specific neuroanatomical structures while remaining committed to a certain level of biophysical realism (i.e., by modeling the amygdala based on animal physiology experiments). Here, we show an adapted figure from X. In this exemplar case, each larger module is comprised of individual nonlinear units (black units, maximum activation; white units, zero activation; gray units, intermediate level of activation), as is typically done in PDP models. *Large arrows* denote connections across modules, which are modeled as feedforward and excitatory, corresponding to pathways in the actual rat brain (although they are simplified here). Connection strengths across the modules are modulated as a function of learning by incorporating an extended Hebbian rule. (Reprinted from Armony JL, Servan-Schreiber D, Romanski LM, Cohen JD, LeDoux JE. Stimulus generalization of fear responses: effects of auditory cortex lesions in a computational model and in rats. *Cereb Cortex*. 1997;7(2):157–165. doi:10.1093/cercor/7.2.157)

MATHEMATICAL MODELS OF BEHAVIOR

Telegram: @medical_k

www.konkur.in

The computational psychiatry approaches discussed above, biophysically based circuit modeling and connectionist modeling, aim to develop models with elemental components that instantiate how neural systems transform their inputs into outputs. These approaches are often limited in the range of cognitive behaviors to which they can be applied, due to our limited knowledge of the relevant neurophysiologic mechanisms. An alternative approach to modeling cognition is to develop mathematical models that provide an account of the psychological computations underlying a given cognitive function. These models are often grounded in so-called normative accounts that aim to define the algorithms that optimize performance at a task and to characterize constraints that limit such task performance.

Although developed to explain behavior, these models can potentially make important links to neural circuits. For example, experiments can reveal that activity in specific brain areas represents the internal variables of the model, providing support for this computational account and providing insight into the division of labor among brain systems. In turn, such neuroscientific findings can inform the algorithms and modules that compose the computational architecture of the model.

Impairments in decision making are common cognitive symptoms across psychiatric and neurologic disorders. Mathematical models of behavior can formalize these symptoms in rigorous and quantitative terms, potentially isolating specific components of decision-making computations that are altered in a given psychiatric condition. These models typically have fewer parameters than the neural systems models described above, which enables them to be more easily fit to behavioral data or to explore the full range of a given parameter. In that sense, behavioral models can provide a deeper intuition of the full range of a possible behavioral repertoire and help rigorously define the behavioral states that may be abnormal or maladaptive.

Reinforcement Learning

One form of dysfunction in decision making is a disruption in the process through which one learns the values of available actions. Mathematical modeling and experiments have made great progress in studying this process in the context of RL. In RL, an agent learns the values of stimuli and actions through successive trials of feedback (reward and

Telegram: @medical_k

www.konkur.in

punishment) and selects actions based on these values to maximize one's overall outcomes.

A class of *temporal-difference RL* (TDRL) models has been widely applied to explain the process of learning the mapping from stimuli and states to actions. In these models, actions are selected on the basis of the total expected value for that action. The value of each action is learned through sequential updating based on a *reward prediction error* (RPE). In its simplest form, the RPE is the difference between the reward received after that action and the expected value of the action. Thus, if the reward is greater than expected, a positive RPE signals that the value should be increased. If the reward is equal to that expected, the RPE should be zero. The formulation of the RPE can be extended to incorporate additional factors, such as temporal discounting of future outcomes. TDRL models are well supported by behavioral studies, as well as neuroscientific studies that have found brain areas that signal action values and RPEs. In particular, DA neurons in the subcortical ventral tegmental area (VTA) quantitatively reflect internally computed RPEs through bursts of action potentials.

Many key aspects of addiction can be modeled as dysfunction in a TDRL model. It is thought that drugs of abuse access the natural RL systems in the brain, leading an agent to over-select drug-seeking actions. Specifically, drugs of abuse can intervene in the pathways that activate the DA neurons that are involved in signaling RPEs. For instance, cocaine can induce phasic firing of DA neurons in the VTA. In TDRL, this can interfere with RPE signaling, strongly increasing the learned values for drug-seeking actions so that they come to dominate behavior. Modeling studies have found that implementing this drug-induced component to RPE signaling in a TDRL model can parsimoniously explain a number of important aspects of addiction-related behavior.

The TDRL model described above, which learns the values of actions for a given state, applies to habit-related learning. More elaborate RL models have also been developed to explore the roles of multiple learning systems in the brain. In addition to this habit-related form of learning (also called model-free RL), there is another type called model-based RL. Model-based RL calculates the values of actions from the values of future states, using an internal representation of the causal structure of the environment (i.e., knowing which states are reached through the actions). Model-based RL is more computationally demanding for the agent (but

Telegram: @medical_k

www.konkur.in

also more flexible) than model-free RL and is associated with cognitive processing in the PFC.

By comparing behavior in RL tasks to model performance, researchers can probe the relative reliance on model-free versus model-based RL. Cognitive deficits may impair the function of model-based RL, leading to an increased reliance on model-free RL. Researchers have designed behavioral paradigms to measure the relative contributions of model-free versus model-based RL in decision-making. Studies have found, both in addiction and in obsessive-compulsive disorders, that there is a favoring of the habitual model-free RL compared to healthy controls. These findings support the view that these disorders exhibit habitual, repetitive behaviors.

Decision Making via Sequential Sampling

Another topic of mathematical modeling of decision making is the process of categorically selecting among available options. This has been most extensively studied in the context of two-alternative forced-choice (2AFC) tasks. In 2AFC tasks, the decision-making process can be formulated as the sequential accumulation over time of evidence in favor of one option or the other. The drift diffusion model (DDM) is a phenomenologic but mechanistic model that is widely applied to 2AFC tasks and is likely the optimal solution in certain contexts.

In the DDM, a decision variable evolves in time, accumulating noisy evidence. Because evidence sampling is inherently noisy, the decision variable undergoes a biased random walk, with a mean drift rate in one direction determined by the net evidence in favor of one option over the other. Computationally, the two choices correspond to a lower and an upper bound; when the decision variable crosses a bound, the corresponding choice is made. Because the noise is different on each decision-making trial, the choice and reaction time vary across trials. One strength of the DDM is that it generates not just a proportion of choices but a full distribution of reaction times that can be used to fit empirical choice data. At the neural level, the DDM has received support from electrophysiologic recordings from a number of cortical areas that show slow ramping of neural activity during decision making.

The DDM can also explain aspects of impaired decision making by describing behavior in terms of the values of DDM parameters. This has the potential to more precisely isolate and quantify differences in decision-

Telegram: @medical_k

www.konkur.in

making behavior. Consider, for instance, a clinical group that shows a propensity toward selecting one option over the other. In the DDM framework, this could be due to one decision boundary being closer than the other. Alternatively, the mean drift rate may include a component of the drift rate in favor of that option. Critically, these two potential mechanisms have dissociable effects on the patterns of errors and reaction times. Therefore, fitting subjects' behavioral data can isolate which alteration better describes behavior in a group of subjects.

Bayesian Approaches to Inference

Another fruitful area of research is the mathematical formalism of belief formation. This is most clinically relevant in cases where strong but abnormal beliefs can result in internal states that are clinically characterized as delusions. Here, the biggest impact has been achieved by a class of mathematical models of *Bayesian inference*. Bayesian inference describes how the estimated probability of event *A* should be updated by observation of event *B*, according to Bayes' theorem:

$$P(A \mid B) = \frac{P(B \mid A) \times P(A)}{P(B)}$$

where $P(A \mid B)$ is the probability of *A* given that *B* is true, $P(A \mid B)$ is the probability of *B* given that *A* is true, $P(A)$ is the probability of *A*, and $P(B)$ is the probability of *B*. Therefore, the *posterior* $P(A \mid B)$ is proportional to the *likelihood* $P(B \mid A)$ times the *prior* $P(A)$. The prior probability, the expectation for event *A* to occur, plays a key role in the inference of the posterior estimate from the observation of event *B.*

In the context of delusion formation, Bayesian models hypothesize that psychosis is a neural and psychological state that is marked by abnormal priors about the world. Abnormal priors may result from a state of aberrant salience, that is, events in the environment are hypothesized to be more salient than usual, perhaps due to elevated DA signaling in the striatum. Bayesian models can, in turn, be applied to a range of behavioral experimental contexts where expectations are formed and then confirmed or violated, with the reported posterior estimates providing a window into the abnormal priors. Studies in this area support the view that abnormal priors (or posterior probability) lead to the formation of abnormal inferences, which could lead to a stable internal belief that is not

Telegram: @medical_k

www.konkur.in

supported by current evidence (i.e., a delusion). Put simply, Bayesian models of behavior, when applied to psychiatry, have postulated that delusions may be an extreme state of abnormal inference. This framework has been subsequently linked to abnormal prediction error coding and extended to a neuroimaging context, providing a putative neural marker of abnormal belief formation.

MODELING NEUROPHYSIOLOGIC BIOMARKERS

A major goal of clinical neuroscience is the discovery of robust neurophysiologic biomarkers for psychiatric disorders. Understanding the mechanistic basis underlying these biomarkers could aid in the development of treatments, by mapping specific circuit perturbations to neurophysiologic measurements. Biophysically based circuit modeling is well suited for linking these levels, as the models link synapse-level parameters to network-level dynamics. Models can make predictions for how physiologic biomarkers are affected by putative synaptic disruptions. In turn, model predictions provide the basis for inference in the other direction, to test hypotheses regarding the site of a synaptic perturbation with measured changes in physiologic biomarkers. Therefore, biophysically based circuit modeling provides a means to interpret specific biomarkers and generate hypotheses that can be tested further with synapse-level and cellular-level measurements. This understanding allows for interpretation of aberrant neural dynamics measured in patients in terms of circuit perturbations, which generates specific and testable hypotheses for experimental studies in animal models and clinical populations. Two topics studied in this way are cortical oscillations and large-scale resting-state brain networks.

Oscillations

Cortical circuits generate a wide range of oscillatory dynamics that arise from strong recurrent network interactions. Abnormal oscillations have been observed in a number of psychiatric and neurologic disorders, typically measured through EEG or MEG. Such oscillatory deficits are observed both in local dynamics, and in long-range coupling between brain areas. In schizophrenia, oscillatory abnormalities in the gamma range (30 to 80 Hz) are of particular interest. Cortical circuit models, comprised of pyramidal cells and interneurons, have been used to explore

Telegram: @medical_k

www.konkur.in

the disruption of gamma oscillations in response to perturbations implicated in psychiatric disorders such as schizophrenia.

Computational and experimental studies support a model in which neocortical gamma oscillations arise from a feedback loop of excitatory pyramidal cells reciprocally connected with perisomatic-targeting, fast-spiking (and parvalbumin-expressing) inhibitory interneurons. In these circuit models, gamma oscillations can arise through a patterned cycle of activation of pyramidal cells and interneurons. Excitatory input causes pyramidal cells to fire. This activity then recruits inhibitory interneurons to fire short delay. This feedback inhibition suppresses firing in the circuit. After this synaptic inhibition decays, the cycle begins again. Models show that such oscillatory behavior arises naturally in systems with strong recurrent excitation and inhibition if the feedback inhibition is slow or delayed with respect to the excitation. As in the case of working memory function described above, gamma oscillations depend on strong recurrent interactions between excitatory and inhibitory cells, and oscillatory dynamics are sensitive to E/I disruptions.

A number of computational studies have developed models of cortical microcircuits generating gamma oscillations to study how gamma-range synchronization is affected by synaptic perturbations implicated in disease states, with a specific focus on schizophrenia. These studies have characterized how the schizophrenia-associated disruptions of parvalbumin-expressing interneurons can impair the generation of gamma oscillations. Modeling studies have also characterized how gamma oscillations may be affected by dopaminergic modulation and antagonism of NMDA receptors on specific cell types. In each of these cases, the models provide testable hypotheses for the physiologic effects of synaptic manipulations.

These models have proven useful in understanding the circuit basis of aberrant cortical dynamics in disease states. However, the roles of aberrant oscillations in cognitive deficits and psychiatric symptoms remain unclear. There is still controversy regarding whether oscillatory synchronization is fundamentally necessary for the computations performed by neocortical circuits during cognition. Theoretical models have shown that oscillatory synchronization can subserve specific computational functions, such as efficient information transmission between neural populations. Further computational studies are needed

Telegram: @medical_k

www.konkur.in

that posit specific roles for oscillations in cognitive processes and make specific predictions for how behavior could be impaired in disease states.

Large-Scale Brain Dynamics

An emerging topic in computational neuroscience is the dynamics of large-scale brain networks. Progress in this area has the potential to provide insight into the growing body of experimental literature characterizing psychiatric disorders with whole-brain functional neuroimaging via fMRI. These data may provide important biomarkers of disease states. One common approach in fMRI is to analyze low-frequency fluctuations present in the blood-oxygenation-level-dependent (BOLD) signal during rest. In particular, resting-state fMRI can provide a pattern of functional connectivity, that is, the variability of the BOLD signal across brain parcels. These patterns of functional connectivity can be related to the underlying structural connectivity between brain areas, which can be measured noninvasively in humans through diffusion tractography,

Recent computational models have been developed to capture how the global pattern of resting-state functional connectivity emerges through long-range interactions among cortical areas. These large-scale network models simulate the dynamics of multiple nodes, each representing a cortical parcel. The nodes interact through an anatomical coupling matrix reflecting long-range connections, typically derived from tractography studies. Ongoing temporal dynamics in the nodes produce patterns of correlated fluctuations in activity across the network. The functional connectivity of the model can then be calculated and compared to the functional connectivity observed in experiments.

In one class of these resting-state models, each node is simulated with reciprocally connected pools of excitatory pyramidal cells and inhibitory interneurons, with diffusion tractography in humans used to define the structural connectivity pattern of excitatory long-range projections between nodes. Each node receives fluctuating background input to drive dynamics. As in the microcircuit models, the biophysical basis of these large-scale models makes them directly applicable to address the dynamical consequences of anatomical and physiologic changes induced by disease processes or pharmacologic manipulation. Changes in the strengths of local and long-range connections may induce differential effects in the patterns of functional connectivity. The models reveal that

Telegram: @medical_k

www.konkur.in

resting-state functional connectivity is sensitive to both the structure of underlying anatomical connectivity and the physiologic parameters that scale local and long-range connections. This can be used to test synapse-level hypotheses for a disease state by their predictions for resting-state alterations observed via fMRI. For instance, the hypotheses of elevated versus reduced E/I balance in local cortical circuits make dissociable predictions for the patterns of variability and covariability in the cortical BOLD signals, which can be tested in patients with schizophrenia.

FUTURE CHALLENGES

Integration Across Levels of Analysis

This chapter describes how computational psychiatry has offered a method to bridge levels of analysis, from local neuronal circuits to large-scale neural systems and, ultimately, psychiatric symptoms. The challenge that still faces this rapidly growing field is how to provide a formal bridge between these levels of inquiry for most psychiatric symptoms. We highlighted example cases where such progress has occurred—namely, in the context of working memory and fear conditioning. In such cases, computational psychiatry has begun to establish a formalism for how to link local circuits to large-scale neuronal dynamics and expression of behavior. However, the current models in this area of computational psychiatry are still simplistic in their repertoire of behavior and are designed to capture a very limited range of experimental contexts.

To accurately capture more complex cognitive and affective behaviors, models must incorporate multiple interacting brain areas possessing various distributed and modular computations. In this area, biophysically based modeling will be informed by connectionist-style models that are more abstract and removed from biophysical detail but that can be readily applied to modeling psychological processes and interactions among distributed neural systems. Similarly, a highly related challenge facing computational psychiatry is to provide a formal extension of biophysically based modeling to large-scale distributed brain networks beyond the microcircuit level, as this level of analysis offers the potential for the development of disease-related biomarkers. For instance, a key extension of such models would be to capture, in a biophysically realistic way, the large-scale thalamocortical functional loops that may play a critical role

Telegram: @medical_k

www.konkur.in

across a range of psychiatric disorders. The next generation of computational psychiatry studies will be vital to formalize these bridges across levels of analysis.

Computational Phenotyping

Psychiatric diagnoses are made using inclusionary and exclusionary criteria based entirely on co-occurring sets of symptoms. The Diagnostic and Statistical Manual of Mental Disorders (DSM) has been iteratively revised to improve diagnostic reliability and provide clear guidance for clinical decision making. However, consequently, a key objective of psychiatric research has been to identify biomarkers of disease under DSM categories, often via case-controlled studies that search for mean differences between groups of asymptomatic controls versus patients meeting diagnostic criteria for a single disorder. The challenge with using such a system is that patients with the same diagnosis may exhibit highly distinct behavioral and neural phenotypes, suggesting that considerable heterogeneity exists within diagnostic categories. It is appreciated by both researchers and clinicians that individuals' psychiatric symptoms present with substantial heterogeneity, which cuts both within and across diagnostic categories. This conceptual problem is captured in the case of existing tension between category-based DSM-style diagnostic rubrics and the dimensional Research Domain Criteria (RDoC) framework. Instead of making an a priori decision regarding which framework may be better for a given psychiatric symptom or syndrome, we posit that perhaps there should be a parallel movement toward "precision psychiatry." Simply put, it may be possible to harness advances in computational psychiatry to generate individual-level inferences regarding the type of underlying computational mechanisms that govern the observed patterns of neuroimaging effects or behavioral symptoms.

The current state of the art in this area of research focuses on group effects. That is, the majority of work that has emerged in computational psychiatry has focused on explaining group-level effects across a given diagnosis. We argue that one highly promising future application of computational psychiatry may be to provide individual-level computational phenotyping based on mechanistic models. Such a level of precision may possibly provide a method to manage the massive clinical heterogeneity that exists both within and across our current clinical rubrics in psychiatry. Ultimately, mapping such clinical heterogeneity onto underlying

Telegram: @medical_k

www.konkur.in

computational mechanisms will be vital to develop better mechanistically informed treatments.

A necessary and important step toward developing more effective and targeted treatments for psychiatric symptoms is a reliable and specific mapping onto underlying neural features. The limitations of categorical frameworks have been reflected in initiatives such as the RDoC, which advocated for studying a dimensional framework for mapping functional domains onto neural circuits. Such efforts have motivated large-scale, multisite, transdiagnostic studies for mapping symptom and neural variation across psychiatric disorders. These larger datasets have made it viable to explore multivariate brain–behavioral relationships across psychiatric spectra, paving the way toward quantitatively grounded individualized treatment and moving beyond traditional clinical scales that may not optimally parse neurobehavioral heterogeneity. For instance, despite many data-driven factor analytic studies of the psychiatric symptom space in the literature, a common approach in psychiatric neuroimaging studies remains “to relate” composite scores (such as total “positive” or “negative” psychosis symptoms) to neural measures. Critically, these analyses do not test the possibility that neural alterations in psychiatric disorders may be better captured by a weighted combination of symptoms, which would not be reflected in summed composite scores.

While such weighted combinations can be tested using multivariate approaches such as canonical correlation analysis (CCA), these studies themselves are prone to overfitting, leading to a failure to replicate results. This is often because of the intrinsically high dimensionality of the neural and behavioral data evaluated against a relatively low number of subjects. Indeed, recent work has demonstrated that in most cases for CCA, the sample size must be at least an order of magnitude greater than the number of neural/behavioral features used to detect a true effect (e.g., assuming a canonical correlation of $r = 0.3$). Even with prior dimensionality reduction of the neurobehavioral feature space (a common practice that typically reduces the number of features from hundreds of thousands down to hundreds), this necessitates a sample size of thousands of subjects. Of note, most current state-of-the-art clinical neuroimaging studies have target enrollment totals of 200 to 600 subjects, although several population-based and prodromal studies have achieved enrollment numbers in the thousands. Thus, while multivariate methods remain a promising and powerful approach to simultaneously computing

Telegram: @medical_k

www.konkur.in

maximal covariation between neural and behavioral features, the reproducibility and reliability of the results must be assessed.

In computational phenotyping, the parameters of a model are fit to best capture the empirical data for a single subject. Computational phenotyping could take advantage of a range of empirical data and modeling approaches. For instance, an RL model could be fit to a subject's decision-making behavioral data. Similarly, a biophysically based network model could be fit for a subject's resting-state neuroimaging data. The promise of this approach is that these model parameters may have diagnostic value, potentially leading to more predictive biomarkers. These model parameters may allow effective classification according to diagnostic criteria and may reveal clinically relevant clusters or dimensions within a diagnostic category or be predictive of a patient's response to treatment. Longitudinal studies will be needed to validate the diagnostic potential of computational phenotyping.

Modeling Treatments

Finally, of utmost relevance to psychiatry, computational modeling has the potential to provide a method for simulating possible effects of treatments (or compensations) that can occur across the described levels of analysis. For instance, some modeling efforts have already begun to generate predictions for how compensations onto NMDAR or GABAR synapses in local circuits can impact cortical disinhibition that adversely affects working memory computations. However, this area of research is at present underdeveloped and has future potential for guiding intuition in cases where complex neural dynamics are involved.

In order for any computational features to be clinically actionable for guiding treatment design, it is necessary to relate the feature(s) to targetable neural mechanisms. BOLD neuroimaging measures do not inherently provide information about the underlying mechanisms nor how these mechanisms may be disrupted to produce psychiatric symptoms. It is, therefore, important to validate neuroimaging measures using mechanistically informed neurobiologic features (genetic, cellular, or circuit-level measures) that can act as "molecular benchmarks." One such example is pharmacologic neuroimaging maps, which contain information about characterized mechanisms of action and can be used as mechanistic references for symptom-neural maps. For example, by quantifying a patient's similarity to one molecular target map versus

Telegram: @medical_k

www.konkur.in

another (e.g., NMDA antagonism via ketamine versus serotonin receptor agonism via serotonin), it is possible to evaluate a single patient's differential similarity to one potential treatment mechanism versus another. Another approach is to use gene expression data for genes implicated in psychiatric pathophysiology, such as transcriptomic maps derived from the Allen Human Brain Atlas. Quantifying the relationships between the transcriptomic patterns of certain genes (e.g., genes encoding neurotransmitter receptor subunits or interneuron markers) and neuroimaging phenotype maps can inform how specific mechanisms and neural systems are implicated in observed brain–behavioral features. These transcriptomic maps may thus provide an independent benchmark for treatment targets that may be associated with a specific receptor.

Here, further development and refinement of biophysically based models have particular advantages. Given the relevant cellular detail, such models can actually generate both biomarker and behavioral predictions of disruptions on specific synaptic sites. Such a level of detail may be out of reach in cases that are not informed by animal models. Nevertheless, this is precisely the point of the cutting-edge interplay between future research in computational psychiatry and clinical neuroscience. We posit that future studies in this area hold the exciting promise of rationally guiding treatment development in psychiatry, grounded in basic neuroscience.

1.25 Nuclear Magnetic Resonance Imaging and Spectroscopy: Basic Principles and Recent Findings in Neuropsychiatric Disorders

Graeme F. Mason, Ph.D., John H. Krystal, M.D., and Gerard Sanacora, M.D., Ph.D.

Historically the role of MRI in psychiatry has been limited to the use of structural MRI in ruling out known organic causes of emotional, cognitive, and behavioral symptoms. At present, there is a growing interest in the use of MR technology in psychiatry, largely owing to its noninvasive nature and its increasing ability to provide information on the structure, function, and physiology of the brain. While the potential usefulness of MR in the diagnosis of psychiatric disorders is immense, the current clinical applications remain extremely limited. However, the last decade has seen an explosion of MR research applications related to the study of the pathophysiology of psychiatric disorders and the mechanisms of action related to various forms of treatment. Imaging measures are also now included explicitly in the National Institute of Health's Research Domain Criteria (RDoC). In the context of the RDoC, the imaging results are specifically for research purposes, attempting to characterize pathophysiologic processes across a spectrum of disorders with various forms of measurements rather than limiting imaging to its standard diagnostic purposes.

HISTORY

MRI and other MR techniques were originally called nuclear magnetic resonance (NMR). The "nuclear" part of the name derives from the basis of the technique in energy transfer to and from the nuclei of atoms. The "magnetic" in the name refers to the use of magnetic fields in the

Telegram: @medical_k

www.konkur.in

experimental environment. The “resonance” component of the name comes from the use of particular frequencies of energy used for the measurements. Since its introduction, NMR has been used for basic investigations of chemistry and physics, but with its introduction to medical applications, the word “nuclear” has generally been dropped because patients may associate it erroneously with ionizing radiation, nuclear power, and nuclear weapons. Technical advances continue, not only in data acquisition but also in analysis, including artificial intelligence. A history and survey of many MR techniques has been published recently (Kose, 2021).

In 1946, Edward Purcell (1912–1997) and Felix Bloch (1905–1983) independently demonstrated NMR at Harvard and Stanford Universities, and for this discovery, they shared the 1952 Nobel Prize in Physics. Early NMR measurements were performed with a *swept field,* in which a narrow-banded radio frequency application was performed as the sample was exposed to a time-varying magnetic field. To enhance the efficiency of the measurement, pulse-and-Fourier-transform NMR was developed and successfully demonstrated at Varian Instruments in Palo Alto, California, in 1964 by Richard Ernst (born 1933), who proceeded to extend the concept to MRI and received the Nobel Prize in Chemistry in 1991. Raymond Damadian, a New York physician, observed in 1969 that tumors had different MR-related characteristics that provide the potential to differentiate cancerous tissue from healthy tissue, thereby demonstrating a potential clinical application of NMR. Dr. Damadian applied for the first patent for an MRI machine in 1972, in which he described the purpose of the device. In 1973, Zenuemon Abe and colleagues published a method that produced images by a slow process of acquiring signals sequentially as the position of the object was shifted through a series of positions, and in 1976 Dr. Damadian published a similar method applied to a mouse. A dramatic breakthrough for MRI occurred when Paul Lauterbur (1929–2007) of SUNY Stony Brook and Sir Peter Mansfield (born 1933) of Nottingham, England, independently developed the acquisition of MRI by means of magnetic field gradients, which will be discussed in this chapter, and that achievement led them to share the 2003 Nobel Prize in Physiology or Medicine.

BASIC PHYSICS OF NMR, MRS, AND MRI

Telegram: @medical_k

www.konkur.in

For human use, the techniques are typically called MRI and MRS. Although MR methods are based on a quantum mechanical property called *spin,* they make use of phenomena that, for most purposes, are most appropriately described using classical mechanics.

Spin, the Larmor Frequency, and Net Magnetization

The primary points of this section are (1) only certain species of nuclei can be detected, (2) the frequency of detection depends on the species of nucleus observed and the strength of the magnetic field of the scanner, and (3) only a very small fraction of the nuclei can actually be detected.

The fundamental basis of MRI and MRS lies in quantum mechanics because the atomic nuclei that produce the signals are quantum particles. The nuclei carry a positive electrical charge, and observable nuclei have a quantum mechanical characteristic called *spin.* A spin of ½ is one of the basic properties of protons and neutrons. That is, a proton or a neutron can have a spin of either +½ or −½, and when neutrons and protons combine to form a nucleus, their spin values combine to yield a nucleus with the net of their spins. The most abundant form of hydrogen has a nucleus that is simply a proton, so the spin of the nucleus of ^{1}H is ±½. The most common form of carbon has a nucleus that is composed of six protons and six neutrons, half with spin +½ and half with spin −½, such that in combination, they yield a nucleus for ^{12}C that has no spin; thus, ^{12}C is not observable with MR techniques. However, 1.1% of naturally occurring carbon is ^{13}C, and the additional neutron that resides within its nucleus confers upon ^{13}C a net spin of ½; therefore, ^{13}C can be observed with MR techniques. Table 1.25–1 lists several MR-observable nuclei that have been applied to study the human brain.

Nuclei that have nonzero spin can be detected with NMR by applying energy and observing their responses, and so investigators who develop MR technology often discuss the behavior of spins in a magnetic field and the manipulation of spins during a measurement. When a charged particle like the atomic nucleus has spin, it produces a *magnetic dipole,* which can be imagined as a small bar magnet with North and South ends.

www.konkur.in

Table 1.25–1.
MR-Detectible Nuclei and Some of Their Applications to Brain Research

Nucleus	γ (MHz/Tesla)	Sensitivity Per Atom (% of ^1H)	Application
^1H	42.58	100.0	Amino acid neurotransmitters and neuronal and glial compounds; imaging of water and lipids
^2H	6.54	1.89×10^{-8}	Metabolism of fats, glucose, acetate: Deuterium Metabolic Imaging (DMI)
^{31}P	17.25	.0666	High-energy phosphate levels, intracellular pH, phospholipid head groups
^{13}C	10.71	.0174	Metabolism of amino acid neurotransmitters, glucose, lipids, acetate
^{15}N	−4.32	-3.83×10^{-4}	Metabolism of ammonia, amino acids
^{17}O	−5.77	1.89×10^{-7}	Cerebral oxygen consumption, production of H_2O
^{19}F	40.08	83.5	Cerebral pharmacokinetics of fluorinated drugs like fluoxetine and fluvoxamine
^{23}Na	11.26	1.60×10^{-3}	Effects of hypoxia, pharmacologic challenges to sodium pumps
^7Li	16.55	4.62×10^{-3}	Cerebral pharmacokinetics of lithium

When the nuclei with spin are placed in a strong magnetic field of magnitude B_0, they *precess* around the axis of that field (Fig. 1.25–1) with a frequency called the *Larmor frequency* or the *resonance frequency*, with γ and B_0 defined in the following paragraph.

Telegram: @medical_k

www.konkur.in

$$v = \gamma B_0$$

The Larmor frequency is the frequency that must be transmitted to affect the sample, and it is also the frequency that is received by the MR scanner. Equation 1 shows that the Larmor frequency depends on the strength of the static magnetic field, as well as on γ. The frequency of detection of a nucleus in a clinical magnet operating at a magnetic field strength B_0 of 3 Tesla (abbreviated 3 T) is twice the frequency of detection of the same nucleus at 1.5 T. The Larmor frequency of the most abundant isotope of hydrogen, ^1H, is 63 MHz at 1.5 T and 126 MHz at 3 T, the most common clinical field strengths. These frequencies lie in the FM band of the radio, and accordingly, MR scanners are usually in rooms that are electrically sealed to prevent ambient signals from contributing what looks like noise in the data. The other variable that affects the frequency is γ, the *gyromagnetic ratio,* which differs for each species of the nucleus. So, because the value of γ for the common hydrogen nucleus is approximately four times as large as that for ^{13}C, the Larmor frequency of hydrogen is about four times as large as that of ^{13}C.

The reason for the large static magnetic field is to create a condition called *net magnetization.* In the absence of an external magnetic field, the spins of the nuclei in the magnetic field are oriented randomly in space, and if you were to draw an arrow through the spin orientation of each nucleus, then collect all those arrows into a common starting point, you would have a ball in which every arrow was paired with an equal and opposite arrow on the other side of the ball (Fig. 1.25–2A.1) so that the directions of the arrows averaged to zero. That is, zero net magnetization in the absence of an external magnetic field (Fig. 1.25–2B.1). To create the potential for a signal, some nonrandomness must be introduced. In the presence of a strong magnetic field, the spins become slightly biased in one direction (Fig. 1.25–2A.2), such as one might imagine from a dandelion seed head under a slight breeze, and creates the net magnetization (Fig. 1.25–2B.2). It is this small bias in the alignment of the nuclei that MR scanners can detect, and the greater the net alignment, the larger will be the signal that can be detected from the sample. The net magnetization expressed as a fraction of the total spins is given by the *Boltzmann distribution*

Telegram: @medical_k

www.konkur.in

FIGURE 1.25–1. Individually, nuclei are particles that have the quantum mechanical property *spin*. By virtue of their charge and the spin, they behave as small magnets that can be aligned either with or against the large magnetic field of the MR scanner (B_0), rotating at the *Larmor frequency.*

$$N_{high}/N_{low} = 1 - (\nu h B_0/kT)$$

where k is the Boltzmann constant, h is Planck's constant, and T is the absolute temperature. Most people have little occasion to use Equation 2, but it illustrates several important features of NMR measurements. First, a larger net magnetization can be obtained if a nucleus with a larger gyromagnetic ratio is used. Hydrogen has the largest ratio and has the sensitivity to be used for routine anatomic and other imaging. Sodium has a low ratio and is less sensitive and more difficult to use for imaging. Second, a larger B_0 yields more net magnetization, so a stronger magnet can yield more signal. This is why Earth's field MR has not been used for studies of the brain: a 3-T magnet is 67,000 times stronger than the Earth's average magnetic field, and so the signal available at Earth's field is thousands of times lower. In practical terms, measurements on 3-T machines have twice the signal available from a 1.5-T machine, while 7-T machines have over 4½ times the signal available. Third, lower temperature adds signal, but for measurements in humans, T is usually fixed at about 37 °C (310 K). Finally, if one plugs in typical temperatures and magnetic field strengths used for human clinical scans, the equation shows that for hydrogen, the net magnetization consists of only 0.0004% to 0.0008% of the nuclei in the sample.

Detection of the Net Magnetization

Telegram: @medical_k

www.konkur.in

The techniques of MRS and MRI in vivo detect the quantities of net magnetization in various locations and elucidate the properties of the cellular environment. For MRS, there is the particular purpose of discovering in what chemicals the magnetization resides, and for MRI, the specific purpose is to measure the spatial distribution of the magnetization. Having the nuclei precess at the Larmor frequency and follow a net distribution oriented along with the scanner's magnetic field sets the stage for MR detection, but one more component is necessary to obtain a signal.

Within seconds of placing a subject in the scanner, the nuclei in the brain are in a fully *relaxed* state (Fig. 1.25–2A.2 and B.2). In the jargon of MR, a fully relaxed state is one in which the nuclei have a very small net orientation with the magnetic field, according to their Boltzmann distribution. Each spin precesses about the axis of the magnet, and as each one precesses, it causes a minute magnetic field to oscillate at the Larmor frequency. Those oscillating fields are how a signal can be detected, but, at any instant, for every spin oriented in one direction about the axis, there is another spin oriented in the opposite direction, and their oscillating magnetic fields cancel one another. In this condition, no signal can be detected in the sample. To solve this problem and detect the precessions, one must get the spins into a coordinated group precession. A magnetic field oscillating at the Larmor frequency (called radiofrequency, or *RF*) is applied, generally lasting a few hundred microseconds to a few milliseconds, and the nuclei absorb energy from the transmission, which causes the whole assembly of spins, including its net magnetization, to rotate out of alignment with the large, static magnetic field of the scanner (Fig. 1.25–2A.3 and B.3). As the energy rotates the net magnetization toward the perpendicular to the scanner's magnetic field, the spins acquire *phase coherence.* That is, the net magnetization is put in a position that has the net spins precessing together instead of having a random distribution about the *Z*-axis. In that position, their tiny oscillating magnetic fields occur coherently, which the detector can pick up as a signal, which also has the Larmor frequency. The energy is detected with a *probe,* sometimes also called a *coil,* which is placed around or against the part of the body that is being studied. In many cases, the same coil is used for transmission and detection. After the energy is applied, the signal gradually dies away as the spins that

Telegram: @medical_k

www.konkur.in

comprise the net magnetization disperse their orientation and return to alignment with Z.

Regarding terminology, as the net magnetization is rotated away from the magnetic field orientation, any magnetization that is perpendicular to the scanner's magnetic field is called *transverse magnetization* (Fig. 1.25–2A.3). In the terminology of classical mechanics, MR can only detect the component of the magnetization vector that lies in the *transverse* plane (Fig. 1.25–2B.3). If less energy is used, then a lower flip angle is achieved, and less signal can be detected. It is possible to rotate the magnetization through any angle, including 180 degrees, which is a special rotation called an *inversion,* and it is used frequently for MRI and MRS.

Quantum and Classical Mechanics

Many explanations of MRI and MRS are based principally on quantum mechanics. The explanations are often daunting and are generally unnecessary. A phenomenon is called "quantum mechanical" if classical mechanics are unable to explain the observed behavior. For example, a rotating bicycle wheel can be described with great effort using quantum mechanical calculations, but the wheel's behavior is explained with great precision and considerably greater ease with classical mechanics. Therefore, a rotating bicycle wheel is considered a classical phenomenon, not a quantum mechanical phenomenon. In the case of MR, observations of a single spin can be explained only with quantum mechanics, but when many spins are observed, as is the case for an MRI study of the brain, the nuclei behave as a set of spins that have a continuum of orientations, though slightly biased along the magnetic field. The behavior is explained completely in the realm of classical mechanics. This point is described in detail by Hanson (2008).

www.konkur.in

FIGURE 1.25–2. Magnetization in an MR experiment shown with perspectives of quantum and classical mechanics. **A:** Quantum mechanical: **A.1** and **A.2:** In the presence of an external magnetic field, the individual spins are aligned with or against the field, and a slight majority, on the order of just 0.0004 percent, is aligned with the field. The very small size of this ratio is the reason that MR is considered to be insensitive compared to other forms of imaging. **A.3:** When a radiofrequency burst is applied at the Larmor frequency of the spins to apply what is called a 90-degree pulse, the net distribution is randomized so that the spins are evenly distributed with and against the field. At the same time that the spins are randomized, they acquire *phase coherence,* coming together in one orientation with respect to the *XY* plane. **A.4** and **A.5:** As time passes, interactions of the individual spins with the environment changes their orientation in the *XY* plane according to T_2 relaxation, so that they gradually disperse and lose that phase coherence. **A.6:** Eventually the spins not only have lost any net *XY* orientation, and they also have retuned to their original state along Z, so the small portion of net magnetization now looks like **A.2**. **B:** Classic mechanical: **B.1:** In the absence of a magnetic field, the spins of **A.1** average to zero, just a dot, no net magnetization, and hence no available signal. **B.2:** In the presence of the external magnetic field, there exists a magnetization vector whose size is proportional to the sum of the small majority of spins that have net alignment with the field. **B.3:** When a 90-degree pulse is applied, the magnetization vector rotates to the *XY* plane. This is the average orientation of the vectors shown in **A.3. B.4** and **B.5:** After the excitation, the magnetization vector shrinks over time as the individual spins in **A.4** and **A.5** gradually point in various directions in the *XY* plane. **B.6:** The net magnetization eventually loses all its *XY* orientation and returns to the *Z* axis according to T_1 relaxation.

T_1, T_2, and T_2* Relaxation

Once the magnetization vector has been rotated to the transverse plane, phenomena called *relaxation* to eliminate the signal and return the vector

Telegram: @medical_k

www.konkur.in

to the Z axis through exponential processes called T_1 and T_2 relaxation, or *longitudinal* and *transverse* relaxation, respectively (Fig. 1.25–2A.5,6, and B.5,6). Longitudinal relaxation returns the magnetization to alignment with the scanner magnetic field at a rate governed by the exponential time constant T_1. As will be explained later, this relationship can be used to create contrast among materials with different values of T_1, such as gray matter and white matter.

Repeating scans too rapidly with too large an excitation angle leads to a reduction in signal amplitude through a process called *saturation.* Transverse magnetization can only be generated from Z magnetization, which is created during the T_1 relaxation process. Therefore, if too little time is allowed for recovery of Z magnetization, then the signal will be reduced on repeated scans. For full relaxation after a 90-degree pulse, typically, a delay of several seconds is required. Less saturation occurs when a lower angle of excitation is used, but that also results in the generation of less transverse magnetization. In practice, the most efficient acquisitions incorporate a compromise, in which an excitation angle of something less than 90 degrees is used, and an interscan delay of less than three T_1s is allowed between scans.

In vivo, T_1 relaxation depends on the static magnetic field strength, the rate of tumbling of the molecules in which the spins reside, and the distance between the relaxing nucleus and other charged spins in the sample. As a consequence, as magnetic field strength rises, the value of T_1 increases. As will be shown later, the dependence of T_1 on field strength can be exploited to make more effective experiments but can also place some limitations on measurements at different magnetic field strengths.

For measurements in vivo, long before the magnetization vector has returned to the Z axis, the signal decays to nothing because of T_2 relaxation. T_2 relaxation destroys the phase coherence of the component of the magnetization in the XY plane, such that the MR signal decays in an exponential process (Fig. 1.25–2A.4,5 and B.4,5). The signal gradually dies away, yielding a *free induction decay,* or FID. T_2 relaxation is primarily due to interactions of the nucleus with other spins in the sample, and in the brain, in vivo, its value is largely independent of magnetic field strength. As phase coherence is lost, the signal from each spin in the sample becomes increasingly canceled by another spin in the sample so

Telegram: @medical_k

www.konkur.in

that gradually the average signal coming from the sample approaches zero. The value of T_2 depends largely on the mobility of the molecule in which the nucleus resides: The greater the restrictions on motion, the shorter the T2 will be. For example, the white matter has an abundant, rigid structure that prevents water from diffusing rapidly and rotating freely, and the white matter has a shorter T_1 than cerebral spinal fluid (CSF), in which the water is free to rotate. The differences between white matter and gray matter provide an effective basis for high contrast for diseases in which fluid must be emphasized in MRI. The T_2 of bone is very short and is therefore not typically detected in MRI or MRS.

A parameter related to T_2 is T_2*, which results from the inhomogeneity of the magnetic field. Such inhomogeneity can derive from macroscopic causes, such as an interface between tissue and bone or air. The sinuses, ear canals, and temporal bones cause large inhomogeneities that are often troublesome for MRI and MRS studies. Inhomogeneities also result from microscopic influences, such as the presence of deoxyhemoglobin. T_2* is the time constant for an exponential loss of phase coherence, but the process also occurs with the dephasing of magnetization in different parts of the sample due to tissue inhomogeneities or shape. The sample volume could be an image pixel or region selected for an MRS measurement. If one corner of an image pixel experiences a slightly higher magnetic field strength, then the Larmor frequency in that corner will be a little higher. Perhaps the center of the image pixel has a lower frequency, so the Larmor frequency in the middle of the pixel will be lower. As time progresses, the magnetization in different parts of the sample will eventually randomize their phase, such that any signal coming from one part of the sample will be canceled by signals with the opposite phase from another part of the sample. In certain kinds of MRI and MRS studies, such effects can dramatically reduce a signal, causing regional darkening of images in MRI and blurring and loss of signal in MRS.

Influences on Frequency and Identification of Molecules in MRS Measurements

The main points of this section are that the major factors that influence a resonance frequency are (1) magnetic field strength and (2) gyromagnetic ratio, which affect primarily what transmitter frequency will be used. Smaller influences are the electron cloud conformation and the

Telegram: @medical_k

www.konkur.in

interactions with other nuclei in the molecule, which together imbue MRS with its ability to distinguish neurochemicals from one another.

The primary actor in the differentiation of chemicals is *shielding,* a phenomenon in which the electron cloud in a molecule partially blocks the static magnetic field that penetrates the nucleus. Consider the cases of glutamate and glutamine (Fig. 1.25–3). The fourth carbon in the chain (C4) of glutamate resides next to a carboxyl group whose oxygen atoms are highly electrophilic. The nearby oxygen atoms of the carboxyl group draw the electrons at that end of the molecule to themselves so that the C4 carbon nucleus of glutamate is more exposed to the large magnetic field and therefore has a larger Larmor frequency. Stated differently, the carboxyl group reduces the shielding of the carbon nucleus, slightly modifying the value of B_0 and thereby causing the carbon to resonate at a slightly higher frequency. Now consider glutamine, which has only one oxygen near the C4 carbon position, in addition to the nonelectrophilic amide group, and so the electrons more fully shield the glutamine C4 carbon nucleus. The C4 of glutamine resonates at a lower frequency than the C4 carbon of glutamate.

FIGURE 1.25–3. Neurochemicals differ slightly in the Larmor frequencies of their atoms according to chemical identity and location within the molecule. The frequencies differ according to their magnetic environment, and an electron cloud provides shielding for the nuclei. In the case of the $-CH_2-$ of glutamate, whose carbon is numbered 4, adjacent to the carboxyl group, the electrophilic oxygen atoms on the carboxyl group draw the electron cloud toward themselves, leaving the hydrogen nuclei exposed to the large static magnetic field. The nuclei of the corresponding hydrogen atoms in glutamine do not have the adjacent electrophilic oxygen atoms to unshield them and therefore experience a slightly lower magnetic field strength. Therefore, the resonance frequency of glutamate at 1.5 T is about 7 Hz higher than that of glutamine.

Telegram: @medical_k

www.konkur.in

Glutamate and glutamine are also separated in the ^{1}H spectrum. At a magnetic field strength of 1.5 T, the resonances of the two hydrogen nuclei attached to the C4 of glutamate and glutamine are centered 7.7 Hz apart for glutamate relative to glutamine. At 3 T, the same hydrogen nuclei resonate 15.4 Hz apart. At 7 T, they resonate 36 Hz apart, which separates the signals more effectively at the higher magnetic field strength. Because MRS studies are performed across a wide range of magnetic field strengths, some common set of units are used to ease the identification of chemicals based on their resonance frequency. The frequency of resonance for nuclei at a particular position in a given molecule is called the *chemical shift,* and the units are parts per million or *ppm.* The notation of ppm is obtained by dividing the frequency difference in hertz by the Larmor frequency in megahertz (i.e., 10^6 Hz). The result has units of hertz per million hertz, or ppm. In these units, those protons of glutamate and glutamine are said to be centered .11 ppm apart, no matter what the static magnetic field strength.

Chemical shifts must be seen as relative differences in frequency location. By convention, for ^{1}H and ^{13}C MRS, the field has agreed that the signal from trimethylsilylpropionate (TSP) be designated as the reference compound with a shift of 0 ppm. All other compounds, by convention, are described by their frequencies relative to that of TSP. For example, lactate has protons that resonate 1.33 and 4.15 ppm away from TSP, respectively (Fig. 1.25–4). For reasons based on the original techniques used to obtain MRS measurements, called *swept field NMR,* lower chemical shifts are termed *upfield,* and the higher chemical shifts are called *downfield.*

The final influence on the frequency of a nucleus is *J-coupling,* which is the influence of neighboring nuclei with spin upon one another. The state of the spin of one nucleus exerts a very slight effect on the *transition energy* of the neighboring spin. To describe J-coupling, a quantum mechanical explanation is necessary. The transition energy is the amount of energy that a spin can absorb and change its energy state, and it is a defined, fixed amount and must be delivered at precisely the Larmor frequency. If one spin is coupled to another, usually through a covalent chemical bond, one spin will change the other's transition energy to a slightly higher or a slightly lower value. Because the transition energy is ultimately what defines the resonant frequency of a nucleus, half the spins have a slightly higher frequency and half a lower frequency. A nucleus that is affected by one nearby spin, such as the $–CH_3$ group at 1.33 ppm

Telegram: @medical_k

www.konkur.in

in lactic acid, has a *doublet* or two resonances instead of one, each representing half of the total resonance for $–CH_3$, as is the case for the methyl group of lactate, in which three identical hydrogen nuclei are affected identically by a single adjacent hydrogen (Fig. 1.25–4A). If nuclei are adjacent to two spins, then their resonance is divided into a *triplet,* as demonstrated by the spectrum of ethanol (Fig. 1.25–4B). Nuclei adjacent to three spins, such as seen in the hydrogen adjacent to the methyl group of lactic acid, yield a quartet that arises from the effect of the three methyl protons of lactic acid on the single ^1H at 4.11 ppm (Fig. 1.25–4A) or the $–CH_2$ protons of ethanol (Fig. 1.25–4B). The spectral distance between each resonance in the multipeak structure is *J* Hz and is typically reported in hertz, not ppm because the splitting due to *J*-coupling is independent of magnetic field strength. For the $^1H–^1H$ splitting of Figure 1.25–4, the value of *J* usually lies between 3 and 15 Hz.

SYSTEM HARDWARE

Before moving from the basic physics of MR to methods of MRI and MRS, it is helpful to examine the MR machine itself. MR machines are composed of three or four main components: A magnet, a *transmit path,* and a *receive path,* and almost all MR scanners also have *gradient coils.* The magnet is the source of B_0, which is what creates the net magnetization. The transmit path generates the transverse magnetization. The receive path detects the signal from the sample and carries it back to the computer for storage.

Telegram: @medical_k

www.konkur.in

FIGURE 1.25–4. Effects of chemical shift and *J*-coupling. Chemicals in MRS studies are identified primarily on the basis of their chemical shifts, but significant information also arises from the *J*-coupling interaction of spins. **A:** Lactate has resonances at 4.15 and 1.33 ppm from TSP. The methyl protons are *equivalent* and are all centered at 1.33 ppm. However, they interact with the adjacent single proton at 4.15 ppm and split their resonance into a doublet centered at 1.33 ppm. The single proton at 4.15 ppm interacts with all three methyl protons and is split into a quartet. **B:** Ethanol has a methyl group whose resonance is centered at 1.2 ppm and interacts with an ethylene group whose resonance is centered at 3.7 ppm. The two protons split the methyl

Telegram: @medical_k

www.konkur.in

resonance into a triplet, while the three protons of the methyl group divide the ethylene resonance into a quartet.

The magnet (Fig. 1.25–5) consists of hundreds of miles of superconducting wire wound in precise formations. When a magnet is installed, a strong vacuum is applied to remove all ambient air and water from around the wire. Then the evacuated container is filled with liquid helium to maintain its superconductivity at a temperature of 4 K, or −453 °F. The helium bath is insulated by a vacuum chamber to reduce boil-off. Liquid helium is expensive, and a recent worldwide shortage is expected to continue for several years, so in many magnets, the helium structure lies within a bath of liquid nitrogen or a refrigeration unit. The helium in the magnet must be maintained at high purity because humidity or air that enters the helium chamber (called a *dewar*) will solidify and may create a blockage that can result in an explosion. Another sort of failure is a *quench,* which is a sudden loss of charge in the electrical windings of the magnet, simultaneously with the almost instantaneous expulsion of helium from the magnet. Such events can be caused by a loss of vacuum around the helium container, a failure to maintain the helium at an adequate level, or the introduction of a ferromagnetic object in the vicinity of the magnet.

Telegram: @medical_k

www.konkur.in

FIGURE 1.25–5. A whole-body MR scanner. Magnets for MRI are usually cylindrical, with a hole through the middle. The hole accommodates a set of cylindrical gradient coils that are used for shimming and experiments that require spatial information, such as imaging. The gradient coil cylinder has a bore large enough to accommodate a human torso or, in some new models, just a person's head. A patient bed slides in and out of the scanner. On top of the magnet are vents to allow for the boil-off of helium and, in many cases, nitrogen gas. There is also an entry point to allow charging of the superconducting windings when the magnet is installed and to allow controlled shut down if the magnet needs to be de-energized after some years of operation.

The magnet is constructed with additional circuits called *shims,* which are used to fine-tune the homogeneity of the magnetic field. The quality of MRI and MRS improves dramatically with the homogeneity of B_0. The magnets are designed and built to achieve a homogeneous magnetic field within a sphere in the center of the magnet, but when a magnet is placed at the site where it will operate, the homogeneity is disrupted. Initial adjustments to B_0 homogeneity are made using small pieces of metal, called *shims,* placed strategically at different places in the bore of the magnet in a painstaking process, and then engineers adjust the magnetic field homogeneity further with the shim circuits. Likewise, when a person is placed in the scanner, the homogeneity is altered, and it is necessary to

Telegram: @medical_k

www.konkur.in

adjust the shim circuits to compensate. For many cases, it is only necessary to apply three linear adjustments to the magnetic field, but for some applications, including MRS, second- or third-order changes must often be applied.

The transmit path begins with a frequency source whose output is modified to obtain a desired amplitude, phase, and shape. The modulated signal is sent to a radio frequency amplifier to boost the transmission, often into the range of kilovolts. The transmission is directed to the coil that is around the head, where it generates an oscillating magnetic field, which by convention is called B_1.

Part of the transmit path is the radio frequency coil. A typical coil for brain imaging and spectroscopy is shown in Figure 1.25–6. The coil surrounds the brain so that relatively uniform coverage is achieved. Another type of detector, a *surface coil,* is used for cases in which localized coverage with high sensitivity is required. All coils must be tuned to the Larmor frequency, and to do that, adjustable capacitors form part of the circuit. The coil not only transmits to the brain but also receives the signal from the brain and therefore forms the beginning of the receive path. The signal in the receive coil has an amplitude of microvolts at the Larmor frequency. If it traveled unaltered through many feet of wires to the computers for processing and storage, then the noise that accumulates along its path would overwhelm the signal. Therefore, as close as possible to the coil, magnet-compatible *preamplifiers* are used to boost the received signal to a level of millivolts. The signal is modified to shift the frequency into the auditory range, covering kilohertz, and stored on a computer. Typical causes of coil failure include a preamplifier damaged by leakage of radio frequency transmission into the receive path or damage to capacitors from power-induced cracking or sparking. Such failures become more likely in a head coil by transmitting high power levels into coils, especially when a sample whose size and conductivity differ significantly from a human head.

Telegram: @medical_k

www.konkur.in

FIGURE 1.25–6. A typical coil used for MRI and MRS of the brain. Built for whole-brain coverage, this coil surrounds the head. The ideal would be a long, empty conducting tube, but to accommodate a head, it must be short, and to allow for patient comfort and construction constraints, it must have discrete conducting elements. Four of the elements are housed within the bars that can be seen along the upper part of the coil. The other elements are housed in the bottom section of the coil, beneath where the head rests during a scan.

Gradient coils form an almost universal fourth component of hardware in an MR scanner. In the absence of gradient coils, MR signals are obtained with little or no information about what part of the sample they represent. For example, if a standard brain imaging protocol is run without gradient coils, then the result would be an MR spectrum of a large water signal and a small fat signal. The *X, Y,* and *Z* gradient coils provide the positional information. When current is directed through the *X* gradient coil, a spatially linear ramp is added to B_0, such that $B_{0\text{effective}} = B_0 + G_x x$, where G_x is the gradient strength in units of millitesla/centimeter, and x is the distance from the magnet's center. Similar relationships exist for the *Y* and *Z* gradients and the *y* and *z* directions in the magnet. When power is

Telegram: @medical_k

www.konkur.in

applied to the gradients, the Larmor frequency depends linearly on the position within the magnet, and by this encoding, images can be obtained. Patients commonly ask the source of the loud noises of an MR scanner, and the answer is the gradient coils. When the current is switched on and off rapidly, it generates a magnetic field that opposes the primary field of the magnet and generates large forces that manifest as loud noises. Patients may also sense vibrations inside the scanner from the same cause.

FOURIER TRANSFORM

Having examined the basic physics and the MR machine, it is helpful to turn to one of the most basic analytical tools that are used for MR studies. The purpose of this section is to explain and illustrate the relationships between the observed signals and the processed images and spectra of MRI and MRS. The signals are observed over periods of milliseconds, and those time-dependent signals must be transformed into spatial pictures in the case of MRI and spectra in the case of MRS.

MRS and MRI both make use of a mathematical operation called a *Fourier transform,* which is used in many fields to switch between time and temporal frequency (e.g., seconds and hertz) or between space and *k-space* (centimeters and reciprocal centimeters). Every time-dependent signal can be represented as a set of frequencies, measured in hertz, and every object can be expressed as a set of signals in *k*-space. The idea behind Fourier transforms is that any shape can be created by adding the right frequencies and amplitudes of sinusoidal signals together. Figure 1.25–7 shows the decomposition and recreation of a profile of the Taj Mahal in India. The Fourier transformation at the upper right is plotted as a histogram of weightings associated with the range of frequencies that make up the profile, with low frequencies in the center of the graph and higher frequencies on either side. The panels at the center-left show that the contributions of the lowest frequencies to the profile have to do with large features. From the low frequencies, one can see that the profile has a large object in the middle and something large on either side, but there is little detail. The next panels to the right show the effects of adding progressively higher frequencies, which gradually produce finer features. That is because the higher-frequency components of the Fourier transform contain the details of a signal. When all of the frequencies are

Telegram: @medical_k

www.konkur.in

included, the original image is obtained. The Taj Mahal is built from sine waves.

FIGURE 1.25–7. The Fourier transform is based on the premise that the shape of any object can be created with the right combination of sinusoidal waves. In this example, a profile of the Taj Mahal is shown on the **upper left**, and its Fourier transform is shown on the **right**. If the center group of frequencies, labeled **a**, are plotted and summed (**two center-left panels**), then a general shape of the profile is achieved. If the next group of frequencies, labeled **b**, are plotted and added (**two middle panels**), then the shape of the center dome begins to take shape. The next band of frequencies, labeled **c**, can be included (**right center panels**) to show the presence of the pairs of towers on each side of the central dome. When all frequencies are included, the original picture is seen (**bottom**). Two principles are shown by this example: An object can be expressed as a series of sinusoids, and the details of an object lie primarily with the frequencies that lie farthest from zero.

Telegram: @medical_k

www.konkur.in

Aside from its appearance in dreams, the Taj Mahal may have little to do with psychiatric brain imaging, but it illustrates the fundamentals of the Fourier transform. Signals in MRS are acquired as a function of time, just as one can record sounds as time-dependent vibrations (Fig. 1.25–8A). The Fourier transform of the sounds reveals the frequencies and volumes of sound that comprise a note, just as the Fourier transform of an MRS signal reveals the frequencies and amplitudes of signals that uniquely identify neurochemicals that make up the FID (Fig. 1.25–8B). The MR signals in brain imaging are acquired in the *k*-space domain and undergo Fourier transformation to generate the standard anatomic pictures. Low-frequency data are those that reside near the center of *k*-space, and just as for the picture of the Taj Mahal, the data that resides near the center of *k*-space lack details but indicate primarily how large the head is and that the shape is roughly circular. The information about sulci and other fine details is found farther from the center of the *k*-space (Fig. 1.25–9). Schemes exist to acquire only the center or the outer edges of *k*-space to save time in cases that do not require all of the information about the image, but the great majority of brain imaging is done with standard coverage of *k*-space.

Telegram: @medical_k

www.konkur.in

FIGURE 1.25–8. The Fourier transform allows time-dependent signals to be expressed in terms of frequency, and in this respect, MRI is indistinguishable from sounds. **A:** The upper graph shows the sound of a note played on a saxophone and cymbal by the author's daughter and son. Fourier transformation reveals some of the frequencies that are generated from the instruments. The richness of the sound of a saxophone derives largely from the combination of frequencies and various amplitudes of tones that it emits, and the cymbal's characteristic sound derives from the multitude of

Telegram: @medical_k

www.konkur.in

frequencies in addition to its primary pitch at 540 Hz. **B:** The MRS signal, viewed relative to the Larmor frequency, is indistinguishable from sound; the MRS signal also appears as a time-dependent oscillation. Some early MR scanners were connected to audio speakers to allow the operators to make quick evaluations of signal quality. In this case, the Fourier transform converts a complicated time-domain measurement into a spectrum with easily identifiable features that are typical for a sample of healthy brain tissue. The volume contains *N*-acetylaspartate (NAA), creatine + phosphocreatine (Cr + PCr), myoinositol (MI), choline, scylloinositol (SI), glutamate (Glu), and glutamine (Gln).

FIGURE 1.25–9. *K*-space data (**top**) paired with associated images (**bottom**). Typical *k*-space coverage is uniform and yields a standard brain image (**left pair**). If only the center of *k*-space is acquired (**center pair**), then the image loses much of its detail, which is analogous to the example of the reconstruction of the profile of the Taj Mahal in the earlier example. If only the outer regions of *k*-space are acquired (**right pair**), then only the fine details remain.

MRI METHODOLOGY

MRI methodology is about seeing boundaries and differences in tissue composition, which requires the generation of *image contrast*. The word "contrast" is often used clinically to mean an injectable *contrast agent,* but

Telegram: @medical_k

www.konkur.in

the general meaning of contrast in MRI is anything that differentiates the appearance of one material from another. To that end, the contrast in brain imaging is obtained by exploitation of differences in T_1, T_2, blood oxygenation, diffusion coefficient, and concentration of water or fat. The most basic neuropsychiatric application of MRI is the mapping of brain anatomy, and this is generally done on the basis of the natural contrast from T_1, T_2, and T_2* of brain water. On the side of clinical applications, the purpose is often to check for particular causes of symptoms, such as tumors or multiple sclerosis. All image sequences consist of one or more region-specific radio frequency excitations followed by applications of gradients to scan *k*-space. The resulting *k*-space distributions undergo Fourier transformation to create images. By convention, MRI results are displayed such that the bottom of sagittal or coronal images points toward the feet and the right side of axial or coronal images points toward the patient's left.

The most basic MRI sequences are called *gradient-echo* and *spin-echo.* The gradient-echo sequence is simply an excitation pulse in conjunction with gradients to localize the sources of the signals (Fig. 1.25–10). For each slice, the measurement consists of a slice-selective excitation pulse applied while a slice-selection gradient is applied. The longer the pulse and the stronger the gradient, the thinner the slice will be; scanners equipped with stronger gradients are generally able to provide thinner slices. A *phase-encoding gradient* is then applied perpendicular to the slice selection in one of the in-plane dimensions to shift the acquisition to a fixed distance in *k*-space; larger phase-encoding gradients shift the acquisition farther in *k*-space. After the phase-encoding gradient, a preparatory gradient is applied in the second in-plane dimension to shift the acquisition in the second dimension of *k*-space. Finally, a *read gradient* is applied in that second dimension of *k*-space. The process is repeated, using a slightly different phase-encoding gradient strength each time to provide appropriate coverage of two dimensions of *k*-space, allowing the generation of a two-dimensional image. With a gradient-echo image, signal loss occurs due to distortions in the magnetic field, such as seen near the sinuses and other tissue/air/bone interfaces, which can be avoided with a spin-echo sequence. The spin-echo sequence contains all of the elements found in a gradient-echo sequence, but with the addition of a 180-degree pulse called a *refocusing* pulse applied halfway between the excitation pulse and the acquisition, one effect is to refocus

Telegram: @medical_k

www.konkur.in

magnetization lost due to magnetic field inhomogeneities and thereby recover the signal, such as near the sinuses. A spin-echo sequence also provides a way to obtain tissue contrast and visualize certain pathologies, as will be discussed shortly.

FIGURE 1.25–10. Coverage of *k*-space for brain imaging. **A:** The gradient-echo sequence is a pulse-acquire measurement that includes gradients to localize the signal. (1) A slice-selection gradient is applied with a frequency-selective pulse to excite the magnetization in a slice. (2) The slice selection gradient disperses the magnetization, so a slice refocus gradient is applied to refocus it before the acquisition. (3) Phase encode gradients move the magnetization in the phase encode direction. (4) A read rephase gradient opposite to the read gradient is applied to move to one edge of *k*-space. (5) A read gradient moves the signal through *k*-space in the read direction. **B:** The *k*-space data are shown at the left, with indications of the path that was covered by the read and phase-encoding gradients. Transformation of the *k*-space data results in the image shown at the right.

T_1 Weighting, Injected Contrast Agents, and T_2 Weighting

T_1-based contrast exploits the different rates of realignment of spins with the static magnetic field. T_1 weighting is exploited in different ways, including injections of exogenous agents, but a common noninvasive approach is *inversion recovery* (IR), with timing set to null, or blacken, regions of the image with the long T_1 of CSF. IR imaging works on the principle that the detectible *XY* magnetization can only be created from *Z* magnetization, which means that the elimination of *Z* magnetization in the CSF will eliminate the source of the signal in areas that contain CSF. When a 180-degree pulse is applied to the magnetization, the net magnetization is inverted, and it immediately begins to return to the alignment with the magnetic field. The T_1 of white matter is the smallest, so the magnetization in white matter recovers first. The T_1 of CSF is the

Telegram: @medical_k

www.konkur.in

longest, so its magnetization recovers most slowly, and if the images are acquired near the point at which its Z magnetization reaches 0, the CSF will appear black in the images. The gray matter has an intermediate T_1, so its value will be recovered enough to detect but not as much as that of white matter: Gray matter will appear significantly darker than white matter. Figure 1.25–9 shows such an image. T_1-weighted images are commonly used for structural analysis, including volumetric research.

Another way to obtain T_1-based contrast is with the use of an injectable agent, most of which contain gadolinium. The contrast agents pass through the blood but do not cross the healthy blood–brain barrier (BBB). The gadolinium that is trapped in the molecule decreases the T_1 of the hydrogen nuclei in the water around it and brightens the image intensity wherever it appears. In cases in which the BBB has been disrupted, as is the case with some tumors, the gadolinium agent enters the abnormal tissue easily, and the region appears bright in the images (Fig. 1.25–11).

Losses of signal due to the T_2 decay of the water signal can be used to highlight CSF relative to white matter and gray matter, which lose signal significantly more quickly during echo delays. A T_2-weighted image typically uses a spin-echo type of image, which combines an excitation pulse to create XY magnetization and then one or more 180-degree pulses to track the T_2 decay that progresses with time after the excitation pulse. In the case of multiple sclerosis (Fig. 1.25–12), the fluid in pockets within the ventricles, sulci, and lesions have longer T_2 values than the other tissue. If a long echo delay is used, then the signals from gray and white matter decay to 50% or less of their maximum values, while the signal from the fluid remains strong.

One disadvantage of T_2-weighted images is the poor contrast between gray and white matter. However, an advantage is that the types of image sequences used for T_2 weighting typically eliminate inhomogeneity-related signal loss, called T_2*-loss, which typically darkens images near the ear canals and sinuses. The sequences employed for T_2 weighting avoid this behavior.

Most MR images are acquired to evaluate structure. A treating physician may be interested in checking for tumors or multiple sclerosis, as already demonstrated in Figures 1.25–11 and 1.25–12. Other common clinical purposes are the detection of atrophy or cerebral malformations.

Telegram: @medical_k

www.konkur.in

An area of structural MRI that may move beyond its current status as a research tool is volumetric analysis (Fig. 1.25–13). A variety of approaches exist, both manual and automated, but their purpose is to measure the volumes of brain regions, often with separate quantification of white matter and cortical tissue. The specific goal of the research is usually to characterize particular populations of patients with respect to the volumes of various brain structures, commonly the frontal lobe, the hippocampus, or the corpus callosum.

Diffusion MRI

The diffusivity of water can provide a mechanism of contrast for MRI. The most common form, *diffusion-weighted imaging* (DWI), reduces the signal in each image pixel based on the *diffusivity* of water. The process by which the signal is reduced is similar to that of T_2^* decay: Gradients are used as an artificial source of T_2^* with a strong spatial dependence. A spin-echo–type sequence is applied with the diffusion gradients on each side of the refocusing pulse. Nuclei that diffuse very little between the gradients experience the same magnetic field strength and are refocused by the spin-echo, but nuclei that diffuse appreciably *along the direction of the gradient* experience two different magnetic fields and are incompletely refocused, yielding less signal than is seen for the stationary nuclei. DWI can reveal abnormalities in otherwise normal-appearing tissue, as in regions of edema that surround a cerebral infarct. Regions with edema show greater signal reductions because water can diffuse more readily when the tissue structure is disrupted and filled with more fluid.

www.konkur.in

FIGURE 1.25–11. Acoustic schwannoma in the left cerebellar–pontine angle. The T_1-weighted image before the injection of the contrast agent (**left**) demonstrates a mass in the left cerebellar–pontine angle. After administration of the gadolinium contrast agent (**right**), blood vessels are highlighted, and because the tumor is not protected by the blood–brain barrier, the mass is more clearly characterized as being partially cystic. There is enhancement in the internal auditory canal (*arrow*), which is consistent with an acoustic schwannoma.

Water does not diffuse equally in all directions in the brain because the microenvironment restricts the mobility of water. For example, in white matter, water diffuses much more easily along the length of the fiber tracts than across them. That means that fiber tracts that run in the same direction as the diffusion gradient will show a greater signal reduction than fibers that run perpendicular to the orientation of the diffusion gradient. Application of diffusion gradients in six or more different orientations allows the directionality of the diffusion of the water, the *diffusion tensor,* to be measured for every image pixel, generating *diffusion tensor images* (DTIs). Measurement of the orientation of water diffusion permits a measurement of *fractional anisotropy,* which provides a measure of the randomness of tissue structure. For example, if tissue is highly ordered, then the diffusion of water will be restricted and more oriented than is the case for tissue that is disordered. A more calculation-intensive use of DTIs

Telegram: @medical_k

www.konkur.in

comes from following the diffusion tensors through chains of pixels to track fibers. Fiber tracking allows detailed analyses of anatomic connectivity (Fig. 1.25–14), which holds great potential clinically but, for now, remains a research tool.

Imaging Blood Flow

MRI is used clinically to image blood flow in the head. A physician may need to differentiate between a degenerative disorder and a compromised blood supply for a region of the brain. For that purpose, *MR angiography* (MRA) and perfusion MRI can provide helpful information. The example of Figure 1.25–15 shows *time-of-flight* angiography, which uses a gradient-echo measurement to make images in which inflowing water has more magnetization than stationary spins and thereby appears brighter than the surrounding tissue. Another approach to image perfusion is to use an injection of an intravascular contrast agent that enhances the T_1 relaxation and increases the signal on a T_1-weighted MRI. A T_1-weighted MRI is obtained without the agent and then with the agent, and the image pixels that are associated with flowing blood will be brighter with the contrast agent.

Another approach is *arterial spin labeling* (ASL), which is based on the manipulation of nuclei in water outside an image slice and the detection of changes in image intensity as those nuclei arrive in the slice of interest. One approach is to acquire two images, one a baseline image and the other identical, but for the application of an inversion pulse (*spin tagging*) to generate negative magnetization in the water in a slab of the neck, including any water that happens to be flowing up the arteries when the inversion pulse is applied. If images are acquired through slices of the brain, then any of the water that flows with the blood up from the neck will have a negative signal. Upon subtraction of the pair of images from one another, pixels that represent static brain water will approach zero, but pixels that lie in the path of blood flow will appear up to twice as bright as those in the baseline image. In this way, blood flow can be mapped without the injection of a contrast agent.

FIGURE 1.25–12. Multiple sclerosis (MS) in periventricular regions. **Left:** A fast spin-echo image enhances materials with large values of T_2, including cerebral spinal fluid (CSF) in the sulci and the ventricles. The MS lesions are enhanced, but it is difficult to differentiate them from the normal CSF. The periventricular MS lesions have T_1 values that are significantly lower than the value for CSF, so T_1 weighting can be used to differentiate the lesions from fluid. **Right:** The lesions are more conspicuous with the fast spin-echo, fluid-attenuated inversion recovery image (FLAIR) image. The FLAIR sequence incorporates an inversion-recovery pulse that uses T_1 relaxation to suppress signals from the CSF, making it easier to detect lesions that are adjacent to CSF spaces.

APPLICATIONS OF STRUCTURAL IMAGING TO PSYCHIATRY

To date, the clinical utility of structural imaging in psychiatry has been limited to ruling out organic brain diseases. However, the methodology has provided information that has helped to shape many of the current theories related to the pathophysiologic mechanisms associated with several psychiatric disorders, suggesting that both neurodevelopmental and neurodegenerative abnormalities are associated with the various disorders. The use of imaging to contribute to the understanding of disease forms a key part of the RDoC criteria of NIH. Recent advances in the methodology now provide promise that the technique may soon find clinical utility in the diagnosis and prognosis of some psychiatric disorders.

MRI Applications to Dementia

The diagnosis of dementia comprises several illnesses that are characterized by memory loss and other cognitive disturbances. The most common illness associated with dementia is Alzheimer disease, which is characterized by the presence of amyloid plaques and neurofibrillary tangles in several cortical and subcortical limbic regions. The disease is

Telegram: @medical_k

www.konkur.in

associated with neuronal and glial pathology, as well as global and regional brain atrophy and loss of gray matter. Structural imaging is now beginning to emerge as a clinically relevant component of Alzheimer disease diagnosis. Although the current diagnostic criteria for Alzheimer disease used by the National Institute of Neurological Disorders and Stroke—Alzheimer Disease and Related Disorders and *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition, text revision (DSM IV-TR) do not consider MRI data in the diagnostic process, a recent position paper published on the basis of an international conference held to reevaluate the National Institute of Neurological Disorders and Stroke—Alzheimer Disease and Related Disorders diagnostic criteria suggested that MRI be used diagnostically as a supportive feature in the diagnosis of Alzheimer disease.

Several MRI changes, including increased numbers of subcortical hyperintensities, generalized atrophy, and ventricular enlargement, are associated with normal aging. However, it is well established that some changes seem more specific to the diagnosis of Alzheimer disease and may be clinically useful in formulating the diagnosis and prognosis of the disorder. MRI evidence of medial temporal lobe (MTL) atrophy appears to be most closely associated with the disorder. MTL atrophy is extremely common in individuals with Alzheimer disease, with rates reported to be between 71 and 96 percent depending on disease severity. MTL atrophy is often observed in the early stages of mild cognitive impairment (MCI), making it potentially useful as a prognostic tool. However, the sensitivity and specificity associated with the current MRI methodology limit its clinical usefulness in prognostic imaging. One approach that may help to improve the clinical utility of MRI in the diagnosis and prognosis of Alzheimer disease and other forms of dementia is to follow the rate of change in brain structures over time. Longitudinal follow-up studies have shown the rates of volume loss to be significantly greater in subjects with prodromal Alzheimer disease (up to 5 percent brain volume/year) compared to those experiencing normal age-related reductions (0.1 percent brain volume/year). Other methodologic advances are also in development that may help to improve the clinical utility of MRI in the diagnosis of Alzheimer disease. Methods providing an improved ability to rapidly and reliably assess the volumes of specific subregions of the MTL, such as the hippocampus and the entorhinal cortex, provide some promise. Several recent studies suggest hippocampal volume loss

Telegram: @medical_k

www.konkur.in

determined by MRI volumetric analyses in subjects with MCI is capable of predicting conversion to Alzheimer disease in the subsequent years. Further advances in the ability to assess the specific subfields of these regions could lead to dramatic improvements in the specificity and sensitivity of the studies. Examples of these methods include voxel-based morphometry, an image analysis technique that can simultaneously identify multiple areas of cortical and subcortical degeneration, and surface mapping techniques that use specific cortical features as constraints to guide the matching of anatomy across subjects to provide information on cortical gray matter thickness for specific brain regions. All of these techniques are aided in part by the development of what are today considered high-field (3 to 4 T) and ultrahigh-field magnets (7 T and above). The possibility of increasing accuracy by the addition of other measures like flurodeoxyglucose positron emission tomography (FDG-PET) is showing promise. Although these techniques were originally developed for neuroscience research, their potential clinical relevance is becoming appreciated in providing increased structural resolution and even the potential application of imaging microscopy.

FIGURE 1.25–15. Imaging vasculature by *time-of-flight* (TOF) angiography. **Left:** Images are acquired with rapid repetitions that saturate the signal from nonvascular nuclei, thereby reducing the signals from tissues other than flowing blood. **Right:** After being processed to select image regions that show enhanced signal intensity, flowing blood is identified.

Telegram: @medical_k

www.konkur.in

DTI studies have identified significant frontal, temporal, and parietal white matter diffusion tensor changes in MCI and Alzheimer disease patients that appear to correlate with cognitive functioning. Other recent studies have also found relevant microstructural changes in the normal-appearing white matter of patients with Alzheimer disease and MCI, although fractional anisotropy may not be particularly sensitive to the disorder. The changes are consistent with a hypothesized loss of axonal processes in the frontal and temporal regions in Alzheimer disease.

MRI Applications to Schizophrenia

Structural neuroimaging studies have provided some of the most important evidence of abnormal cortical development in patients with schizophrenia. Initial studies reported consistent cerebroventriculomegaly, reductions in total cortical volumes, and regional volumetric deficits, particularly in frontal and temporal cortical regions. One consistent exception to this rule was the striatum, where treatment with typical antipsychotics produces increased volume in patients compared to healthy subjects or never-medicated patients. With the application of segmentation techniques to separate cortical gray and white matter within MR images, it became clear that both tissue compartments showed regional deficiencies in patients. The application of more recent techniques has enabled investigators to describe abnormal patterns of cortical gyrification, curvature, and reduced cortical thickness in patients, although to date, abnormalities are insufficient to discriminate patients from healthy comparison subjects on an individual basis.

Structural MRI also has been useful for characterizing features of the heritable risk for schizophrenia. Schizophrenia is associated with a heritability estimate of 70% to 90%. Consistent with this view, family members of individuals with schizophrenia show a pattern of reductions in cortical gray and white matter volume that resembles but is milder than that associated with schizophrenia. Both the degree of polygenic risk for schizophrenia based on common gene variants that individually have a very small effect and rare mutations that have a significant impact on schizophrenia risk are associated with brain structural changes as measured by MRI.

Structural MRI also has provided some insights into the progressive course of this disorder and the impact of antipsychotic treatment. The most striking findings have been in childhood-onset schizophrenia, where

Telegram: @medical_k

www.konkur.in

a series of neuroimaging studies using a variety of MRI approaches, including specified regions of interest, automated voxel-based morphologic analysis, and deformation analysis (an extremely sensitive approach for measuring within-subject change), have clearly shown that the development and evolution of schizophrenia are associated with a progressive deviation of regional cortical volumes from those of healthy comparison populations. In adolescents and young adults who manifest symptoms of the schizophrenia prodrome, “ultra high risk” state, or who are in their first episode of schizophrenia, many of the changes associated with chronic schizophrenia are already present. Despite earlier data to the contrary from computed tomography (CT) imaging, there are now a growing number of studies in adults with chronic schizophrenia that indicate that even at this stage of the disorder, there is subtle but progressive cortical gray and white matter volume loss in a number of cortical regions, relative to time-dependent volumetric reductions in age-matched healthy subjects. In an era where nearly all patients with schizophrenia receive some degree of pharmacotherapy, studies face the challenge of distinguishing the long-term trajectory of cortical volume changes associated with the illness from the long-term effects of antipsychotics that might emerge over decades of treatment. In this regard, it is interesting to note that some data suggest the possibility that treatment with some “second generation” or “atypical” antipsychotic medications may reduce the short-term, that is, 1 to 2 years, progression of cortical volume reductions or the typical antipsychotic treatment-related increase in basal ganglia volume in patients with schizophrenia. There is hope that these types of studies might reveal neuroprotective effects of future pharmacotherapies for schizophrenia.

DTI has been employed in a growing number of studies that have attempted to characterize disturbances in the organization and integrity of many major white matter pathways associated with schizophrenia. Because DTI measures the movement of water molecules, it is particularly sensitive to the constraining effects of neural projections and their associated glial sheaths upon the normally random diffusion of water, as well as the impact of disturbances in neural and glial integrity. DTI findings in schizophrenia include (1) abnormalities in the degree of anisotropy (lack of organization in the direction that water molecules move within a given voxel), presumably reflecting altered integrity or degree of branching of cortical white matter pathways, and (2) reduced total diffusivity (total

Telegram: @medical_k

www.konkur.in

water movement within a given voxel), a dependent measure related to anisotropy and related to the integrity of white matter pathways, and (3) reduced size, integrity, or branchedness of specific white matter pathways identified using DTI tractography. Using standard techniques, one cannot differentiate the contributions of local dendritic fields, local axonal pathways, and converging inputs from distant neurons.

MR-based perfusion studies have begun to complement other techniques, principally PET and single-photon emission computed tomography (SPECT), in describing cortical perfusion deficits associated with schizophrenia. An early generation of PET studies of perfusion and metabolism deficits associated with schizophrenia yielded the impression that schizophrenia was associated with resting “hypofrontality,” that is, a relative deficit in the metabolism or perfusion of the frontal cortical structures. However, a careful review of this first generation of studies did not yield a firm conclusion on the nature and or validity of resting hypofrontality associated with schizophrenia. More recently, PET, SPECT, and MR-based perfusion studies have been used to characterize task-related alterations in regional cortical perfusion associated with schizophrenia. The novel opportunity provided by MR-based perfusion studies, largely unrealized, is to take advantage of the potential for absolute perfusion quantification in order to reduce interpretation errors when comparing across subjects or across test days where there might be baseline differences that cannot be appreciated using semiquantitative imaging techniques, such as Echo-Planar Imaging (EPI) with Blood-Oxygen Level-Dependent (BOLD) contrast. Studies of cortical perfusion in schizophrenia have been useful to help to evaluate the potential direct vascular effects of substances that might also be of interest with respect to their modulation of neural and glial function, as in the case of nicotine.

MRI Applications to Mood Disorders

Older MRI studies evaluating larger brain regions have yielded few replicable findings related to mood disorders beyond vague reports of lateral ventriculomegaly. However, more recent findings examining specific subregions of the brain have yielded interesting and replicable findings of smaller volumes in several brain regions, including the basal ganglia, thalamus, hippocampus, frontal lobe, orbitofrontal cortex, and gyrus rectus. Perhaps MRI’s greatest contribution to the field of mood disorders research comes from the studies demonstrating reduced

Telegram: @medical_k

www.konkur.in

hippocampal volume in individuals suffering from major depressive disorder (MDD). Hippocampal volumetrics have been studied in several neuropsychiatric disorders. Reduced hippocampal volumes have been reported in epilepsy, Parkinson disease, Huntington disease, Cushing disease, Alzheimer disease, traumatic brain disorder as well as alcoholism, obsessive-compulsive disorder (OCD), and schizophrenia. Despite the confounds introduced by study heterogeneity (age, gender, duration of illness, and responsiveness to treatment) that characterizes the studies in MDD, a 2004 meta-analysis of 12 MRI studies revealed a significant reduction in hippocampal volume in both hemispheres of individuals with MDD. Average reductions of 8% on the left and 10% on the right were reported. Other evidence suggests that the total number of episodes, duration of illness, and exposure to childhood abuse may further contribute to the degree of volume reduction associated with MDD. This data has been taken as strong support for a model of stress-induced hippocampal toxicity involving glucocorticoid receptor activation, hypoxia, and elevated levels of glutamate neurotransmission. However, recent studies also suggest that pediatric patients with familial depression also have reduced hippocampal volumes, suggesting that reduced hippocampal volume may be suggestive of a risk factor for developing MDD.

The anterior cingulate gyrus is another region that has gained much attention due to findings of significant abnormalities associated with mood disorders. Structural MRI has, in one study, demonstrated reductions of 39% and 48% in the mean gray matter volume in the prefrontal cortex ventral to the genu of the corpus callosum in both familial bipolar depressives and familial unipolar depressives. Although this finding has not been replicated consistently in later structural imaging studies, functional imaging studies have consistently found abnormalities in this brain region, and histologic studies have further identified significant glial cell reductions in this area.

Patterns of structural abnormalities in neural regions, including the hippocampus and anterior cingulated gyrus, supporting emotion processing were recently found to differentiate MDD and bipolar disorder (BPD), suggesting a multivariate pattern classification techniques may hold promise as future diagnostic aids. Similar to the case in dementia, future studies using higher field strengths and other methods to allow for

Telegram: @medical_k

www.konkur.in

improved measures of hippocampal subfields are likely to provide marked advantages over the currently used methods.

Findings remain inconclusive with regard to the amygdala, for which several studies have reported no relationship between amygdala volume and mood disorders, while other studies have found either an increase or a decrease in amygdala volumes in mood disorder subjects compared with those of healthy control subjects. Other studies have attempted to define morphometric abnormalities in the basal ganglia related to mood disorders. While there is some evidence suggesting a possible decrease in basal ganglia volume associated with MDD and a potential increase associated with BPD, in general, the data remain inconclusive. Recent advances with high-field magnets such as 7 T may clarify the disparate results, possibly even providing a way to differentiate bipolar psychosis from schizophrenia.

In the area of late-life depression, structural MRI findings have had a large impact on guiding the direction of research. White matter hyperintensities (WMHs) are areas of increased signal intensity that are particularly apparent on T_2-weighted images. As mentioned above, they are commonly associated with aging and are thought to reflect diverse neuropathologic underpinnings related to ischemia, hypertension, myelin pallor, inflammatory disease, amyloidosis, and other causes. WMHs are considered important markers in the study of the consequences of vascular risk factors on the brain and are commonly interpreted as a hallmark of chronic cerebral ischemia. The consistent findings of significantly increased numbers of WMHs in individuals with late-life depression, especially late-onset depression, suggest an etiologically different subtype of MDD. These findings have fueled the cerebrovascular hypothesis of late-life depression that posits that white matter lesions resulting from cerebrovascular disease disrupt fiber tracks within the frontostriatal circuitry.

Recent studies suggest that white matter changes predate the development of late-onset depression and that the severity of the changes predicted subsequent depressive symptoms in the following year even after controlling for age, baseline cognitive function, and depressive symptoms. This adds support to the claim of a causative relationship, but it remains to be determined how important the location and lateralization of the actual WMHs are to the pathogenesis of late-life depression or whether they are merely a marker of progressing vascular disease. Future

Telegram: @medical_k

www.konkur.in

standardized and automated grading systems of WMH, currently in development, should greatly facilitate the use of this modality in clinical practice.

MRI Applications to Alcohol Dependence

MRI studies have been the principal tool to describe in vivo the many sources of neurotoxicity associated with alcoholism, including (1) the direct neurotoxic and gliotoxic effects of ethanol, (2) the neurotoxic effects of poor nutrition that often accompany the abuse of alcohol, (3) the excitotoxicity associated with the ethanol withdrawal state, and (4) the possible disruption in adult-neurogenesis–associated ethanol intoxication and withdrawal. These studies documented a striking age dependence on the overall neurotoxicity associated with alcoholism. Alcohol dependence in adolescents has been associated with pronounced and lasting reductions in cortical volume, suggesting a disruption of a neurodevelopmental process associated with the familial risk for alcoholism or exposure to alcohol. In healthy young adults, careful studies suggest that there are relatively subtle neurotoxic effects of ethanol that may not be present in most heavy drinkers. However, with the onset of “middle age” and progressively thereafter, coincident with increasing cumulative exposure to alcohol and bouts of alcohol withdrawal, there appears to be a progressive sensitivity to alcohol-related neurotoxicity. This toxicity is reflected as loss of both gray and white matter, and these losses appear to be related to cognitive impairments. Gray matter microstructure has been reported to change first, and the damage is more severe in those who drink early, possibly because early heavy drinkers often proceed to heavier drinking than people who begin drinking at a later age. DTI studies provide evidence of disturbance in the integrity of white matter tracks associated with alcoholism. The volumetric changes are particularly severe in patients with Wernicke–Korsakoff syndrome, arising from nutritional deficiency. Generally, there is a gradual and partial recovery of volume loss with extended sobriety, that is, a more rapid phase of volume restoration over several months with some continued recovery over several years. White matter shows evidence of earlier recovery than gray matter, although relapse leads to accelerated white matter damage. Structural MRI research has disproven an early hypothesis that the volumetric brain changes associated with alcohol

Telegram: @medical_k

www.konkur.in

dependence and the initiation of sobriety reflect the dehydration and rehydration of the brain, respectively.

FUNCTIONAL MRI METHODOLOGY

Brain function consumes energy, which is supplied by blood flow to carry oxygen and nutrients to the tissue. Changes in brain function lead to alterations in hemodynamics and blood oxygenation, and such changes affect the magnetization that is detected by MRI. The effects are mediated through the magnetic susceptibilities of oxygenated and deoxygenated hemoglobin, working through local T_2* effects. Deoxygenated hemoglobin perturbs the magnetic field homogeneity in its vicinity, while oxygenated hemoglobin does not. When the level of deoxyhemoglobin increases, the signal in the vicinity of the blood decreases and lower deoxyhemoglobin leads to larger signals around blood vessels. This leads to the phenomenon of BOLD contrast. Sets of images are acquired under two or more conditions, using different functional or pharmacologic challenges, in which case the technique is sometimes called *ph*MRI, and changes in brain function are detected as increased or decreased image intensity (Fig. 1.25–16).

Because brain function is linked to hemodynamics and the extraction of oxygen from the blood, the level of oxygenated hemoglobin depends on brain function. Paradoxically, when brain activity increases, the fraction of deoxygenated hemoglobin *falls* because blood flow increases so dramatically that it overcomes the extraction, and the MR signal in the vicinity of the blood vessel rises. Therefore, if MRI data are acquired in one condition, and then while the patient is performing some cognitive task that increases the oxygen extraction in Area 9, for example, the signal in Area 9 will be higher, with an increase typically on the order of 1 or less. If a cognitive task is selected that instead decreases the utilization of Area 9, then the second image will be darker by a small percentage in Area 9.

Telegram: @medical_k

www.konkur.in

FIGURE 1.25–16. Functional MRI at 3 T during right-hand movement, with sagittal (**left**), coronal (**center**), and axial (**right**) views. The T_1-weighted image forms the base of the display for anatomic identification. A series of images were acquired with the hand alternating between stationary and moving conditions, and then the groups of images were compared to identify regions that showed statistically significant changes in signal during hand motion. The left motor cortex showed activation, with regions of most intense change highlighted.

Although functional magnetic resonance imaging (fMRI) is often said simply to reflect blood oxygenation and/or blood flow, the contrast in fMRI depends on a variety of sources that vary in their degrees of specificity. The mechanisms depend on the diameter of the blood vessels, the blood volume, the rate of blood flow, the amount of deoxygenated hemoglobin in the blood, the strength of the magnet used for the scans, and the method of MRI acquisition. For blood vessels that are larger than 20 μm, it is the *static dephasing* that dominates the signal reduction from deoxygenated hemoglobin. The static dephasing results from the proximity of deoxyhemoglobin in water in the tissue around a blood vessel, and it can be eliminated with a refocusing pulse in a spin-echo–type MRI sequence. For capillary beds and other small blood vessels, the dominant mechanism is *intravascular dynamic dephasing* and *extravascular dynamic dephasing,* which occur when water molecules wander randomly through the area of a distorted magnetic field that surrounds the deoxyhemoglobin. Although intravascular dynamic dephasing provides information about activation, it yields signals that are not always located at the site of activation. The intravascular dynamic dephasing dominates the BOLD response at 1.5 T but exerts progressively smaller effects as field strengths rise. At high magnetic fields such as 7 T, there is a negligible contribution from intravascular dynamic dephasing. The degree of signal

Telegram: @medical_k

www.konkur.in

change from these mechanisms is also influenced by the orientation of each blood vessel with respect to the static magnetic field B_0. The random orientations in capillary beds yield random shifts in B_0 that, once averaged, reduce the signal in a particular image pixel. Larger vessels exert a net change in phase that will also reduce the signal but will do so in an orientation-dependent manner. A change in oxygenation in a large vessel that flows straight across the thickness of a slice will yield an fMRI change that differs from that of a vessel of the same size that flows along the plane of the slice: A different slice orientation can yield a different degree of fMRI signal change even with the same functional task.

Another mechanism of contrast in fMRI is inflow. During an fMRI study, the nuclei in each image slice are repeatedly excited, and the repeated excitations lead to *saturation.* That is, the observed signal from a series of rapid scans is smaller because too little time is allowed for full T_1 relaxation to the maximum Z magnetization. The saturation only occurs for nuclei that have been excited, which are those that are in the slice and remain in the slice. Nuclei that are carried into the slice by blood flow between the scans have experienced no saturation and therefore have greater Z magnetization. They contribute more Z magnetization per unit volume than their resident counterparts. The more saturated the magnetization within the slice, the greater the impact of inflow contrast will be. Inflow contrast is greater when faster scan repetitions and larger slice excitation angles are used. If the blood flow increases, then the spins that arrive will be less influenced by the slice excitation, so increased blood flow contributes a greater signal to the fMRI scan. Any influence that increases blood flow will increase the signal intensity from blood vessels, which may or may not lie in a region of activated tissue, so the inflow contrast contributes nonspecific changes to the fMRI maps.

www.konkur.in

FIGURE 1.25–17. Relative changes of brain energy utilization when changing functional state and their impact on fMRI. The baseline state in the awake human corresponds to a high level of neuronal activity, blood flow, and metabolism. Changes in brain function are typically represented by small changes in brain energy utilization and, as a result, small changes in fMRI image amplitudes. Because fMRI reflects conditions relative to a large baseline, the interpretation of fMRI responses should consider baseline conditions. **Left:** The patient has a higher baseline activity than the control subject, and when the functional task shifts both to the same energetic condition, the patient shows a smaller fMRI response than the control subject. **Right:** The patient and the control subject have the same baseline energy utilization, but the control subject increases energy consumption more than the patient, such that, in this case also, the patient has a smaller fMRI response than the control subject. Other factors that may lead to ambiguities are differences in cerebral vascular coupling to energy demand due to disease or pharmaceutical interventions.

Once the fMRI signal changes have been evaluated, an additional factor must be considered: The meaning of the baseline image. A healthy adult might show an increase of 1% of signal amplitude in the dorsolateral prefrontal cortex (DLPFC) while performing a memory task, while a patient shows a 2% rise in the same region for the same task. In both cases, the baseline activity of the neurons is significant with respect to a variety of pertinent parameters, including electroencephalography (EEG), perfusion, and metabolic measurements (Fig. 1.25–17). One interpretation is that the patient's neural circuitry functions less efficiently and requires more energy to do the same work. An equally viable explanation is that the patient had less baseline activity than the healthy individual but that when the task began, the same region in the patient's DLPFC behaved normally and used a similar amount of energy. In both cases, an abnormality has

Telegram: @medical_k

www.konkur.in

been identified, but the understanding of the underlying pathology differs with the interpretation. When the challenge is pharmacologic, an additional layer of complexity should be considered: The potential influences of the drug, like acute or chronic tobacco use or heavy drinking on the cerebral vasculature, are independent of the functional demands of the tissue.

Taken together, the numerous mechanisms of contrast show that fMRI maps must be considered with respect to their method of acquisition, slice orientation, magnetic field strength, and pharmacologic influence on the cerebral vascular system. The various sources of contrast must be considered when evaluating the meaning and quantity of change that is observed.

APPLICATIONS OF FMRI IN PSYCHIATRY

fMRI is a noninvasive neuroimaging technique that can be used to study the neural correlates of complex cognitive, emotional, and perceptive processes. fMRI research holds tremendous promise for advancing the current understanding of the pathophysiology associated with psychiatric disorders where gross brain structure is preserved, but disruptions of brain function exist. By revealing the neural correlates of symptoms, cognitive biases, and emotional responses, fMRI studies have already been used to elucidate the pathophysiology of dementia, mood, anxiety, psychotic, and addictive disorders and the mechanisms of psychopharmacologic treatments for these conditions. To date, the clinical capabilities of fMRI for informing diagnostic or treatment decisions have not been established. The abnormalities identified by fMRI have thus far lacked sufficient sensitivity and specificity to discriminate individual patients from healthy subjects or from subjects with other illnesses. However, with future advances in the field, such as quantitative fMRI, it is hoped that the technique may ultimately lead the way to a pathophysiology-based classification of psychiatric phenotypes that can be used to improve both research and clinical practice. Examples of such research are provided below.

fMRI of Dementia

fMRI methods provide information that can potentially be used in the study, diagnosis, and prognosis of Alzheimer disease and other forms of

Telegram: @medical_k

www.konkur.in

dementia, as well as providing insights into normal age-related changes in cognitive processing. Evidence that aging is associated with weaker and more diffuse activations, as well as decreased hemispheric lateralization, suggests either compensation for lost regional intensity or dedifferentiation of processing. The weaker activations, especially prefrontally, suggest potential encoding-stage dysfunctions associated with aging. The alterations in these processes that occur with neurodegenerative disease appear to be superimposed on the course of normal aging. fMRI studies have consistently demonstrated that patients with Alzheimer disease have decreased fMRI activation in the hippocampus and related structures within the MTL during the encoding of new memories compared to cognitively intact older subjects, including alterations in what is called the default mode network. More recently, combined PET/structural and fMRI revealed that decreased connectivity was associated with more white matter lesions and greater amyloid burden. Further studies are needed to validate the use of fMRI studies in these populations, particularly longitudinal studies, to investigate the pattern of alterations in functional activity over the course of prodromal Alzheimer disease and the relationship to Alzheimer disease pathology. A major factor to consider is how age- and disease-related changes in vasculature affect the representation of neuronal function by fMRI.

fMRI of Schizophrenia

fMRI has emerged as the primary approach for probing disturbances in the activity of particular brain regions and specified circuits associated with the risk for developing schizophrenia, the symptoms and cognitive impairments associated with schizophrenia, and the impact of antipsychotic treatments. Given the large number of published studies (over 8,700 related papers since 1987 according to PubMed), the range of MR-based approaches included within the rubric of fMRI, and the enormous range of cognitive tests that have been used to stimulate cortical activity, a comprehensive review of fMRI studies of schizophrenia is beyond the scope of this review.

Studies of Low-Frequency Cortical Connectivity

Studies of functional connectivity of brain regions as assessed by fMRI complement the structural evidence emerging from DTI studies that the organization and integrity of white matter tracks are compromised in

Telegram: @medical_k

www.konkur.in

patients with schizophrenia. In these studies, functional connectivity is evaluated by quantifying the covariance of cortical activity across brain regions at rest over extended periods of time.

fMRI studies of perception and cognition alterations associated with schizophrenia support the central hypothesis emerging from MRI, DTI, and functional connectivity studies, that is, that there are widespread alterations in regional brain functional activation that disturb the normal pattern of circuit activation associated with perception and higher cognitive functions including attention, learning and memory, and judgment. Here the neuroimaging issues related to this research are discussed. A common assumption of this research is that these alterations in regional brain activation constitute the basis of the impairments in perceptual and cognitive processes associated with schizophrenia. While this assumption probably applies in a general way to these studies, EPI-BOLD imaging is actually measuring blood flow and volume changes rather than directly measuring neural activation and, as reviewed earlier, current clinical research imaging, typically at 3 T, has modest temporal and spatial resolution with respect to the processes that it attempts to measure. Therefore, it is more accurate to assume that these studies provide an indirect measurement, a biomarker, of neural and glial processes that predominantly occur with spatial and temporal characteristics that exceed the resolution of fMRI. An additional complexity is that the relationship between the demands of a task and its ability to stimulate circuit activation is often nonlinear. That is, it follows an inverted-U pattern. This issue emerged in the study of working memory deficits in schizophrenia, where it was first shown that patients exhibited reduced prefrontal cortex activation when performing tasks that put demands on working memory. Later, using tasks of graded difficulty, it was shown that patients actually showed prefrontal hyperactivation relative to healthy subjects in response to easy tasks but began to show functional activation deficits in response to moderately difficult tasks when healthy individuals were showing further increases in prefrontal cortex activation.

There are a number of additional challenges associated with the interpretation of fMRI studies of schizophrenia. First, because of widespread disturbances in brain structure, it is difficult to ascribe the underlying abnormality to the structure that performs abnormally, as opposed to its inputs. This limitation has profound implications for cognitive functions that are organized in a hierarchical or “bottom-up”

Telegram: @medical_k

www.konkur.in

fashion. That is, judgment depends on memory, which depends on attention and perception. But there are also executive or “top-down” controls of these processes. That is, we are more effective in perceiving and remembering stimuli that we expect or seek. From this perspective, the effort to determine the “central” cognitive impairments of schizophrenia and to ascribe particular cognitive impairments to particular brain regions is a challenging task. Second, because of their circuitry dysfunctions, individuals with schizophrenia may perform more poorly on tasks, or they may successfully perform particular tasks differently than individuals without schizophrenia, analogous to the way that individuals with hearing deficits learn to read lips. With regard to performance failure, studies typically select tasks that can be performed successfully by individuals with and without schizophrenia. However, there are many questions related to the performance deficits themselves. In this case, studies often use tasks with graded levels of difficulty so that the relationships between task difficulty, cortical activation, and performance may be determined. With regard to the second issue, it can be very difficult to know whether divergence between people with and without schizophrenia arises from the primary circuitry dysfunction or from the different strategies that these groups tend to use to solve the same types of problems. This highlights a critical issue for functional neuroimaging, which is the need to define the structures of what people do and how they do it. Since one cannot obtain perfect control of these issues, it is useful and important to evaluate performance and, if possible, strategy. The effort to map circuitry dysfunction associated with schizophrenia, already challenging for the reasons outlined above, is made more difficult because the engagement of brain circuits in cognitive processes is highly state dependent and therefore varies with the level of emotional arousal, the impact of other state-dependent processes (such as the symptoms of schizophrenia), the presence of other neurobiologic modulators (such as the impact of therapeutic medications, exposure to substances of abuse, and other psychiatric and medical comorbidities).

fMRI of Mood Disorders

Over 1,200 fMRI studies exploring various aspects of circuitry related to mood and mood disorders have been reported. Studies investigating the neural circuitry mediating adaptive emotion regulation and cognition have been instrumental in advancing the current understanding of the

Telegram: @medical_k

www.konkur.in

pathophysiology of mood and anxiety disorders. Functional imaging studies using PET, SPECT, and fMRI spectroscopy performed over the last decade have provided us with a much greater understanding of the structure and functional correlates of emotional and cognitive processing as well as mood regulation. Since individuals showing vulnerability to or suffering from episodes of depression, mania, and anxiety appear to exhibit impaired cognitive processing and a decreased ability to effectively regulate mood and affect. These findings are considered highly informative in identifying regions of specific interest to the neurobiology of the disorders. Functional brain imaging studies have identified critical neural circuits that modulate emotional behavior. Several frontolimbic networks including (1) the limbic–thalamic–cortical (LTC) circuit, comprising the amygdala, mediodorsal thalamus, and orbital and medial prefrontal cortices, and (2) the limbic–cortical–striatal–pallidal–thalamic (LCSPT) circuit, which includes components of the LTC circuit as well as areas of the striatum and pallidum, have emerged. Reciprocal connections between the various regions within the circuits are believed to modulate emotional responses. The use of fMRI to study the contributions of these networks to the pathophysiology of mood and anxiety disorders provides several unique advantages. The modality offers excellent spatial and temporal resolution relative to other methodologies, allowing the integration of cognitive and emotional tasks that serve as probes to activate the specific networks and further elucidate the interconnectedness of the individual structures. However, it is important to understand that the measures are always made relative to other measures of brain activation and cannot be considered absolute measures of brain activity.

Although, as would be expected based on the heterogeneity of the illnesses and the multitude of study designs employed in the exploration, the method has yielded many inconsistent findings related to the function of these networks in individuals with mood and anxiety disorders, there is a growing consensus that disruptions in the function of these circuits do contribute to the pathophysiology of these disorders. For example, several groups have found activation of the amygdala, a region involved in the identification and signaling of emotionally significant stimuli, to be increased and abnormally sustained during emotional task performance in subjects diagnosed with mood and anxiety disorders. Interestingly, abnormal amygdalar activation has also been observed in healthy

Telegram: @medical_k

www.konkur.in

individuals with the short allele of the functional promoter polymorphism for the serotonin transporter gene, suggesting a possible link to the increased stress-related susceptibility to depression associated with the genotype.

The cingulate cortex, another region commonly found to exhibit abnormal patterns of cerebral blood flow (CBF) and metabolism in mood and anxiety disorder, patients receive inputs from the thalamus, as well as several cortical regions, and projects to the amygdala and entorhinal cortex via the cingulum. It functions as an integral component of the limbic system, being specifically involved in emotional processing, learning, memory, and the suppression of inappropriate unconscious priming. Activation of the subgenual anterior cingulate cortex (ACC) has repeatedly been measured to be decreased in unipolar and bipolar depression relative to control samples. However, after volume reductions in this region identified by MRI studies have been accounted for, it is possible that the remaining tissue in this area actually exhibits relative hypermetabolism. Depressed patients have been found to have greater activation of this region during the processing of sad stimuli.

Abnormal activation patterns of two other prefrontal cortical regions have also consistently been found to be associated with mood and anxiety disorders. Several studies have reported abnormally elevated levels of CBF and metabolism in the orbital cortex as well as in the ventrolateral prefrontal cortex (VLPFC) (a region believed to play a role in the learning of new affective stimulus associations and the reversal of previously learned associations) in individuals with mood and anxiety disorders. Dysfunction of these regions is postulated to predispose individuals to the perseverative cognitions and emotional responses characteristic of depression. fMRI studies have demonstrated an inverse relationship between the amygdala and ventromedial prefrontal cortex (VMPFC) activation when healthy individuals reappraise the affective meaning of negative pictures. Individuals showing increased VMPFC and decreased amygdala activation during reappraisal show steeper, more adaptive diurnal patterns of daily cortisol, suggesting that the capacity to successfully modulate limbic circuitry has implications for well-being in daily life. A recent study demonstrating a significantly different correlation between VMPFC and amygdala activation in control versus depressed individuals during an effortful affective reappraisal task further supports this notion.

Telegram: @medical_k

www.konkur.in

The DLPFC, a region specifically activated by cognitive tasks related to working memory and attention, has been consistently shown to exhibit abnormal reductions in CBF and metabolism associated with depression. The reduced activity of this region in response to cognitive task performance has been related to the deficits in cognitive performance characteristically observed in conjunction with mood disorders. Several fMRI studies demonstrate decreased DLPFC activity in response to cognitive tasks. Similar to the VLPFC, recent studies also find that depressed individuals display decreased relationships between the amygdala and DLPFC activity, potentially signifying decreased functional relationships among these structures.

The thalamus and the basal ganglia have extensive connections with the amygdala as well as the orbital cortex, VLPFC, and cingulate cortex. In addition, the ventral striatum receives key projections from the ventral tegmental area (VTA), comprising part of a critical reward pathway of the brain. Unipolar depressed and bipolar depressed subjects both manifest abnormal increases in metabolism and CBF in the left mediodorsal nucleus of the thalamus. Functional imaging studies of these regions in mood disorder subjects have shown them to have a decreased striatal response to happy stimuli during episodes of depression and increased striatal activity in a manic state.

In summary, functional imaging studies afford a new window into the neural circuitry of emotional and cognitive processing, thus providing novel information that can be used in the generation and testing of new hypotheses. In conjunction with work derived from other branches of cognitive neuroscience, these studies have led to the general hypothesis that mood and anxiety disorders result from impaired function of the LCSPT circuits responsible for regulating emotional and cognitive processing. Specifically, a “bottom-up” model has been presented in which overactivation of limbic structures such as the amygdala drives enhanced emotional responsiveness to stimuli and further decreases the ability to effectively cognitively process the incoming stimuli due to reciprocal inhibition of the DLPFC. A second “top-down” model postulates that the ability of higher-order cortical structures to modulate limbic activation is impaired in individuals with mood and anxiety disorders. Several studies have used fMRI protocols to identify specific activation patterns reflecting the top-down or bottom-up models that seem to be associated with treatment response. Additional studies are now underway

Telegram: @medical_k

www.konkur.in

to further explore the potential clinical relevance of these models and to determine if the patterns of activation could be used to predict differential treatment responses to the various treatment interventions available.

fMRI of Alcohol Dependence

fMRI studies have provided insights into the functional consequences of alcoholism-related neurotoxicity. Studies suggest that recovering alcohol-dependent patients show abnormal activation patterns in the frontal cortex, thalamus, striatum, cerebellum, and hippocampus related to impairments in attention, learning and memory, motor coordination, and inhibitory control of behavior. Studies have begun to explore pharmacologic modulation of resting circuit activity to probe mechanisms underlying circuit dysfunction in alcoholism, illustrated by blunted responses to benzodiazepines.

Studies also have provided insights into the vulnerability to alcoholism. Adolescents and adults who abuse alcohol or who are at risk for abusing alcohol show circuit-related dysfunction associated with reward anticipation, response inhibition, control of attention, and other dimensions of cognition. In addition, these individuals show increased limbic and orbitofrontal cortex activation when exposed to alcohol-related cues that elicit alcohol craving, associated with structural abnormalities of the brain. Studies are now attempting to utilize these craving-related changes in fMRI for testing putative pharmacotherapies for alcoholism.

^{1}H MRS

In 1983, a spectra of small metabolites, including glutamate and GABA, were observed in the living rat brain by Kevin Behar in the laboratory of Robert Shulman at Yale University. Since that time, MRS studies of the brain have expanded enormously in their variety and in their applications to the study of the human brain. Today, MRS is applied throughout much of the world for diagnosis and basic research on the brain in health and disease.

MRS employs the differentiation of molecules, primarily on the basis of their frequencies. The most commonly used nuclei have been ^{1}H, ^{31}P, and ^{13}C. Figure 1.25–9B shows an example of a ^{1}H MR spectrum obtained in a human brain. The primary components of the MR spectrum are methyl groups of creatine and phosphocreatine, choline, and *N*-acetylaspartate

Telegram: @medical_k

www.konkur.in

(NAA). The two creatine compounds have resonances that overlap in vivo, so they appear as a single peak. Although creatine and phosphocreatine play key roles in cellular energetics, their combined level remains constant in the face of even severe acute challenges such as ischemia. Some chronic effects such as aging have been reported to increase, decrease, or have no effect on levels of tissue creatine, and this is one of the areas that are currently under active investigation in the MRS community. The choline resonance, comprised primarily of phosphocholine and glycerophosphocholine, is believed to reflect membrane degradation and synthesis, with a negligible contribution from acetylcholine. NAA is found primarily in glutamatergic neurons, including neuronal processes, and it is synthesized by *N*-acetyltransferase, a mitochondrial enzyme. Glia have transporters to import NAA and also contain the enzyme that degrades NAA, raising the possibility of a shuttle of NAA from neurons to glia. Indeed, there is evidence that the acetyl group of NAA is incorporated into myelin. Until the early 1990s, decreases in NAA were believed to signify neuronal death, but since that time, studies have found conditions in which NAA decreases and then recovers. NAA is now believed to represent neuronal health, viability, or mitochondrial integrity.

Much of MRS research has been based on these three metabolites that dominate the ^{1}H MR spectrum. Clinical applications have been proposed, including the diagnosis and evaluation of Alzheimer's disease (AD), hepatic encephalopathy, and other disorders. Other metabolites of neurochemical interest that can be detected using ^{1}H MRS are myoinositol, glutamate, glutamine, GABA, and glutathione (GSH), and these have all been scrutinized from a research perspective in a variety of neuropsychiatric disorders. Glutamate, glutamine, and particularly GABA have required advanced MRS methods for detection in the human brain because they overlap with one another and are modulated into complex patterns under the influence of *J*-coupling. Methods classed as *spectral editing* are used to isolate the signals of GABA, glutamate, GSH, and other compounds from larger, overlapping resonances. Research is currently under way to assess if and how total tissue levels of glutamate and glutamine with respect to neurotransmitter activity and whether any of the MRS-detected chemicals can indicate neuroinflammation.

Magnetic resonance spectroscopic imaging (MRSI), also called *chemical shift imaging* (CSI), combines the power of chemical

Telegram: @medical_k

www.konkur.in

discrimination with the ability to map their spatial distribution, and it is most commonly implemented for ^{1}H MRS. Because the signals from most detected neurochemicals are typically five to six orders of magnitude lower than that of water, the signal-to-noise ratio is much lower for MRSI measurements, significantly longer acquisition times are required to obtain adequate sensitivity, and the resolution is lower than what is normally used for MRI. However, the ability to view large areas of the brain simultaneously has led to the beginnings of clinical applications of this approach to conditions in which abnormalities must be localized, as in epilepsy, and conditions of dispersed changes in the brain, such as multiple sclerosis and alcoholism.

FIGURE 1.25–18. ^{31}P MRS in a healthy volunteer, using a 4-T magnet. **Left:** T_1-weighted image obtained with inversion recovery to null the CSF and create contrast between gray and white matter. **Right:** Spectrum that shows, from left to right, phosphomonoesters (PMEs), inorganic phosphate (P_i), phosphodiesters (PDEs), phosphocreatine (PCr), and the γ, α, and β phosphate residues of the nucleotide phosphates. (Courtesy of Jullie Pan, M.D., Ph.D. University of Missouri Columbia.)

^{31}P MRS

In 1978, Britton Chance and colleagues published MR spectra of the phosphorylated metabolites in the brain of a living mouse. ^{31}P MRS yields measurements of high-energy compounds, including phosphocreatine and adenosine triphosphate (ATP), and it can provide measurements of phosphomonoesters (PMEs) and phosphodiesters (PDEs) (Fig. 1.25–18), with applications to study schizophrenia, depression, and other disorders. The ^{31}P isotope nucleus is much less sensitive than that of ^{1}H on a per-atom basis, and further sensitivity is lost when one considers that many of

Telegram: @medical_k

www.konkur.in

the ^{1}H resonances represent methyl or ethylene groups that provide three or two nuclei per resonance instead of just one. Favoring sensitivity is the fact that 100% of naturally occurring phosphorus is the isotope ^{31}P. The unique information that it provides on high-energy phosphates and other metabolites without destroying the tissue make it a powerful tool for brain research. Some laboratories are applying MRSI of ^{31}P to map these neurochemicals throughout the brain.

The dominant resonance in the ^{31}P spectrum of the brain is that of phosphocreatine, which by convention is assigned a chemical shift of 0 ppm. To the right are three resonances that represent the γ, α, and β resonances of nucleotide triphosphates (NTPs). To the left are the PME, PDE, and inorganic phosphate. The PME and PDE resonances are believed to reflect mobile components of lipids and membrane metabolites. Inorganic phosphate is free phosphate that has been released from phosphocreatine and ATP during energy consumption. In cases of extreme insults, such as ischemia, the phosphocreatine resonance falls, the NTP resonances decrease, and the inorganic phosphate peak rises as the high-energy phosphate pool is exhausted and the phosphate groups are released. In psychiatric disorders, the changes are generally more subtle, with some reports of altered PME or PDE, although the directionality and extent of the changes are uncertain at this time. Recent advances have moved kinetic studies of ^{31}P metabolism to application in the brain, from muscle, where they have been used for many years. A technique called *saturation transfer* reduces the signal of ^{31}P in one chemical, like phosphocreatine, and then tracks the signal reduction in ATP when the phosphorus is transferred from phosphocreatine to ATP. This approach has allowed the measurement of phosphocreatine and ATP synthesis in the brain.

^{13}C MRS

Less common is ^{13}C MRS, used to detect the nonradioactive isotope carbon-13, which naturally occurs as 1.1% of the world's carbon. Like most ^{1}H MRS and all ^{31}P MRS, ^{13}C MRS remains a research tool, and in that role, it has proven useful for the measurement of the kinetics of neuroenergetic processes and neurotransmission. Its primary application in the brain has been the measurement of carbon oxidation and glutamate–glutamine neurotransmitter cycling.

Telegram: @medical_k

www.konkur.in

^{13}C carries the powerful advantage of a broad chemical shift dispersion that allows the resolution of many metabolites that cannot be resolved in the ^{1}H MR spectrum. For example, glutamate and glutamine C4 and C3 resonances are completely resolved even at a magnetic field strength of 1.5 T, with the resolution improving further at higher field strengths. The great disadvantage of ^{13}C is that its sensitivity is even less than that of ^{31}P on a per-atom basis, and the sensitivity is further reduced by its low natural abundance. However, that low natural abundance can be turned into an advantage if viewed from the perspective that it contributes very little background signal (Fig. 1.25–19). That low level of background means that if ^{13}C is introduced into metabolic pathways and is incorporated into neurochemicals, then almost everything that is detected is known to result from the added carbon. This was first done in cell suspensions and then rabbits and rats and is now applied by several laboratories to studies of metabolism in the human brain. The most commonly used method today is the administration of ^{13}C-glucose or ^{13}C-acetate, which leads to the labeling of glutamate, glutamine, and GABA through glycolysis, oxidation, and the release and trafficking of neurotransmitters among neurons and astrocytes. The incorporation of ^{13}C is tracked over time simultaneously in multiple metabolites, and the more rapid the metabolic processes in the relevant pathways, the faster will be the appearance of the ^{13}C in the MR spectra. The glucose generally provides more information about neurons, while acetate yields greater sensitivity to glial metabolism.

Telegram: @medical_k

www.konkur.in

FIGURE 1.25–19. ^{13}C MR spectra from a human brain before (**bottom**) and during (**top**) a 2-hour infusion of [1–^{13}C]glucose. Before the infusion, only the 1.1% natural abundance signals can be seen in the spectrum. When exogenous ^{13}C is provided in glucose, through metabolism, the isotope appears in numerous products in the brain and can be detected with ^{13}C MRS. On the left can be seen the glucose itself. The largest single resonance is that of the C4 of glutamate (Glu C4). C3 and C2 of glutamate are also present, as are C4, C3, and C2 of glutamine (Gln). GABA is labeled at the C2, C3, and C4 positions, and aspartate (Asp) is labeled at C2. Lactate (Lac) is labeled at the C3 position. NAA and creatine (Cr) appear similar in the natural abundance and labeled spectra because their synthesis is too slow for significant labeling to occur in 2 hours.

Different methods have been developed to detect ^{13}C, with the appropriate choices based on the applications. The simplest approach is *direct detection,* which requires excitation and detection only of the ^{13}C nuclei. The sensitivity can be increased up to threefold by preapplying radio frequency at the ^{1}H frequency, in what is called the nuclear Overhauser effect (NOE). *Polarization transfer,* a more complex approach, can increase the sensitivity by up to a factor of four by transferring some of the larger polarization of coupled ^{1}H nuclei to the ^{13}C nuclei through covalent bonds, and for the acquisition, the ^{13}C nuclei are observed. *Proton-observed/carbon-edited* (POCE) spectroscopy provides a greater improvement in sensitivity. POCE detects ^{1}H that are bonded to ^{13}C, and because the ^{1}H nuclei are observed, the detection has a much greater

Telegram: @medical_k

www.konkur.in

sensitivity of ^{1}H MRS. The greater sensitivity means that volumes of a few milliliters can be studied instead of 75 mL or more for the methods that acquire data in the ^{13}C domain. The primary disadvantage is that the detection in the ^{1}H domain eliminates the benefits of the high resolution available from the ^{13}C chemical shift dispersion. *Heteronuclear single quantum coherence spectroscopy* (HSQC) provides a way to achieve the resolution available in the ^{13}C spectrum with the sensitivity of the ^{1}H acquisition by yielding data that simultaneously contain the information that would be seen by acquiring both nuclei, and this holds promise for achieving higher spatial resolution.

APPLICATIONS OF MRS IN PSYCHIATRY

As MRI provides information about brain structure and fMRI provides information about regional brain function, MRS provides information related to brain chemistry and metabolism. In many ways, it is the youngest and least developed of the MR methodologies, and until more recently, its application to psychiatry has also been limited by its relatively poor spatial and temporal resolution and need for technical expertise. However, the information provided by MRS studies in vivo over the past decade has proven valuable in identifying neurochemical and metabolic abnormalities associated with several psychiatric disorders that have helped to reshape the current thinking related to the pathophysiologic models of these disorders. With the advent of improved MRS imaging techniques and dissemination of expertise, the modality is gaining greater application to psychiatric research that is allowing the field to examine novel hypotheses related to pathophysiology and pathogenesis of psychiatric disorders.

MRS in Dementia

^{1}H MRS presents the opportunity to obtain noninvasive measures of several neurochemicals related to neurotransmission, energy metabolism, and cellular function. Studies using ^{1}H MRS have shown a trend for a general reduction in NAA measures with increasing age in medial temporal and frontal cortical brain regions, but with greater decreases in dementia and NAA levels related to plaque density. NAA is perhaps the most reliably measured metabolite in the brain due to it being present between 7 and 13 mmol/kg and the physical characteristics of the

Telegram: @medical_k

www.konkur.in

molecule (presence of identical three hydrogen atoms on a methyl group that provide triple the sensitivity of what would be provided by a single proton). As mentioned above, the significance of brain NAA content is not completely understood. It is commonly believed to serve as a marker of neuronal health, but it is also known to reflect aspects of mitochondrial energy metabolism and myelin maintenance. The studies on MCI and AD are in general agreement, reporting patients with these disorders to have decreased levels of NAA and increased levels of myoinositol (a form of inositol normally found in the brain that contributes to osmotic regulation) compared to those of age-matched comparison subjects. One interpretation is that decreased NAA and increased myoinositol are related to the loss of neurons and an increase in gliosis. However, the loss of NAA may reflect decreases in neural function. This hypothesis is supported by the fact that the changes in NAA can be reversed in some conditions. Several groups have also reported a correlation between the reductions in NAA content and clinical neuropsychological scores. Interestingly, this correlation has also recently been reported in healthy volunteer subjects.

Overall, studies of other metabolites have been less convincing in relationship to AD and other dementias, but a few studies suggest decreased levels of glutamate and elevated levels of glutamine can be found in subjects with MCI impairment and AD. Together these findings are believed to reflect a combination of ongoing metabolic dysfunction and increased gliosis. At present, there is no clinical use of MRS in the diagnosis or treatment of dementia.

MRS in Schizophrenia

^{1}H MRS has been applied widely in studies of cortical chemistry in schizophrenia. These studies documented reductions in NAA levels in many cortical and limbic brain regions in schizophrenic individuals and smaller reductions in family members of people diagnosed with schizophrenia. NAA level reductions have been described in some brain regions in medication-naïve patients, but there also do appear to be progressive reductions with advancing illness and continued antipsychotic treatment. Because NAA is localized to neurons, reductions in NAA levels may reflect the postmortem findings of reduced neuronal size and reduced dendritic arborization as well in vivo evidence from DTI studies of disturbances in the integrity of long fiber pathways. However, NAA is

Telegram: @medical_k

www.konkur.in

synthesized by a mitochondrial enzyme. As a result, reduced NAA levels may reflect metabolic disturbances that may be related to mitochondrial dysfunction suggested in postmortem studies or regional metabolic alterations associated with the pathophysiology of schizophrenia or the impact of treatment. This possibility is consistent with the emerging differences between the impact of typical and atypical antipsychotic treatment on NAA levels in patients. Other metabolites have been measured in ^{1}H MRS studies of schizophrenic patients. The most interesting findings to date may be the description of normal or low levels of glutamate and GABA and increased levels of glutamine in medication-free patients with schizophrenia, with evidence accumulating that medication may be responsible for some of the abnormal metabolite levels reported in schizophrenia. Nonetheless, metabolite alterations are observed in high-risk patients prior to the onset of illness and in the early course of schizophrenia. Brain glutamine is synthesized primarily by glia from glutamate which emerges as a by-product of energy metabolism, as well as from glutamate that is taken up by glia following its release by neurons and glia in the context of excitatory neurotransmission. Thus, it is possible that the alterations of glutamine and glutamate in individuals diagnosed with schizophrenia could reflect changes in glutamatergic neurotransmission.

A number of other metabolites have been examined using ^{1}H MRS and ^{31}P MRS in patients with schizophrenia, including glutathione, choline, PME, and PDE. These metabolites are of potential interest because studies of these metabolites suggest that schizophrenia is associated with inflammation and abnormalities in membrane integrity and might be reflective of disturbances in the processing of myelin suggested by postmortem and clinical molecular genetic studies. However, the relationships of these metabolites to specific membrane disturbances associated with schizophrenia remain unclear. Also, in the ^{31}P MRS studies, inconsistencies in the findings made by various groups have called these findings into question, generally. However, they may be consistent with recent findings using magnetization transfer that oxidative phosphorylation is slower in schizophrenia, using a volume of tissue that included a large fraction of white matter indirectly suggest that myelin may be compromised in patients with schizophrenia.

MRS in Mood Disorders

Telegram: @medical_k

www.konkur.in

There has been a rapid increase in the use of MRS in the study of mood and anxiety disorders over the past decade. While the methodology does not yet enter into the clinical practice related to the diagnosis and treatment of mood disorders, it has in part led to an evolution in the concepts of the pathophysiology of the disorders. The majority of studies have used either ^{1}H MRS or ^{31}P MRS to provide information about the abnormalities in neurochemistry and energy metabolism associated with the illnesses. A few other studies have used ^{7}Li and ^{19}F MRS to study the pharmacokinetics and brain concentrations of drugs used in the treatment of mood and anxiety disorders. Recent new work suggests that the use of ^{13}C MRS and ^{31}P will be useful in further defining the pathophysiology of the disorders.

To date, ^{1}H MRS has been the most widely used MRS methodology in the study of mood disorders. While the technology continues to evolve, several of the measures are becoming more routine and reliable, thus allowing for investigators to more confidently draw conclusions from data obtained at different sites using different protocols and spectrometers.

There have been over 200 published studies examining NAA levels in relation to mood and anxiety disorders. However, due to the heterogeneity of the illnesses studied and the variety of regions examined, it remains difficult to draw firm conclusions regarding NAA's contributions to the neurobiology of mood disorders. In general, there have not been consistent findings showing NAA changes in association with major depression. Yet, there have been specific studies suggesting that NAA may be reduced in the hippocampus of depressed and anxious patients. There is also some evidence suggesting that NAA levels may be reduced in the frontal lobe of bipolar patients, potentially serving as a diagnostic marker. The creatine peak is believed to remain relatively constant in most disorders, leading to the use of creatine as an internal standard in many studies. Studies examining creatine in relation to mood disorders appear to be in general agreement with this view, but exceptions do exist. Choline is an essential precursor to membrane lipids and the neurotransmitter acetylcholine. A series of studies seem to demonstrate elevated choline levels in the basal ganglia of mood disorder subjects compared to those of healthy comparisons. These studies have been suggested as evidence of altered membrane turnover and impaired signal transduction mechanisms within the basal ganglia of patients.

www.konkur.in

As the major inhibitory and excitatory neurotransmitters in the brain, it is not surprising that the amino acid neurotransmitters GABA and glutamate have been linked to the pathophysiology of several neuropsychiatric disorders, thus making them extremely interesting targets for MRS investigation. Due to overlapping resonances, these compounds are more difficult to measure using standard ^{1}H MRS methods. This has delayed the use of MRS to study the amino acid neurotransmitters and led many to use the term Glx to refer to the combined measure of the GABA, glutamate, and glutamine. With the development of several new editing techniques, several groups are now capable of isolating the individual peaks. The relatively recent application of MRS to investigate amino acid neurotransmitter systems has proven highly productive in the area of mood disorders research, and there is mounting evidence that suggests markedly abnormal concentrations of GABA and glutamate in several brain regions of mood and anxiety disorder patients. Furthermore, recent studies suggest that antidepressant treatments may be capable of reversing some of these abnormalities. These data helped to increase the awareness of the potential role of the amino acid neurotransmitters in the neurobiology of mood disorders and the mechanism of antidepressant action. Since it is now recognized that glial cell function is critical to amino acid neurotransmitter metabolism, these data, in conjunction with several postmortem findings, have also provided support for a pathophysiologic model of glial cell impairment in relation to MDD. Recent observations of altered brain glutathione levels in mood disorders may also be related to alterations in glial/neuronal interactions.

^{31}P MRS provides in vivo measures of brain membrane phospholipid metabolism, high-energy phosphate metabolism, and intracellular pH. Initial ^{31}P MRS studies in bipolar disorder set out to test the hypothesis that the phosphoinositide pathway is enhanced in bipolar disorder and to explore the contributions of membrane phospholipids and membrane defects in bipolar disorder by measuring levels of PME and PDE. A meta-analysis of these studies found significant diagnosis- and mood state–dependent abnormalities in PME content in patients with bipolar disorder, which suggests dysregulation of brain-signal transduction systems and membrane metabolism may have relevance in bipolar disorder. Further, they suggest that lithium treatment increases PME levels, providing a possible clue into the mechanism of action. Beyond concentration levels, in patients with first-episode bipolar disorder, kinetic ^{31}P MRS has also

Telegram: @medical_k

www.konkur.in

shown slower transfer of phosphate between ATP and phosphocreatine, an aspect that may have profound consequences, given that phosphocreatine functions as a high-energy reserve to maintain levels of ATP.

Other studies have attempted to evaluate whether neuroenergetic defects are related to mood disorders by measuring the concentrations of nucleotide phosphates (the three phosphate residues from NTP) and phosphocreatine. In general, these studies have found lower levels of nucleoside phosphates in the basal ganglia of subjects in depressive episodes, suggesting that high-energy phosphate metabolism is altered in the basal ganglia of subjects with depression and drawing attention to the possible role that the mitochondria may play in mood disorders.

Reduced pH_i has been observed in pathologic states arising from ischemic insult to the brain. Abnormalities in pH_i concentration have also been reported in bipolar subjects. Several studies have found significantly reduced pH_i in both the basal ganglia and whole brain of bipolar subjects in the euthymic state, while other studies have found increased pH_i levels to be associated with the bipolar and depressed states. While the specific pathophysiology underlying these effects remains unknown, the findings have helped to focus attention on the potential contributions of neuroenergetics to mood disorders.

As described earlier in this chapter, the unique physical properties of ^{13}C make it an excellent tool to measure rates of glucose metabolism as well as amino acid neurotransmitter cycling and being a stable isotope, it does not present the risks and challenges associated with radiochemical research. Studies using glucose labeled with ^{13}C have been used to measure the rates of glucose oxidation, glutamate/glutamine cycling, and GABA synthesis. Studies using ^{13}C-labeled acetate have recently yielded measures of glial cell metabolism, a potentially valuable tool considering the recent findings suggesting that glial cell pathology may play a prominent role in the neurobiology of mood disorders. Although the application of ^{13}C MRS in vivo is relatively new to psychiatry, recent data show significantly lower rates of oxidative metabolism in unmedicated patients with major depression. A conceptually new direction is the use of ^{13}C MRS kinetic measures to measure synaptic strength as a test of long-term potentiation/long-term depression using Vtca/Vcycle. Future studies using this modality are likely to provide new insights into the association

Telegram: @medical_k

www.konkur.in

relationships between mood disorders, neuroenergetics, amino acid neurotransmitter functioning, and glial cell function.

MRS in Alcohol Dependence

^{1}H MRS studies evaluating NAA and choline have provided neurochemical evidence that complements the MRI findings related to the emergence and recovery from alcohol-related neurotoxicity. ^{1}H MRS studies of GABA have provided insights into alterations in cortical inhibitory neurotransmissions associated with the recovery from alcohol dependence. During acute withdrawal, cortical GABA levels appear to be normal, consistent with animal studies. With recovery from alcohol dependence, cortical GABA levels appear to decline and may be significantly below the level seen in healthy subjects with extended sobriety. These time-dependent changes in cortical GABA levels during sobriety have been hypothesized to reflect a recovery from the adaptations in $GABA_A$ receptor populations produced by chronic ethanol exposure. ^{13}C measures may reveal factors that promote energetic factors, which promote heavy drinking and relapse, such as the enhanced ability of the brain to oxidize alcohol and its metabolic product, acetate. To the extent that the brain becomes dependent on acetate as a fuel, withdrawal from alcohol may be compounded by the near-absence of circulating acetate once patients stop drinking. Further, when alcohol is oxidized, it creates acetaldehyde, which has been shown to have rewarding properties inside the brain, even though systemically acetaldehyde is aversive.

^{7}Li and ^{19}F MRS

A few studies have attempted to use ^{7}Li MRS to study the pharmacokinetics of lithium as it relates to the treatment of mood disorders. These studies have demonstrated that lithium relatively rapidly clears the BBB and has approximately a 28-hour half-life in the brain. A potentially powerful clinical application of the methodology is the ability to measure brain concentrations of Li relative to serum levels and to assess intracellular versus extracellular lithium. While limited in number, these studies seem to suggest only a modest correlation between serum lithium levels that are commonly used to titrate treatment dosage and brain lithium concentration. Similarly, studies have employed ^{19}F MRS to determine the pharmacokinetics and the relationship between serum and

Telegram: @medical_k

www.konkur.in

brain levels of fluorine-containing drugs such as fluoxetine and fluvoxamine. While such studies are of limited clinical usefulness at present, they may be useful in determining dose-response relationships for other compounds in the future.

FIGURE 1.25–20. Deuterium metabolic imaging (DMI) shows the aberrant glucose metabolism known as the Warburg effect in a patient with an aggressive brain tumor. DMI detects deuterium-labeled substrates and their

Telegram: @medical_k

www.konkur.in

downstream metabolites in vivo using a standard MRI scanner. In the case of glucose, the administration is as simple as drinking the water-dissolved ^{2}H-glucose. The method can be applied in different organs, such as the brain and the liver, and using different deuterium-labeled substrates to measure different metabolic features. This simple and robust MRI method can be easily integrated into existing scan protocols and can become a widespread metabolic imaging modality available in the clinic. (Reprinted with permission of AAAS from De Feyter HM, Behar KL, Corbin ZA, et al. Deuterium metabolic imaging (DMI) for MRI-based 3D mapping of metabolism in vivo. DEUTERIUM METABOLIC IMAGING (DMI)

A recent development that is likely to find practical, widespread use is the MRS of the ^{2}H isotope of hydrogen, commonly known as deuterium, to measure metabolism. Although the isotope has much lower sensitivity than ^{1}H, it has several advantageous qualities. ^{2}H has short T_1, which allows rapid repetitions to accumulate sufficient signal to generate 3D images that currently have resolution similar to that seen with PET. ^{2}H also has a very low natural abundance, a small fraction of 1%, so there is essentially no background signal if one wants to administer ^{2}H as a metabolic tracer. ^{2}H has a very short T_2, which means that distortions of the magnetic field homogeneity in regions of importance to psychiatry (e.g., the orbitofrontal cortex) are negligible by comparison, as well as robustness due to the low resonance frequency, and so metabolism can be accessed throughout the brain (Fig. 1.25–20), without the regional limitations that affect MRS of ^{1}H, ^{13}C, ^{31}P, and some other prominently used isotopes. While ^{2}H in large quantities can cause nausea, DMI uses doses that are far lower, with subjects experiencing no ill effects. Deuterium ultimately clears from the body in the form of water, and measurements can be repeated safely. For some applications, the deuterium can be administered orally in the form of deuterated water or as a glucose solution. A very important aspect of the method is the simplicity: the electronics and software to acquire the data are among the simplest possible for NMR.

PRACTICAL CONSIDERATIONS

Telegram: @medical_k

www.konkur.in

Although the technology invokes some complexities, there are practical considerations of safety and comfort that are of great importance when considering a possible MRI or MRS scan for a patient.

Safety

The primary consideration is the safety of the patient. MRI and MRS are considered to be among the safest ways to examine the human body. Because MRI and MRS use magnetism and radio waves, and not X-rays, they are not known to be mutagenic or associated with cancer risk–like methods that use ionizing radiation. Radio waves can cause heating of tissue, including the brain, so the U.S. FDA has set guidelines for magnet strength and exposure to radio waves, and the manufacturers and operators of MR equipment carefully observe those guidelines. For exposure to the radio frequencies, powers, and durations that are used in human MR scans, no harmful effects have been seen.

MRI and MRS pose some risks for certain people. People who have a pacemaker or certain metal objects inside their bodies are generally not candidates for MR scans because the strong magnets in the MR scanner might cause the implants to malfunction or move. Aneurysm clips pose a particularly major risk. As current technologies increase magnetic field strength, one must take care with metallic products that are designated to be MR-safe. As far as can be achieved, companies attempt to maintain the necessary qualities of their products while removing as much of the ferromagnetism from the material as possible. However, trace levels of ferromagnetism may remain, posing a greater risk as magnetic field strengths increase. The claims of MR compatibility are generally true for the magnetic field strength of 1.5 T or lower, and in some cases, the devices are safe at 3 T. However, many devices have not been tested above 1.5 T, and fewer still above 3 T, so for now, many metallic implants pose an unknown and unacceptable risk above 3 T and should be checked individually for compatibility at a given magnetic field strength.

Another risk is that of a metallic object flying through the air toward the magnet and hitting the patient. To reduce this risk, MR facilities usually require all personnel, including the patient, to remove all metal from their clothing and all metal objects from their pockets. In many cases, patients will be required to wear hospital garb. Nothing metal can be brought into a magnet room except for equipment or supplies that have been specially screened by the MR operators. The doors to the magnet room should be

Telegram: @medical_k

www.konkur.in

kept closed except for brief entry and exit by the operators and patient or by personnel directly approved by the operators. Failure to safeguard against this risk had resulted in catastrophes, such as the death of a child when a magnetic oxygen cylinder crushed his skull at speeds in excess of 50 miles per hour. A less dramatic but more common risk is that of injury to a patient's eye from a flying ballpoint pen or a paperclip.

A common question is about the safety of pregnancy. At magnetic field strengths of 1.5 T, in use since the early 1980s, and 3 T, in use since the early 1990s, no adverse effects of the magnetic field have been associated with pregnancy or reproductive health. Above magnet field strengths of 3 T, far fewer data exist, although no ill effects have been reported at this time. At 7 T and higher, some individuals experience nausea or dizziness when entering or leaving the magnetic field due to magnetic field effects on the inner ear while moving through the region at which the magnetic field changes near the bore of the magnet.

The use of injectable contrast agents poses an additional but small source of risk. There are risks associated with the placement of an intravenous line, including bruising and infection, although the lines should be placed with care under sterile conditions that minimize those risks. The FDA has approved contrast agents that contain the metal gadolinium for use in human subjects and does not recognize any major risks with its use. Less than 3% of patients may experience mild nausea, headache, or dizziness after the injection, and those side effects usually resolve themselves without treatment. Less than 1% of patients experience an anaphylactic reaction, including hives, itching, or difficulty breathing. Subjects should be asked if they have a history of allergic reactions to MR or other injected contrast agents or if they have a history of kidney disease, asthma, allergic respiratory disorders, anemia or other diseases that affect red blood cells. Women who are pregnant are generally not given gadolinium contrast agents in the United States, although in Europe, it has been judged to be safe and is permitted. Women who are breastfeeding are instructed to express milk for 48 hours after the scan before returning to breastfeeding.

A magnet quench was described earlier in this chapter as the sudden de-energization of the magnet, accompanied by a rapid boil-off of liquid helium and possibly nitrogen. Nitrogen and helium are inert and nontoxic, but in confined spaces, they displace oxygen and can cause suffocation. Therefore, MR scanners are equipped with ventilation systems to remove

Telegram: @medical_k

www.konkur.in

those gases in the event of a quench. Furthermore, on the very rare occasion that a quench occurs, the operators are trained to remove a patient immediately from the magnet room. Patients are unlikely to be present at the times that a quench is most likely to occur, these being during magnet energization that occurs at installation or after major equipment upgrades, or when helium is being added to the magnet to replace material that has slowly been lost from the system. Quenches may also occur if a large metal object strikes the magnet. To date, no patients have been injured or killed by quenches.

What to Tell the Patient before a Scan

A patient should be told that the study requires lying on a bed, usually with a detector that has some rods that are placed around the head. The bed is rolled into the scanner, which typically looks like a tube so that the individual's head is approximately centered along the length of the tube, and the feet, legs, and sometimes even the waist lie outside the tube. Patients should be told that the machine does not move, although they will hear knocking and other sounds and possibly feel some vibrations while the scanner is acquiring the data. It is crucial to stress the need to hold still. Movement can lead to images that are blurry or otherwise uninterpretable. If there is an injection of a contrast agent, the individual may feel some discomfort associated with the intravenous line, just as any intravenous catheter may cause some bruising or other discomforts. Otherwise, MR has no painful parts.

Some people feel uncomfortable or anxious because of having to lie still in a tube that is generally less than three feet in diameter and several feet long. If a subject is feeling anxious, then a small dose of an anxiolytic drug such as a benzodiazepine is sometimes administered, as long as it does not adversely affect the measurements. A subject should be told that the operators will monitor them constantly by sight and sound, so a patient can ask the operator to be brought out of the scanner. It is important to warn a patient that some people feel dizzy, develop some stomach upset, experience a metallic taste, or find tingling sensations or muscle twitches. These sensations usually go away quickly, but it is important to tell the research staff if they occur.

The patient should be presented with an MR safety questionnaire to be answered very carefully, and it is important to verify the answers verbally with each patient. If parents accompany a child into the MRI room, the

Telegram: @medical_k

www.konkur.in

parents should be screened likewise. The questionnaire will ask about the surgical history and the presence of a variety of potentially MR-incompatible items, including pacemakers, intrauterine contraceptive devices, aneurysm clips, and injuries from shrapnel and metal work, especially to the eye. Patients commonly ask questions about implanted metal, including dental work and screws used to repair broken bones. Fillings are safe. Most permanently installed dental work is safe. Partial plates that can be removed should be removed before the scan, partly for safety but primarily because ferromagnetic material in some of them can cause T_2* effects that compromise the quality of the MRI or MRS. Bone screws and other surgically implanted materials should be examined in conjunction with the MR facility's safety officer. It is also important to know the manufacturer and model of any implanted devices, even if a patient insists that the device is MRI-safe. Some devices may be safe at 1.5 T, but not 3 T, and others safe at 3 T may pose risks at magnetic fields above 3 T. An X-ray or review of a patient's surgical records may be necessary to evaluate the presence and MRI compatibility of internal materials. The patient should be encouraged more than once to read the safety form carefully and ask questions about any uncertainties, even if the patient thinks that it is probably safe. It is best for a patient to ask about something that poses no risk than to keep quiet out of embarrassment and die.

Jewelry is a major source of questions and sometimes of resistance. Although patients often refuse, they should not enter the magnet room without first removing piercing jewelry, such as tongue rings, nose rings, belly button rings, and earrings. They may claim that a favorite necklace is pure gold, which is nonmagnetic, only to have the MR machine demonstrate the opposite. In some cases, an inadequately anchored piece, such as the backing of an earring, can come loose and pose a flying hazard or become lodged in a joint somewhere in magnet cowell or gradient coil assembly. The more common problem is that the small quantities of ferromagnetic materials distort or, in some cases, generate huge holes to appear in the MRI, even when the patient clearly has an intact head. Safety is enhanced if a blanket ban on jewelry is followed.

A significant number of subjects in the general population are likely to show abnormalities. When these are unexpected, they are called *incidentalomas,* and the proper course of action upon finding an incidentaloma has been and continues to be a subject of debate.

Telegram: @medical_k

www.konkur.in

Observations that are of potential clinical significance should be referred to a radiologist for evaluation and decisions about further courses of action. For example, aneurysms pose a cause for further evaluation. Some conditions, such as an asymptomatic meningioma in an 85-year-old woman, might be best monitored but untreated unless symptoms later emerge. Each case must be evaluated on its own circumstances and according to the policies of each institution.

FUTURE DIRECTIONS

Today, established MR technologies provide a limited but valuable clinical service to psychiatry through their ability to rule out gross structural abnormalities. Presently, most of the methodologies described in this chapter are used to acquire data in academic research settings in efforts to help psychiatrists understand the pathophysiology, pathogenesis, and treatment of psychiatric disorders.

The primary limitations that face MR today are spatial resolution, sensitivity, and cost. Regarding spatial resolution, MRI data in humans are rarely acquired with grid sizes finer than 0.5 to 0.75 μL and, more typically, 1.5 to 2 μL. The sensitivity of MRS is typically far less than that of MRI because the concentrations of the metabolites are far less than those of the water and fat that are usually detected for MRI, with a general limitation of 0.5 to 1 mmol/kg as the detection limit in the human brain in vivo, with volumes in some cases as small as 0.25 mL but more typically 8 mL for ^{1}H MRS and larger volumes for ^{31}P and ^{13}C. Because of the need to detect lower concentrations, MRSI fares more poorly than MRI with regard to resolution and/or sensitivity, but the ability to map chemicals through the brain provides a unique power to investigate mental illnesses. Although whole-brain ^{1}H MRS can be implemented, much of the brain is poorly shimmed and yields no useful data. Methods that greatly improve problematic shimming are also under development and may resolve this problem in the coming years. The DMI method discussed in this chapter is far less affected by such problems and holds great promise for mapping metabolism over the entire brain, similar to FDG-PET emission tomography but without radioactivity. fMRI receives great attention in the psychiatric research community today, and a major limitation that must be kept in mind when interpreting the imaging results is that the measurement is relative, and any function-related changes must be

Telegram: @medical_k

www.konkur.in

evaluated in the context of possible baseline conditions. Cost poses an impediment to increases in diagnostic approaches with new MR methodologies. With scans now costing $500 to $4,000, depending on the procedures ordered and the institution where the scan is done, additional methods will only gain widespread acceptance if they are clearly shown to add clinically significant information.

The future of MR can be viewed from several perspectives. The noninvasive, nonradioactive nature of MR provides a strong impetus for continued development in the diagnostic evaluation of patients and use in basic science research. By virtue of its safety profile, MR is likely to support research on childhood manifestations of psychiatric disorders. Magnetic field strengths for research scanners are increasing, having reached 11.7 T for human use; higher magnetic field strengths for most brain studies represent greater sensitivity. As manufacturers gain experience with higher-field research machines, the technology has in the past lowered the cost of medium-field magnets and led to improvements in reliability and stability. A second potential advance lies with the elimination of helium as the coolant for the superconducting wire in the magnet. Helium currently poses a significant cost of installation and operation of MR scanners. The cost is rising with increasing limitations on worldwide helium supplies, and some industry sources predict exhaustion of the world supply by the year 2030. Researchers around the world are working to develop superconductors with the necessary physical flexibility and ability to carry large electrical currents at liquid nitrogen temperatures and also more powerful permanent magnets (not produced by electric currents); such breakthroughs should lower MR operating costs and eliminate the need for the limited helium supply. Another area of intense investigation is hyperpolarization of ^{13}C, increasing its sensitivity by several orders of magnitude. Researchers are actively pursuing the use of hyperpolarized ^{13}C for use as nontoxic contrast agents for angiography and metabolism. A very different approach, *molecular MRI,* increases the ability to monitor processes such as the migration of nerve cells, gene expression, and targeting of particular cell types. Such molecular imaging abilities remain in the realm of research on animals, but as methods continue to develop, they appear likely to find their way to applications to human diseases. Another major increasing area is multimodal imaging: linking MRI, fMRI, MRS, or other measures, as well as binding those measures with PET. For example, there are now efforts to link metabolite

Telegram: @medical_k

www.konkur.in

level changes to alterations in synaptic density using the PET tracer SV2A.

In the future, MR is likely to find increasing utility as a research tool because it provides a quantitative window on neuroanatomy, function, and neurochemistry. Developers are also working to turn the research methodologies into robust clinical techniques for the testing and use of biomarkers to monitor treatment efficacies. MR studies are becoming increasingly multimodal, with various types of MRI and MRS acquired in single scan sessions and on individual subjects, as well as in complementary measurements with methods like PET and EEG recordings. As outlined above, MR has already begun to change the current thinking with respect to the pathophysiology of psychiatric disorders, neuroenergetics, amino acid neurotransmission, and plasticity. From most perspectives, MR appears likely to continue to do so in the future.

1.26 Electroencephalography in Psychiatry

JASON K. JOHANNESEN, PH.D., AND PATRICK D. SKOSNIK, PH.D.

The *electroencephalogram* (EEG), considered the first functional brain imagining technique, has contributed substantially to the study of pathophysiology across the field of psychiatry. EEG provides a noninvasive measurement of brain activity that is well suited for a range of clinical and scientific applications, with low cost, flexibility in testing environment and equipment, and millisecond-level temporal resolution (considered some key advantages). Approximating "real-time" measurement, EEG is well suited for addressing questions concerning how brain activity changes in response to different conditions, such as states of arousal transitioning from wakefulness to sleep, to basic sensory stimulation (including stages of early sensory registration and perceptual processing), and during more complex mental operations engaging attention, memory, and learning processes. Despite the continued development of high-density digital EEG recoding and associated methods of interpolating sources of underlying neural activations, the strength of EEG remains to be nested in the ascertainment of events as they occur in time rather than the location of activation to precise brain structures. This distinction is commonly discussed in terms of the tradeoff between "temporal" and "spatial" resolution, which applies to all methods of brain imaging and, thereby, should guide the selection of methods most appropriate to investigate questions concerning the timing and sequencing of evolving neural processes versus the sources from which they emanate.

A renascence of EEG methods has been promoted by the accessibility of these instruments to cognitive and clinical scientists who seek cost-efficient and noninvasive means of applying measures of brain function to new experimental, diagnostic, and computational questions. EEG methodology can be exquisitely applied to examine hypotheses on the pathogenesis of psychiatric illness, no longer conceptualized as the result

Telegram: @medical_k

www.konkur.in

of a dysfunction of select brain regions but as a consequence of the failure to integrate neural activity through networks engaged across multiple brain regions. Advances in EEG measurement of brain function have been aided by technologic advances at levels of bioamplification, electrode sensors, and computational algorithms for signal processing and quantification. EEG methodology and its interface with experimental neuroscience continue to hold an important position at the forefront of psychiatry research, contributing both to areas of illness characterization and treatment development. In time, and with necessary large-scale replication, the ultimate goal will be to translate research findings to clinical protocols that can be used to inform the early prediction of illness, differential diagnosis, sample enrichment, and treatments developed for common psychiatric disorders.

Electroencephalography, the practice of recording and interpreting EEG, remains a growing discipline within the field of medicine broadly, encompassing a range of neuroevaluative applications used in the diagnosis of seizure and epilepsy, sleep disorders, head trauma, tumors, infections, encephalopathy, anoxia, and cases where acute toxicity may be suspected. There are a number of examples from clinical research, such as the case of traumatic brain injury secondary to blast pressure waves, where EEG has demonstrated superior sensitivity to pathophysiology than structural brain scans. Diagnostic techniques that rely on EEG measurement include evoked potentials (EP) recorded in response to sensory stimulation. EPs result from the phase-synchronization of the ongoing EEG that is time locked to stimulation, producing characteristic waveforms that are measured in amplitude (voltage change) and latency, and interpreted as a representation of change in brain activity “evoked” by the external sensory event. EPs reflect the earliest stages of sensory processing and help to determine whether the transmission of sensory information is continuous or interrupted along known pathways. Tests common to neurologic evaluation include the visual-evoked response (VER) test, detecting problems with the optic nerve that affects sight, the brainstem auditory-evoked response (BAER) test used to test hearing ability (as used in infants), and the detection of brainstem tumors, and the somatosensory-evoked response (SSER) test. The SSER test makes exquisite use of the EEG’s temporal properties, aiding in the examination of nerve transmission along the spinal cord by measuring the amount of time it

Telegram: @medical_k

www.konkur.in

takes stimulation (usually electrical current) applied to an affected extremity to reach the brain.

In the practice of clinical psychiatry, EEG remains to be used primarily as a screening tool for ruling out organic factors that may contribute to the presentation of psychiatric symptoms, such as a change in perceptual experience (e.g., hallucinations), personality, and behavior. The differential diagnosis of a psychiatric disorder from organic pathology is further informed by medical history and clinical interview. At this time, there are no specific profiles of EEG activity or related diagnostic procedures that, taken alone, would be considered confirmatory of a psychiatric diagnosis. That said, a range of EEG abnormalities are described in the psychiatric literature, with considerable interest in the use of such features as *biomarker*s of underlying pathogenesis disrupting brain function. As an objective, embodied measure of brain function, EEG may have utility in many of the same ways psychiatric symptoms are used, such as the classification of illness subtypes, as measures of disease progression, and as signals that respond to effective pharmacotherapy.

HISTORY

Experimental evidence of brain-derived electrical potentials was first established in 1874 with Richard Caton's (1842 to 1926) discovery of spontaneous electrical activity recorded from the exposed cortices of cats, rabbits, and monkeys. However, the lengthy transition from laboratory experiment to the eventual acceptance of EEG was plagued by intense controversy. Despite the continuing accumulation of evidence, the notion of electrical potentials emanating from the brain was rejected for nearly 50 years by leading authorities. Caton's work was replicated by Vasili Danilevsky's 1877 report that electrical oscillations recorded from the animal brain could be altered by strong sensory stimuli. Three further historical highlights of note include (1) the 1891 demonstration by Adolph Beck that the dog visual cortex produced large electrical potentials when the eyes were rhythmically illuminated (thus laying the experimental foundation for EEG photic driving), (2) Beck and Napoleon Cybulski's 1892 report that local injury to the cortex could alter the characteristics of recorded spontaneous electrical activity, and (3) Cybulski's 1914 report that brain wave seizure discharges could be induced in the cortex by applying electrical stimulation to the cortex (thus presaging the use of

Telegram: @medical_k

www.konkur.in

EEG in epilepsy). Despite this stream of successful experimental work, the EEG phenomenon continued to be scrutinized by the scientific community.

Caton's seminal work was finally brought to light when cited in 1929 by Hans Berger (1873 to 1941), reporting the discovery of the alpha waves (~8 to 12 Hz) at the emergence of the field of *electroencephalography.* The focused perseverance of Hans Berger, a biologically oriented Professor of Psychiatry and Director of the Psychiatric Clinic in Jena, Germany, finally brought EEG to a position of acceptance and clinical utility. After years of unsuccessful attempts to record brain waves from humans (he was able to obtain recordings from animals), he finally succeeded in recording the human EEG in 1924 and, in 1929, published the first in his classic series of 23 papers describing many aspects of the human EEG. Among his vast achievements, Berger demonstrated that brain electrical activity came from neurons and not blood vessels or connective tissue, that recordings from patients with brain tumors contained high-voltage slow waves (his recording technique did not permit localization), that waking *alpha* waves were blocked by eye-opening, and that the characteristics of EEG activity change with age, sensory stimulation, state of consciousness, and physiochemical state of the body. However, acceptance was still temporarily delayed when Lord Adrian, a Nobel laureate neurophysiologist, claimed that Berger's findings were "impossible." Later, in 1934, Lord Adrian publicly confirmed acceptance of Berger's work, and the field of electroencephalography was born.

BASIC PRINCIPLES OF ELECTROENCEPHALOGRAPHY

The term *electroencephalogram,* coined by Hans Berger, refers to the graphic record of brain electrical activity or brain waves. The related term, *electroencephalograph,* refers to specialized instrumentation used to record electrical potentials at the scalp surface. The abbreviated term, *EEG,* may be used interchangeably to refer to either the record or the recording instrument. As rendered by EEG, the brain wave reflects the transient difference in electrical potential (greatly amplified) between any two points on the scalp or between an electrode placed on the scalp and one located at a neutral off-scalp location (e.g., ear lobe, mastoid, nose), used as a reference. In a simplistic sense, the EEG is an extremely

Telegram: @medical_k

www.konkur.in

sensitive voltmeter, with the unit of measurement being the microvolt (μV), representing dynamics occurring on a scale of millionths of a volt. Typical EEG signals range from approximately 30 to 80 μV but can be as low as 1 μV (for early EPs) or as high as 150 or 200 μV in some high-voltage "spike" discharges. The difference in electrical potential measured between any two EEG electrodes fluctuates or "oscillates" rapidly, usually many times per second. It is this oscillation that produces the characteristic waveforms that even many lay persons now recognize as the appearance of "brain waves."

The earliest EEG recordings involved only one pair of electrodes or one *channel* of recording, and although this could detect certain normal and abnormal features, effective clinical application remained for the future. Soon, the ability to record two channels of EEG was accomplished, making it possible to record activity simultaneously from homologous locations in each hemisphere. Before long, the rapid advances in recording technology allowed four- and eight-channel recordings to be made, and EEG became a viable clinical tool. Eventually, 10-, 12-, and 16-channel recording machines became the standard workhorses of clinical and research EEG laboratories around the world. EEG equipment capable of simultaneous recording from 32 to 64 channels is now commonplace in most EEG laboratories, with 128- and 256-channel systems also used in research where "high-density" recording may lend further accuracy to the estimation of current sources. The ability to simultaneously record brain waves from many scalp locations is important because it allows the detection of asymmetries across and within cortical regions, permits recording arrays to locate focal or regional abnormal features more clearly, and increases the ability to detect various *artifacts* (i.e., sources of signal of noncerebral origin that contaminate the EEG).

Brain wave activity captured on the scalp by EEG is a result of the summed extracellular electric potential fields generated by large numbers of neurons. EEG cannot detect the electrical activity generated by a single neuron or even by several neurons close to the scalp. Rather, the scalp-recorded EEG signals are the result of summated field potentials generated by excitatory and inhibitory postsynaptic potentials (i.e., EPSPs and IPSPs) in vertically oriented pyramidal cells of the cortex. An EPSP in a dendrite produces electrical negativity in the immediately surrounding area, but the electrical field becomes positive with increasing distance from the source. The reverse occurs with an IPSP, generating an electrical

Telegram: @medical_k

www.konkur.in

positivity nearby and a negative field at a distance. The summation of EPSPs and IPSPs is enhanced because the neurons are tightly packed together and oriented vertically in parallel. In order to be detectable by surface EEG electrodes, neural activity has to be strong enough to cross other tissue and fluid (i.e., CSF, dura, skull, scalp). It is the transduction of current across tissue and fluid of different densities, with different electrical resistance, that contributes to the wide diffusion of current as it is recorded over the scalp. This is one important aspect of EEG recording that must be considered when making assumptions about the underlying source and the direction of the current projection. The transduction of electrical activity from cortex to scalp relies on the ability of the brain to synchronize large populations of cells, which can occur either spontaneously or in response to a stimulating event. Neuronal activity that is unsynchronized cancels out due to destructive interference and thus does not contribute substantially to the electric field potentials recorded as scalp EEG. Because of the manner in which the dominant intrinsic brain waves are generated, EEG is maximally sensitive to cortical neuronal activity and relatively insensitive to electrical potentials generated at subcortical structures. However, there are exceptions, as subcortical neuronal events may influence cortical neuronal firing via afferent transmissions along subcortical–cortical tracts.

Probably the first observation about brain waves, going back to the time of Caton, was that many recorded potentials oscillate and repeat in a rhythmic fashion. Indeed, the term *intrinsic rhythms* is often used to refer to normal background activity, and the term *dysrhythmic* is used for activity with irregularities in oscillatory patterns that may be suggestive of pathology. Within reasonable limits, the repetitive rhythmic nature of the EEG is stable across individuals and within individuals over time, barring the introduction of pathophysiologic events. Indeed, the quantified EEG signal has been shown to have high test–retest reliability in a number of recording situations, with coefficients of $r = 0.90$ reported in healthy adults and in psychiatric samples. Examination of test–retest reliability in task-related EEG, recorded under conditions of mental challenge, also tends to produce high-reliability coefficients. However, the reliability of these measurements is also known to be influenced by stimuli, task conditions, and trial count. The stability of EEG spectral characteristics may also have a genetic basis, with an average biometric heritability estimate of 0.78 reported for a large-scale ($N = 4{,}026$) community sample of adolescent

Telegram: @medical_k

www.konkur.in

twins and their parents. Although the EEG does reflect state-dependent changes, sensitive to states of wakefulness and relaxation, for instance, its reliability within individuals over time has been interpreted by some authors as evidence of an EEG set point, a natural, spontaneous rhythm that is individually characteristic and stable over time. The concept of a set point suggests that repeated testing with averaging across test sessions would help to eliminate measurement error, thus maximizing the chances of detecting the onset or progression of neurodegenerative processes. Given further evidence that EEG characteristics are to some extent heritable, EEG measures may also be useful for monitoring the evolution of neuropathology in individuals regarded to be at elevated risk for developing a psychiatric disorder due to family history.

Despite the more than 130 years that have passed since the original recording of EEG by Richard Caton, over which a variety of abnormal findings have been reported in many psychiatric conditions, EEG methods have yet to find a prominent role in the training and clinical practice of psychiatry. This is in contrast to EEG's well-established position in clinical neurology as an approved subspecialty, sanctioned by the American Board of Medical Specialties (ABMS) and the American Board of Psychiatry and Neurology (ABPN). De-emphasis of EEG training in psychiatry is likely a consequence of factors unique to the psychiatric diagnosis itself. Prominent among these factors are the complex and heterogeneous nature of psychiatric disorders in general, for which there are currently no formally accepted diagnostic techniques beyond the clinical interview. The lack of familiarity of psychiatrists with EEG techniques, and heightened standards for evidence-based practices, are additional factors to contend with when considering the feasible application of EEG in routine psychiatry practice.

Basics of EEG Interpretation

The interpretation of the EEG record is essentially a problem of learning to recognize all of the myriad intrinsic waveforms, their expected distributions over cortical regions, and their range of variation in amplitude and degree of symmetry. Although there is little doubt that 64, 32, or even 16 channels of oscillating waves appear quite confusing to the beginner, there is an inherent regularity to the brain's electrical output that an experienced electroencephalographer comes to recognize. Because of this inherent regularity, the intrinsic EEG rhythms and their range of

Telegram: @medical_k

www.konkur.in

variation that characterizes the wake, drowsy, and various sleep states become easily identified through practice and experience. The various electrophysiologic phenomenon of nonencephalic origin, which need to be distinguished from EEG signals, also produce localized or regional waveforms of stereotypical appearance that one can learn to identify. The primary job of the interpreter is to identify those EEG waveforms that appear to fall outside of what one might call the *normal range of variation* of the intrinsic background activity and therefore are (1) frankly abnormal with known pathophysiologic correlates or (2) controversial abnormal waveforms of potential clinical relevance, pending the results of further continuing clinical investigation.

Interpreter Reliability

Because the EEG record is obtained by precisely measuring the microvolt fluctuations of electrical potentials over the scalp, a misconception often emerges that EEG interpretation is purely objective in the sense that measurements of temperature, weight, length, and volume are objective. In truth, there is a large, subjective element of judgment in EEG interpretation, and the achievement of skill in this area only follows a period of thorough training and the guiding hand of clinical experience. Accepted EEG abnormalities do not always appear in the EEG tracing in clear-cut textbook form, and there are always ambiguities in areas where EEG activity that is clearly normal becomes blurred and shades off into waveforms that are unequivocally abnormal.

Although the important topic of reliability of clinical EEG interpretation has not received extensive study, it has generally been assumed that high levels of interpretation reliability can be obtained through training and clinical experience. Two formal methods of assessing reliability involve comparing the independent readings of two or more EEG interpreters (*interrater reliability*) and asking one electroencephalographer to blindly reinterpret a sample of EEGs after an elapsed time (*intrarater reliability*). When these methods have been put to the test in studies of board-certified clinical neurophysiologists asked to classify EEGs into one or more diagnostic categories, findings have suggested that clinical interpretation of EEG should receive much greater attention as a matter of training and practice (Grant et al., 2014). It was reported that while trained readers tended to provide high confidence ratings of their interpretation (median score of ≥99% accuracy), intrarater reliability coefficients ranged

Telegram: @medical_k

www.konkur.in

from 0.33 to 0.73 with an aggregate value of 0.59, while interrater coefficients ranged from 0.29 to 0.62, with an aggregate value of 0.44. The take-home point of this study is that while experienced epileptologists have very high confidence in their EEG interpretations, this confidence may not be founded in actual performance and that further training to improve EEG accuracy and reliability is needed. One suggestion for accomplishing this goal is through continuing medical education modules that measure and report EEG reliability scores to individual users.

EEG RECORDING AND RELATED METHODOLOGY

Much has been written about the complexities of EEG recording, interpretation, and the corresponding level of skill needed to obtain an adequate EEG. What may be insufficiently recognized is the fact that there are also clinical situations in which a greatly simplified EEG obtained by a properly trained registered nurse or resident can have substantial diagnostic usefulness. There are some important EEG findings of particular relevance to emergency room settings and, possibly, even to some acute psychiatric admission or triage units that can be obtained in only 10 minutes by clinicians with a minimum level of technical skill. Clinical cases presenting moderate to marked confusion and agitation, delirium, or possible nonconvulsive status epilepticus (NCSE) may have diffuse EEG abnormalities that are more or less continuous in the tracing, detectable almost as soon as the recording is turned on. Such findings do not require sophisticated localization studies, and their presence, or absence, is diagnostically relevant. Prompt access to an EEG laboratory may not always be possible, especially on weekends or evenings. Thus, on-site screening may be most helpful.

Beyond routine screening EEGs described above, recording the EEG does, in fact, require a considerable amount of skill and experience. It is not merely a technical act performed by a technician. The unfolding clinical EEG record is a constantly moving and shifting display of complex waveforms recorded simultaneously from numerous scalp locations, and the EEG patterns differ dramatically during wakefulness, drowsiness, and various sleep levels. The appearance of the EEG also changes from one recording montage to another, along with differences in the reference selected, while a host of normal and abnormal EEG waveforms and contaminating artifacts must be identified in their obvious and subtle

Telegram: @medical_k

www.konkur.in

forms. Identifying the source of artifacts and minimizing their intrusion on the EEG is most critical during the recording procedure, as the application of offline removal and correction procedures requires an advanced skill set and appreciation of the intricacies of how such transforms may inadvertently change the appearance of features retained in the EEG. In addition to having the skills to correctly apply electrodes and operate amplifiers and recording equipment, better technologists are also capable of sophisticated EEG interpretation. It may not be obvious how important this is. EEG abnormalities do not always emerge in clear-cut, textbook form but instead may be distorted and, hence, ambiguous. Interpretative ability is necessary to recognize probable abnormalities and then arrange recording montages and monitor states of patient alertness (wake or sleep) in ways that can enhance the patterns and allow a more definite interpretation by the electroencephalographer. A minimum of 1 year of full-time training, including didactic instruction and supervised, hands-on recording and interpretation experience, is necessary for an EEG technologist to achieve competence. Formal training schools for EEG technologists exist in many places, and the graduates can become registered EEG technologists by taking and passing a two-part written and practical examination.

Working in a psychiatry environment has its own challenges that technicians must be comfortable handling. First and foremost is being able to competently manage the needs of a disturbed individual. It should be appreciated that clinical EEG is typically administered under conditions proximal to an acute change in mental state; therefore, psychiatric symptoms may be exacerbated. An EEG technologist who practices in a psychiatric setting must know when to terminate a procedure, call for help, and try to de-escalate a situation. Even the most cooperative psychiatric patients can also present challenges for EEG recording due to increased eye and involuntary body movements associated with tardive dystonia and akathisia. Muscle activity, particularly of the eyes, mouth, and jaw, produces changes in electrical activity on a much larger scale than brain activity and can contaminate an EEG record to the point where no reliable interpretation can be made. Given that good awake recording is necessary, sedation is not an acceptable procedure. On the other hand, the need for sleep in order to more completely assess *paroxysmal* activity, such as spike-wave discharges associated with seizures, may require that other steps be taken to help the patient to fall asleep. This may require

Telegram: @medical_k

www.konkur.in

decreasing the lighting and allowing the patient to relax. Room temperature in EEG recording environments is ideally kept between 70 °F and 75 °F (21 °C to 24 °C), a comfortable temperature at which an individual would not be expected to perspire (which can cause skin potential artifacts). It is also important to minimize changes in body temperature that could contribute to perspiration at the scalp, as sweat interacts with electrolytic gel applied to maintain conductance and reduce electrode impedance, produces slow drift and other artifacts affecting EEG signal, and can contribute to “salt bridging” of adjacent electrodes (essentially connecting electrodes together so no differentiation can be made between signal recorded at the bridged sites). Perspiration and associated changes in skin conductance are also associated with increased sympathetic arousal, which should be recognized in agitated or highly anxious patients. For these reasons, patients should be encouraged to remove heavy clothing or excessive layers if tested in street attire, and, as stated previously, every effort should be made to keep the patient comfortable and relaxed. Explaining the purpose of the procedure, the EEG apparatus, and the signals obtained by EEG recording (e.g., an analogy to an ECG of cardiac activity but with electrodes placed on the head to record brain activity) during electrode application can go a long way in helping the patient feel informed and at ease with the process. Careful procedures will prolong the recording time in psychiatric patients. However, in laboratories where psychiatric patients are not routinely evaluated, technicians may be inclined to hurry the procedure when it should be slowed down.

EEG Apparatus

The basic components of the EEG recording apparatus are the (1) electrodes, (2) amplifier, and (3) recording device, including means of visualizing, acquiring, and storing the EEG record. Each will be discussed in the following sections.

Electrodes. As EEG emerged into the clinical arena, electrodes simply were placed on the scalp symmetrically by eye, using salient landmarks on the head as reference points, and not all laboratories used the same placement system. Eventually, in 1947, it was decided at an International EEG Congress held in London that some effort should be made to standardize the system of electrode placement so that clinical and

Telegram: @medical_k

www.konkur.in

research findings would be more directly comparable across different laboratories. The challenge was taken up by Herbert Jasper, who developed the *10–20 International System* of electrode placement, which has become standard worldwide since 1958. The system is based on two anatomical landmarks for positioning; the *nasion,* identified as the depressed area between the eyes above the bridge of the nose, and the *inion,* which is the highest point of the external occipital protuberance, located by a prominent bump at the back of the head near the lowest point of the skull. Briefly, measurement is taken from the total nasion-to-inion distance, and the midpoint is marked at a distance of 50% between these points (and 50% of the transverse distance between the preauricular points on the ears). The 10–20 nomenclature refers to the distance between electrodes, positioned at either 10% or 20% of the actual anterior–posterior or transverse distance of the skull (Fig. 1.26–1A,B). Each electrode location is associated with an underlying area of the cerebral cortex, indicated by the letters F, T, C, P, and O, reflecting frontal, temporal, central, parietal, and occipital lobes, respectively, followed by either the lowercase letter “z” for midline electrodes or a number indicating homologous left- (odd numbers) or right- (even numbers) sided locations. Thus, electrodes O1 and O2, for example, are placed over the left and right sides of the occipital region, respectively. Electrode Cz also referred to as the vertex, is the most centrally located electrode and is used as the midpoint for alignment to the intersection of nasion-to-inion and transverse distance measures. The standard 10–20 system is based on a total of 21 electrodes, with 19 scalp sites, including two electrodes at frontal polar sites (Fp1, Fp2) and two electrodes affixed at earlobes (A1, A2) which have traditionally served as a common reference for scalp electrodes.

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–1. A: International 10–20 Electrode Placement System, as viewed from the top of the head. **B:** A left-lateral diagram of the head showing the locations of the routine 10–20 electrodes. Note the relationships between electrodes placed on the scalp and underlying brain structures.

Although precise localization with respect to underlying functional anatomy should not be assumed, some basic generalizations have been made concerning electrode location and the nature of brain activity detected in their region. For instance, the frontocentral electrode Fz is located in proximity to frontal lobe structures important to intention and motivational processes, while central sites near the vertex (C3, Cz, C4) are sensitive to sensory (particularly auditory registration) and motor processes, and occipital locations O1 and O2 to early-stage visual processes. In addition, temporal sites (T3, T4, T5, T6) have shown sensitivity to memory and emotional processes, with temporoparietal electrode sites (P7, P8) typically selected for experimental studies on the neural activity involved in structural facial encoding. Again, the mention of these findings is not intended to insinuate that EEG is an effective tool for localization of function to a known source but rather to provide examples that illustrate the importance of multichannel recording and standardized electrode placement for characterizing unique and spatially distributed brain signals. Of note, the functional associations described above would not be inferred from routine clinical EEG but rather from experimental

Telegram: @medical_k

www.konkur.in

stimulus-evoked and task-related procedures, to be discussed later in this chapter.

The 10–20 system enables expansion of electrodes to provide greater coverage, with additional electrodes typically placed at 10% of the distance between the original 10–20 locations. The American EEG Society (currently the American Clinical Neurophysiology Society [ACNS]) has developed a nomenclature for the designation of as many as 75 defined electrode locations. However, it must be stressed that extremely large numbers of scalp electrodes are unnecessary for currently established clinical EEG applications. For currently accepted clinical indications, optimally useful EEG recordings can be achieved with as few as 16 (minimum recommended standard) or, at the most, 32 scalp electrodes. While preparation and setup time must always be considered as a constraint on the number of electrodes that can feasibly be applied in a given recording situation, arrays of 128 or even 256 scalp leads are not uncommon in specialized research applications where the aims of data collection include current source analyses and three-dimensional modeling (benefitting from additional electrode placements below scalp). An example of an extended 64-channel electrode array can be seen in Figure 1.26–2.

The 10–20 placement system has several advantages. Because the placement system is based on rigorous measurements, electrode placement error, particularly the asymmetrical placement of electrodes for homologous electrode pairs, is greatly minimized. The system also renders recordings entirely comparable between laboratories, as well as across serial recordings obtained from a single subject. Because percentages of distances between landmarks on the head are used for placement locations, scalp electrodes overlie the same cortical regions despite differences in head size. Furthermore, the relationships between electrodes placed on the scalp and underlying brain structures have been well established (Fig. 1.26–1) by using placements on cadavers (with holes drilled at the electrode sites to later identify the cortical area under the electrode), as well as studies using CT scanning.

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–2. An expanded 64-electrode array. Such extensive placement systems are primarily used for special research studies and are rarely used for clinical recordings.

Scalp electrodes must be applied carefully. The skin under the electrode must be clean and completely free of oil or grease. A common practice is to rub the area with a slightly abrasive cleansing electrolyte material that also removes some of the superficial epidermis. When this is done, a metal disc electrode can be applied to the scalp by using a conducting electrode gel. Electrode impedance should be maintained at equal to or less than 10,000 ohms (Ω) (10 KΩ) and closely matched across electrodes, ideally within 1 KΩ of each other. The electrode application procedure should not be uncomfortable for the subject.

Telegram: @medical_k

www.konkur.in

However, scalp abrasion has typically been used to perforate the most superficial layer of skin as a method to reduce scalp impedance. Modern EEG systems designed for research enable high-impedance recording through the use of *active electrodes* (of note, active systems have not yet been approved for clinical use). Active electrode systems do not require skin abrasion, and rather, acceptable signal-to-noise quality is achieved through preamplification at the electrode stage. Placing the first stage of amplification nearer to the scalp reduces the propagation of electrical interference through the shielded electrode cable to the amplifier, at which point line noise is amplified at the same scale as the EEG signal. Active electrodes do not overcome the necessity to assure good conductance at the scalp site through careful setup and application of electrolyte gel but may reduce overall preparation time by foregoing the need for scalp abrasion common to passive electrode systems.

Beyond the standard montage of scalp electrodes, certain applications may require additional electrodes specially designed to record from deep brain structures. Nasopharyngeal (NP) electrodes are inserted into the nostrils to achieve EEG recording with closer proximity to the basal temporal lobe that can be obtained by scalp electrodes (Fig. 1.26–1B); these leads are designated Pg1 and Pg2 in the 10–20 placement system. No actual penetration of tissue occurs. The NP lead is a long (as long as 15 cm for adults), curved S- or Z-shaped insulated wire with a silver ball (the electrode) on the tip, which is rotated laterally after insertion in order to place the ball in contact with the roof of the nasopharynx. With a cooperative patient and a skilled technologist, the procedure can be well tolerated. Although this lead is presumed to be better positioned to detect activity from the orbitofrontal cortex, temporal pole, and hippocampus, it has numerous disadvantages. Chief among these is a high propensity to produce pulse and respiration artifacts and the fact that NP leads cannot be used when a deviated septum or nasal inflammatory process is present. They also are contraindicated, with many psychiatric patients displaying behaviors such as confusion, agitation, or belligerence who could pull the leads out, possibly lacerating the nasal passage. Their use also may interfere with obtaining a sleep-activated EEG and, not infrequently, otherwise cooperative patients simply refuse the procedure.

MONTAGE SELECTION. A common misconception is that the EEG records the voltage detected at each electrode site. Instead, each channel on the

Telegram: @medical_k

www.konkur.in

EEG chart represents the shifting or oscillating difference in electrical potential *between* two electrodes. Thus, in a multichannel recording, the activity from each channel represents the shifting difference in voltage between two selected electrodes. When 16, 21, or more electrodes are placed on the head, the number of possible electrode pairs becomes large, and how these pairs are arranged among the recording channels can become complex. In EEG parlance, the way electrode pairs are arranged for a recording is called a *montage,* and although many montages are possible, only a limited number have become popular and useful. Prior to the advance of digital EEG equipment, selection of the montage was done prior to recording and would determine how the EEG was visualized in the paper record. When digital EEG equipment is used, montages are preprogrammed. A recording is performed using one montage, but the recorded (digitized) signal can be viewed offline in any configuration desired.

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–3. Example of an 18-channel bipolar montage with anterior to posterior linkages. The numbers between electrode locations designate recording channels. Thus, the number 6 means channel 6, which measures the difference in electrical potential between F3 and C3 electrodes.

Montages are designed to facilitate the detection of EEG abnormalities in different brain regions and to facilitate comparisons between left and right hemisphere activity. There are general guidelines for how montages are to be set up. The most important rule is simplicity for the sake of interpretation. Additional rules include the stipulation that odd numbers refer to the left-side, whereas even numbers refer to right-side electrodes (Fig. 1.26–1A). Furthermore, left-side electrodes are routinely displayed at the top of or before right-side electrodes on the record. Similarly, anterior

Telegram: @medical_k

www.konkur.in

electrodes are displayed on top of or before more posteriorly placed electrodes.

There are two main types of montages: referential and bipolar. With referential montages, all electrodes are referenced to a single common reference point that traditionally consisted of linked ears (the mastoid prominence can be used in place of the ear lobe), with variations being left or right ear reference alone, ipsilateral ear reference in which all electrodes in one hemisphere are referenced to the ear on that side, or a contralateral ear reference in which all electrodes in one hemisphere are referenced to the opposite-side ear. Given the risk of unintended distortion of EEG (causing artifactual asymmetry between hemispheres), that can occur when using references based on bilateral sites, particularly if the impedance is not carefully balanced between the two electrodes, single, midline, sites including the nose or vertex (Cz) have been recommended in some cases. An in-depth discussion of arguments in favor and against the various reference options is beyond the scope of this chapter, but suffice it to say that no one option will be ideal (or collectively accepted) for all EEG recording applications. A host of “reference-free” recording approaches have also been employed in digital EEG recordings to circumvent a choice of reference altogether. Reference-free montages are based on common average or other mathematical derivations of signal from all electrodes, such as *current source density* (CSD), defined by the second spatial derivative of the local field potential (LFP) (for a detailed discussion of field potentials in EEG, the reader is referred to the text of Nunez and Srinivasan, 2006). As per some suggested guidelines, the selection of a reference electrode should entail a location that is electrically neutral, uncontaminated by obvious physiologic (e.g., mastoid reference can be sensitive to cardiac signal if not properly located) or motion (e.g., nose reference can be sensitive to head movement if not properly affixed) artifact, and relatively distal to electrodes in the region of interest (e.g., EEG activity most proximal to reference is most extensively subtracted). A referential montage would most likely be chosen for applications in which it is important to ascertain the magnitude of an abnormality in terms of how large a sharp wave or slow wave is in microvolts in one region compared to another.

Bipolar montages, on the other hand, are useful (and, indeed, are much more widely used in neurology practice) for pinpointing the area of maximal abnormality or the exact source of abnormal activity. In bipolar

Telegram: @medical_k

www.konkur.in

montages, electrodes are referenced from one scalp location to an adjacent scalp location in chains of electrodes going across the head from front to back (Fig. 1.26–3) or from left to right (Fig. 1.26–4). Thus, one can think of a given channel of EEG activity as being derived from two inputs. The majority of abnormal cerebral activities tend to appear at the surface as negative potentials.

FIGURE 1.26–4. Example of a 16-channel transverse bipolar montage.

By convention, the first electrode of a pair constitutes input 1, whereas the second electrode provides input 2. Thus, in the electrode pair C3-P3, for example, the first electrode, C3, constitutes input 1. The direction of deflection in the EEG waveform is based on whether input 1 is, relatively

Telegram: @medical_k

www.konkur.in

speaking, “more negative” or “less negative” (i.e., relatively more “positive”) than input 2. If the electrode designated as input 1 is closer to the source of a negative field and, hence, more “negative” than input 2, an upward deflection (i.e., negative to positive/up) will be observed as an indication of input 1’s closer proximity to the source of an event. Conversely, if input 1 is more distant from the source of the field than input 2 and, hence, less negative, then the deflection of the bipolar pair is downward (i.e., positive to negative/down). As bipolar pairs of electrodes move in a longitudinal or transverse direction from one side of a strong and highly localized negative field to the other side, the deflection changes direction across bipolar pairs as input 1 shifts from being relatively more negative to relatively more positive than input 2. This change of deflection is called a *phase reversal* and is a powerful method for the localization of sharply focal abnormalities.

One additional montage configuration deserves special mention because it may be particularly useful in psychiatric EEG. This is a montage that combines referential and bipolar electrode arrangements. Following four bipolar connections from the frontal regions through the temporal areas and ending in the occipital region, a referential placement connects each posterior temporal region (T5 and T6) to the opposite ear. This arrangement allows the activity of low amplitude to be highlighted by the referential electrodes for further examination via the bipolar electrode pairs. This montage is commonly referred to as the *Queen Square montage* (Fig. 1.26–5).

The appearance of EEG activity varies greatly from one recording montage to another. Large interelectrode distances often yield higher voltages, whereas a close spacing between electrodes in bipolar pairings tends to reduce voltage since both electrodes will overlie approximately the same portion of an electrical field, and the signal common to both cancels out. Furthermore, specific EEG patterns visible in one montage may be distorted or even completely canceled out in another montage. Although some montages may permit differentiation of activity between two or more brain regions, other montage choices may not do so. For example, EEG sleep patterns are well visualized and differentiated in central and occipital regions when a common (monopolar) reference recording is made. However, differentiation between central and occipital sleep activity is no longer possible when bipolar anterior–posterior linkages are used (C3-O1 and C4-O2), and, with transverse bipolar links

Telegram: @medical_k

www.konkur.in

between homologous electrodes, the sleep patterns may not be visible at all. The issue is not merely academic. Discharges of interest to the electroencephalographer that are detectable in some recording montages may be completely or nearly undetectable, despite their neurophysiologic presence, when a different montage is being used. As previously mentioned, while traditional analog EEG required any change in a montage to be done before recording, modern digital EEG is much more flexible in allowing changes of reference (i.e., rereferencing) or montage to be done as an *offline* procedure (i.e., after data is recorded). In the case of digital EEG, a change in the reference does not alter the EEG record, only the appearance of the data for the purpose of visualization.

www.konkur.in

FIGURE 1.26–5. Diagram of the Queen's Square montage. This is an 18-channel montage modified to include two referential leads to highlight temporal lobe activity.

EEG Amplifiers. Biopotentials recorded at the scalp are very small and require amplification (typically with a voltage gain of 1,000 to 100,000 times or 60 to 100 dB) in order to be visualized and, subsequently, analyzed. Indeed, scalp potentials are typically smaller in scale than many sources of interference, including nonencephalographic biopotentials (e.g., myographic, ocular, cardiac), electric line noise, and shifts in voltage that occur with poor electrode conductance at the recording surface. Therefore, a critical requirement for an EEG amplifier is the ability to boost brain signals while minimizing the amplification of these contaminating

Telegram: @medical_k

www.konkur.in

signals. This is achieved through the use of a *differential amplifier* using two input sources, one from the electrode and the other from a common system reference. The term “differential” refers to the manner in which a signal is amplified, wherein the difference between the two input voltages is passed through to the amplification stage while any common voltage shared between inputs (regarded as noise) is rejected. The proportion of common voltage rejection relative to the amplified difference signal can be quantified as the *common-mode rejection ratio* (CMRR), expressed in decibels (dB) as a unit of relative gain. As previously mentioned, the quality of EEG recording depends highly on the ability to achieve and maintain low impedance at scalp and reference sites. With regard to CMRR, it is especially important to ensure that impedance is balanced across electrodes, in that unequal impedance reduces the differential amplifier’s ability to detect and reject common-mode signals. Early analog EEG amplifiers required adjustment of *sensitivity* (i.e., the ratio of input voltage to pen deflection) to find the range of amplification that would boost low-voltage signals high enough to be visualized but prevent high-voltage signals from pushing recording pens above their deflection limits where “squaring off” of waveform peak would occur. The necessity to adjust sensitivity, or gain, in this manner is eliminated in modern EEG amplifiers that employ analog-to-digital (A/D) conversion, replacing pen and paper with software for control of EEG acquisition, visualization, and data storage. Most software allows input gain can be adjusted as needed for visualization at any point during EEG acquisition, with no consequence to the actual recording of the signal.

A feature found both in traditional analog and modern digital EEG amplifiers is an online filter, placed before the sampling stage, where it functions to limit the bandwidth of incoming signals in accord with the sampling theorem. This filter is set to the amplifier’s *Nyquist frequency,* defining the highest frequency of a discrete signal that can be accurately characterized at a specific sampling rate. High signal frequency relative to sampling rate can produce *aliasing* in the recording, a distorted rendering of a sinusoid that results from undersampling. *Nyquist theorem* dictates that the sampling frequency (F_S) must be at least twice the frequency of the highest frequency contained in the signal (F_C). Accordingly, Nyquist frequency is constrained by the amplifier sampling rate, as expressed mathematically in the equation $F_{Nyquist} = F_C < F_S/2$, with both signal frequency and sampling rate measured in cycles/samples per second

Telegram: @medical_k

www.konkur.in

using the common unit Hertz (Hz). Thus, the first stage of filtering may be regarded as an "*antialiasing filter*" used to attenuate EEG frequencies at and above the limit that can be accurately sampled. Aliasing has become less of a concern over time as amplifiers used in clinical applications sample minimally at rates of 256 to 512 Hz, which is more than sufficient to characterize EEG within the range of most human brain functions (e.g., ~1 to 100 Hz). Indeed, modern digital amplifiers are capable of sampling well beyond 1,000 Hz, and usually up to 20 kHz, though doing so comes at the cost of much larger data files, with higher computer processing speed and storage space requirements, and little useful information gained. One notable exception to this generalization is testing of the auditory brainstem response (ABR), which can include events sampled at rates of 7 kHz to 50 kHz using specialized amplifiers.

Digital Recording. Over the last 30 years, the analog EEG traces of the old EEG machines have been largely replaced by computer systems providing an A/D conversion of the recorded EEG signals, as well as amplification, digital filtering, storing, and quantitative analysis of multichannel EEG. Digital systems are now commonplace in the laboratory and clinical settings, are relatively inexpensive, and offer several practical advantages. They can help reduce the space problem of storing paper records over many years and also allow review of an EEG record using multiple montages, filters, and vertical (gain or sensitivity) and horizontal scaling (e.g., paper speed) selected after the original recording. Moreover, digital recording systems allow many new and exciting possibilities for EEG signal processing and quantification that rely not only on time-series analysis but also spectral–frequency, time–frequency, related methods of coherence and phase synchrony, and spatial–temporal source localization and modeling (to be discussed in subsequent sections).

FREQUENCY FILTER SETTINGS. Nearly all of the EEG activity that is analyzed for clinical or research purposes falls within the frequency range of 0.5 to 50.0 Hz (and occasionally up to 100 Hz). Filters are used essentially to limit the range of frequencies to a bandwidth containing features of interest. It has become conventional in clinical EEG to use a *low-pass filter* setting of 70 Hz, which means that EEG frequencies above this filter setting become progressively attenuated while those below the filter

Telegram: @medical_k

www.konkur.in

setting as allowed to “pass” through and are retained for further analysis. At the other end of the spectrum, most laboratories also employ a *high-pass filter* between 0.5 and 1.0 Hz to reduce the registration of frequencies below this level. Because the EEG is represented as a two-dimensional image of amplitude over time, with the visualized waveform representing a summation of all frequencies, a *band-pass filter* (combines a high- and low-pass filter) may be used to isolate discrete frequency bands (e.g., alpha band, 8 to 12 Hz) of interest from the broadband signal.

Unfortunately, scalp electrodes pick up a variety of electrical potentials of noncerebral origin, and many of these have frequencies within or close to the EEG frequency spectrum. Frequency filters may, to some degree, mitigate against the distorting effects of frequencies generated by artifacts. However, filters must be used judiciously and with caution because they also can filter out real brain waves that one wishes to observe. For example, slow waves generated by changes in skin conductance during sweating (galvanic skin response) can be of a sufficiently high magnitude to completely obliterate genuine EEG activity in the affected recording channels (bilateral frontal-anterior temporal areas around the forehead are particularly prone). Raising the high-pass filter setting to 5 Hz effectively eliminates this source of contamination in the recording but does so at the expense of attenuating any real generalized or focal slow activity that also may be present. It is also common practice to adjust the low-pass filter downward from 70 to 35 or even 15 Hz to eliminate or reduce unwanted electromyographic (EMG) activity from the recording. Again, the choice to do this involves a compromise because attenuating high-frequency activity may obscure the accurate detection of certain fast spike discharges. Of note, adjusting filters in this way is permissible for clinical applications, with the goal of identifying significant features at the individual level. Naturally, the selection of filter settings in research applications must be kept standard across data samples so as not to systematically introduce differences that would invalidate the measure and would be based primarily on the resolution of the frequencies important to the experiment or neurophysiologic processes being evaluated.

EEG CHARACTERISTIC FEATURES

Telegram: @medical_k

www.konkur.in

While the appearance of the raw EEG may vary somewhat between individuals, the range of frequencies, voltages, and waveforms that characterize the normal EEG during wake and sleep has been well established. The normal EEG tracing is composed of a complex mixture of many different frequencies, and based upon modern spectral analysis; consistent, recognizable patterns can be observed in most healthy individuals. Some frequency bands are expressed more strongly over some cortical regions than others (e.g., alpha over occipital cortex). Moreover, the frequency profile varies considerably as the subject being recorded transitions from alert wakefulness into sleep. Following the lead of Berger, discrete frequency bands within the broad EEG frequency spectrum are designated with Greek letters. However, it should be noted that the sequence of Greek letters is not entirely logical and, in fact, derives from historical precedents. For example, the term alpha rhythm, discovered by Berger, was chosen because it was the first rhythm detected and described. By contrast, the designation theta derives from the fact that activity in this frequency range was initially thought to originate in the thalamus.

Normal Intrinsic Frequencies

A brief discussion of the most established and recognizable *intrinsic rhythms* follows. Examples of each of these rhythms can be found in Figure 1.26–6, which provides visual representations of raw waveforms, the spectral (EEG power) bands they occupy, and general functional association. The recognition of these intrinsic rhythms enables the electroencephalographer to interpret EEG records in a clinical context. An in-depth review is beyond the scope of this chapter, and the interested reader is directed to the 2020 comprehensive text of Greenfield, Geyer, and Carney.

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–6. Example of the typical intrinsic brain rhythms observed in the normal EEG. The **middle panel** illustrates a prototypal example of each rhythm in the raw EEG. The **far-right panel** demonstrates how each rhythm would appear after a time x frequency transform.

Delta. Delta activity (≤3 Hz) is not present in the normal waking EEG but is a prominent feature of deeper stages of sleep, particularly stage 3. A slower delta rhythm (<1 Hz) is also observed when an individual is under anesthesia. The delta rhythm has been shown to be primarily generated by thalamocortical circuits. The presence of a significant generalized or focal delta in the waking EEG is strongly indicative of a pathophysiologic process.

Telegram: @medical_k

www.konkur.in

Theta. EEG with a frequency of 4 to 7 Hz is referred to as theta activity. A small amount of sporadic, arrhythmic, and isolated theta activity can be seen in many normal waking EEGs, particularly in frontal-temporal regions. While ongoing theta activity is somewhat limited in the waking EEG, it can be a feature of drowsiness during sleep tracing and is highly prominent in stage 1 sleep. Brief periods of theta activity have also been shown to be associated with mental activities such as problem solving and processes related to memory. The fact that theta appears to be generated in the hippocampus supports the role of theta in memory. Theta rhythms are also generated in the neocortex, particularly during working memory tasks. Excessive theta during waking states, generalized or focal in nature, suggests a focal pathologic process such as CBF reduction or metabolic encephalopathies.

Alpha. Highly rhythmic EEG with a frequency range from 8 to 12 Hz is termed alpha activity and was the first brain rhythm to be described by Berger in 1929 (i.e., the Berger rhythm). Alpha constitutes the dominant brain wave frequency of the normal closed-eye waking EEG and is also common in states of relaxation or during periods of minimal mental activity. Hence, alpha has routinely been interpreted as constituting an EEG correlate of an “idling brain.” In middle-aged adults, the vast majority of individuals exhibit an alpha frequency at, or close to, 10 Hz, whereas, with normal geriatric populations, a slower alpha frequency of 8 to 9 Hz is not uncommon. Alpha activity is most prominent over the posterior cortex, particularly the parietal, posterior temporal, and occipital cortex, with the occipital region being best suited to detect this activity. In fact, the neural generators of alpha activity appear to be the visual cortex, with some influence from the visual thalamus. The detection of alpha activity diminishes as one records from more anterior locations, and this frequency is rare at prefrontal electrode sites. Alpha activity is abolished, or at least severely attenuated, by eye-opening. Further, alpha activity also disappears as one enters sleep (indeed, one of the criteria for stage 1 sleep is <50% alpha activity per epoch). Alpha activity can be highly responsive to cognitive activity, such as focused attention or concentration. For example, under closed-eye recording conditions, alpha can be blocked or attenuated by engaging in visual imagery, numeric calculation, or almost anything requiring significant concentration. Alpha

Telegram: @medical_k

www.konkur.in

frequency can be increased or decreased by a wide variety of pharmacologic, metabolic, or endocrine variables.

Beta. Frequencies in the 13 to 29 Hz range are termed beta waves, and they are one of the dominant frequencies in normal adult waking EEGs, particularly over frontocentral regions. Beta rhythms are typically associated with alertness, and it is not uncommon for beta to appear as runs of rhythmic activity as opposed to sporadic isolated waves. Mixed frequency EEG, including beta, is also observed in REM sleep. In addition, research has shown that beta frequencies are correlated with peripheral EMG activity, suggesting that rhythmic beta in the motor cortex plays a key role in the generation of motor commands. The voltage of beta activity is also almost always of a smaller amplitude than that of the lower frequencies described above. Hence, along with gamma (see below), beta rhythms are not as easily visualized in the raw EEG compared to delta, theta, and alpha (Fig. 1.26–6).

Gamma. One of the most studied EEG frequencies during the past several years is the gamma rhythm, which is typically considered to be activity in the 30 to 80 Hz range (note that some investigators extend gamma up to 100 Hz). Gamma rhythms were largely ignored throughout most of the history of EEG research, which was due to in part to (1) recording methodologies, and (2) the notion that such higher frequencies were nonneural in origin (i.e., noise). However, seminal work in the 1990s by researchers such as Rodolfo Llinás, Andreas Engel, Wolf Singer, and others demonstrated that transient gamma rhythms play a key role in the integration or “binding” together of neural networks in order to generate coherent cortical representations. Since that time, the role of gamma rhythms in human sensation, perception, and cognition has gained wide support. Abnormalities in gamma rhythms are now thought to be a core feature of several psychiatric disorders, most notably schizophrenia.

EEG Artifacts

EEG artifacts, as previously alluded to, refer to any source of recorded activity that is not of cerebral origin and, therefore, contaminates accurate characterization of the desired signal. The various sources of artifacts are unfortunately abundant but can generally be reduced to two sources: *physiologic* and *extraphysiologic.* Physiologic artifacts are real biosignals

Telegram: @medical_k

www.konkur.in

recorded from the patient but generated by sources other than the brain. Extraphysiologic artifacts are those caused by external sources, including EEG or other medical equipment, and typically electronic devices located on the person or in the recording environment. Familiarity with the appearance of each artifact in the EEG, and its associated source, is critical for the EEG technician as most of these contaminating signals can be mitigated during recording but tend to be much more difficult to remove from the recorded data.

Physiologic Artifacts. Important physiologic features to be aware of during EEG recording and interpretation are ocular artifact, muscle artifact, perspiration, and cardiac artifact, though others (e.g., lingual motion) also exist. Eye blinks and vertical shifts in eye movement can be prominently observed in the EEG record, identified by rapid changes of voltage over brief intervals over frontal electrode sites, particularly the frontal poles (Fig. 1.26–7). Blinks and *vertical electrooculogram* (VEOG) responses can be further captured in EEG recoding by affixing electrodes above and below the orbit of one eye as a bipolar channel. Similarly, horizontal eye movement, or “saccades,” produces a characteristic artifact that appears as a change in voltage that tends to flatten over a brief period of time, with phase reversal observed between left- and right-sided frontal electrode channels (the side of positive deflection indicates the direction of eye movement). Like VEOG, *horizontal electrooculogram* (HEOG) responses are detected in scalp EEG channels (particularly F7 and F8), but optimal characterization benefits from a bipolar channel of electrodes placed near the outer canthi of the eyes. Fortunately, several “blink correction” algorithms have been developed and can be employed in digital EEG data to remove VEOG/HEOG artifacts from the EEG record (Fig. 1.26–8).

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–7. Electrooculographic (EOG) artifact. **Panel A:** Vertical EOG (VEOG) activity caused by eye blinks. VEOG recorded from electrodes affixed above and below the orbit of the right eye, also evident in frontal poles (Fp1, Fp2) and adjacent frontal sites with attenuated signal distributed posteriorly. **Panel B:** Horizontal EOG (HEOG) caused by lateral shifts in gaze, recorded at electrodes affixed bilaterally at outer canthi of eyes.

EMG activity of the temporalis muscle, indicating jaw clenching or chewing, and of the frontalis muscle, indicating tension and contraction of the forehead, appear as a high-frequency artifact that can spread across a large portion of scalp electrodes (Fig. 1.26–9). It is more difficult to correct EEG for this type of EMG artifact offline and could result in rejection of large segments of data if prominent. As mentioned previously, a low-pass filter may be used to attenuate EMG artifacts, but the use of this option may equally affect frequencies of interest. Therefore, it is best to reduce this form of artifact during EEG recording by training the patient to relax facial muscles beforehand and stopping recording, as necessary, to remind them. Obviously, anything that contributes to the use of these muscles, such as squinting to read in a dark room, chewing gum, or talking, should be avoided during EEG recording.

Telegram: @medical_k

www.konkur.in

Perspiration artifacts (galvanic skin response) can be detected by a slow, undulating drift in signal over long durations (e.g., 2 seconds), thus being easy to differentiate from cerebrally generated activity. However, it also resembles slow roving eye motion. Perspiration artifact is caused by sweat (sodium chloride) interacting with electrolytic gel and electrode metals and tends to be most prominent over frontal electrode sites (Fig. 1.26–10). Properly temperature-regulated recording environments and instructions to patients to dress in layers that can be removed as needed are the best solutions for avoiding perspiration, which can be difficult to reduce once it begins. Less frequently seen are artifacts from an electrocardiogram (ECG), though certain physical characteristics of the patient, such as a short neck or heavy, “barrel-chested” build, tend to increase their presence. ECG artifacts reflect both electrical and mechanical actions of the heart and can be detected by a consistent, rhythmic pattern with a period that aligns closely to pulse rate (thus, near 1 Hz) and are observed most commonly in temporal electrode sites and references placed at ears or mastoid (when electrodes placed too low and nearer to the carotid artery). Although ECG artifact is not likely to directly affect many scalp EEG channels, the intrusion of ECG into reference channels could give this appearance during data acquisition using a reference montage or after data has been rereferenced offline. These problems are then best avoided by moving reference channels, when possible, to a location where the ECG signal is not picked up.

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–8. Ocular correction. **Panel A:** EEG shows ocular motion artifact on VEOG and HEOG channels with propagation to scalp electrodes. **Panel B** shows the same data following offline ocular correction by Gratton & Coles method. Note that correction is applied only to scalp electrodes in this case, leaving the original artifact present in VEOG and HEOG.

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–9. Electromyographic artifact. **Panel A:** Jaw (temporalis) muscle tension. **Panel B:** Forehead (frontalis) muscle tension. These artifacts can typically be ameliorated by asking the subject to relax facial muscles when observed.

Extraphysiologic Artifacts. The main sources of extraphysiologic artifacts have to do with equipment and environmental issues that can be minimized through careful attention to proper electrode setup, cleaning and maintenance of equipment between uses, and mitigation of ambient electromagnetic noise sources in the recording room. Electrical devices such as computer monitors, lights, and poorly shielded power cables emit a 60 Hz signal, the line frequency of AC delivery in the United States (50 Hz in most other parts of the world). Electrodes with high or unstable impedance due to poor contact with gel/scalp or break in the lead will be particularly susceptible to picking up ambient noise in the recording environment, which is identified by persistent 60 Hz activity that appears as a fast sine wave imposed over background EEG (Fig. 1.26–11). Some EEG acquisition software packages enable viewing EEG in spectral frequency mode, which can quickly identify the characteristic peak at 60 Hz if there is any doubt.

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–10. Sweat drift artifact in EEG record referenced to the mastoid. Drift at frontal poles (electrode Fp1, Fp2) suggests sweat on the forehead. Drift common across remaining scalp electrodes suggests sweat at mastoid reference electrodes.

Maintaining proper electrode contact over long EEG recordings may require reapplication of gel, which can always be a first troubleshooting step for addressing noisy channels. Detection of a connection problem, which may also be caused by electrode movement, is not difficult as the resulting effect on the recorded signal in no way resembles true EEG (Fig. 1.26–12). In these cases, there tend to be very large changes of voltage, which may “rail” out of range at gain settings used for regular EEG monitoring, with no regularity in the signal.

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–11. Panel A: 60 Hz ambient noise in unreferenced EEG viewed at a range of 100 μV. **Panel B:** Power spectral analysis by Fast Fourier Transform (FFT) depicting prominent 60 Hz activity in **Panel A** segment. **Panel C: Panel A** EEG segment viewed in bipolar reference montage at 100 μV. Note that 60 Hz activity remains present in EEG but cancels out as a common signal when referenced.

One common artifact that is more difficult to prevent in the electrode is a "pop," appearing as a steep and rapid deflection in voltage, usually isolated to a single electrode (unless a reference or a channel is included in a bipolar montage) and occurrence (or may reoccur a few times sporadically), that is caused by the discharge of electrical potential between the scalp and electrode where electrical charges can store (as if in a capacitor). The pop is the only extraphysiologic artifact mentioned here (though this list is not exhaustive) that may resemble abnormal EEG activity, with some characteristics similar to epileptiform activity. Importantly, pops can be distinguished from true neurophysiologic paroxysmal activity by the fact that they tend to occur in only one electrode at a time, thus do not give the appearance of voltage change from an electrical field source, and appear with an asymmetric morphology characterized by relatively steep rise and slow recovery. These characteristics should differentiate pops from interictal spikes to the trained eye.

EEG Quantification and Feature Detection

Telegram: @medical_k

www.konkur.in

EEG recording, combined with stimulus-evoked paradigms and experimental measures of mental task performance, provides a powerful methodology for studying neural dynamics of human brain function and pathology. EEG data is dimensional and complex, based on a time series of events sampled with high temporal resolution (i.e., millisecond level) and distributed spatially across multiple scalp locations (e.g., montages of 32 to 256 channels). If one considers a sampling rate of 256 samples per second, across 32 scalp channels, for 10 minutes of recording, each parameter representing a lower bound of what is possible for digital EEG recording and typical for a recording session (which may last hours), the resulting data matrix could conceivably include 4,915,200 discrete data points. While examples of clinical EEG discussed thus far would not entail a detailed analysis of each sample point by the electrode (this would never be done under any circumstance), with objectives that are routinely achieved by visual inspection of data over time scales of several seconds, such abundant data no doubt contains important features that cannot be ascertained (or even seen) through visual inspection and clinical judgment alone. The advent of digital EEG recording technology, among other advantages over analog paper EEG, makes highly detailed EEG analysis possible through computerized signal processing. Basic processes such as *segmentation,* dividing the time series record into shorter periods or epochs based on experimental events, and *averaging* over multiple segments (consistencies in signal average together while noise averages out) provide efficient means of isolating important features in data, upon which a number of additional signal extraction methods can be applied. Digital EEG analysis is broadly referred to as "*Quantitative EEG*," abbreviated to *Q-EEG* or *qEEG,* emphasizing measurement of the magnitude and differentiation of features contained within the EEG rather than qualitative decisions over whether or not an observed feature indicates a pathophysiologic process. However, even while the heavy computational burden is now passed on to the machine, Q-EEG still requires the same human judgments concerning data quality and interpretation. When the issue of artifact contamination of the Q-EEG is not properly addressed, one has a situation described a generation ago by computer programmers, namely, "garbage in, garbage out," leading to erroneous conclusions about the processed data. Software used for Q-EEG analysis includes automatic or semiautomatic functions for removal of artifact, based on thresholds for acceptable amplitude or change in

Telegram: @medical_k

www.konkur.in

amplitude over time, which can be used to mark and remove some sources of EEG contamination. However, these *artifact-rejection* procedures cannot typically mitigate all problematic conditions, such as the low-frequency activity of a drowsy patient, and visual data inspection should always be undertaken as the first step of the analysis.

FIGURE 1.26–12. Physical electrode movement in a referential montage. **Panel A** shows the effect at a single electrode (C4), suggesting the electrode is being physically shifted in position and unseated from the point of scalp contact. **Panel B** shows a consistent pattern of shift across all electrodes, indicating movement at the reference electrode site.

Beyond the initial data cleaning, the technician or experimenter is faced with many more technical decisions regarding the selection of time points and signal extraction methods used to best characterize the neurophysiologic phenomena under examination. It is sensible, if not required, for some processing steps to be taken before others, but each involves a number of decisions over parameters for which there is no common agreement or standardization. Furthermore, there is usually more than one way to implement a given function, which may differ between software packages, and the user (typically lacking extensive training in computer science and engineering) may be unaware of the intricacies and assumptions involved in each. There are also a number of free, open-source toolkits available for EEG analysis that enable the inclined user to customize various analysis routines. Therefore, while digital recording and analysis greatly increase the capacity to explore and

Telegram: @medical_k

www.konkur.in

extract features from EEG, the application of such methods remains to be more of an exquisite art than a standardized practice.

The most commonly used method for EEG quantification is spectral analysis, principally based on the *Fourier transform.* The Fourier transform decomposes a signal represented as a function of time into its constituent frequency components. Given the analogy of a chord played in music, playing the chord as an arpeggio (e.g., the A major chord played as individual notes A-C#-E) enables the listener to appreciate the frequency and loudness of each note as a component of the chord's overall harmonic quality. In a similar way, the Fourier transform represents a signal as a measure of *spectral power* (square of the signal amplitude) according to the *total power* of the broadband (e.g., chord) and *band power* of individual frequencies (e.g., notes). In EEG signal processing, the Fourier transform is most commonly implemented as the *Fast Fourier Transform* (FFT), which applies an efficient algorithm for computing the Fourier transform achieved by reducing the total number of samples submitted to computation by their base 2 logarithms. Applying FFT, therefore, assumes that the data represents a fixed-length waveform with a total number of samples that can be expressed as a factor of 2-to-the-nth power (e.g., 64, 128, 256, 512). The frequency resolution of the FFT is also dependent on the length of the data sampled, with longer segments of data needed to resolve lower frequencies. For example, the lowest frequency that could be characterized accurately using a segment length of 1 second is 1 Hz, while resolving a 0.1 Hz signal would require a segment length of 10 seconds. When using FFT, it is also important to keep in mind that the analysis treats all samples within the segment equally without regard to time; therefore, it is insensitive to time-varying functions and most appropriate for signals assumed to be stationary. Quantification of changes in spectral power that occur over a period of time is made possible through *time–frequency decomposition.* A variation on the FFT, called the *short-time Fourier transform* (STFT), has been developed for this purpose, but EEG analyses typically employ more sophisticated algorithms based on the *wavelet* transform. The theory and mathematical computation involved in the wavelet transform are beyond the scope of this chapter, but an eloquent description written in the context of EEG analysis can be found in the methods handbook of Cong, Ristaniemi, and Lyytinen (2015). The basic point to keep in mind in differentiating FFT, or time to frequency transformation, and wavelet, or

Telegram: @medical_k

www.konkur.in

time–frequency transformation, is that frequency extraction by FFT applies to the entire time window of analysis (signal is not localized in time) while wavelet analysis provides localization of frequency extraction to each sample of the time window. The latter is advantageous when examining change in frequency component structure as signals evolve over time and so tends to be the more appropriate analysis for perceptual–cognitive experiments. That said, there are still cases where FFT may be preferred, given that time resolution does come at a cost to frequency resolution.

In both the clinical and research literature, several types of time–frequency outcome measures are often discussed, which vary depending on the paradigms used to elicit them and the signal processing techniques utilized. Most commonly, oscillatory activity measured by time–frequency decomposition is differentiated into three categories: transient evoked, steady-state evoked, and induced (Fig. 1.26–13).

Q-EEG using frequency-based analyses has contributed largely to the appreciation of EEG as an ensemble of neurophysiology-generated oscillatory components with unique functional properties. For instance, it has been suggested that the delta rhythm, traditionally regarded as a pathologic finding in the awake EEG, has been related to internal concentration (i.e., conditions in which subjects have to disregard external input). Further examples include the association of frontally generated theta activity with encoding and working memory functions, the slow alpha band (7.5 to 9.5 Hz) with attentional processes, the fast alpha band (9.5 to 13.5 Hz) with memory retrieval, and beta activity with the integration of sensory information. Furthermore, functions associated with frequencies above 30 Hz, the so-called gamma band, have been more recently discovered and are currently a major focus in psychiatric research. The demonstration of a stimulus-induced gamma oscillatory activity in the mammalian brain was the first empirical evidence that synchronization of neural groups (individually coding for different aspects of the sensory input) serves a basic “binding” process in the central nervous system (CNS), enabling information communicated over sensory afferents to combine in forming a unified percept. While high-frequency gamma synchronization is thought to support communication of short-range local networks, slower oscillatory rhythms have been implicated in cognitive processes requiring integration over large cortical distances (e.g., among

Telegram: @medical_k

www.konkur.in

areas of different sensory modalities) that extend over longer periods of time (e.g., memory encoding).

FIGURE 1.26–13. Transient and steady-stated–evoked activity are phase- and time-locked oscillations (**A** and **B**) elicited by discrete or steady-state sensory stimuli. For both of these types of activity, averaging across trials has the effect of canceling out nonphase-locked oscillations (due to destructive interference), leaving the evoked response intact and magnified. Hence, time–frequency analysis can be performed on the averaged EEG (i.e., after averaging all the individual trials). By contrast, induced activity is typically elicited during higher perceptual processing, for example, during the perception of coherent motion or of illusory shapes (see **Panel C**). These responses are often nontime locked (jittered across time from trial to trial). Hence, averaging the trials cancels out the response of interest due to destructive interference and is not visible in the time–frequency transform (bottom of **Panel C**, left). However, these responses can be detected if the time–frequency analysis is performed on the single trials, and the time–frequency transforms of individual trials are then averaged (**Panel C**, right). (Adapted from Skosnik PD, Cortes-Briones JA. Electroencephalography and cannabis: from event-related potentials to oscillations. In: Preedy VR, ed. *The Neuropathology of Drug Addictions and Substance Misuse*. Academic Press; 2016:851–862, with permission from Elsevier.) (See color panel.)

Time- and frequency-based analyses mentioned thus far (Figs. 1.26–6 and 1.26–13) have paved the wave for more precise characterization of neural activity and function. However, they may fall short in providing a fully accurate representation of neural communication in that the

Telegram: @medical_k

www.konkur.in

information extracted by these methods remains spatially localized (e.g., analyzed based on one electrode or field of electrodes). Furthermore, while these methods effectively quantify the magnitude of neural activity as an average representation of time, the degree of consistency in activation across time segments is lost. Relationships between frequency ensembles located at different spatial locations or occurring at different time points, determined as a measure of synchronization, can be ascertained using *coherence* measures. Coherence analysis follows frequency (e.g., FFT) and time–frequency (e.g., wavelet) decomposition of the signal and is applied to a complex form of these data as a measure of the strength of association in the linear dependence of two signals. Coherence analysis can be applied to stationery and time-series data as a measure of the relationship of spectral power between two regions (i.e., *spatial coherence*), the dependence of one frequency on another (i.e., *cross-spectrum coherence*), and of consistency in the phasic cycle of oscillatory activity over repeated trials (i.e., *intertrial coherence*). Taken together, the combination of spectral power and coherence measures greatly enhances the ascertainment of neural dynamics comprising the human EEG and increases the capability to understand the functional interactions of brain areas on a large spatial scale.

Q-EEG Topographic Analysis and Source Analysis

Computerized EEG topography (CET) or Q-EEG mapping was developed for multichannel Q-EEG data. The technique enables the construction of a two- or three-dimensional matrix for a topographic representation of Q-EEG parameters, such as instant amplitude or band power. Matrix points that do not correspond to recording electrodes are calculated by interpolating the values of the nearest three or four recording electrodes. As for other imaging techniques, statistical probability maps can also be implemented for comparisons between different subject populations or experimental conditions. Color-coded maps make the multichannel information more immediately intelligible; however, the topographic information provided by the technique is critically dependent on the reference electrode used for EEG recording. To address this issue, several transformations have been proposed that provide reference-independent data, including average-reference (i.e., subtraction of the mean of all electrodes from each electrode value) and surface Laplacian or CSD approaches previously mentioned. However, it is imperative to

Telegram: @medical_k

www.konkur.in

realize that the topography at the scalp, even when resulting from reference-independent calculations, does NOT allow physiologic inferences on the underlying brain generators due to the so-called inverse solution problem. Essentially, this problem appreciates the imprecision of localizing sources of field potentials as recorded at the level of the scalp since numerous neural activation patterns can generate the same scalp topographies.

FIGURE 1.26–14. Example of EEG source analysis using sLORETA. The time–frequency transform on the left indicates a burst of transient gamma activity to an auditory click stimulus, which was localized to the primary auditory cortex (right).

Thus, in 1989 Frank Duffy, Dietrich Lehman, Fernando Lopes da Silva, and other eminent scientists formed the International Society for Brain Electromagnetic Topography (ISBET), established to promote the application and further development of techniques investigating brain electromagnetic activity, topography, and source analysis. In recent years, different algorithms have been proposed to solve the inverse problem. They can be divided into *equivalent current dipole models* and *current distributed source models.* According to recent comparative studies, the dipole models are suitable only when a single source is expected. Among the distributed source methods, *low-resolution brain electromagnetic tomography* (LORETA), or more recently, *standardized low-resolution brain electromagnetic tomography* (sLORETA), have proven greater effectiveness in terms of localization error, particularly when multiple sources and noise are present. Briefly, the sLORETA method is a properly standardized discrete, three-dimensional distributed, linear, minimum norm inverse solution. The particular form of standardization used in

Telegram: @medical_k

www.konkur.in

sLORETA endows the tomography with the property of exact localization to test point sources, yielding images of standardized current density with exact localization, albeit with a low spatial resolution (i.e., neighboring neuronal sources will be highly correlated). sLORETA is currently a method of choice since it has no localization bias, even in the presence of measurement and biologic noise. In the current implementation of sLORETA, computations are made in a realistic head model using the MNI152 template with the three-dimensional solution space restricted to cortical gray matter, as determined by the probabilistic Talairach atlas. Thus, sLORETA images represent the standardized electric activity at each voxel in neuroanatomic Montreal Neurological Institute (MNI) space as the exact magnitude of the estimated current density (Fig. 1.26–14). Several studies have reported consistency between sLORETA and other neuroimaging methods such as fMRI. The LORETA/sLORETA software is based on the pioneering work of Roberto Pascual-Marqui and his group, and relevant references can be freely downloaded (http://www.uzh.ch/keyinst/loreta.htm). It should be noted, however, that methods/models of source localization, analysis steps, and relevant software packages continue to evolve.

Status of Q-EEG in Applied Clinical Practice

Despite advances in EEG signal extraction enabled by digital technology, there are few specific conditions for which Q-EEG has gained acceptance as a clinical diagnostic tool, and in these cases, it is used only to enhance the interpretation of conventional clinical EEG. According to the AETNA Health Insurance list of approved indications (last reviewed on April 15, 2021), Q-EEG is medically necessary only as an adjunct to traditional EEG for the following conditions (from http://www.aetna.com/cpb/medical/data/200_299/0221.html, accessed November 17, 2021):

1. For the ambulatory recording of EEG to facilitate subsequent expert visual EEG interpretation; *or*
2. For continuous EEG monitoring by frequency trending to detect early, acute intracranial complications in the operating room or ICU; *or*
3. For evaluation of certain members with symptoms of cerebrovascular disease whose neuroimaging and routine EEG studies are not conclusive; *or*

Telegram: @medical_k

www.konkur.in

4. For evaluation of dementia and encephalopathy when the diagnosis remains unresolved after initial clinical evaluation; *or*
5. For screening for possible epileptic seizures in high-risk ICU members; *or*
6. For screening for possible epileptic spikes or seizures in long-term EEG monitoring; *or*
7. For topographic voltage and dipole analysis in presurgical evaluations for intractable epilepsy.

The list of indications described is no more inclusive than those recommended nearly 20 years prior by the ACNS and American Academy of Neurology (AAN) Executive Board's publication, appearing in the journal *Neurology* in 1997. Also consistent with the conclusions of the ACNS/AAN report, AETNA considers the use of Q-EEG "experimental and investigational" for all other indications due to the lack of adequate scientific evidence to support its clinical utility. Psychiatric conditions listed explicitly among unsupported indications include alcohol and substance use disorders, anxiety, Asperger syndrome and other autism spectrum disorders, attention deficit disorders, bipolar disorder and major depression, panic disorder, PTSD, and schizophrenia, in addition to cases of acquired injury involving mild or moderate head injury, sports concussion, and tinnitus, among others. Furthermore, despite favorable reports in the research literature, Q-EEG has yet to receive approval for use in predicting the efficacy of psychotropic medication.

EEG IN APPLIED CLINICAL PRACTICE

Despite the fact that EEG originated in psychiatry, the strongest initial impetus for its use came from neurology, particularly the study of epilepsy. The years from 1934 to 1940 saw a marked proliferation of EEG studies focused on structural brain lesions and a variety of seizure disorders. In 1934, the team led by Fred Gibbs discovered the classic three-per-second spike-and-wave complex, which proved to be specific to petit mal absence attacks. Before the decade ended, they had described EEG patterns associated with grand mal and myoclonic seizures and a diffuse spike-and-wave pattern that was slower in frequency than petit mal (and given the confusing name of petit mal variant) and that was associated with grand mal seizures and a high incidence of mental retardation. They also introduced the term *psychomotor seizures* (now *complex partial seizures*

Telegram: @medical_k

www.konkur.in

[CPSs]) and described the EEG manifestations characterizing an ictal psychomotor attack. Later, in 1947 and 1948, they described the anterior temporal spike focus that became the interictal EEG correlate of this disorder. On the other side of the neurologic coin, the study of structural brain lesions was advanced through landmark EEG discoveries of the 1930s to 1950s. In 1935, Otfried Foerster and Helmut Altenberger reported that focal slow waves in the EEG recording often appeared near brain tumors, and 1 year later, Grey Walter made a major advance by demonstrating a technique for EEG localization of brain tumors. Denis Williams at Oxford subsequently began using EEG recordings to study and localize traumatic intracranial injuries received during World War II. Finally, through the collaboration of neurosurgeon Wilder Penfield and psychologist (turned neurophysiology researcher) Herbert Jasper, who brought EEG to the Montreal Neurologic Institute in 1937, a technique for direct intracranial EEG recording termed *electrocorticography* (ECoG) was developed. ECoG was applied to the detection of epileptogenic zones for surgical resection as part of the groundbreaking *Montreal procedure* in the 1950s.

Normal versus Abnormal: General Considerations

One of the factors that may have limited the perception of EEG as a useful assessment tool in psychiatry is the simplistic attempt to conceptualize EEG findings as a normal-versus-abnormal dichotomy. Psychiatric practitioners commonly ask if their patient's EEG is abnormal and seem content with an affirmative or negative answer. The expectation was that if the EEG was abnormal, then this meant that the patient belonged to neurology, and if normal, that would confirm the psychiatric status of the patient. Furthermore, much of the published research literature reports the percentage of abnormal EEG findings in a given study population without stating the exact nature of the abnormalities. In actuality, the simple normal–abnormal dichotomy is inconsistent with the dynamic nature of EEG, particularly when interpreted by conventional visual inspection without the use of more objective means of quantification that could equate EEG to more common and reliably discernable measures of the physiologic function used in medicine (e.g., blood pressure). Rather than being considered as a dichotomy, the range of EEG findings exists on a broad continuum anchored on one end by unequivocally normal EEGs and extending in the other direction to

Telegram: @medical_k

www.konkur.in

features of possible and, eventually, more definite clinical significance. Some EEG patterns that are correctly classified as abnormal are on the low end of the continuum of clinical expressivity and may not always contribute strongly to diagnostic decisions. The psychiatrist receiving a report of a minor finding of limited clinical relevance may understandably begin to question the value of EEG when no current or past history of organic signs are detected. The bottom line is that one should not ask simply if an EEG is abnormal, as if it were one side of a dichotomy, but instead should ask what specific features were present and what, if any, known clinical correlates may be associated with that feature. Even when questions remain about the clinical significance of an abnormal feature, this finding should not simply be disregarded and, at least, could indicate a need for follow-up EEG, additional brain imaging, neuropsychological assessment, review of medications or illicit drugs used, or other laboratory measures of cardiac and metabolic function.

In addition to the confusion caused by the reliance on the normal–abnormal dichotomy, literature reports stating that 10% to 20% of the normal population have abnormal EEG findings could lend uncertainty regarding the value of the EEG in psychiatric practices. Because such statements are almost never properly clarified, they tend to be terribly misleading. Clearly, there can be an understandable reluctance to follow up on an abnormal EEG report if one has read in a presumably authoritative source that 20% of the normal population have abnormal EEG findings, decreasing the impression of their diagnostic specificity and, logically, clinical utility. More importantly, there also may be an equally understandable reluctance to refer a patient for an EEG study for the same reason. To place the issue in proper perspective, the reports of substantial percentages of abnormal EEGs within the normal population are heavily skewed by the inclusion of minor findings that often have low levels of clinical or diagnostic relevance. A comprehensive review of the literature on EEG findings in normal control populations by Nash Boutros and colleagues highlights the fact that most control studies have been seriously compromised by failure to screen subjects for a variety of medical and psychiatric variables that can impact EEG results. This group had previously reanalyzed data from numerous published EEG control population studies. When borderline EEG findings were removed from the data, the incidence of EEG abnormality dropped to 3.2% of 6,182 healthy adults and 3.5% of 1,450 healthy children, with the prevalence of

Telegram: @medical_k

www.konkur.in

accepted paroxysmal EEG abnormalities reduced to only 1.14% of a sample of 11,560 mixed-age healthy subjects.

Variants of Normal EEG

Sleep Patterns. The EEG patterns that characterize drowsy and sleep states are different from the patterns seen during wake. A detailed accounting of the nuances of sleep EEG is beyond the scope of this chapter. Briefly, the rhythmic posterior alpha activity of the closed-eye waking state subsides during progressive drowsiness and is replaced by irregular low-voltage theta activity and sporadic vertex sharp waves, which indicate entry into stage 1 sleep. The progression into stage 2 sleep is marked by the appearance of 12- to 14-Hz sleep spindles (also called sigma waves) and k complexes. These patterns eventually give way to high-voltage (>75 μV) delta waves, which indicate stage 3 deep sleep. Lastly, REM sleep is characterized by low-voltage, mixed frequencies that resemble waking EEG. Some individuals may also exhibit low-amplitude sawtooth waves in REM sleep.

Changes with Age. The appearance of the EEG changes dramatically from birth to advanced age. From a preponderance of irregular medium- to high-voltage delta activity in the tracing of the infant, EEG activity gradually increases in frequency and becomes more rhythmic with increasing age. Rhythmic activity in the upper theta–lower alpha range (7 to 8 Hz) can be seen in posterior areas by early childhood, and, by the time mid-adolescence is reached, the EEG essentially has the appearance of an adult tracing. The interpretation of EEGs obtained from children demands a solid grounding in the age-related changes during this period and is best performed by one specializing in pediatric EEG. For the sake of the current chapter, it is sufficient to raise awareness that the developmental period (among other factors to be discussed) must be considered in making absolute determinations regarding whether or not the presence of a given feature (e.g., presence of waking delta wave activity) is clinically significant. This topic of age-related change in EEG and trajectories of pathology receive detailed treatment in the text *Developmental Psychophysiology,* edited by Louis Schmidt and Sidney Segalowitz.

Controversial Sharp Waves or Spike Patterns

Telegram: @medical_k

www.konkur.in

Early in the emergence of clinical EEG, a considerable amount of heated controversy developed around the clinical significance of certain sharp wave or spike patterns that were easily identified in the EEG tracing. These so-called controversial patterns deserve a specific mention here because they have been observed consistently in numerous studies to be more prevalent in psychiatric populations than healthy or general medical patient populations. Despite the increased prevalence in psychiatric patients, defining the clinical and neurobiologic correlates of these patterns has proved to be an elusive goal. The task is made difficult because none of these patterns is specific to a diagnostic category, and none predictably correlates with seizure disorders. Because the physiologic or pathologic correlates of these patterns have not been well studied using currently available methodologies and assessment techniques, the assertion that they are irrelevant to neuropsychiatric conditions is not fully supportable. At a minimum, the appearance of such patterns may give support to the possible organic nature of presenting symptoms. The number of accepted and still controversial EEG abnormalities is quite large and well beyond the scope of this chapter.

Paradigms for Eliciting Pathophysiologic Features

Over the years, electroencephalographers have recognized that certain *activating procedures* tend to increase the probability that abnormal discharges, particularly spike or spike-wave seizure discharges, will occur. Some activating techniques remain standard in many laboratories, others are used only rarely for specific purposes, and still, others introduced in the past largely have been abandoned because they were not easy to use or involved risk. It has long been recognized that seizure manifestations or aberrant behaviors with a pathophysiologic basis involving seizures can be triggered by specific stimuli. In this regard, cases of audiogenic, musicogenic, photogenic, and reading epilepsy readily come to mind, even though such cases are rare, and most practitioners have never encountered them. Seizure phenomena related to other sensory system inputs (e.g., somatosensory and gustatory) are even rarer. Sometimes, it may be possible for laboratory personnel to duplicate or approximate sensory triggers in various modalities to determine if they activate EEG seizure discharges combined with overt symptoms. Some of the more conventional activating techniques are described below.

Telegram: @medical_k

www.konkur.in

Photic Stimulation. In the earliest days of EEG, it was known that the frequency of normal EEG activity recorded from posterior scalp regions could be made (within narrow limits) to follow the frequency of a flickering light that was flashed slightly faster or slower than the intrinsic brain wave frequencies, a phenomenon that came to be referred to as *photic-driving.* An illustration of this phenomenon is presented in Figure 1.26–15, depicting the instantiation of a steady-state response of approximately 9 Hz over the visual cortex following stimulation at a 9-Hz flicker rate. When it also became known that photic-driving would sometimes cause paroxysmal discharges to occur in the EEG, *intermittent photic stimulation* (IPS) emerged as a technique for eliciting EEG abnormalities referred to, under conditions of stimulation, as *paroxysmal photosensitive responses* (PRRs). Although there is some variation between laboratories, IPS generally involves placing an intense strobe light (at least 0.70 J) approximately 30 cm in from the nasion and flashing at frequencies that can range from 1 to 50 Hz, depending on how the procedure is carried out. It is recommended that a round stimulator be used to best ensure uniform stimulation of the entire retina. In addition to flashing light, flickering grid stimuli may be used to further assess pattern-specific photosensitive responses, which may be indicated in patients who tend to have seizures induced by television watching or video gaming. Some laboratories sample independent flash frequencies separately and randomly, without necessarily sampling all frequencies between 1 and 50 Hz, while others use a *zoom technique* in which the flashes start at a low frequency, such as 1 Hz, and are then gradually and continuously increased to higher frequencies. In some individuals, IPS produces facial, and eye muscle jerks called a *photomyoclonic response* (PMR). More than 40 years ago, Henri Gastaut observed that PMR occurs in 0.3% of normal subjects, 3% of epileptic patients, and 17% of patients with psychiatric disorders. The PMR also is enhanced in the early stages of alcohol withdrawal in chronic alcoholics and after a sudden withdrawal from barbiturates and other sedatives. The clinical relevance of PMR in psychiatric patients is yet to be fully explored in systematic research.

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–15. Photic driving using checkerboard pattern presented at 9 Hz flicker rate. **Panel A:** 10-second display of EEG at the beginning of photic stimulation. The onset of the visual checkerboard display, indicated by "s" at the bottom of the display. **Panel B:** 1-second segment based on average EEG for 10-second period prior to stimulation recorded at electrode Oz. **Panel C:** Visual-evoked potential (VEP) based on an average of 10 seconds recorded during stimulation at electrode Oz. The VEP represents an oscillatory pattern of 9 cycles over a 1-second segment. **Panel D:** VEP represented as time–frequency decomposition by wavelet transform of frequencies of 1 to 50 Hz at electrode Oz, with peak activity at approximately 9 Hz. The scalp plot (bottom right) indicates activity is generated primarily over occipital electrode sites.

In terms of activating EEG abnormalities, one looks for a PRR that consists of bilaterally synchronous, usually diffuse, spike-and-wave discharges of various frequencies or diffuse, multiple spike-wave complexes. When the resting EEG is normal, and a seizure disorder or behavior that is suspected to be a manifestation of a paroxysmal EEG dysrhythmia is suspected, IPS can be a valuable activation to use. Its primary limitations, especially as a routine procedure, are the "false positive" incidence of PRR in individuals with no history of seizure disorder or current symptoms suggestive of such and similarly low sensitivity in cases of verified seizure disorder. The persistence of the spike-wave discharges after the cessation of the IPS may also be indicative of a PRR. Moreover, a pathologic process might be indicated by the spread of the spike-wave activity to lead outside the occipital region.

Polysomnography—Sleep Study. Largely because of the pioneering studies and perseverance of Fred and Erna Gibbs, EEG recording during sleep, natural or sedated, now is widely accepted as an essential technique for eliciting a variety of paroxysmal discharges, when the wake

Telegram: @medical_k

www.konkur.in

tracing is normal or for increasing the number of abnormal discharges to permit a more definitive interpretation to be made. A variety of focal and diffuse spike and spike-wave discharges, as well as several minor or controversial paroxysmal patterns, occur much more often during drowsiness and light sleep than during the wake recording, and some of them are seen almost exclusively during the sleep recording. Paroxysmal patterns differ substantially among themselves in the degree to which their appearance in the tracing is sleep-activation dependent. Although most clinical EEGs should contain drowsy- and light-sleep tracings to be complete, stage 3 deep sleep with generalized high-voltage delta slowing have almost no activating property and is not clinically useful.

Sleep Deprivation. It has been shown that the stress produced by 24 hours of sleep deprivation alone can lead to the activation of paroxysmal EEG discharges in some cases. This effect is presumably independent of the known activating properties of natural or sedated sleep itself. Sleep deprivation is without risk for the healthy patient but may be contraindicated for patients medically or physically compromised. The primary disadvantage is the tendency for sleep-deprived individuals to enter into a deep sleep (stage 3) immediately at the start of the recording, thus reducing the chances of detecting spike activity. The optimal method is to ensure that the subject stays awake until the recording begins and remains so for the initial recording period, after which a gradual transition into drowsy sleep can be observed.

Drug Activation and Suppression Tests. Psychiatrists evaluating a patient with an atypical behavioral reaction to a drug (e.g., an unusually severe response to a small amount of alcohol or other abused drug or some other highly idiosyncratic response) may consider a drug-activated EEG to determine if ingestion of the drug activates a seizure or other paroxysmal abnormality of clinical significance. In the past, drug activation using hypoglycemic agents (e.g., tolbutamide) and convulsants (e.g., pentylene tetrazol) was used to activate epileptiform discharges. However, this type of activation has been essentially eliminated from clinical work in recent years due to the high incidence of discharges produced by these drugs in healthy subjects and the low value of positive findings in individuals with epilepsy. Today, drug modulation of EEG remains to be used as an investigative procedure for ascertaining drug effects on presumed neurophysiologic mechanisms, both with relevance to

Telegram: @medical_k

www.konkur.in

enhancing functions in the case of drug development and in modeling pathologic conditions in healthy subjects using the pharmacologic challenge design. While drug activation is no longer used in routine clinical practice, drug suppression paradigms are still regarded as useful for the identification of focal epileptiform activity. Seizure foci can be difficult to detect on EEG when in the case of generalized discharges and accompanying spread of activation across electrodes. In a drug suppression test, generalized discharges can be reduced by intravenous injection of diazepam or barbiturate methohexital (e.g., methohexital suppression test; MHXT). The rationale behind this approach is that by using drugs that block excitatory neurotransmission and/or enhance inhibitory transmission, much of the background EEG is suppressed while autonomous epileptogenic lesions, which are resistant to synaptic blockade, continue to fire. This approach can therefore improve the localization of epileptiform lesions against background EEG and generalized activity that is dependent on synaptic input.

Hyperventilation. Hyperventilation is one of the oldest and still one of the most frequently used activation procedures in clinical laboratories. While remaining reclined with the eyes closed, the patient is asked to overbreathe through their open mouth for 1 to 5 minutes (not useful beyond 5 minutes), emphasizing deep breathing rather than rapid breathing. The purpose is to empty the lungs to the extent of producing hypocarbia, and to reduce oxygen and glucose supply to the brain through cerebral vasoconstriction. The normal EEG response to hyperventilation (referred to in EEG parlance as a *buildup*) consists of an increase in generalized medium- to high-voltage synchronous slow waves in the delta range, which then quickly subside when overbreathing stops (within 1 to 2 minutes normally). Not everyone has a build-up response to hyperventilation, and children are far more likely to respond with diffuse EEG slowing than adults. Indeed, this procedure is not effective in the older adults, who show minimal reactivity of the cerebral vasculature to hypocarbia, and is contraindicated in those aged 65 and older. In terms of activating EEG abnormality, hyperventilation is especially effective in eliciting the classic diffuse three-per-second spike-and-wave complex of petit mal seizures when the pattern does not first appear in the standard waking EEG. Hyperventilation may, to a lesser degree, activate other synchronous diffuse spike-wave patterns, and activation of focal seizure

Telegram: @medical_k

www.konkur.in

activity has been infrequently reported. An interesting observation is that significantly low blood glucose levels have been associated with large, synchronous delta wave hyperventilation buildups that may persist beyond 2 minutes after overbreathing is stopped. Accordingly, a large delta wave buildup in an adult may signal the existence of covert, unsuspected pathologic hypoglycemia. If this suspicion presented itself during a recording, a good idea would be to give a sugar drink to the patient and then repeat hyperventilation later. If the glucose ingestion reduces or abolishes the large hyperventilation buildup, then the suspicion of hypoglycemia is likely confirmed. In general, hyperventilation is one of the safest EEG activating procedures and, for the majority of the population, will present no physical risk. However, it may pose a risk for patients with cardiopulmonary disease or risk factors for cerebral vascular pathophysiology, thus would also be contraindicated in these cases.

Brief Synopsis of EEG Findings in Organic Pathophysiology

The EEG has a high degree of sensitivity to a wide variety of medical conditions and events that impinge on CNS function. For this reason, EEGs sometimes have contributed to the detection of unsuspected organic pathophysiologies influencing a psychiatric presentation. The range of EEG findings in medical disease is enormous and far beyond the scope of this chapter, but we touch on four of the most common organic pathologies informed by EEG in the context of a diagnostic workup.

Seizure Disorder. The hallmark EEG finding for a seizure disorder is the generalized, hemispheric, or focal spike or spike-wave discharge, or both. However, this statement constitutes a large oversimplification because many types of EEG abnormalities have been associated with seizures at one time or another, and some patients with a bona fide seizure disorder have been known to have normal interictal EEG tracings. Indeed, while epileptiform activity detected on EEG is a reasonably specific indicator of epilepsy, sensitivity can be quite low, ranging from 25% to 56%, with only about 50% of patients diagnosed with epilepsy evidencing *interictal epileptiform discharge* (IED) of their first EEG examination (of note, this rate can increase to 80% in sleep EEG). Furthermore, seizure disorders have many possible etiologies, whether genetically based or a consequence of head trauma, cerebrovascular pathophysiology, metabolic disorders, structural brain lesions, infectious

Telegram: @medical_k

www.konkur.in

or toxic encephalopathies, certain drug-abuse withdrawal states, or iatrogenic causes to name only a few. The diagnosis of seizure disorder based on EEG findings should consider family and personal medical history while also keeping in mind that seizures can be idiopathic.

The classification of seizure types is also broad, and the majority of specific seizure manifestations may be of little concern to the practicing psychiatrist. One of the exceptions may be *absence* (i.e., petit mal) seizures, during which the patient presents with grossly impaired consciousness marked by pronounced confusion, greatly slowed mental processes, and stuporous or somnolent behavior. Although these seizures tend to be brief, normally lasting only 15 to 30 seconds, absence episodes can reoccur as many as 100 times per day. The psychiatrist is most likely to encounter this clinical presentation in the emergency room, where it is often confused with other functional or organic syndromes or intoxicated states. If suspected, then the status can be confirmed quickly by an EEG demonstration of continuous, diffuse spike-wave activity. Typical absence seizures also may be of relevance to the child psychiatrist as this type of epilepsy has a peak incidence from childhood to early adolescence and, in some cases, may be mistaken for inattention or other functional behavioral reactions. Spike foci in the anterior temporal region associated with CPSs (also known as psychomotor or temporal lobe seizures) should also be of interest to the psychiatrist due to the wide range of possible seizure manifestations, consisting of almost any combination of “automatic” motor movements, sensory disturbances, psychiatric symptoms, or autonomic signs. The symptom cluster almost always remains the same from one attack to another, and the “automatic” behavior during the ictal event may be quite unusual, with the patient undressing, picking at clothing and lip-smacking, walking in circles and yelling, trying to climb on a table while making guttural noises, experiencing hallucinatory symptoms, or almost any other action. When continuous or closely spaced CPS attacks (complex partial status) lasting hours or longer than a day occur, they may mimic hysterical dissociative states.

Spike activity of various kinds and locations is sometimes found in the EEGs of psychiatric patients with no obvious seizure manifestations. In such cases, one might consider possible relationships to episodic aberrant behavior (particularly explosive aggressiveness), if present, as well as a trial of anticonvulsant medication. Sometimes, such spike

Telegram: @medical_k

www.konkur.in

discharges in the nonseizure psychiatric patient may indicate an elevated risk for iatrogenic seizures after treatment with neuroleptic medication.

Structural Lesions. Brain tumors are the leading cause of new-onset seizures in adults. EEG is rarely used for the diagnosis of structural and space-occupying lesions, which are typically assessed with CT or MRI. Nonetheless, it should be noted that 90% of cortical brain tumors can be detected and localized on the scalp with routine EEG.

Closed Head Injury. Generalized or focal slowing is the main characteristic of EEG following head trauma, appearing over the site of the trauma or over a *contrecoup* (e.g., the side opposite the side of impact) location. Attenuation of posterior alpha is another hallmark feature associated with a head injury. The basic premise guiding the interpretation of these observations is that the frequency and power of scalp-recorded EEG depends on the numbers of activated neurons and the integrity of their connections. Therefore, in the case of injury, reductions in neurons and disruption of normal connectivity result in attenuation of signal power and a shift to slower frequency. The EEG change may be relatively transient with resolution over days or weeks, or it may persist for extended periods of time. Focal spiking may be taken as an early indication of a posttraumatic seizure disorder. Subdural hematomas after a head injury may present with focal delta slowing or more widespread slowing and, on occasion, amplitude asymmetry of waking EEG with the voltage decreased over the site of the hematoma. That said, conventional EEG is generally not regarded as clinically useful in cases of mild traumatic brain injury (mTBI), particularly beyond the first several hours following injury and when loss of consciousness (LOC) with injury is 2 minutes or less. EEG findings may appear normal early in the postinjury period following mTBI despite the presence of postconcussive symptoms, such as headache, dizziness, fatigue, irritability, impaired memory and concentration, insomnia, and sound and light sensitivity. Clinically significant EEG changes in association with mTBI, if at all present, may not be recognized as deviant until compared with follow-up EEG taken later in the postinjury period. Of note, literature reviews suggest that as many as 20% of cases with noncomplicated mTBI recover from clinical symptoms within the first 24 hours, and as many as 85% within 1 week following injury. Similarly, abnormalities detectable by conventional clinical EEG tend to resolve within months of injury.

Telegram: @medical_k

www.konkur.in

While routine clinical EEG may not be regarded as a useful tool for routine screening of mTBI, at least not beyond the detection of posttraumatic seizure activity, there is evidence that Q-EEG may hold some promise. Numerous studies by Robert Thatcher and colleagues, as well as others, have reported Q-EEG findings associated with the postconcussion syndromes following mild to moderate closed head trauma. Reported Q-EEG changes involve a combination of increased theta power, decreased alpha power, increased theta–alpha ratios, and increased coherence between frontal and temporal areas in the resting EEG. A number of studies have applied discriminative analysis to Q-EEG collected in mTBI versus control sample, yielding high classification accuracy, and have demonstrated the utility of Q-EEG in predicting functional disability. Q-EEG and related topographic analysis are likely to outperform routine clinical EEG in these cases because the quantification process aims to identify sharply focal or regional alterations in activity according to statistically significant deviations from normative parameters, which could remain below the threshold for accurate visual detection. The use of Q-EEG in the assessment of mTBI nevertheless remains a heavily debated topic, with supporting evidence criticized for the composition of study samples and other methodologic choices.

Metabolic and Endocrine Disorders. EEG is not a tool that one would use in assessing endocrine or metabolic disorders. Yet the majority of these conditions alter the EEG, and unexpected abnormal findings during routine EEG screening have occasionally been the first positive laboratory results leading to the subsequent identification of mild endocrine or metabolic disturbance. Because metabolic and endocrine disorders, as well as certain vitamin deficiencies and toxic exposures, affect the brain in a global fashion, they tend to produce diffuse, generalized slowing of wake frequencies, with the degree of abnormality correlated with the severity of the disorder. As would be expected, focal slowing is almost never seen, and paroxysmal spike activity is quite rare, although spike activity has been observed in cases of hypocalcemia, acute intermittent porphyria, and exposures to some toxic substances (e.g., lead, carbon monoxide). Early hepatic disease is commonly associated with generalized slowing in the theta range, which may increase in severity with elevated blood ammonia levels. If the disorder progresses to hepatic encephalopathy, a distinctive and diagnostically relevant EEG pattern

Telegram: @medical_k

www.konkur.in

called *triphasic waves* (or, more informally, *liver waves*) can emerge, characterized by frontally dominant or diffuse 1.5- to 3.0-per-second high-voltage slow waves initiated by blunt or rounded spike-like transients. For a thorough review of the effect of various metabolic disorders on EEG, the reader is directed to the referenced chapter by Pang and colleagues.

EEG IN PSYCHIATRY

Psychiatry Overview

Starting in approximately 1938, a flurry of continuing EEG investigations began to reveal an increase in the overall prevalence of minor abnormalities in almost all psychiatric populations as compared to healthy or nonpsychiatric individuals, which continue to be investigated to this day. On the other hand, two major factors led to the rapid disillusionment of the field of psychiatry with EEG. The first was the lack of specificity of EEG abnormalities to known psychiatric syndromes. The second factor, alluded to previously, was the continuing discovery of EEG abnormalities correlating with epilepsy, tumors, encephalopathies, stroke syndromes, and coma. With discoveries of significant EEG changes accompanying neurologic problems on the rise and EEG abnormalities associated with psychiatric symptomatology remaining to be relatively obscure and noncontributory to the diagnostic process, the field of *clinical EEG* (and later *clinical neurophysiology*) became more firmly established as a subspecialty of neurology, with a de-emphasis of EEG among psychiatrists.

The recent surge of interest in the neurobiology of psychiatric disorders, the emergence of the clinical field of *neuropsychiatry,* and the unprecedented advances in computerized analyses of EEG and other neurophysiologic signals have resulted in a strong rekindling of interest in electrophysiology among psychiatrists. In 1995, John Hughes undertook the mammoth task of compiling a comprehensive outline of the broad area of EEG and psychiatry with 181 significant references selected for citation from before 1950 until 1994. When such compilations are inspected, the findings reveal that more than one-half of the EEG-psychiatry references appear after 1980, and one-third were written within the 5 years preceding Hughes' 1995 report. Continued inspection of the literature indicates that this trend has not abated. A *PubMed* search using the terms "EEG + Psychiatry" identified an additional 12,054 articles published in this field

Telegram: @medical_k

www.konkur.in

since 1995 (a nearly twofold increase since 2015), including both clinical and basic science research. Furthermore, two scientific organizations have been established for the primary purpose of accelerating the translation of electrophysiologic research findings to clinically utilizable laboratory tests. In 1991, the American Psychiatric Electrophysiology Association (APEA) was founded. In 1999, the APEA merged with the American Medical EEG Association (AMEEGA), and the EEG and Clinical Neuroscience Society (ECNS) was formed (http://ecnsweb.org).

In spite of the enormous research potential recognized in psychiatry, electrophysiologic methods are still of limited impact in clinical practice, where their primary applications are to aid in differential diagnostic purposes (i.e., the exclusion of “organic” brain pathology) and the investigation of sleep disorders. There is no accepted indication of EEG methods for the diagnosis of DSM-5 psychiatric disorders or for drug treatment choice and monitoring. This may seem surprising when considering that (1) robust results of Q-EEG abnormalities have been reported and independently confirmed for major psychiatric disorders, especially for schizophrenia; (2) evidence has been provided that abnormalities of event-related potentials (ERPs) and of eye movements are related to genetic risk factors, symptom dimensions, prognosis, and diagnostic subtypes of schizophrenia and depression; and (3) EEG and related methodologies already provide translational paradigms and have demonstrated promise in predicting the likelihood that novel therapies and compounds will exhibit clinical efficacy in preclinical development as well as in clinical trials. However, it should also be acknowledged that despite acceptance of psychiatric disorders as “brain disorders,” there are currently no tests from any discipline of brain imaging or behavioral assessment that have been formally integrated into the clinical diagnostic formulation. Perhaps this disconnect reflects the fact that it is not brain function, *per se,* but disordered behavior (e.g., reduction in normal routine behavior, elevation in abnormal behavior causing distress to self/others) that signifies the need for clinical attention and, thereby, serves as the basis for diagnosis and treatment decisions. In this respect, it is understandable that even the strongest evidence linking an electrophysiologic feature to a symptom or disorder may not necessarily indicate the use of that feature as a diagnostic measure when clinical symptoms are acutely present.

Telegram: @medical_k

www.konkur.in

Where then could electrophysiology find a place in applied clinical psychiatry? One promising area is in the early detection of pathophysiologic processes during preclinical periods that could eventuate in psychiatric illness. For example, the prodromal period of psychosis (i.e., DSM-5 Attenuated Psychosis Syndrome) is now well recognized as a stage of disease progression during which at-risk individuals (e.g., presenting genetic liability, subclinical symptoms) begin to express functional impairment, which may correspond to a combination of factors affecting critical periods of brain maturation. Early detection has been a topic of great interest to psychiatric research as well as to the *National Institute of Mental Health* (NIMH), which, under the directorship of Thomas Insel, coalesced eight independent research laboratories in forming the *North American Prodrome Longitudinal Study* (NAPLS) consortium. Early *p*sychosis *p*rediction and *p*revention (i.e., EP3) was subsequently identified as a NIMH priority issue in 2013, with plans to focus funding efforts on this area for the following 5 years. These developments are consistent with aims to reduce the disability of severe psychiatric illness through early detection and intervention, reducing long periods of untreated illness that may precede a first clinical encounter. EEG methodology has figured prominently in the conceptualization and data collection of NAPLS investigations, with paradigms demonstrated to be sensitive to the pathophysiology of schizophrenia used as predictors of conversion to formal psychotic disorder during the prodromal stage. EEG has provided a highly valuable assessment tool for this work, having the advantages of being low-risk, noninvasive, and well-tolerated by this study population. Importantly, EEG has established sensitivity to normal neurodevelopmental processes that are hypothesized to be altered in the schizophrenia disease process. Finally, it should not be overlooked that EEG systems can be purchased at a relatively low cost, enabling standardization of recording apparatus and methodology across centers participating in multisite research. Innovations of the NAPLS study have included traveling subjects and additional calibration procedures to assess the reliability of instrumentation across sites and has firmly established the feasibility of large-scale data collection efforts in psychiatry.

Nonspecificity of Results

Two particular problems plague and hinder research in the field of EEG abnormalities in psychiatric populations. First is the belief that EEG

Telegram: @medical_k

www.konkur.in

abnormalities can be found in up to 20% of otherwise healthy individuals. The second major problem is another pervasive belief that interictal epileptiform activities, in the absence of clinically diagnosable seizures, are incidental (or nonspecific) findings without clinical relevance. Well-designed studies addressing these two important issues are needed to allow further research in this field to be more meaningful.

Moreover, there are only a limited number of ways in which brain electrical activity can respond to normal or pathologic influences. Brain waves change simply by becoming faster or slower in frequency or lower or higher in voltage, or perhaps some combination of these two responses. Thus, very similar patterns of EEG abnormality can emerge from different etiologic causes. For example, a neoplasm, subdural hematoma, brain abscess, cerebral vascular accident, or closed head injury may result in similar, although not always identical, focal EEG slowing. Generalized slowing is a common abnormal finding for which the etiologic causes include cortical atrophy, drug-induced encephalopathy, ECT, encephalitis, certain endocrine disorders (hypothyroidism and hypopituitarism), porphyria, head trauma, lead exposure, hypocalcemia, and Wernicke encephalopathy, to name but a few. The nonspecificity of results or the failure to specifically denote etiology is a genuine limitation, but one that is not as bleak as one may think.

Concerns raised regarding the sensitivity and specificity of EEG abnormalities do pertain primarily to conventional clinical EEG, which realistically only permits examination of the few dimensions of data that can be ascertained by visual inspection. The same concerns, though still appropriate, may, in time, be alleviated to an acceptable level given advances in the field of Q-EEG. Q-EEG profiles, as well as deviations on evoked responses, have produced high sensitivity and specificity in classification analysis comparing subjects with psychiatric disorders to healthy comparison and other diagnostic groups. Although, by and large, Q-EEG remains a research tool, its potential to contribute to diagnostic decision-making has been demonstrated in small-scale proof of concept studies. Clinical development to date has been hampered, in part, by the availability of sufficient normative samples and of statistical tools suited for the task of conducting classification in large, intercorrelated data sets. The application of modern machine learning (ML) algorithms shows promise as a solution for uncovering the bounds of disease classes using “unsupervised” models that alleviate dependence on known diagnostic

Telegram: @medical_k

www.konkur.in

categories and can be optimized to make use of the complex dimensionality of EEG represented in spatial, temporal, and spectral domains.

Applied EEG in Psychiatry

As stated previously, the role of EEG in applied clinical psychiatry remains fairly limited to the differential diagnosis of organic etiologies. In this regard, the EEG can be most useful when the presenting symptoms, age of first symptom onset, or response to treatment is atypical, suggesting that a more structural cerebral pathology may be contributing to the syndrome being evaluated. In such cases, the presence of paroxysmal EEG activity or focal or diffuse slowing should be ruled out. If paroxysmal activity is identified, then it is important to be clear that such an EEG finding is not sufficient grounds to diagnose epilepsy unless, retrospectively, the symptoms can be seen as being of an epileptic nature. The presence of a paroxysmal EEG abnormality in a patient with an atypical presentation, particularly in the absence of a family history of the diagnosis that is being considered, should lead the clinician to be wary of and less confident in the diagnosis. It may be a good practice at the current state of knowledge to take advantage of the *not otherwise specified* category. Whether anticonvulsants are indicated in these situations remains a question open to clinical judgment. Early studies in this area suggested that anticonvulsants can sometimes block EEG epileptiform discharges and also can lead to dramatic clinical improvement in individuals exhibiting aggressive behavior. Furthermore, carbamazepine (Tegretol) was thought to be clinically useful in individuals with schizophrenia who exhibited temporal lobe EEG findings and aggressive tendencies without a history of seizure disorder. Based on current practice, it would seem as though prescribers are comfortable using adjunctive anticonvulsant therapy for many indications, irrespective of EEG findings, as would be suggested by common prescription of this medication class in anxiety disorders, dementia, schizophrenia, depression, bipolar disorders, and in cases of drug and alcohol withdrawal syndromes. Prescription in these cases, perhaps with the exception of drug withdrawal, is not based on the question of seizures but rather on the efficacy of anticonvulsants for treating psychiatric symptoms, including aggression, mood swings, mania, and panic symptoms.

Telegram: @medical_k

www.konkur.in

Similar comments can be made regarding the presence of a focal slow-wave abnormality in the EEG. A minimal focal slow-wave abnormality is unlikely to reflect a serious space-occupying lesion in a patient with a normal neurologic examination. However, if no logical explanation for the minor focal slowing is apparent (e.g., old head injury) and the finding did not appear on earlier EEGs, then a repeat EEG may be valuable to determine whether the finding is static or progressive. Clinicians should use their clinical judgment regarding when imaging (and what imaging) should be performed. If a space-occupying lesion is suspected, then a CT scan is usually sufficient. An MRI is more likely to yield abnormalities if the status of the lesion is less acute (e.g., old head injury). The presence of a focal slow abnormality, similar to the presence of paroxysmal activity, should cause the clinician to be wary of the diagnosis. Consideration also should be given to obtaining a neuropsychological evaluation to assess whether the focal cerebral abnormality identified by the EEG has any clinically correlating deficits.

The situation is different when an EEG is obtained in the course of managing an unstable or nonresponsive patient. The most important data to be gained from an EEG performed on an acutely agitated patient are the presence of diffuse slowing (indicating a delirious encephalopathic state) or ongoing epileptic activity NCSE. In both conditions, the EEG abnormality is fairly obvious and can be detected in a short period of time by temporarily retraining the patient, if needed, and using an electrode cap to minimize setup time. The EEG can be extremely useful in ruling out delirium secondary to medication toxicity, and, in this respect, it should be noted that diffuse EEG slowing (suggestive of a diffuse encephalopathic process) may be seen despite serum plasma levels within the therapeutic range.

When dealing with geriatric populations, sensitivity to organic pathology should be particularly heightened. In addition to the evaluation for dementia and delirium, EEG could be invaluable when there is a suspicion of seizures, and, in this respect, it is noted that older adult patients may account for as many as one-fourth of the cases of new-onset epilepsy. One also must keep in mind that a normal EEG in a patient diagnosed with dementias, once past a mild stage, should raise the suspicion that a depressive disorder, or other reversible cause, may be contributing to the clinical picture.

EEG Findings in Psychiatric Disorders

In addition to the general considerations regarding the interface between EEG and psychiatry, a number of psychiatric disorders deserve specific mention. Findings deemed promising for clinical applications will be briefly reviewed.

Schizophrenia. EEG abnormalities have been extensively examined in schizophrenia patients. A recent literature review entailing 133 published studies revealed that common EEG abnormalities observed in schizophrenia are also detected at the time of the first psychotic episode, as well as in high-risk clinical individuals, including increases in delta and gamma band. Moreover, some of these features appeared predictive of transition to psychosis in at-risk samples and associated with poorer functional status, suggesting utility as markers of disease progression and prognosis. The EEG literature in chronic schizophrenia is extensive, including at least 30 meta-analytic studies covering specific EEG and ERP measures investigated as putative psychosis-related biomarkers, including mismatch negativity (MMN), P50 sensory gating, the P300, and the gamma-band auditory steady-state response (ASSR) (see ERP sections below).

A study published in 2015 by the *Bipolar and Schizophrenia Network on Intermediate Phenotypes* (BSNIP) multicenter consortium examined the polygenic architecture of resting-state EEG frequency activity in samples of schizophrenia, psychotic bipolar disorder, and healthy individuals using 1 million single-nucleotide polymorphisms (SNPs) derived from DNA. Multivariate data clustering and component extraction methods identified five frequency and nine SNP components, with theta and delta activity found to correlate with gene components involved in brain development, neurogenesis, and synaptogenesis. Increased anterior delta and posterior theta abnormality were present in both schizophrenia and bipolar samples, while theta differed between the two disorders. Theta abnormalities were also mediated by unique gene clusters involved in the glutamic acid pathway and synaptic cell adhesion processes. These results replicated prior findings pertaining to excess resting slow-wave activity in schizophrenia and further differentiated the component structure of this abnormality from psychotic bipolar disorder patients, thus elevating the specificity of this feature to a diagnostic differential that is difficult to make using conventional clinical assessment. These findings further point

Telegram: @medical_k

www.konkur.in

to plausible genetic networks, consisting of genes previously implicated in schizophrenia as well as novel mechanisms that could underlie abnormal features observed in resting EEG.

Catatonia. Although the routine EEGs of catatonic patients with known functional etiology tend to be normal, catatonia could be a symptom of a number of serious medical conditions, including epilepsy and encephalopathy secondary to a variety of general medical conditions. Neuroleptic malignant syndrome has presented, at times, as catatonia, and, in such cases, the EEG is likely to show a picture of diffuse slowing indicative of an encephalopathic process. Although a well-known patient whose usual presentation includes catatonic symptoms may not need an EEG, it is advisable to obtain an EEG on every new patient who presents with catatonic symptoms.

Panic Disorder. Panic attack symptoms carry a significant resemblance to symptoms induced by temporolimbic epileptic activity, particularly those originating from the Sylvian fissure. Fear, derealization, tachycardia, diaphoresis, and abdominal discomfort are characteristic symptoms of simple partial seizures with psychiatric and autonomic symptomatology. Studies comparing symptomatology of patients with panic disorder to patients with CPSs have reported many similarities, suggesting that there may be a common neurophysiologic substrate linking the disorders. Notable conclusions of this literature are that individuals suffering from panic disorder show a higher rate of unspecific EEG abnormalities that include a unique increase in beta power, thought to align with the common clinical observation of hyperarousal in these patients. Although some evidence may suggest that IEDs occur at higher than normative baseline rates in panic disorder, relationships between panic symptoms and seizure activity remain far from clear, with EEG findings ranging from paroxysmal epileptiform discharges to asymmetrical increases in slow-wave activity and focal slow-wave abnormalities (reportedly observed in up to 25% of patients with panic disorder). Along these lines, it has been suggested that the use of anticonvulsant drugs, including valproic acid (Depakene), be considered in cases of panic disorder if conventional anxiolytic treatment is inefficacious.

On the other side of the coin, panic attacks also have been demonstrated to occur more frequently in epileptic patients. In some cases, these attacks could lead to overmedication for seizures if their

Telegram: @medical_k

www.konkur.in

nature is not precisely defined. Again, EEG monitoring during multiple attacks is indispensable in rendering such an evaluation. Other reports have concluded that the most common psychiatric disorder that must be differentiated from temporal lobe epilepsy is panic disorder. Epileptic seizures are commonly briefer and more stereotyped than panic attacks. Additionally, aphasia and dysmnesia often accompany seizure activity.

Obsessive-Compulsive Disorder. As recently reviewed by Zaboski et al. (2021), utilizing EEG in the study of the neural underpinnings of obsessive-compulsive disorder (OCD) is relatively scarce and has to date, primarily revealed disruptions in the P300 and in the spectral power of resting EEG. For example, EEG studies in patients with OCD reported a widespread increase of slow waves, with an additional report of epileptiform activities over the left temporal lobe. The frequency of these abnormalities varies among studies.

Q-EEG studies have more often involved the anterior regions of the scalp, supporting the hypothesis of frontal dysfunction in the pathogenesis of OCD. The cingulate gyrus, in particular, has been implicated as a locus of dysfunction by Q-EEG topographic brain mapping. Data concerning the involvement of a specific frequency band have been heterogeneous, probably due to differences in methodologies, small study sample sizes, and a broadly heterogeneous patient population in terms of the presentation of OCD symptoms. Although not given the coverage that might be deserving of the topic in the current chapter, EEG biofeedback or, more precisely, *neurofeedback* has gained interest as a nonpharmacologic treatment option for individuals suffering from OCD. Basically, neurofeedback involves a graphic representation of ongoing EEG to the patient, who may learn to implicitly modulate activity upward or downward toward what would be regarded as normalization from a pathophysiologic baseline. Again, although varied in terms of the specific EEG frequencies and locations involved in OCD therapy, neurofeedback has been approved by the FDA as a treatment for stress management and, like stress, may benefit from improved self-regulation that can be achieved as a common therapeutic mechanism of neurofeedback.

Mood Disorders. Depression may result from a variety of brain and other somatic diseases (e.g., tumors, dementia, and vascular accidents) that EEG can help to identify. With this exception, the diagnosis of mood disorders is typically not informed by EEG. Nevertheless, research

Telegram: @medical_k

www.konkur.in

findings of EEG abnormalities in depression, starting with the first publication by Fredrick Lemere in 1936, have provided many intuitive interpretations relating the clinical features of depression to brain mechanisms. Of note, Lemere's first paper, in which he proposed *"… The ability to produce 'good' alpha waves seems to be a neurophysiological characteristic which is related in some way to the affective capacity of the individual …*," followed Hans Berger's original report on the human EEG by only a few years and, indeed, referred to 10 Hz alpha waves as "Berger rhythms." Observations involving an abnormality in the alpha frequency have continued to be the major story pertaining to EEG research and conceptualization of depression up through current times. Since the early 1980s, work credited to Richard Davidson and colleagues has highlighted frontal alpha asymmetry and the associated *Approach-Withdrawal* model (aka the dispositional model) as an explanatory synthesis of the neural basis of depression. Briefly, an asymmetry of frontal alpha involving hyperactivation of the right hemisphere relative to the left has been interpreted as the interplay of *approach* (facilitating appetitive behaviors in association with positive affect) and *withdrawal* (facilitating avoidance of aversive stimuli in association with negative affect), with a reduction in left-sided alpha, thought to reflect deficient approach system activation in depression. The model further stipulates that relatively higher right-sided withdrawal system activation contributes to anxiety and other forms of psychopathology. EEG research has continued to support this seminal finding of frontal alpha asymmetry and, to some extent, this formulation of depression, with studies by other groups suggesting that alpha asymmetry more likely reflected a state rather than a trait feature in major depression. New models based on alpha asymmetry have since been proposed, including the capability model, which postulates that brain activity elicited under emotional challenge will be a stronger indicator of psychopathology than when measured at rest, and therefore entails testing with emotionally provocative stimuli.

Few large-scale EEG studies have been carried out in acute, drug-free subjects during a manic episode, probably due in part to the difficulty of obtaining such data. However, Joyce Small and colleagues published several papers in the late 1990s on a sample of approximately 200 patients admitted to the Larue D. Carter Memorial Hospital of Indianapolis in acute manic states, many of whom received follow-up EEGs when

Telegram: @medical_k

www.konkur.in

medicated, after medication washout, and when rehospitalized during subsequent episodes. Q-EEG was also performed in a subsample of about 40 patients who were cooperative enough to test. Remarkably, the majority of EEG data collected was interpreted to be normal. A slight increase in abnormal features (16% of the sample) was associated with a positive family history of mood disorder, and spike-wave activity was observed in 17% of the sample. Q-EEG differentiated patients on the basis of prescribed pharmacotherapy, with higher theta activity at baseline predicative of poorer response to psychotropic drugs. Abnormal hemispheric laterality was detected in a smaller portion of patients (9%), which implicated left hemisphere involvement.

Recent evidence suggests the usefulness of baseline Q-EEG measurements in the prediction of positive as well as negative outcomes of treatments with antidepressant drugs. Andrew Leuchter and his team introduced cordance, a Q-EEG measure combining relative and absolute power, to investigate correlates of response to fluoxetine in unipolar depression with a double-blind, placebo-controlled paradigm. Significantly more depressed subjects with high cordance in the theta band responded to fluoxetine in comparison to those with low cordance. The results were interpreted as suggesting that only depressed subjects with low baseline dysregulation respond to treatment. More recent studies conducted by Leuchter's group have also found a change in prefrontal cordance measures to be predictive of a positive response (e.g., reductions in Hamilton Depression Scale scores) to placebo conditions. However, the direction of change in concordance indicating improvement has not been entirely consistent across studies.

Attention-Deficit/Hyperactivity Disorder. Attention-deficit/hyperactivity disorder (ADHD) is a prevalent disorder among children and adolescents, as well as adults. The prevalence of abnormalities in the conventional EEG is higher in ADHD than that in age- and gender-matched healthy control subjects, with approximately one-third of ADHD children having abnormal routine EEGs and a significant proportion exhibiting spike or spike-wave discharges. In fact, some studies even report abnormal EEG incidence to be as high as 60% for this disorder.

Q-EEG has identified increased theta activity, particularly in the frontal lobe regions, as a consistent finding in ADHD. Even when learning

Telegram: @medical_k

www.konkur.in

disability is removed as a confounding variable, increased theta remains as one of the most prevalent EEG findings in this disorder, replicated by a number of groups from different parts of the world. In addition to being a consistent finding, the theta increase seen in ADHD is resistant to age effects, whereas abnormalities of beta EEG frequency tend to decrease with age. It also should be noted that early work suggests that increased theta abnormality frontally may be a strong predictor of response to methylphenidate and other psychostimulants and that favorable clinical responses may be associated with a normalization of the EEG abnormality. Because decreased beta activity has sometimes been reported in ADHD, some investigators have tried to examine the theta-to-beta ratio as a stronger measure of ADHD-related EEG abnormality with a higher detection power. There are, however, additional Q-EEG reports of an increase (instead of decrease) in beta activity in similar patients, raising questions concerning whether or not different subtypes of ADHD differentially affect beta activity. Finally, discriminant function analyses of Q-EEG data have been shown to be capable of significantly discriminating between healthy attention-deficit disorder and ADHD and learning disability subpopulations.

Dementia and Delirium. Because patients with advanced dementia rarely have normal EEG, a normal test result can play an important role in diagnosing cases of pseudodementia (symptoms of dementia secondary to depression or psychosis). When dementia and depression coexist, it becomes important to have some idea about the relative contribution of each disorder to the overall clinical presentation.

The routine EEG is also useful in following the progression of Alzheimer disease and may be useful in differentiating the Alzheimer etiology from that of frontotemporal dementia (FTD), which has been associated with either normal routine EEGs or mild frontal slowing despite progressive behavioral deterioration. Relatively normal EEG in FTD should therefore not be taken as an indication that behavioral features in these patients result from primary psychiatric causes.

A number of publications strongly support the utility of Q-EEG as diagnostic and prognostic tests for early Alzheimer disease. Collaborative work between centers in Stockholm and New York City, under the leadership of Christoph Lehmann, provided diagnostic efficiency statistics for EEG-based classification of mild Alzheimer disease from healthy

Telegram: @medical_k

www.konkur.in

controls of 85% sensitivity and 78% specificity. On the basis of available literature, EEG measures are likely to rapidly emerge as a cornerstone of the diagnostic workup for suspected Alzheimer disease.

The differential diagnosis of acutely disturbed and disorganized patients often includes delirium. In acutely agitated delirious patients, the EEG is often helpful in indicating whether the alteration in consciousness is due to (1) a diffuse encephalopathic process, (2) a focal brain lesion, or (3) continued epileptic activity without motor manifestations. Most often, patients with delirium have toxic metabolic encephalopathy. In general, with the progression of the encephalopathy, there is diffuse slowing of the background rhythms from alpha (8 to 12 Hz) to theta (4.0 to 7.5 Hz) activity. Delta activity (<3.5 Hz) usually does not become prominent until the patient approaches nonresponsiveness. The major exception to this rule is seen during withdrawal from alcohol and during delirium tremens. Instead of diffuse slowing, as described previously, excessive fast activity dominates the EEG in patients with alcohol withdrawal delirium. Patients in alcohol withdrawal who are not delirious could have a normal EEG. The low-voltage fast activity also can be induced by benzodiazepines, and this should be borne in mind when interpreting the EEG. The EEG thus can be helpful in differentiating between alcohol withdrawal delirium tremens and encephalopathies from other causes, including iatrogenic encephalopathy. The typical changes observed with delirium are slowing or even loss of the posterior dominant rhythm, slow-wave increase, reduced reactivity to eye opening, and intermittent, especially frontally located, rhythmic delta activity. These changes are thought to relate to the dopaminergic–cholinergic dysbalance as the final common pathway of delirium with a lack of cholinergic stimulation. In contrast to delirium cases revealing a cholinergic deficit as a common pathophysiologic feature, alcohol or benzodiazepine abstinence delirium results in decreased EEG voltage and an increase in fast activities, while nonconvulsive seizure state may be indicated by rhythmic activity and typical epileptiform discharges. Serial EEG assessments are considered the gold standard of delirium diagnostics.

Q-EEG is capable of detecting subtle changes and is especially useful for the evaluation of frail older adults with a high prevalence of dementia, accumulated organic brain disease, and age-related EEG changes. Using relative power measures, alpha decrease and delta increase, as well as the reduction in peak or mean frequency and diminished fast-to-slow-

Telegram: @medical_k

www.konkur.in

wave ratios, have been found to indicate delirium. In the presence of dementia, Q-EEG greatly improves delirium detection and monitoring, especially when supplemented with simple activation procedures.

Autism Spectrum Disorders. Several types of EEG abnormalities have been found in autism spectrum disorders (ASDs), including epileptiform activity, background slowing, and abnormal EEG hemispheric asymmetry. Altered mu rhythms (transient, nonoccipital alpha rhythms that occur over motor cortex) have also been reported, which some have postulated to indicate altered “mirror neuron” function, referring to neurons that fire both when an individual performs an action and when observing the same action performed by another. Of the various EEG abnormalities reported, epileptiform activity has been the most consistent finding in ASDs, detected at rates of 18.9% up to 60.7% of individuals with autism. Interestingly, approximately one-third of children with ASDs go on to develop epilepsy. That being said, several reviews have concluded that there is no justification for the use of anticonvulsant medications or surgery in children with pervasive developmental disorders without seizures; that is, there is no evidence that treatments to eliminate EEG spikes will have a therapeutic benefit on the behavioral abnormalities in autism.

EEG ALTERATIONS FROM MEDICATIONS AND DRUGS

A great many medications, as well as substances consumed for therapeutic or recreational purposes, can produce some degree of alteration in the EEG. This section attempts to highlight those compounds most relevant to clinical and research psychiatry.

Pharmaco-EEG

During the 1970s, several laboratories consistently obtained a classification of psychotropic drugs on the basis of EEG changes induced by a single dose routine in healthy subjects. Pharmaco-EEG methods are currently commonplace in preclinical studies to identify, at early stages of drug development, the therapeutic indications of new drugs, to test drug bioavailability or “target engagement” at the CNS level, to evaluate pharmacokinetic profiles based on correlation with drug plasma

Telegram: @medical_k

www.konkur.in

concentration, to predict therapeutically useful dosages, and compare the bioavailability of different formulation of drugs. Pharmaco-EEG studies identified the antidepressant activities of mianserin and doxepin, which had been classified as antiallergic and anxiolytic, respectively, by preclinical studies, as well as the sedative activity of fenfluramine, classified as a psychostimulant by animal studies. The discovery of the antidepressant activity of mianserin was instrumental in the development of new animal tests, which, in turn, promoted the discovery of new antidepressants, such as fluvoxamine (Luvox) and fluoxetine (Prozac). For fluvoxamine and sertraline (Zoloft), pharmaco-EEG studies enabled the identification of therapeutic doses in the early stages of drug development.

Few attempts have been made to translate pharmaco-EEG methods to psychiatric clinical settings, where this approach could inform the expectation for therapeutic benefit in response to a given psychotropic drug or dose level. Pharmaco-EEG methods for response prediction were applied in research, mainly involving the examination of Q-EEG changes following either a single administration of a drug (the so-called test-dose procedure) or at a point early in the course of treatment. Such methods, if proven capable of providing a reliable prediction of the therapeutic response to treatment, could have an enormous clinical impact when considering that failure to respond to initial treatment tends to increase attrition from care, the severity of prognosis, and ultimately the costs associated with psychiatric illness.

Regarding early prediction of treatment response, several QEEG studies of first-generation antipsychotics (FGA) in schizophrenia produced consistent findings but with ultimately no clinical impact. For instance, administration of high-potency FGA medication was found to produce an increase of alpha activity, particularly in the slow alpha range (7.5 to 9.5 Hz), that several independent groups found predictive of a favorable clinical response.

The test-dose procedure seldom has been used in pharmaco-EEG studies of response prediction in depressed patients. In one example, Q-EEG cordance (an index combining relative and absolute power) was measured during pretreatment and following 1 and 4 weeks of antidepressant therapy in a sample of treatment-resistant inpatients. Responders showed a decrease, while nonresponders showed an increase in prefrontal theta cordance after the first week of treatment.

Telegram: @medical_k

www.konkur.in

These findings, in line with other brain imaging results, suggest that early changes in prefrontal activity mediate the clinical response to antidepressants.

In conclusion, Q-EEG indices could be a valuable complement to a patient's clinical assessment, providing further guidance to inform the clinician's choice of the appropriate drug treatment. Toward this end, guidelines have been published by the International Pharmaco-EEG Society (IPEG), with the goal of standardizing the acquisition and processing of data obtained in pharmaco-EEG studies. The introduction of these methods in clinical routine will require the replication of findings in large patient populations as well as the investigation of new drugs recently introduced in the clinical practice.

Psychotropic Medications—General Considerations

It is well known that psychotropic agents can affect the EEG. For the routine EEG, with the exception of the benzodiazepines and some compounds with a propensity to induce paroxysmal EEG discharges, there is little, if any, clinically relevant effect when the medication is not causing any toxicity. For example, benzodiazepines, even in small doses, generate a significant amount of beta activity that is seen diffusely and can last substantially longer (up to 2 weeks) than might be expected given the rapid response and peak occupancy (typically 1 to 4 hours) of these drugs. This response is so universal that it has been suggested that if a particular brain region fails to exhibit the expected benzodiazepine-induced beta activity, the area may be in some way damaged.

Psychotropic Medications—Toxic Effects. It has long been accepted that the EEG is sensitive to the neurotoxic effects of psychotropic medications, and clinical vignettes illustrating the value of EEG in detecting a neurotoxic reaction to medications commensurate with clinical deterioration have been reported. It is often stressed that such a scenario could occur at any time during the course of treatment because many factors impact the patient, and the symptoms could be subtle. An EEG investigation may be useful when patients undergoing long-term therapy present with clinical deterioration, particularly if the patient is known to be taking the medication and the serum plasma levels are within the therapeutic range. Such clinical situations also may highlight the need for having baseline EEGs available for comparison when a patient presents

Telegram: @medical_k

www.konkur.in

with clinical exacerbation. Normative EEG databases are available but are based on cross-sectional evaluations and do not take into account the dynamic nature of psychiatric disorders or changes due to medication status. Thus, for the purpose of detecting toxicity, routine clinical EEG remains of immediate relevance to the everyday management of patients prescribed psychotropic medication. The appearance of significant diffuse EEG slowing in a patient who is receiving psychotropic medications and whose clinical condition is not stable (particularly the older adults) should prompt the clinician to consider medication toxicity, in addition to other causes of encephalopathy (e.g., electrolyte imbalance and thyroid problems, to name only two).

Psychotropic Drug-Induced EEG Abnormality (Nonparoxysmal and Paroxysmal). Almost from the time psychotropic medications were introduced, it was known that some of these compounds could precipitate EEG abnormalities, including paroxysmal EEG discharges (spike and spike-wave activity) in some individuals. Usually, medication-induced paroxysmal EEG activity remains behaviorally silent and is not accompanied by iatrogenic overt seizure manifestations.

GENERAL ANESTHETICS. General anesthetics primarily induce their effects by binding to affecting neuronal ion channels. In terms of EEG signatures, anesthetics initially evoke a frontal fast activity followed by a disruption of alpha rhythms. As the anesthesia deepens, EEG activity becomes slower and of low voltage (not unlike deep sleep), and burst-suppression patterns can be observed. At the deepest levels, EEG activity ceases and can even resemble patterns seen in comatose states.

BARBITURATES. Barbiturates are now minimally used for medical or recreational purposes. The mechanism of action of this class of drugs involves binding to a specific site on the $GABA_A$ receptor, thus potentiating the effects of the inhibitory neurotransmitter GABA. When barbiturates are taken for medical or recreational purposes, beta activity is introduced into the EEG, particularly over frontal regions. Higher doses are associated with lower frequencies and dissolution of the alpha rhythm (as drowsiness and sleep ensue). Abrupt withdrawal from barbiturates after long-term exposure can produce EEGs containing generalized paroxysmal activity and spike discharges, which often are not associated

Telegram: @medical_k

www.konkur.in

with overt motor seizure manifestations. These effects may be seen for days up to 3 to 4 weeks after the last drug exposure.

TRADITIONAL NEUROLEPTICS. The primary mechanism of action of the typical antipsychotics/neuroleptics (e.g., chlorpromazine, haloperidol) is the antagonism of the D2 dopamine receptor. EEG changes with the neuroleptics include an increase in alpha activity, a shift to lower frequencies, and a decrease in beta activity. At high doses, seizures and spikes may occur.

ATYPICAL ANTIPSYCHOTICS. Atypical antipsychotic agents such as clozapine and risperidone have different mechanisms of action compared to traditional neuroleptics and have an affinity for 5HT2a, alpha-adrenergic, and D4 receptors, among others. EEG frequency changes during the administration of clozapine include increases in delta, theta, and beta, which are prominent over frontal, central, and parietal areas. Some paroxysmal slowing and spikes can occur, along with rare instances of seizure. Little is known regarding the EEG correlates of other atypical antipsychotic drugs.

TRICYCLIC ANTIDEPRESSANTS. Older generation tricyclic antidepressants (TCAs) (e.g., imipramine, doxepin) typically act as both serotonin and norepinephrine reuptake inhibitors. They can increase the amount of slow and fast rhythms, decrease the frequency of alpha, and can induce paroxysmal slow waves and spikes. At higher doses, they can induce seizures, which can be particularly concerning given that tricyclics have a somewhat narrow therapeutic range.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS. By definition, selective serotonin reuptake inhibitors (SSRIs) increase synaptic levels of serotonin by binding to the serotonin transporter. These agents tend to decrease alpha activity while increasing theta frequencies. Further, the rates of seizures are less in SSRIs compared to tricyclics.

LITHIUM. Lithium is still commonly used in the treatment of bipolar disorder and can induce marked changes in the EEG. Lithium salts, particularly at intoxicating levels, are associated with diffuse EEG slowing and paroxysmal spikes, and triphasic waves, which can remain after serum levels have normalized.

Telegram: @medical_k

www.konkur.in

BENZODIAZEPINES. Like the barbiturates, benzodiazepines potentiate the action of GABA, although the mechanism of action entails binding to a separate benzodiazepine site on the $GABA_A$ receptor. As such, benzodiazepines are commonly used for their anxiolytic and anticonvulsant properties. Benzodiazepines at therapeutic doses are potent enhancers of beta rhythms and, in addition, slightly increase theta power. Decreases in alpha frequencies are also noted. Benzodiazepines are well known to reduce epileptiform activity and, indeed, are the first drugs of choice for status epilepticus.

OTHER THERAPEUTIC AGENTS. While beyond the scope of the current chapter, a host of other nonpsychiatric therapeutic agents have been shown to induce robust effects on the EEG. Most notably, EEG changes in the context of antiepileptic drug treatment are well documented. Further, antibiotics, immunosuppressants, and antineoplastic agents, among others, have all been shown to affect EEG signatures. For a thorough treatment of these medication types, see referenced chapter by Bauer and Bauer.

Drugs of Abuse

The recreational use of addictive drugs remains a significant public health issue. In fact, in terms of the cost of illness, it has been estimated that drug addiction ranks second only to cardiovascular disease. Hence, drug dependence is becoming of increasing concern for those involved in the assessment and treatment of psychiatric disorders. Nearly all drugs of abuse are capable of altering the frequency spectrum of the EEG, and the degree of alteration varies with recreational versus heavy use and whether the EEG was obtained during acute intoxication, during intervening periods of abstinence, or during clinical withdrawal in the addicted individual.

With only infrequent exceptions, the use of an abused drug does not introduce frank clinical abnormalities into the visually analyzed EEG tracing. This is especially true for recreational drug use and is even the case for dependent and addictive use as well. For this reason, drug abuse alone is not a sufficient reason for EEG referral. Although the alterations of EEG frequency and voltage in the visually analyzed EEG produced by many abused drugs are often unimpressive, topographic Q-EEG analyses can reveal marked alterations of the EEG spectrum that constitute

Telegram: @medical_k

www.konkur.in

significant deviations from population norms (even though the clinical implications may not be clear). Nonetheless, it is important to appreciate the various effects of different drug classes on the EEG.

Alcohol. Ethyl alcohol, or ethanol, exhibits many of the same pharmacodynamics as benzodiazepines (i.e., acting as a positive allosteric modulator of the $GABA_A$ receptor). Hence, many of its behavioral and EEG effects are similar. There is considerable consensus that an increase in the amount of alpha activity and a slight slowing of alpha frequency typically accompany alcohol consumption and that higher blood alcohol levels increase the amount of theta. Some reports have indicated that chronic alcohol consumption may be associated with a lower voltage and slightly faster resting EEG, although the clinical relevance of this remains obscure.

Alcohol withdrawal can lead to epileptic seizures as a result of perturbations of GABA and glutamate neurotransmitter/receptor function. Higher-frequency beta activity may be substantially increased in the addicted alcoholic undergoing withdrawal, and if delirium tremens complicates the clinical picture, then excessive fast activity may dominate the EEG. EEG signatures during acute alcohol withdrawal can be desynchronized with low voltage, and generalized spikes may be observed. Alcohol-related seizures need to be differentiated from true epileptiform activity with comorbid alcohol dependence. Routine EEG can be extremely helpful in this regard. A normal EEG during periods of sobriety, particularly if associated with an abnormal EEG during early withdrawal, strongly suggests that the seizures are withdrawal induced. It should be noted that the EEG tends to normalize faster (with the exception of a generalized decrease in amplitude) during withdrawal from alcohol as compared to that from barbiturates.

Opiates. The effects of opiates such as morphine and heroin on the EEG are similar to those of alcohol and involve slight reductions in alpha frequency. They also may increase the voltage of the EEG, particularly the power of theta and delta activity. Opioid anesthesia has also been shown to induce spike discharges resembling benign epileptiform transients of sleep. However, when an opiate overdose produces a comatose clinical presentation, the EEG usually consists of clinically abnormal diffuse slowing.

Telegram: @medical_k

www.konkur.in

Cannabis. Marijuana, or cannabis, remains one of the most prevalent drugs of abuse. Moreover, rates of its consumption are on the rise due to the trend of decriminalization and the acceptance of the use of “medical marijuana.” Cannabis, or its primary psychoactive constituent delta-9-tetrahydrocannabinol (THC), affects the brain via central cannabinoid receptors (CB1Rs). CB1Rs act primarily by affecting the release of the neurotransmitters GABA and glutamate. As reviewed by Skosnik and Cortes (2016), the effects of cannabis/THC on EEG can be broken down into effects on resting EEG (intrinsic rhythms), ERPs, and evoked/induced oscillations.

Acute cannabis smoking typically produces minimal visible effects on traditional EEG. In terms of contemporary studies utilizing Q-EEG, chronic cannabis users typically show reductions in power in the alpha-, theta-, and beta-frequency bands while in the nonintoxicated state. Acute THC has been shown to reduce resting theta power, which has been correlated with altered memory performance. Both chronic and acute cannabis/THC has been shown to disrupt the P300 ERP, which is congruent with cannabis’ effect on attention and memory. Finally, both chronic and acute cannabis/THC has been shown to disrupt sensory-evoked and induced gamma rhythms, which may provide a mechanism for the perceptual-altering effects of cannabinoids.

Finally, it should also be noted that one of the other nonpsychoactive constituents in cannabis (cannabidiol) has been shown to have antiepileptic properties. Hence, this may represent a potential future direction in the “medicinal” use of cannabinoids.

Psychostimulants. Psychostimulants such as cocaine, amphetamine, and methylphenidate act primarily to increase central dopamine function. They typically increase the amounts of beta and alpha activity and generally reduce EEG voltage. Overdose with psychostimulants produces typical coma patterns in the EEG. The effect of psychostimulants on ERPs has yielded mixed results, although they may exhibit some effects similar to those observed in disorders of dopamine function such as schizophrenia.

Inhalants. Inhalation abuse of volatile substances (e.g., airplane glue, cleaning fluid, paint thinner, and gasoline) can produce a nearly instantaneous sensation of euphoria, and, in the early period of use, there may be no obvious residuals after the acute response subsides. However,

Telegram: @medical_k

www.konkur.in

with continued inhalant abuse, serious neurologic and neurocognitive deficits can emerge that may not be completely reversible with abstinence. The immediate effects of inhalation of volatiles on the human EEG appear not to have been well studied. Where persistent neurologic or neurocognitive sequelae follow chronic inhalant abuse, clinically abnormal diffuse EEG slowing in the lower theta to upper delta range may be seen.

Hallucinogens. Drugs such as lysergic acid diethylamide (LSD) and mescaline appear to have only minor effects on the visualized EEG and do not produce clinically relevant changes. However, recent studies of the drug ecstasy (MDMA) have shown abnormalities in several ERPs, which may be related to the purported memory-impairing effects of long-term MDMA use.

Tobacco. Tobacco (nicotine) does not appear to produce dramatic alterations in the analog EEG. However, topographic Q-EEG analyses reveal striking EEG changes with acute exposure to, as well as withdrawal from, tobacco. The immediate effects of smoking include a decrease in slower frequencies (especially theta), increased power of frequencies in the upper one-half of the alpha-frequency band, and beta activity. Twenty-four hours of tobacco deprivation produce a marked decrease in alpha frequency, with a corresponding marked increase in the relative power (amount) of theta activity. The effects of acute smoking and abstinence are essentially opposite to one another. Further, nicotine has been associated with alterations in “sensory gating,” as indexed by studies of P50 ERP suppression. However, these effects can vary depending on whether they are examined during acute nicotine exposure use or during withdrawal from nicotine.

Caffeine. The use of coffee and products containing caffeine are quite prevalent. The use of caffeine is of little concern to the clinician interpreting the visually analyzed EEG. Withdrawal from caffeine in the caffeine-dependent individual, however, produces a markedly significant increase in the amplitude, or voltage, of theta activity—an effect that is reversible within 15 minutes of consuming one cup of coffee.

Other Drugs of Abuse. In recent years, several novel synthetic drugs of abuse have emerged, most notably “K2/spice,” which are synthetic

Telegram: @medical_k

www.konkur.in

cannabinoids, and “bath salts,” which are synthetic psychostimulants/hallucinogens typically in the cathinone family. However, little research has been performed on these substances, particularly in the context of EEG.

EEG AND EXPERIMENTAL RESEARCH PARADIGMS

The majority of EEG conducted in the field of psychiatry may indeed be for research purposes, including studies both on the intrinsic rhythms ascertained under normal resting conditions as well as a number of experimental paradigms associated with different sensory–perceptual and cognitive tasks. The high temporal resolution of EEG essentially provides “real-time” measurement of changes in brain activity in response to experimental conditions. EEG allows the experimenter to study changes in brain activity related to overt processes, such as differences in the auditory response to frequently versus infrequently presented stimuli, as well as more covert processes ranging from the anticipation of stimulus delivery (e.g., contingent negative variation; CNV) to presupplementary motor area activation (e.g., lateralized “readiness” potential; LRP) in preparation of a button press or consolidation–retrieval processes associated with working memory following presentation of a stimulus set. As illustrated by these examples, EEG is an ideal tool for assessing differences or changes in neural activity generated as a sequence of mental operations over a time course. Regardless of whether or not such functions can be localized to discrete cortical or subcortical regions, which is never the first aim of EEG research, the ability to precisely record changes in neural activity in response to known events (e.g., under controlled test conditions) enables the researcher to ask, and potentially answer, a limitless set of questions concerning human information processing and abilities affected by psychiatric illness.

Evoked and Event-Related Potentials

The genesis of experimental EEG research no doubt has roots in *EP* methods, which continue to see routine clinical use in neurology practice as a test of CNS function. Briefly, EPs are electrophysiologic responses to external stimuli, usually administered over several repetitions with changes in stimulus properties (e.g., frequency, intensity) across presentations. EPs can be generated in any sensory modality but in most

Telegram: @medical_k

www.konkur.in

clinical applications involve *visual-evoked potentials* (VEPs), and *brainstem auditory-evoked potentials* (BAEPs) measured by EEG, or *somatosensory-evoked potentials* (SSEPs) measured electromyographically (i.e., EMG). An important point to keep in mind regarding the EP is that the response is time locked to the delivery of a stimulus and, therefore, can be strictly regarded as "evoked." This point distinguishes the EP from the conceptually and semantically similar *ERP*, which also represents an electrophysiologic response to stimulation. However, the subtle difference that distinguishes these measures can be appreciated in the examples of so-called overt versus covert brain processes provided in the preceding paragraph; whereas the overt auditory-evoked response can be regarded as an EP, examples of ERPs including the CNV and LRP occur prior to stimulus delivery and, therefore, reflect brain activity engaged in the process of performing mental operations that is not necessarily time locked, or "evoked" in response, to a stimulus. The term "event-related" has therefore replaced "evoked" over time in the research arena, where EEG recording is used to study both "bottom-up" sensory-evoked responses as well as changes in neural activity associated with higher-order cognitive processes that may be represented by induced brain signals.

Another basic principle regarding the EP or ERP is that these potentials are usually of small magnitude (as small as a few microvolts) compared to the ongoing EEG activity (reaching 50 μV or more). This is due to the fact that EPs/ERPs represent only the components of the EEG that are consistently present across repeated trials of stimulus delivery, which may consist of hundreds of trials. The EP/ERP is extracted from the digital recording by averaging, resulting in a signal that reflects a change in neural activity in response to stimulus events with ongoing background EEG activity (which is not time locked to the stimuli) canceled out by the averaging process. The resulting average is then graphed as a change in voltage over time plots and can be quantified by measures of peak amplitude and latency.

By convention, BAEPs are labeled with the Roman numerals I, II, III, IV, and V, reflecting the order of the component, with components I to III generated by the auditory branch of cranial nerve VIII and components IV and V by the upper brainstem. ERPs (as well as SSEPs and VEPs) are labeled according to both their polarity and latency. The letters "P" or "N" indicates the positive or negative direction of deflection relative to the

Telegram: @medical_k

www.konkur.in

prestimulus baseline, though whether the polarity is depicted graphically in an up or down direction seems to be a matter of personal choice and, in many cases, polarity does reverse depending on electrode location due to the dipolar distribution of associated electrical fields. Labeling nomenclature representing ERP peak latency is done more simply, with exceptions. While the ERP associated with the label “P300” is a positive deflection peaking at around 300 ms following stimulus delivery, the short-hand “P3” can also be used, signifying the third positive deflection of the ERP, which follows P1 or P100 at around 100 ms and P2 or P200 at around 200 ms. Time courses and conventional labeling of ERPs most commonly studied in psychiatry are presented in Figure 1.26–16.

When a stimulus is presented to the brain, it travels through the receiving sensory organ and the brainstem (except for visual and olfactory stimuli) on its way to the primary cortical regions representing the particular sensory input. EPs recorded over primary sensory cortices indicate how the stimulus was received and registered by the brain, thereby providing a test of the integrity of the underlying neural architecture. For instance, the BAEP is measured in EEG waves arising within the first 10 ms following delivery of an auditory stimulus, thought to reflect the intactness of the auditory pathway, and most are useful for the diagnosis of hearing loss. It cannot be stated with certainty at this time whether basic EPs are broadly or specifically affected by psychiatric disorders, as ERPs have been the focus of most contemporary neuropsychiatric research. However, disturbances in early sensory processes are thought to be fundamental to schizophrenia pathophysiology, for example, and may conceivably involve impairment detected at the earliest stages of sensory processing.

Regarding the stage of information processing, a basic delineation has been made between *early-latency potentials,* which would include the BAEP and other components occurring before 10 ms poststimulus, *mid-latency potentials* occurring up to 200 ms, and *long-latency potentials* occurring after 200 ms. As a general rule of thumb, early-latency potentials are thought to mainly reflect processing dependent on *exogenous* factors determined outside of the CNS, such as stimulus intensity or rate. Exogenous potentials can be measured regardless of a subject’s level of consciousness, are thought to be fundamentally unaffected by cognitive processes, and represent basic sensory registration. Once received by the brain, a stimulus undergoes

Telegram: @medical_k

www.konkur.in

psychological processing and evaluation, and these operations influence later ERP waves that are broadly distributed outside of primary sensory cortices. While ERPs also contain exogenous components (though typically recorded at sampling rates too slow to accurately measure early-latency potentials), mid-latency and long-latency potentials tend to be of most interest to experimental research. In later stages of information processing, ERPs increasingly reflect activity relating to cognitive processes, such as anticipation, encoding, and recognition, thus can be influenced by the level of alertness and attentional resources devoted to the experimental task. Accordingly, mid-latency and late ERPs mainly reflect *endogenous potentials,* with measurements of amplitude or other characteristics reflecting the interaction of stimulus properties and experimental task demands with individual differences in information processing. Because ERPs are sensitive to experimental manipulations, various paradigms have been developed to study brain function at the interface of sensory and cognitive processing. These paradigms have demonstrated many abnormalities during mid-latency and later processes across the psychiatry research literature and thus are of considerable interest for their potential as clinical tools.

Mid-Latency Components (P50 and N100)

Three of the most examined ERP components in the auditory modality are designated P50 (a positive component occurring between 35 and 80 ms after stimulus onset), N100 (a negative component occurring between 80 and 150 ms after stimulus onset), and P200 (a positive component occurring between 150 and 250 ms after stimulus onset). Figure 1.26–16 shows a typical example of these mid-latency ERPs. These components share the characteristic that their amplitude decreases with repetition (habituation or sensory gating). The P50 and N100 components have been studied extensively in psychiatric patients.

Telegram: @medical_k

www.konkur.in

FIGURE 1.26–16. Schematic illustrating prototypical ERPs. Time is shown using a logarithmic scale. Stages of information processing from automatic preattentional to higher-order attentional processes are shown from left to right, respectively. (Adapted from Skosnik PD, Cortes-Briones JA. Electro-encephalography (EEG) and cannabis: from event-related potentials (ERPs) to oscillations. In: Preedy VR, ed. *The Neuropathology of Drug Addictions and Substance Misuse*. Academic Press; 2016, pp. 851–862, with permission from Elsevier.) (See color panel.)

The P50 is a positive voltage, mid-latency ERP component peaking at around 50 ms poststimulus, best elicited by discrete auditory stimuli (e.g., brief white noise clicks). In the standard P50 gating or "dual-click" paradigm, the amplitude of the P50 to a second paired click (S2) is attenuated relative to the P50 amplitude to the first click (S1). A 500-ms interstimulus interval is typically utilized and is optimum to elicit gating. While the P50 to S1 is thought to be related to the capacity of the brain to register salient stimuli, the reduction of the P50 amplitude to S2 (compared to S1) reflects the automatic suppression of inhibitory gating of redundant and irrelevant stimuli. It is thought to be mediated by the

Telegram: @medical_k

www.konkur.in

hippocampus, temporoparietal region, auditory cortex, and prefrontal cortex. Deficient P50 suppression is commonly associated with schizophrenia and has been proposed as a candidate endophenotype for psychosis risk (representing a physiologically detectable feature linked to the underlying genetic cause of illness), supported in part by evidence for linkage to several psychosis risk genes and by a similar reduction in P50 suppression observed in first-degree family members of schizophrenia probands. Evidence for an inhibitory abnormality (i.e., sensory gating deficit) in schizophrenia patients has been accumulating over the past 30 years. In an early meta-analysis of proposed endophenotypes of schizophrenia, sensory gating of the P50 response was found to represent a magnitude of deficit equal to or greater than the most robust findings reported across neuroimaging and behavioral studies.

The N100 component is a large exogenous ERP that exists regardless of task demands (although it can be modulated by attention). The N100 is generally associated with early perceptual processing with origins in the primary sensory cortices and is elicited in response to various forms of auditory and visual stimuli, regardless of the experimental context. Of note, while the visual N100 is regionally localized over occipital and posterior parietal electrode sites, the N100 (like all auditory ERPs) tends to be maximal over the central or frontocentral sites, representing the confluence of potentials generated in bilateral auditory cortices. The N100 component has also been shown to exhibit suppression similar to the P50 ERP when assessed using the dual-click paradigm and is similarly affected in schizophrenia patients. Work by Johannesen and colleagues showed that reductions in N100 amplitude in schizophrenia, whether elicited by paired clicks or by pure tones presented at shorter interstimulus intervals (~1,200 ms apart), appear to have equally large effect sizes when contrasted against healthy comparison subjects, thus appear more dependent on internal neural processing than on the stimulus features used to elicit the auditory response. In the same study, while P50 and P300 measures failed to differentiate schizophrenia from bipolar disorder, the N100 provided unique variance in classifying these psychiatric groups with reasonable (72%) accuracy. Of note, the classification of schizophrenia from bipolar participants based on N100 was only slightly less accurate than the classification of schizophrenia against matched healthy participants (79% accuracy) using an optimal multivariate model consisting of several ERP and spectral-frequency measures. Therefore,

Telegram: @medical_k

www.konkur.in

auditory processes indexed by the N100 appear to represent a consistent (e.g., obtained in different experimental contexts), robust, and perhaps diagnostically relevant neurophysiologic deficit among individuals with schizophrenia.

P300

The P300 is a late positive, postattentional ERP component thought to be related to directed attention, contextual updating of working memory, and the attribution of salience to deviant or novel stimuli. This response is typically elicited utilizing standard “oddball” paradigms in which low-probability target stimuli (~10% to 20%) are embedded within a repeating sequence of high-probability standard stimuli (~80% to 90%) differing in some physical dimension (e.g., frequency, duration, amplitude). It this thought that the P300, particularly the P300b component (elicited in response to designated targets), reflects activity from a distributed neural network including areas such as the thalamus, hippocampus, inferior parietal lobe, superior temporal gyrus, and frontal cortex. Cognitive and affective neuroscientists have been conducting basic research on P300 since it was discovered over 40 years ago, providing a rich knowledge base that has yet to be fully exploited by clinical scientists.

Mismatch Negativity

The MMN is an automatic, preattentive, negative voltage ERP component that is generated primarily in the superior temporal and prefrontal cortex. The MMN is hypothesized to index the automatic, preattentive processing of the “mismatch” between standard and periodic deviant stimuli, indexed by the amplitude of a negative component over latencies of 100 to 200 ms measured in waveforms created by the subtraction of ERPs produced by the deviant and standard stimuli. The MMN experiment is similar to the P300 oddball paradigm, where the serial presentation of a standard stimulus (e.g., 10-ms presentation of 1,000 Hz tone) is occasionally interrupted by deviants that differ in subtle ways (e.g., 10-ms presentation of 1,500 Hz tone, 50-ms presentation of 1,000 Hz tone). However, unlike the P300, attention to the stimuli is not required and is normally redirected from the primary auditory discrimination task by a concurrent, noninterfering task (e.g., reading, visual target detection). Also, unlike the P300, which is sensitive to both auditory and visual stimuli, MMN has been mostly studied as it relates to acoustic information processing.

Telegram: @medical_k

www.konkur.in

Because it is virtually sensitive to any feature of an acoustic stimulus, including frequency, duration, and learned features such as rhythmic patterns and timing of stimulus delivery, the MMN has been especially useful in the evaluation of problems associated with specific aspects of auditory processing. Deviations in MMN are reported across several psychiatry disorders, including depression, alcoholism, and dementia, but have received the most attention in schizophrenia.

In a longitudinal investigation of first-hospitalized schizophrenia patients, Salisbury and colleagues (2007) showed that reduction in the MMN over a 1.5-year period following the first hospitalization was associated with progressive reductions in Heschl gyrus gray matter volumes in schizophrenia but not in psychotic bipolar or healthy comparison subjects, who evidenced no significant change in or correlation between MMN and gray matter measures. This important finding links an experimental electrophysiologic process to the brain structure and highlights the sensitivity of MMN to neurodegenerative processes that may be uniquely involved in the etiology of schizophrenia.

Error-Related Negativity

The error-related negativity (ERN), typically studied in a choice reaction time task, occurs approximately 60 to 150 ms after an incorrect choice has been made. The ERN has been posited to reflect sensitivity to error detection, the remedial actions that are taken to compensate for the error, and the conflict generated by the process. Time–frequency analysis indicates that the ERN is mainly comprised of anterior theta activity that appears to originate from the ACC, part of a neural system involved in behavioral regulation and self-monitoring. Because it appears to involve both affective and cognitive information processing and evaluation, it is not surprising that the ERN is also sensitive to clinical features of various psychiatric disorders, including OCD and other anxiety disorders, major depression, and externalizing psychopathology related to behavioral disinhibition. The findings of these studies suggest that anxious individuals because they generate larger ERNs, are more sensitive to making errors, while depressed individuals and those with disorders associated with behavioral disinhibition are less so. These results are generally consistent with expectations given the clinical characterization of these disorders.

SUMMARY AND FUTURE DIRECTIONS: EEG IN THE SYSTEMATIC STUDY OF PSYCHOPATHOLOGY

It is now firmly established that EEG anomalies, including ERPs, are associated with a wide variety of psychiatric conditions, including schizophrenia, mood disorders, anxiety, ADHD, and substance abuse disorders, which a voluminous research literature associated with each.

Because ERPs are derived from the EEG, it is possible to use time–frequency analysis to identify the constituent EEG spectra, which, because they are time locked to the stimulus presentation, compose the ERP waveform. This type of analysis, in effect, renders a possible determination of the amount of each EEG frequency present at each point in time, elapsing from the onset of a stimulus to the resolution of the associated ERP. These transient-evoked oscillations (Fig. 1.26–13) can be partitioned into the same frequency bands identified for spontaneous/resting EEG but represent stimulus-elicited rhythms that are likely to serve roles that are functionally different from those associated with their appearance in resting EEG. For example, while higher resting low frequency (e.g., delta, theta) is associated with pathology in a number of clinical conditions, higher activation of low-frequency activity under task-related conditions (e.g., working memory) is often interpreted to indicate better brain function. With respect to the P300 ERP, higher amplitude (better function) is mainly dependent on the activation of delta and theta frequencies, accompanied by a reduction in alpha frequency.

Using one example, transient-evoked oscillations are beginning to provide insights regarding brain dynamics and psychopathology, especially regarding the development of alcohol dependence. Reduced delta- and theta-evoked oscillations have been associated with risk for the development of alcoholism over and above the risk associated with reduced P300 amplitude, suggesting that the decomposition of the P300 ERP into constituent oscillatory components may improve the sensitivity of this measure over the band-passed signals (typically filtered at 0.5 to 12 Hz or as high as 24 Hz) characterized by ERPs. These evoked oscillations have also been linked to gene variants involved in cholinergic and GABAergic neurotransmitter systems, which have been implicated in the neurochemical pathways involved in many psychiatric conditions. This line of ERP or evoked oscillation research conducted in alcoholism exemplifies an evolving scientific effort to use experimental

Telegram: @medical_k

www.konkur.in

electrophysiologic assays of human information processing as fundamentally biologic, and perhaps genetically related, indicators of risk for the development of psychiatric disorders.

TRANSLATION OF RESEARCH FINDINGS TO CLINICAL APPLICATIONS

In the absence of a guiding system or accepted approach for evaluating and integrating new measurement approaches to clinical decision making, EEG findings that carry significant promise are likely to continue to remain interesting research findings discoverable only by investigators who intend to embark on similar research. Without translating such findings into diagnostically robust, clinically meaningful, and psychometrically validated procedures, the evolution of EEG in psychiatry appreciated by the academic community is unlikely to translate to clinical applications. We review and comment on the guidance provided in 2007 by Nash Boutros and Cynthia Arfken as illustrative of steps taken to psychometrically develop a diagnostic tool:

Step 1: A biologic variable is observed to be deviant from healthy controls in a particular patient population. The demonstration of test–retest reliability of the finding using blinding procedures is an essential component of this early step. The goal is to refine a measure and the procedures used to obtain it to a standard, assuring the measure is repeatable and generalizable across intended use scenarios. Such an endeavor cannot feasibly be undertaken by a single laboratory or even a small collection of research sites and requires a cooperative effort among large groups of investigators committed to harmonizing measurement methodology and who are able to generate the financial resources required to support such an effort. In practice, the intention would be to obtain samples diverse enough to represent demographic, regional, and perhaps international differences required to estimate meaningful population parameters. The NAPLS consortium is one example of such an effort, involving eight study cites across the United States and one in Canada, who collectively applied for grant funding under a common mechanism, and coordinated measurement efforts led by experts of

Telegram: @medical_k

www.konkur.in

each site who informed the standardization of test protocols across sites.

Step 2: Demonstration of the potential clinical usefulness of the specific finding. The two most important objectives at this step are a demonstration of the difference between the target patient population and appropriate control groups (these should be groups of patients with diagnoses that commonly appear on the differential diagnostic lists of the target disorder). Estimation of the effect size of the finding could be a reasonable guide to which findings should be considered good candidates for Step 3 studies. Of note, guidance on clinical meaningfulness may take several forms, depending on the criteria by which "meaningfulness" is demonstrated. While separation of diagnostic entities fulfills basic criteria concerning the typicality of a diagnostic feature as representative of a broader class, the "meaningfulness" of biomarkers alone remains a highly contested issue between drug developers and federal regulatory authorities, particularly in cases of disorders of the CNS. Accordingly, additional consideration should be given to precedent provided by current medical standards. For instance, if a new technology (e.g., remote ambulatory EEG monitoring) is demonstrated to perform as well as a clinical standard for diagnostic surveillance (e.g., clinic-based sleep study), the path to development is more straightforward. In examples where EEG is considered useful as a prognostic indicator, such as early detection of illness or as a measure of early response to treatment, criteria for clinical meaningfulness would be predicated not only on the presence of the marker in a known disease state but on its predictive power to inform future outcomes.

During Step 3: The performance characteristics of the test should be established. Specifically, the sensitivity, specificity, and positive and negative predictive values of the biologic marker should be examined. These criteria consider not only the measures' ability to accurately identify the intended index cases (e.g., diagnostic group, treatment responder, those who transition from "at-risk" stage) with high sensitivity (positive marker indicates condition) but also to accurately discriminate these cases from those who belong to other classes (negative marker indicates the absence of condition), reflecting a measure's specificity to a classification outcome. Depending on the intended use and risk–benefit of the decision the classifier is used to

Telegram: @medical_k

www.konkur.in

inform, preference may be given to measures that optimize sensitivity over specificity or vice versa.

Step 4 defines the clinical application of the test and helps standardize the technique used in large and multicenter clinical trials. Multicenter trials should guide methodology for standardization of laboratory procedures used to conduct the test as well as obtaining data regarding cost-effectiveness and impact on both short-term and long-term clinical outcomes. It is strongly recommended that studies describing efforts toward developing diagnostic testing should adhere to the guidelines proposed by the Standards for Reporting of Diagnostic Accuracy (STARD) initiative (see https://www.equator-network.org/reporting-guidelines/stard/).

Given this rubric for the development of clinical diagnostic and/or endpoint measures, which is considered appropriate for the translation of EEG research methods to clinical tools, it should also be appreciated that when undertaken in isolation of broader stakeholders informing health care policy, these efforts may fall short in scope or support required for acceptance and integration with current standards of care. In this way, effective translation will also benefit from the input of insurance payers, patient advocacy groups, private industries (e.g., EEG manufacturers, pharmaceutical companies), and federal regulatory authorities such as the Food and Drug Administration (FDA), whose remit is to protect public health by ensuring the safety and efficacy of drugs as well as medical devices. The interested reader is directed to publications provided by the FDA Critical Path Initiative. Launched in 2004, the CPI is FDA's national strategy for transforming the way FDA-regulated medical products are developed, evaluated, and manufactured. At this time, few initiates involving EEG are under consideration. That said, the FDA recently provided 510(k) clearance for a remote EEG wearable device that enables physicians to monitor the EEG of individuals from the home as they continue their daily activities. FDA clearance pertains to examples where a new device manufacturer is able to demonstrate that the product is "substantially equivalent" to a similar market device that has already been approved and requires the device manufacturers to notify the FDA of their intent to market a medical device within a specified time frame. The path to approval of a new device or measure with no market equivalent (i.e., predicate) is more complex by comparison, requiring that, through clinical

Telegram: @medical_k

www.konkur.in

testing results, the agency can conclude that the benefits of the test outweigh the known risks. A current effort to establish EEG measures as drug development tools, involving a collaboration of pharmaceutical industry sponsors invested in CNS drug development, academic leaders, and an EEG device manufacturer, is provided here as another example of what, through careful science, may be on the horizon for EEG in psychiatry: ERP Biomarker Qualification Consortium (https://erpbiomarkers.org/).

1.27 Radiotracer Imaging with Positron Emission Tomography and Single Photon Emission Computed Tomography: Fundamental Principles, Methodology and Role in Neuropsychiatric Research

Mark Slifstein, Ph.D., John H. Krystal, M.D., and Anissa Abi-Dargham, M.D.

OVERVIEW

Radiotracer imaging is a methodology with the unique ability to quantify spatially localized neurochemical information *in vivo* in the brains of humans and preclinical species. Radiotracers are chemical probes designed to interact with neurochemical systems, either by binding to target molecules such as neuroreceptors, reuptake transporters, or intracellular enzymes or by acting as substrates for the metabolic pathways of endogenous substances in parallel with them. “Tracer” refers to an experimental approach in which a chemical substance containing a quantifiable reporter probe is introduced into a biologic system, and its interaction with the system is “traced” by the probe. It is implicit that the tracer will be introduced in a small enough concentration so that the normal function of the system is not noticeably perturbed by the presence of the tracer itself. Tracer methods were in use for decades before the advent of modern imaging methods and technology. George De Hevesy pioneered the use of radioactive isotopes incorporated in tracers in the mid-20th century to study a wide range of chemical phenomena, including biologic systems. Other investigators developed pharmacokinetic models based on tracer methods to quantify processes such as the perfusion of blood in biologic tissues, which form the foundation of the pharmacokinetic models used in modern radiotracer imaging, but the acquisition of experimental data frequently involved invasive measurements in animals. Approaches that were noninvasive enough to use routinely in living humans did not become

Telegram: @medical_k

www.konkur.in

available until the late 1970s and 1980s, when technologic advances in imaging systems and computational power made such methods feasible. In radiotracers, the reporter probe is a radioactive atomic isotope incorporated in a molecule that is designed to interact with a (neuro)biologic system. Radioactive isotopes have nuclear configurations that are unstable; individual radioactive atoms decay to a more stable state at unpredictably random times, but when a large number of radioactive atoms are present, the rate of decay at any time is a very well–characterized fraction of the initial rate. There are many different schemes by which radioactive isotopes decay, but all involve the release of energy. When they decay, radioactive isotopes used in imaging release high-energy photons (also called γ-rays) that readily pass through biologic tissue and are then detected in imaging systems external to the body. Photon energy is usually described in units of electron volts (eV, 1 eV = $1.6*10^{-19}$ Joules, the energy change that an electron would experience when passed through a 1-volt potential difference. 1 keV = 10^3 eV, 1 MeV = 10^6 eV), and photons released by isotopes used in imaging range from ~150 keV for some isotopes to 511 keV for others; most materials other than very dense ones, such as lead or the inorganic scintillating crystals used as detectors in imaging systems, are transparent to photons in this energy range. Radioactive atoms are incorporated into a very small portion of the tracer molecules; these are termed labeled molecules and are assumed to be well mixed within the tracer sample so that at any given time, the rate of decay measured in a location within the tissue will have a known proportionality to the number of unlabeled tracer molecules there. By counting the number of photons that originate in a local volume within the brain over an interval of time, the concentration of the radiotracer in that volume can be inferred. The ability to spatially localize the source of radioactivity requires the use of computational methods known as tomographic reconstruction. The mathematical theory behind tomography was already well established in the early part of the 20th century but was only practically implemented in the final decades of the century with the advent of fast, powerful computers in combination with the development of electronics and detector materials that could provide the necessary spatial, temporal, and energy resolution. There are two imaging modalities that utilize similar experimental methods but differ in the way photons are counted and the mode of decay of the radioactive isotopes used. These are positron emission tomography (PET) and single photon emission tomography (SPECT). The term emission refers to the fact that the radioactive isotope is part of a molecule that is injected intravenously (or, less frequently, inhaled or ingested) so that the detected photons are emitted from within the body. This is in contrast to transmission imaging such

Telegram: @medical_k

www.konkur.in

as x-ray and computed tomography (CT) scans, in which a beam of photons is directed at the body from an external source, and the portion that passes through without interacting with the intervening tissues is counted on the opposite side. Psychiatry researchers have used PET and SPECT imaging to characterize many aspects of neurochemistry in sample cohorts of subjects with many different neuropsychiatric conditions. While the number of radioactive isotopes used in imaging is small, the number of radiotracers that these can be incorporated into, and biochemical systems that can be studied, are virtually limitless, and many different tracers have been used in research studies with human subjects. Currently, in psychiatry, these imaging methods are used almost exclusively in research. They do not yet have the sensitivity or specificity to be used diagnostically. Most radiotracer studies in psychiatric populations have based their conclusions on statistical inference from moderately large sample cohorts in which there is considerable overlap in the measured quantities between patients and comparison subjects. But these studies provide important clues to other investigators working in basic neuroscience or drug development about processes that may be pathologic in psychiatric conditions and can be examined more closely using *in vitro* methods or in preclinical species, or that might suggest molecular targets for pharmacotherapy. In this sense, radiotracer imaging is an important translational tool for understanding brain neurochemistry in psychiatric patient populations. In the remainder of this chapter, the physics and technology of imaging, pharmacokinetic models, and experimental designs used in psychiatric imaging research will be described, followed by a survey of the radiotracers, molecular targets, and psychiatric populations that have been studied and some well-replicated results.

BASIC PHYSICAL PRINCIPLES

Radioactivity, Radionuclides, and Photon Emission

Half-Life. As stated above, the time at which any individual radioactive atom will undergo decay is random and unpredictable. However, radiotracer doses contain a very large number of labeled molecules. For example, a typical PET dose contains on the order of 10^{10}-labeled molecules, each of which has the same probability of decay per unit time, independently of all the others. In this setting, the rate, or number of decays per unit time, follows an exponential formula, $A(t) = A(0)e^{-\lambda t}$, where A(t), the activity, is the number of decays per unit time at time t, A(0) is the initial activity, and λ is a very well–characterized rate constant that is different for each radioactive isotope. The

Telegram: @medical_k

www.konkur.in

Système International (SI) unit of radioactivity is the Becquerel (Bq), equal to 1 decay per second. An older, though still frequently used unit is the Curie, equal to $3.7*10^{10}$ decays per second. For the range of activity used in imaging, it is more convenient to use units of MBq (10^6 Bq) and mCi (10^{-3} Ci). It is also convenient to factor λ into $\ln(2)/T_{1/2}$, where $T_{1/2}$, the half-life, is the time it takes for A to decrease to half its initial value. The choice of time and the total activity when the initial measurement A(0) is made does not affect the half-life; following any measurement, the activity will decrease by 50% after an additional $T_{1/2}$ has passed. Half-lives and other parameters for the isotopes most commonly used in PET and SPECT are given in Table 1.27–1. The isotopes used in radiotracer imaging are also referred to as radionuclides.

Decay by Positron Emission and PET Radionuclides. In decay by positron emission, a proton within the atomic nucleus is converted into a neutron and a positron (and an extremely low mass, uncharged particle called a neutrino). A positron is a particle with the same rest mass as an electron but opposite electric charge. When the positron is ejected from the nucleus, it will have initial kinetic energy that will be reduced as the particle interacts with the surrounding matter. The sequence of collisions with nearby matter will cause the positron to follow an unpredictable path with many changes of direction, and it will usually come to rest within nanoseconds of its release and within 1 to 2 millimeters of its source atom for the most commonly used PET radionuclides (Table 1.27–1). At that point, the positron and a local electron will be attracted to each other by their opposite charges and undergo an annihilation reaction, in which their masses are converted to energy. Two photons will be produced, each having the energy of the rest mass, 511 keV, of an electron, as the energy from the rest masses of the positron and electron is conserved. The photons travel away from each other in directions that are very nearly opposite to each other (the total momentum is conserved: the momenta of the positron and the electron are nearly zero at the time of the annihilation, and the momenta of the photons are opposite and sum to zero, although the angle is usually slightly different than 180 degrees due to a small amount of residual momentum in the particles at the time of the annihilation event) (Fig. 1.27–1). PET technology exploits the fact that two nearly collinear photons are emitted simultaneously from the location of the annihilation event by utilizing the principle of coincidence detection (see below). The two radionuclides most commonly used in PET brain imaging are ^{11}Carbon (^{11}C, $T_{1/2} \cong 20$ minutes) and ^{18}Fluorine (^{18}F, $T_{1/2} \cong 110$ minutes). ^{15}Oxygen (^{15}O, $T_{1/2} \cong 2$ minutes), incorporated in ^{15}O-labeled water, can be used to assess cerebral blood flow, but its use for this purpose has been mostly superseded

Telegram: @medical_k

www.konkur.in

by MRI techniques. Also, ^{13}Nitrogen (^{13}N, $T_{1/2} \cong 10$ minutes), incorporated in ^{13}N-labeled ammonia, is used frequently in other areas such as cardiology. Other positron emitters such as ^{64}Copper (^{64}Cu, $T_{1/2} \cong 12.7$ hours) have been used as radionuclides in settings where longer half-lives are desirable, but to date, ^{64}Cu has not been applied in neuroimaging. The radionuclides used in PET are not naturally occurring, and their short half-lives place strict constraints on how long before the study and, therefore, how far away from the study site they can be produced and incorporated into radiotracers. Production of PET radionuclides is performed in a particle accelerator called a cyclotron, an instrument that is produced by several medical device manufacturers but is large, expensive, requires a high level of skill to operate and maintain, and is subject to regulatory scrutiny because it produces radioactivity. Rapid incorporation of the radionuclide in a radiotracer requires elaborate chemistry and quality control instruments and highly skilled chemists to perform these tasks. An approximate rule of thumb is that a radiotracer must be able to be synthesized and undergo tests for sterility and chemical purity in an hour or less to be suitable as an ^{11}C-labeled radiotracer. The use of ^{11}C is therefore restricted to sites that can produce it locally at the time of the PET scan, and PET studies using ^{11}C radiotracers are performed almost exclusively at large academic medical centers that can support the required staffing and equipment. While the requirements for producing ^{11}C-labeled radiotracers are clearly demanding, there are some major advantages to ^{11}C that makes its use very desirable. First, the ubiquity of carbon in virtually all molecules of interest as tracers means that labeling can potentially be performed by substituting ^{11}C for ^{12}C in an organic molecule without altering its biochemical properties. Second, the 20-minute half-life allows for multiple scans on the same day so that scanning can be performed under different experimental conditions on a subject in a single study session. Academic medical centers also routinely produce ^{18}F-labeled radiotracers. There is clearly less time pressure in the production of ^{18}F-labeled tracers than with ^{11}C. In addition, the 110-minute half-life of ^{18}F allows enough of a time window for ^{18}F tracers to be produced by specialized manufacturers with facilities located within several hours of traveling time from the study site. Furthermore, ^{18}F labeling is preferable for cases where the pharmacokinetics of the radiotracer require scans of several hours duration, as in this case, ^{18}F will continue to provide a reliable signal for the entire scan duration, whereas ^{11}C activity would become very low, leading to unreliable data late in the scan. However, multiple ^{18}F scans on the same day in a single subject are challenging to analyze accurately due to activity from the first scan overlapping with activity from the second scan.

Table 1.27–1. Characteristics of Commonly Used PET and SPECT Radionuclides

Nuclide	$T_{1/2}$, (minutes)	Imaging Photon Energy (keV)	Usual Imaging Modality	Mean Positron Range (mm)
^{11}C	20.4	511	PET	1.1
^{18}F	109.8	511	PET	0.6
^{15}O	2.03	511	PET	2.4
^{123}I	787.8	159	SPECT	
^{99m}TC	360.4	140	SPECT	

FIGURE 1.27–1. Schematic representation of the decay of unstable carbon 11 to stable boron. A positron is ejected from the carbon nucleus, eventually colliding with an electron. The pair annihilate, and two 511 keV photons are released in opposite directions. Distances are not drawn to scale.

SPECT Radionuclides. As the name implies, SPECT scanners measure single emitted photons, unlike PET scanners that utilize coincidence detection. In theory, PET radionuclides could be used in SPECT systems, but other radionuclides that also emit photons in a usable energy range and decay with longer half-lives are more practical. A SPECT radionuclide that has proven to be particularly useful for brain imaging is ^{123}Iodine (^{123}I, $T_{1/2} \cong$

Telegram: @medical_k

www.konkur.in

13.1 hours). ^{123}I decays by the process of electron capture, in which an orbital electron combines with a proton to form a neutron (plus a neutrino), and a characteristic x-ray photon is emitted when another, outer orbital electron, fills the orbital shell vacated by the transformed electron. There are multiple electron capture decay schemes that ^{123}I can undergo, leading to the release of photons of different energies, but approximately 83% of decays result in the emission of 159 keV photons, and these are the ones detected by SPECT scanners. ^{123}I can be produced in a cyclotron, but the long half-life allows for ^{123}I- or ^{123}I-labeled radiotracers to be distributed within a several thousand-mile radius of the manufacturing site. Across all SPECT applications, the most commonly used radionuclide is ^{99m}Technicium (^{99m}TC, $T_{1/2} \cong 6$ hours). ^{99m}TC is a "metastable" product of the decay of ^{99}Molybdenum (^{99}Mo, $T_{1/2} \cong 66$ hours), meaning that its nucleus is in a moderately excited state that will decay to the more stable ^{99}TC form without transmuting to a different element. ^{99m}TC can decay to stable ^{99}TC by several processes, but approximately 88% of decays result in 140 keV photon release, and these photons are detected by SPECT scanners. ^{99m}TC is most commonly distributed to imaging sites in ^{99}Mo generators, portable devices containing ^{99}Mo produced in large nuclear reactors. The ^{99}Mo decays to ^{99m}Tc in the generator, and the ^{99m}Tc can be separated from ^{99}Mo by chromatographic methods. ^{99m}TC, however, does not readily cross the blood–brain barrier (BBB), whereas ^{123}I does so more easily due to the more lipophilic nature of iodine. As a result, the majority of SPECT radiotracers for brain imaging are ^{123}I labeled.

Physical Principles of Emission Tomography

γ-Ray Detection. The same tissue-penetrating property that makes the 511 keV photons emitted in PET and the 140 to 159 keV photons emitted in SPECT useful for imaging leads to the necessity for special materials to detect and transduce their energy into a form more amenable to processing by the electronic systems that count them. Detectors in PET and SPECT are dense inorganic scintillating crystals that interact with, that is, stop the high-energy photons resulting from radioactive decay and emit a portion of the absorbed energy in the form of lower energy photons in the visible to UV range. The most commonly used scintillator in SPECT is thallium-doped sodium iodide (NaI(Tl)). Many scintillating detectors have been used in PET; some of the most frequently used ones are bismuth germinate (BGO), lutetium oxyorthosilicate (LSO), and lutetium yttrium orthosilicate (LYSO). Each has different properties that are more optimal for some applications than others.

Telegram: @medical_k

www.konkur.in

After the scintillator releases its lower energy photons, the next stage in signal transduction for both PET and SPECT is to convert that signal into an electrical current that represents the detected event in the electronic circuits that perform the remainder of the activity-counting process. This component is called the photosensor. Up to and through the first decade of the 2000s, the photosensor in most commercially produced scanners was the photomultiplier tube (PMT). PMTs are evacuated glass tubes with a light-sensitive material on the end that interfaces with the scintillator (the cathode) and a sequence of metal plates (dynodes) along the length of the tube that are maintained at successively higher voltages. Light striking the cathode will induce electrons to leave the surface and strike the nearest dynode, inducing more electrons to break free from that plate and strike the next one. The cascade continues, with enough amplification of the electron stream by the last stage (the anode) to form a current in the range that is suitable for the next stage of the electronics (Fig. 1.27–2). Common configurations for detectors and PMTs in PET are rectangular blocks of detector material attached to a small number of PMTs. The blocks are assembled into polygonal rings that surround the imaging field of view (Fig. 1.27–3), and a number of rings are assembled concentrically to form a cylindrical imaging gantry. Similar designs are feasible in SPECT, but more commonly, SPECT scanners contain several large slabs of detector materials attached to large arrays of PMTs that rotate around the subject to obtain data from all angles (Fig. 1.27–3). Recently, there has been a great deal of progress in developing solid-state photosensors to replace PMTs, driven largely by the development of hybrid PET-MR scanners (see below). PMTs interact with and do not operate properly in the strong magnetic fields generated by MRI scanners, whereas solid-state photosensors can operate in that environment. Two designs that have been studied extensively are called avalanche photodiodes (APMs) and APMs operating in Geiger mode (referred to as silicon photomultipliers, SiPMs). APMs and SiPMs have become the standard photosensors in many more recently produced scanners, not just PET-MRs.

Telegram: @medical_k

www.konkur.in

FIGURE 1.27–2. Representation of a detector block with scintillator crystal attached to an array of photomultiplier tubes (**left**) and a photomultiplier tube (**right**) with a schematic display of the amplification of the electron stream.

Coincidence Detection in PET. In PET, radioactive decay events are recorded when two 511 keV photons strike two detectors simultaneously. The path between the two detectors is referred to as a line of response (LOR). An electronic circuit detects if two-photon arrival events occur within a very narrow time interval called a coincidence timing window. The coincidence timing windows on modern scanners are in the range of 3 to 6 nanoseconds. Each detected coincidence event causes a computer to increment the count total for that LOR by one unit (Fig. 1.27–3).

Photon Detection in SPECT by Collimation. In SPECT, decay events are localized to an LOR by the use of lead collimators. These are usually formed from blocks of lead that are attached to the detectors and have long, narrow channels that only allow photons from a narrow set of angles with respect to the detector to pass through. The simplest design utilizes parallel cylindrical channels, all of which are perpendicular to the flat face of the detector, but many different configurations are in use with different scanner designs and different image reconstruction algorithms. The necessity for collimation in SPECT causes its scanners to utilize a smaller portion of the photons that are emitted from radioactive decay than PET scanners. The overall efficiency with which scanners convert radioactivity in the field of view to detected counts is referred to as sensitivity. Because of collimation, SPECT systems have lower sensitivity than PET systems.

Telegram: @medical_k

www.konkur.in

FIGURE 1.27–3. A PET ring detector (**left**) with a representation of a coincidence timing circuit and a 3-headed γ-camera for SPECT (**right**). In PET, an electronic pulse generator sends a signal to a coincidence detection circuit. If two pulses are detected within a coincidence timing window from two detectors, an event is counted on the LOR between them. In SPECT, photon detections are restricted to LORs defined by the collimators. The detector arrays rotate around the imaged object.

Image Reconstruction

The data obtained with both PET and SPECT are called projection data. For each LOR, a single number is recorded that contains counts from all loci along the LOR. Conversely, as the direction in which photons are released following a decay event is random, each location in the imaging field of view that contains activity will contribute counts to several, possibly many, LORs. The LOR data contain enough information to reconstruct a facsimile of the original distribution of decay events, but this requires the application of mathematical models of the projection data and numerical implementations of the models on computers. There are two general approaches to reconstruction, filtered backprojection (FBP), and iterative reconstruction. Both involve some degree of mathematical complexity, and there are many variants of each. Below, only the general concepts of both methods are described, not specific implementations. The projection data are stored as a numerical array called a sinogram, which is organized by angle and radial distance from the origin (the center of the field of view). For each angle θ and distance d, the value recorded in the sinogram at the point (θ, d) is the number of detected events (the counts) in the LOR that is perpendicular to the line through the origin at angle θ and passes through that line at distance d from the origin (Fig. 1.27–4). The name sinogram derives from the fact that an

Telegram: @medical_k

www.konkur.in

object with radioactivity only at a single spatial point would be recorded as a sine wave in the (θ, d) representation. The reconstructed image is usually represented with Cartesian coordinates in a rectangular grid of pixels (in two dimensions) or voxels (for “volume element” in three dimensions).

FIGURE 1.27–4. Depiction of back-projection. A point source of activity is placed in the upper left quadrant of the field of view. The **top row** and **bottom left panel** depict three different LORs and their locations in the sinogram of the point source. The **bottom right panel** shows the result of back projecting all LORs; the only ones that are non-zero are those that pass through the location of the point source.

Filtered Backprojection. FBP, sometimes called analytic reconstruction, was the most common approach to image reconstruction from the inception of CT up until the early 2000s, partly because the iterative methods, which appeared in several published papers in the 1980s, were too computationally intensive, and therefore too slow, for the computers of that time period. Iterative reconstruction programs, which lead to visually clearer reconstructed images, are now routinely provided as part of the software package with commercially produced scanners, but many researchers still prefer FBP reconstruction due to statistical issues described below. The basic equations of FBP are derived from mathematical formulas called the Radon transform and the inverse Radon transform, theoretical constructs first described in the early part of the 20th century explaining the relationship between a mathematical function defined in two-dimensional space, that is, f(x,y) which defines a single numerical value for each (x,y) pair of Cartesian coordinates, and its projections. FBP is a discretized version of the inverse Radon transform; that is, a version based on a finite number of LORs rather than a full continuum of angles and distances from the origin. The first step can be

Telegram: @medical_k

www.konkur.in

thought of as overlaying the projections from all the LORs and summing (Fig. 1.27–4). This step is called back projection. Because the loci that contain radioactivity contribute to all the LORs that pass through them, the back-projected data will have elevated intensities in these positions. However, pure back projection would also attribute activity along each entire LOR containing counts, so an adjustment called spatial filtering is applied prior to back projection to remove the starburst-like artifact that would otherwise result (Fig. 1.27–5). This is a conceptual description of FBP; real implementations use more sophisticated computer algorithms, and mathematical procedures such as Fourier transforms. The main advantage of FBP is that it is fast. However, there are disadvantages. The filtering step and the fact that there are a finite number of LORs combine to reduce spatial resolution and introduce the so-called streak artifacts (Fig. 1.27–6).

FIGURE 1.27–5. Filtered back-projection. The object is a Shepp-Logan phantom, a set of superimposed ellipses of different intensities used as a standard for comparing reconstruction algorithms. There are several different filters that can be used. The one used here is called a ramp filter.

FIGURE 1.27–6. Comparison between FBP (**left**) and OSEM (**right**). The image is summed data from a 120-minute [^{11}C]MDL100907 scan, shown in the transverse (**top**) and coronal (**bottom**) views. The radiotracer binds to the serotonin 5-HT_{2A} receptor. The summed image represents a combination of distribution of the tracer throughout the brain during the early part of the scan and specific binding to receptors in the later part. Streak artifacts are visible in the FBP, especially in the space between the scalp and brain. The FBP reconstruction also has a more mottled appearance than the OSEM reconstruction.

Iterative Reconstruction. A number of algorithms have been proposed that treat the relationship between projection data and voxel values probabilistically by framing reconstruction as a statistical estimation problem. These treat the voxel values as a sample drawn from a probability distribution and seek to estimate the most probable distribution of counts in voxels, given

Telegram: @medical_k

www.konkur.in

the measured projection data and the known physical properties of the imaging system, such as the detector geometry. They are called iterative because they start with an arbitrary estimate of the voxel values and then successively improve the estimate by updating a formula that takes the current estimate as input and returns an improved estimate as output. Each cycle through the procedure is called an iteration. The iterative algorithm that is available in the software packages provided by most commercial scanner manufacturers is called Ordered subset expectation maximization (OSEM), a modified version of the expectation maximization (EM) algorithm. EM and OSEM are based on the maximum likelihood (ML) principle. ML estimation procedures are statistical methods that establish formulas to estimate the parameters in a parametric probability distribution from observed sample data. For example, the conventional formula for estimating the mean μ of a Gaussian random variable as the sample average can be derived from the ML principle. The Likelihood is the formula for the probability of the observed sample data, expressed as a function of these data and the parameters of the distribution. As the name suggests, ML methods seek the value of the parameter(s) that maximizes the likelihood of the observed data. Voxel data are usually modeled as Poisson random variables; the Poisson distribution can take on only nonnegative integer values and has a single parameter λ which is the mean of the distribution. In the EM and OSEM approaches, counts emanating from each voxel are treated as statistically independent of every other voxel. The mean or expected value of the counts at voxel j is assumed to be λ_j, the parameter of the Poisson distribution for that voxel. These, however, are hidden variables because the only observed data are the projection data on LORs. The EM algorithm is designed to obtain the ML parameter estimate for the distribution of a hidden variable when only incomplete data, such as the projection data, are available (the projection data along with the unobserved voxel means are called the complete data). For the particular case of projection data and the assumed Poisson distribution of voxel values, the procedure leads to a simple and elegant formula that is guaranteed to converge, over the course of successive iterations, to the set $\{\lambda_j\}$ of ML estimates of voxel means. However, the full Poisson EM algorithm requires a huge number of computations, given the large number of LORs and voxels in PET and SPECT image data, and was therefore not practical to apply on the computers available at the time the EM algorithm was proposed. The OSEM algorithm is a modified version introduced in the 1990s that made iterative reconstruction feasible. By cleverly ordering the full set of LOR data into a sequence of smaller subsets and updating the voxel estimates based on computations performed on each

Telegram: @medical_k

www.konkur.in

successive subset rather than only once after each complete iteration through all the LORs, fewer equations need to be solved, and the necessary number of iterations, and therefore the computational load, is reduced significantly. Unlike full EM, OSEM is not guaranteed to converge to the ML estimate of the voxel values, but practical experience has shown that it leads to very satisfactory image reconstructions after a fixed, small number of iterations (Fig. 1.27–6). The main advantage of OSEM reconstruction is that it leads to clearer images without streak artifacts or the level of random noise that is seen in FBP reconstruction (Fig. 1.27–6). A disadvantage is that following necessary preliminary corrections to the sinogram data prior to reconstruction for several noise sources that occur, especially in PET, the Poisson distribution assumptions are not completely satisfied, and this can lead to bias in which the true proportionality between brain regions with high and low activity is not preserved, although the bias is relatively small. For this reason, many neuroimaging researchers, who are more interested in quantification than visual presentation, have historically preferred FBP to OSEM. But continued refinements to EM-based algorithms along with increasingly powerful computer hardware have led to faster and less biased iterative methods, making recent versions more competitive for quantitative imaging.

Another recent development is the practical application of time of flight (TOF) information in iterative reconstruction algorithms. If the location of the annihilation event is not identically midway between opposing detectors, the photons will arrive at the detectors at slightly different times. Theoretically, if this timing difference were known exactly, the location of the coincidence event along the LOR could be identified as well. In reality, most scanners can only resolve the timing differences down to a precision of a nanosecond (10^{-9} s) or more, leading to too much uncertainty in the estimate of the location of the event for this information to be useful in brain imaging. Timing resolution has been improved considerably, though, in more recently manufactured scanners, with tested values as low as 210 picoseconds ($2.1*10^{-10}$ s) in some systems. This allows for localization down to several centimeters. While still not precise enough to adequately identify the location of the annihilation event by itself, this information can be incorporated into the iterative reconstruction algorithm, significantly improving the signal-to-noise ratio of the reconstructed image.

Factors Affecting Image Quantification and Image Quality

The sections above describing the release and subsequent detection of photons are idealized in the sense that it is assumed that 100% of photons pass through biologic tissue without any interaction and that 100% of photons

Telegram: @medical_k

www.konkur.in

or coincident pairs striking the detectors are perfectly converted into detected counts. In reality, there is some interaction between photons and tissue, LORs are not really lines but three-dimensional columns in which the probability of detection is greater at the center than toward the edges, and electronics have finite limits to their temporal and energy resolution. These factors and others degrade the overall image quality and spatial resolution, some severely enough to require corrective procedures to be applied prior to the reconstruction phase.

Photon Attenuation. While many of the photons from radioactive decay do pass through tissue unimpeded, a fraction of them do not. For γ-rays in the energy range of those released by PET and SPECT isotopes and matter like biologic tissue, the majority of interactions are due to Compton scattering, in which the photon collides with an atom and is deflected from its original path, with some of its energy absorbed by an orbital electron from the atom. Less frequently, the photon is completely absorbed in the collision, and the atom ejects an electron, a process called the photoelectric effect. The reduction of detected photons due to these interactions is called attenuation. The probability of attenuation decreases with increasing γ-ray energy and increases with the density and thickness of the intervening matter between the photon source and the detector. For a given kind of matter, such as soft tissue, the probability that a photon passes through without being attenuated is an exponential function of the depth of the tissue where the photon is released; the probability is proportional to $e^{-\mu d}$ where d is the depth in centimeters and μ is the linear attenuation coefficient of the material in units of cm^{-1}. The attenuation in air is nearly zero, so only the thickness of the tissue is a factor in attenuation, not the total distance to the detectors. The linear coefficient μ is a function of both the energy of the photon and the nature of the material through which the photon is passing; the larger μ is, the greater the attenuation. Because PET photons have higher energy than SPECT photons, they will undergo less attenuation. For example, μ in water for 511 keV photons is 0.097 cm^{-1}, whereas for 150 keV photons, it is approximately 0.15 cm^{-1}, and μ in soft tissue is similar to μ in water. Without correction for attenuation, voxels located deep in tissue would have lower detected counts than voxels closer to the surface having the same concentration of radiotracer. Therefore, attenuation correction is a necessary step in quantitative imaging. The fact that PET utilizes coincidence detection allows the implementation of a very accurate form of attenuation correction. This is because the probability of either photon from annihilation not being attenuated is independent of whether or not the other is attenuated, and therefore the

Telegram: @medical_k

www.konkur.in

probability of both photons not being attenuated is the product of their probabilities; it is proportional to $e^{-\mu d1}e^{-\mu d2} = e^{-\mu(d1+d2)}$ which depends only on the total length of tissue, d1 + d2, traversed by the LOR, and does not depend on the location within the LOR where the annihilation event occurs (Fig. 1.27–7). Attenuation correction in PET is usually applied to the sinogram prior to reconstruction by multiplying the value of each LOR by a correction factor measured in a separate scan called a transmission scan. In dedicated PET systems, this is usually performed by rotating a point source or a rod containing multiple point sources of a positron-emitting material of known activity around the measured object (the subject's head) and recording the fraction of activity detected on the opposite side. Different approaches are required for hybrid PET-CT and PET-MR scanners (see below). In single-photon detection, as in SPECT, other strategies must be employed. While some sophisticated algorithms for measuring attenuation using a transmission source have been devised for application in SPECT, uniform attenuation correction is most frequently applied. In this approach, an image of an elliptical object with voxel values equal to the correction factors for water is aligned to the reconstructed SPECT image, and the values in the two images are multiplied on a voxel-by-voxel basis.

Photon Scatter. Compton scattered photons are not absorbed in the tissue completely but rather change their trajectory and continue at reduced energy. The direction of change is random, and the reduction in energy increases as the angle of deflection increases. In PET imaging, the scattered photon and its partner will arrive at two detectors within a coincidence timing window, and therefore the annihilation event will be misattributed to an LOR that does not pass through the true location. In SPECT imaging, the photon will be misread as a photon emanating along an LOR from the location of the scattering event in the scattered direction. In both modalities, detector circuitry can discriminate photon energy and reject low-energy photons to some degree, but there is enough overlap between the range of accepted energies and the energies of scattered photons such that many scattered photons are counted as true decay events. Scatter adds random noise unrelated to the true radiotracer distribution and would degrade the image quality considerably if not corrected. There have been many scatter correction methods proposed and implemented. Modern scanners incorporate sophisticated software algorithms that utilize information from the attenuation map generated from the transmission image to make probabilistic models of the scatter distribution, which are subtracted from sinogram data prior to reconstruction.

Telegram: @medical_k

www.konkur.in

FIGURE 1.27–7. Attenuation. The ellipse in the center represents a hypothetical object (i.e., a head) in the field of view. In SPECT, the photon traveling to the left would have the probability proportional to $e^{-\mu d1}$ of not being attenuated, and the one traveling to the right would have a probability proportional to $e^{-\mu d2}$ of not being attenuated. In PET, the coincidence event along this LOR would have a probability proportional to $e^{-\mu(d1+d2)}$ regardless of where along the LOR it originated.

Random Coincidences in PET. An additional source of noise specific to PET is accidental, or random, coincidences. These arise when two photons from distinct annihilation events arrive at two detectors within a coincidence timing window and are counted as an annihilation event along the LOR connecting the two detectors. Random coincidences are uniformly distributed across the field of view and cause an artifact of elevated background activity level, roughly in proportion to the square of the singles rate (the rate at which individual photons are detected). As with scatter, random coincidences would considerably degrade the image quality if not addressed. Most scanners have a delayed coincidence timing channel, an electronic circuit that allows estimation of random coincidences by purposely counting pairs of detected photons as coincidence events that arrive several nanoseconds further apart than a coincidence timing window and are therefore known not to have originated from the same annihilation event. The estimated random coincidences are subtracted from sinogram data prior to any other processing. In regions of the field of view where there is no, or very low, true activity, this step can lead to apparent negative counts.

Spatial Resolution. All imaging systems have characteristic spatial resolutions and indices of the smallest object dimensions that they can distinguish. Resolution in PET and SPECT systems are limited by the physical characteristics of the scanner, such as the finite width of LORs (as opposed to infinitesimally thin lines) or the fact that projection data are measured at a finite number of angles and distances from the origin at each angle, rather than the full continuum of angle and length values. Resolution limiting factors specific to PET are the range of positrons and the fact that the annihilation events are only localized within a sphere of 1 to 2 mm radius from the sites of the decay, and that the angle between released photons is not identically 180

Telegram: @medical_k

www.konkur.in

degrees. Resolution in SPECT is limited by collimator design and the distance of the imaged object from the collimators. The resolution of imaging systems is measured empirically by imaging radioactive sources of standard shapes and characterizing the accuracy of the image. If a small point source or a thin line source of activity is placed in the field of view, the reconstructed image spreads in a bell-shaped curve around the point or line called the point spread function (PSF) or the line spread function (LSF). Resolution is usually reported as the full width at half maximum (FWHM) of the PSF. This is the length, in millimeters, between the two points at which the value of the PSF is half of its maximum central value (Fig. 1.27–8). The PSF and FWHM are usually not constant across the field of view; they vary slightly with position but are typically reported as one average number. They are also dependent on the method of image reconstruction applied; performance evaluation reports are usually conducted using standardized methods to facilitate comparisons across scanners and reports. Most modern production PET scanners have FWHM in the range of 4 to 5 mm. Some specialized PET scanners have FWHM in the range of 2 to 3 mm. Resolution in SPECT is dependent on the collimator system in use. Clinical, rotating head SPECT scanners have FWHM in the range of 10 to 12 mm. Specialized small animal SPECT scanners that can exploit the close proximity of the animal to the collimator and use special collimator designs can have submillimeter FWHM. Images are usually reconstructed with voxel dimensions that are smaller than the FWHM to avoid having a checkerboard-like or pixelated appearance. As a result, each voxel will contain overlapping information from the voxels that are adjacent to it.

Hybrid Imaging Systems

In the years since 2000, scanner manufacturers have begun producing multimodal scanners having a PET or SPECT component combined with an additional imaging system such as CT or magnetic resonance (MR). In fact, dedicated PET systems for imaging humans have become increasingly rare, with the majority of recently produced systems containing a CT component. Hybrid PET-MR scanners are also becoming more commonplace, with all major manufacturers now producing systems for clinical use. The adaptations necessary to use these systems and their potential to expand the information obtained in the context of neuroimaging are briefly described.

PET-CT and SPECT-CT. A CT system is mounted along the same axis as the PET or SPECT system. The CT and radionuclide imaging are performed in sequence, not simultaneously, as the locations of the imaging detectors for the two systems are different. Very accurate coregistration of the images is possible because the distance between the patient positions for the two modalities is known precisely and can be used for image fusion in which the neurochemical information from the radiotracer image is superimposed on the more anatomically precise, high-resolution CT image. This has proven to be very valuable for imaging the chest or abdomen, as organs are easily identifiable on CT images but not on PET or SPECT images. It is of less value for brain imaging because CT images do not distinguish between soft tissue types. MRI images, on the other hand, do distinguish between gray matter,

Telegram: @medical_k

www.konkur.in

white matter, and CSF, and MRI is, therefore, a preferred modality for anatomical coregistration and structure identification. Frequently in neuroimaging studies, MRI images will be obtained in a separate session, and coregistration will be performed by software methods. PET-CT and SPECT-CT systems utilize the CT scan as a transmission scan for attenuation correction. An advantage of this use is the high signal-to-noise ratio obtainable in the CT images. The photons from CT scanners are x-rays spread over a relatively broad energy spectrum from ~40 to 140 keV. These have different (higher) attenuation than the higher energy photons from PET or SPECT and require the use of a lookup table method to transform their μ values into appropriate values for the other modalities.

PET-MR. Unlike PET-CT, the PET and MRI components are concentric, and images are acquired simultaneously. For whole-body imaging, the main advantages are the ability to obtain anatomical images without the additional radiation burden of CT and reduced overall imaging time. For neuroimaging, there is the potential, in addition to the anatomical information from the MR, to simultaneously utilize other MR techniques such as perfusion imaging, magnetic resonance spectrometry, or BOLD fMRI, greatly expanding the experimental information that can be obtained in a single imaging session. An ongoing technical challenge is attenuation correction. The concentric scanner ring design and the current size of the components from both modalities preclude the inclusion of rod or point sources of radioactivity used for conventional transmission scans. On the other hand, the MRI images, while providing very precise anatomical information about brain tissue, provide no direct information about the attenuation of high-energy photons. In addition, skull bone and other materials in the PET field of view, such as the patient bed or the MRI RF coil (which is outside the MR field of view) that do attenuate photons are not detected with MRI (skull can be detected using special fast echo RF pulse sequences and manufacturers have started to include these in their software). Current approaches for brain imaging involve coregistering acquired MRI images to standard atlases and using standardized μ values from lookup tables. Other, simpler methods, such as fat/water tissue segmentation algorithms in which each voxel is assigned to a tissue type with a standardized μ value, have proven adequate for whole-body scanning. While much progress has been made over the past decade, attenuation correction in PET-MR remains an active area of research; improvements and refinements can be expected as the technology matures and interest grows.

Safety

Telegram: @medical_k

www.konkur.in

Radiation Exposure and Internal Dosimetry. Radioactive decay leads to the deposition of energy in tissue when positrons, electrons, or photons interact with molecules in tissues. While the type and amounts of radiation that PET and SPECT research subjects are exposed to are very unlikely to lead to acute effects, the long-term impact and the possibility of genetic damage are less well understood. Risk/benefit considerations have led governments and international advisory groups to propose guidelines and regulations for exposure limits to research subjects. These are based on the linear nonthreshold model that assumes observations made at much higher exposures with qualitatively different radiation can be extrapolated to the levels that research subjects are exposed to in PET and SPECT studies. There is not currently a consensus among radiation biologists as to the validity of this assumption, but in the absence of definitive data, a conservative approach has been adapted. In the United States, there are FDA regulations limiting maximum radiation exposure to research subjects. Other countries are guided by the recommendations of the International Commission on Radiological Protection (ICRP). The amount of energy deposited in any organ or part of the body is a complicated function of the tissue type, the form of the organ, the isotope, and the distribution of the radiotracer throughout the body. The estimated radiation exposure associated with a radiotracer is most often determined through a combination of mathematical models, computer simulations, and test scans known collectively as internal dosimetry studies. The distribution of the radiolabel throughout the body will differ between radiotracers according to how the tracer is metabolized and cleared, and this is determined empirically by acquiring whole-body scans, either in a small cohort of human subjects or in animals with the application of scaling factors to account for size differences between species. Organ radiation doses are calculated as weighted sums of the energy due to decays occurring in the organ itself and the energy deposited in it from decay events originating in other parts of the body. The unit of absorbed dose is the Gray (Gy, joules per kg tissue). An older unit is the radiation absorbed dose (rad, 1 rad = 0.01 Gy). Exposure is usually reported as an absorbed dose per injected unit of radioactivity, such as mGy/MBq (1 mGy = 10^{-3} Gy) or rad/mCi. In the ICRP guidelines, absorbed doses are multiplied by an additional quality factor that accounts for the type of radiation, leading to different units (the guidelines also apply to workers with occupational exposures to more damaging types of radioactivity than used in PET and SPECT). After multiplication by the quality factors, Gy are transformed into units called Sieverts (Sv), and rads become Roentgen-Equivalent Man (rem). However, the quality factors are all equal to 1 for the

Telegram: @medical_k

www.konkur.in

types of radiation from PET and SPECT isotopes so that Sv are numerically equivalent to Gy and rems are numerically equivalent to rads. The weighting coefficients used to calculate the radiation dose to each organ as a sum of contributions of activity originating from all organs are derived from tables generated through detailed computer simulations that account for organ shape, size, composition, and distance from other organs in mathematical models of humans of different sizes, ages, and sexes. The FDA regulations are based on the concept of the critical organ, in which the total allowable radiation per study is limited by the absorbed radiation dose to the single organ with the highest exposure. The ICRP guidelines are based on weighted averages of doses to a predetermined set of organs. There have been multiple revisions of these guidelines and the names and definitions of the weighted sums. The names have been somewhat confusingly similar (dose equivalent, effective dose, equivalent dose, effective dose equivalent, etc.), but the standard as of ICRP Publication 103 (2007) is the effective dose (ED, Sv) equal to a weighted sum of absorbed doses from 28 specified organs and tissues. While the precise dose limits differ from tracer to tracer, several scans per subject per study can be performed with most radiotracers while remaining within the allowable exposure range.

Pharmacologic Toxicity. Compounds that are administered to human research subjects must undergo extensive toxicology screening prior to approval. The low mass dose usually administered to research subjects, in the range of several μg or less, generally keeps the dose many orders of magnitude lower than the level at which physiologic effects are noticed. This is especially true of radiotracers that are neuroreceptor antagonists. At tracer doses, these maximally occupy several percent of the receptors, well below the amount necessary for pharmacologic effects on neurotransmission. On the other hand, some agonist radiotracers have been known to elicit a pharmacologic response even at very low mass doses. Two examples are the μ-opioid agonist [^{11}C]carfentanil, which can cause sedation and hypoventilation at μg doses, and the dopamine D2/D3 receptor agonist [^{11}C]-(+)-PHNO, which can cause transient nausea several minutes after a bolus injection.

PHARMACOKINETIC MODELS AND METHODS, EXPERIMENTAL DESIGNS

General Framework and Compartment Models

Telegram: @medical_k

www.konkur.in

Above, some of the physical and image processing theories, technology, and algorithms used to create a PET or SPECT image were described. From the experimenter's perspective, all these components lead to one key characteristic of the imaging data that makes quantitative neuroimaging feasible: in each spatial location within the image, the measured amount of activity is proportional to the concentration of the tracer at that location. These measured amounts can be extracted as the average activity over a well-defined brain region of interest which can be as large as thousands of voxels or as small as a single voxel. Imaging data can then be statistically fitted to mathematical models of the observed biologic processes, and parameter estimates can be derived to quantitatively characterize the processes. The imaging data can range from single, static snap shots of the tracer distribution obtained from 10 to 20 minutes of scanning to sequential dynamic images that record the kinetic profile of the tracer over the course of hours. The mathematical models can range from simple measurements of the ratio of radiotracer concentrations in different tissues to detailed differential equation models that relate the pharmacokinetic profile of the brain concentration of the radiotracer over hours to the concentration in arterial blood plasma, collected in parallel with the brain images over the same time period. The radiotracer enters the brain from the bloodstream, and the most comprehensive models combine an equation for transport across the BBB with equations for the interaction of the radiotracer with biologic processes of interest in brain tissue; simpler models can sometimes be derived from these if appropriate conditions are met. The transport equation is usually based on Fick's principle, in which the net rate of influx or efflux across the BBB is proportional to the gradient in radiotracer concentrations between brain tissue and blood. Models of biologic processes can be broadly categorized according to whether the radiotracer is a ligand that binds reversibly to a target molecule or is a substrate for a metabolic pathway and becomes irreversibly trapped at some stage. A general, flexible framework that encompasses the reversible and irreversible cases is the compartment model (Fig. 1.27–9). A compartment model describes radiotracer kinetics with a simple set of rules, in which states of the radiotracer are represented as compartments, drawn as boxes, and changes of state are represented as flow between compartments, denoted by arrows showing allowable directions of flow between compartments, at rates that are proportional to the tracer concentration in the source compartment. Corresponding to the compartment diagram is a system of differential equations describing the rates. Outcome measures containing relevant biologic or pharmacokinetic information are formed as functions of the rate constants. The rate constants are unknown parameters; they are estimated by

Telegram: @medical_k

www.konkur.in

using a computer-based data fitting procedure that provides the best fit of the model to the measured PET or SPECT data. The most common criterion for best fit is least-squares minimization, in which the program searches through the entire plausible range of rate constants and finds the ones that minimize the sum of the squared differences between the measured data, recorded as discrete “frames” at a sequence of time points over the course of the scan, and the model predictions at these time points, although many data fitting and parameter extraction procedures are in use in addition to the conventional least-squares approach.

FIGURE 1.27–9. Some of the mathematics of compartment models. The box representations (**left**) for reversible and irreversible 2TC models. The center column shows the associated differential equations. These are derived by the simple rules that the overall rate of change of a compartment is a weighted sum of all source compartment concentrations (ones with *arrows* pointing into it) minus a weighted sum of the compartment concentration itself if the compartment is reversible (*arrows* pointing out of it). The weights are the rate constants labeled K_1, k_2, k_3, and k_4. The **right** column shows outcome measures. For the reversible tracers, all outcome measures are equilibrium ratios of concentrations. Because they are equilibrium ratios, the rates of change of each compartment (the **left** side of the equations in the center column) are 0, and the concentration ratios can be derived as functions of the rate constants. For the irreversible model, the steady-state representation of C_{PRE} can be derived in a similar way, and then substitution into the differential equation for the rate of accumulation of C_M leads to a rate constant expression for K_{in}.

Reversible Models. Reversibly binding tracers are used most frequently to quantify receptor, transporter, enzyme, or other protein density in the brain. These tracers are also referred to as radioligands. The modeled processes for reversible radioligand binding are bimolecular association between the radioligand and target protein and unimolecular dissociation of the target-ligand complex. The differential equation for this process is the mass action

Telegram: @medical_k

www.konkur.in

law. The canonic compartment model applied to reversible radioligands is the two-tissue compartment model (2TC, Fig. 1.27–9). The 2TC model requires that the concentration of radiotracer in arterial plasma be measured during the scan as an input to the model. This is invasive, as it requires arterial catheterization, and technically demanding, as it requires the application of chromatography to estimate the fraction of radioactivity in the blood that is due to unmetabolized radioligand rather than radiolabeled metabolites that form in the periphery and accumulate in the blood over the course of the scan. For some radiotracers, there are methods for estimating relevant parameters that do not require an arterial plasma input function, but even these are often conceptually derived from the 2TC, highlighting its central role in models of reversible tracers. There are two main simplifying assumptions in the 2TC. When the radioligand crosses the BBB, it is initially in a free, unbound state. From the free state, it can associate specifically with the target protein it was designed to bind to, or it can loosely bind to membranes nonspecifically. Specific binding is characterized by certain properties: it is saturable (it cannot exceed the concentration of the available target protein regardless of how high the ligand concentration is), and it is displaceable by other ligands that bind to the same site. Conversely, nonspecific binding is not saturable and not displaceable. Also, compared to the rate of the specific binding process, free and nonspecifically bound radiotracer equilibrate rapidly. The first simplifying assumption is that this equilibration occurs instantaneously so that free and nonspecifically bound radiotracer are combined into a single compartment called the nondisplaceable compartment (C_{ND}). Only the free fraction of C_{ND}, denoted f_{ND}, is able to bind specifically to the target molecule. The bound state is the Specific binding Compartment (C_S). The second simplification is called the tracer dose approximation. The bimolecular association term of the mass action law contains the product of the unbound target protein concentration and the free radiotracer concentration. The tracer dose approximation is that the concentration of radioligand is so low that, at most several percent of the target is bound, and therefore the target concentration can be treated as if it is constant. To satisfy the tracer dose approximation condition, very low mass, usually several micrograms or less, of radioligand are injected. This also limits the possibility that the radiotracer will pharmacologically perturb the system under study. In theory, models could be formed that do not include these simplifications—free and nonspecifically bound tracer could be treated as separate compartments, and the equations of the full mass action law without the tracer dose assumption could be implemented, but experience has proven the 2TC model to be the most comprehensive model that is also robust and stable enough for reliable

Telegram: @medical_k

www.konkur.in

parameter estimation. The two compartments, C_{ND} and C_S, represent states that are occurring simultaneously in the same voxels and cannot be separated in the image. Only their sum, $C_T = C_{ND} + C_S$ (T for Total concentration), can be observed; the relationship between C_{ND} and C_S must be inferred through the model. The concentration of the radiotracer in arterial plasma is denoted C_P. There are two types of related outcome measures derivable from the 2TC model. These are distribution volumes and binding potentials. These represent equilibrium ratios of radiotracer concentrations under tracer dose conditions (Fig. 1.27–9), but they are rarely estimated under equilibrium conditions. Rather, they are derived from dynamic scan data, usually acquired following a bolus injection of the radiotracer, as functions of the estimated rate constants. Some of the mathematics leading to the derived relationships between distribution volumes and rate constants are provided in greater detail in the legend to Figure 1.27–9. Distribution volumes represent equilibrium ratios between tracer concentration in compartments and tracer concentration in arterial plasma. For the 2TC model, there are three relevant distribution volumes: $V_{ND} = C_{ND}/C_P$, $V_S = C_S/C_P$ and $V_T = V_{ND} + V_S$. Binding potentials are parameters that are proportional to the ratio of specifically bound to free radiotracer at equilibrium. There are several forms of binding potential with different constants of proportionality, resulting from different ways of approximating the free concentration, but the version that is frequently reported in PET and SPECT studies is BP_{ND}, the ratio C_S/C_{ND} at equilibrium. From the distribution volume definitions, BP_{ND} can be seen to equal V_S/V_{ND}. Physiologically, BP_{ND} is equivalent to $f_{ND}B_{MAX}/K_D$, where B_{MAX} (nM) is the concentration of the target protein. Receptor studies report this as B_{AVAIL} to emphasize the fact that some portion of the total concentration B_{MAX} may not be available to bind to the radiotracer due to phenomena such as baseline receptor occupancy by the endogenous neurotransmitter or trafficking of receptors between the cell surface and cytoplasm. K_D (nM) is the equilibrium dissociation constant (reciprocal of the affinity). From the equilibrium definition C_S/C_{ND}, it is apparent that BP_{ND} is a ratio of specific binding, the quantity of most interest, to nondisplaceable concentration, which incorporates nonspecific binding, essentially a nuisance variable. For this reason, BP_{ND} is sometimes thought of as a signal-to-background ratio. In studies where C_P is measured, V_T can be estimated in all brain regions. BP_{ND} can be estimated through the use of the 2TC model provided there is a reference tissue, a brain region with negligible target protein concentration (Fig. 1.27–10). In a reference tissue, $V_T = V_{ND}$. An additional assumption applied in all

Telegram: @medical_k

www.konkur.in

compartment models that is well supported by data within experimental error is that V_{ND} is the same in all brain tissues so that V_T in the reference tissue provides an estimate of V_{ND} throughout the brain (Fig. 1.27–10). In theory, BP_{ND} is equivalent to the ratio of rate constants k_3/k_4 in the 2TC model. But in reality, this is not a reliable method to determine BP_{ND} when applying a statistical curve fitting to real data. The individual rate constants and their ratios suffer from poor identifiability—many different combinations of rate constants can fit the same data well. V_T, on the other hand, is identifiable, and a more robust way to estimate BP_{ND} in all brain regions is through distribution volumes as [V_T(region)—V_T(reference tissue)]/V_T(reference tissue). Also, if there is a reference tissue, there are mathematical models that eliminate the arterial plasma concentration C_P from the equations and estimate BP_{ND} directly from the relationship between the target-rich brain regions and the reference tissue; these allow BP_{ND} estimation without the requirement for arterial blood samples.

FIGURE 1.27–10. Time activity curves and 2TC fit at baseline and after receptor blockade. The data are from [^{11}C]raclopride scans, a dopamine D2-like receptor tracer, in a nonhuman primate at baseline (**left**) and following D2 receptor blockade with haloperidol (**right**). The figure illustrates several aspects of 2TC models. Distribution volumes (V_T) at baseline are 3.9 in the striatum, 1.4 in the thalamus, and 1.0 in the cerebellum. Using cerebellum V_T as an estimate of V_{ND} leads to BP_{ND} = 2.9 in the striatum and 0.4 in the thalamus. Following receptor blockade, all regions appear similar to the cerebellum, and all V_T are close to 1, illustrating the concept that V_T in the reference tissue, the cerebellum, provides a good estimate for V_{ND} in regions containing receptors.

Experimental Designs for Reversible Models. The most direct application of reversible models is the comparison of target protein density across groups or conditions. If the assumption is made that K_D and f_{ND} do not differ, on average, between scans being compared, then BP_{ND} can be taken to represent differences in B_{MAX} or B_{AVAIL}. Another flexible paradigm that can model many different phenomena is to compare the relative change in BP_{ND} across conditions within subjects, sometimes denoted as ΔBP_{ND}: ΔBP_{ND} = [BP_{ND}(condition 2) – BP_{ND}(condition 1)]/BP_{ND}(condition 1). The most common applications are those in which condition 1 is a baseline measurement, and condition 2 is a scan following a pharmacologic challenge that perturbs the system. Stimulant challenges induce an endogenous ligand for the binding site, such as a neurotransmitter in the case of receptor binding, to be released and compete with the radioligand for binding sites. Another example is a depletion paradigm, in which the challenge prevents or reduces the synthesis of the endogenous substance that normally binds to the site under baseline conditions, leading to the unmasking of the underlying B_{MAX}. ΔBP_{ND} also provides an estimate of the target fraction, or percent occupancy, attained by an exogenously administered drug. In the simplest case, when there is only a single competing ligand occupying some portion of the target molecules in condition 2 and no competitors in condition 1, BP_{ND} will be reduced by the factor $1/(1 + [L]/K_{DL})$ where [L] is the concentration of the competitor, and K_{DL} is the equilibrium dissociation constant of L for the target. The factor $1/(1 + [L]/K_{DL})$ equals 1 – occupancy, where occupancy is the fraction of the target concentration occupied at equilibrium by L at concentration [L]. Therefore, ΔBP_{ND} provides an estimate of the target occupancy attained by competitor L, and PET imaging has become an important tool in drug development and characterization of existing drugs. In vivo occupancy studies with PET have become nearly de rigueur for demonstrating target engagement by candidate drugs, and the need for such studies has motivated the development of tracers for new target molecules under investigation as sites for drug therapy. Occupancy study designs have included both simple measurement of receptor occupancy in stably dosed patients and more comprehensive designs utilizing experimental ranges of doses to form models of the relationship between doses or drug plasma levels and target occupancy, with estimates of related parameters such as ED_{50} or EC_{50} (dose and blood plasma concentration at which 50% of the target is occupied). Studies where ΔBP_{ND} is used to measure changes other than target occupancy by an exogenously administered drug, especially ones that utilize pharmacologic

Telegram: @medical_k

www.konkur.in

challenges to induce changes in neurochemical systems outside of the normal physiologic range, likely involve underlying pharmacokinetics or biophysical processes that are more complicated than the simple competition model implies, but ΔBP_{ND} is still an informative parameter to quantify the magnitude of the challenge effect.

Irreversible Models. The most commonly used irreversible compartment model also contains two tissues but has no route of return from the terminal compartment to the intermediate compartment as in the reversible model; the radiotracer or radiolabeled metabolic byproduct is effectively trapped in the final state. This model is most often applied in cases where the radiotracer is a substrate for several, but not all, of the steps in the metabolic pathway of an endogenous substance, with the radiolabel retained on the metabolic byproduct of each of these steps. If the process by which clearance from the last shared step is slow enough such that virtually all of the accumulated radiolabeled metabolite remains in that state for the duration of the scan, it can be treated as a trapped or irreversible state. Unlike the reversible models, irreversible models do not have a broadly agreed-upon nomenclature, but here the terminology C_{PRE} (for precursor, subsuming all reversible states in the brain prior to the last, trapped state) and C_M (for metabolite, the trapped state) are adapted. While there is no equilibrium state in an irreversible model, a hypothetical steady state can be envisioned in which the efflux and influx of C_{PRE} to and from the arterial plasma are just balanced by the forward transformation of C_{PRE} to $C_{M,}$ and the concentration C_{PRE} remains constant. From the compartment model equations, this steady-state would satisfy the condition $C_{PRE} = [K_1/(k_2 + k_3)]C_P$. The overall rate of trapping, equal to k_3C_{PRE}, would then equal $[K_1k_3/(k_2 + k_3)]C_P$. The expression $K_1k_3/(k_2 + k_3)$ is called K_{in}, the steady-state uptake rate constant of the tracer, and is the usual outcome measure estimated in irreversible models. In a similar fashion to reversible models, if a reference tissue for the irreversible process exists, a modified version of K_{in} can be estimated without the need for collecting arterial plasma.

Examples of Irreversible Models. The assumptions in irreversible models are more specific to the individual applications than with reversible models. A general sense of the way they work is most readily described through the examples of [^{18}F] DOPA and ^{18}FDG, two of the most widely used metabolism tracers in brain PET.

Telegram: @medical_k

www.konkur.in

[^{18}F] DOPA is a substrate for amino acid decarboxylase (AADC), the enzyme that catalyzes L-Dihydroxyphenylalanine (DOPA) into dopamine within the dopaminergic terminals. [^{18}F] DOPA readily passes the BBB and cell membranes and is metabolized by AADC into 6-fluorodopamine (6-FDA), effectively ^{18}F-labeled dopamine, in dopaminergic terminals. 6-FDA, like endogenous dopamine, does not cross the BBB and so is “trapped” in the proximity of the terminals and the cycle of vesicular loading, release through exocytosis and reuptake into the terminal, in parallel with endogenous dopamine in the striatum, where reuptake through dopamine transporters is the dominant mode of clearance from the synapse. K_{in}, estimated with the irreversible trapping model, represents a marker of presynaptic dopaminergic condition. The trapping is only approximate because 6-FDA is a substrate for monoamine oxidase (MAO) and for catechol-O-methyltransferase (COMT), and the radiolabeled metabolic by-products from 6-FDA metabolism can readily diffuse across the BBB. Several approaches have been proposed to incorporate the slow efflux from the brain, sometimes called k_{loss}, into the modeling and design of [^{18}F] DOPA experiments, but many studies quantify K_{in} with the more basic irreversible model. [^{18}F] DOPA data sets can comprise anywhere between one and several hours of dynamic imaging. Several brain regions, including the cerebellum, can function as a reference tissue for [^{18}F] DOPA imaging.

^{18}F-labeled 2-fluoro-2-deoxy-D-glucose (^{18}FDG) is by far the most widely used PET radiotracer. Originally developed for quantifying brain glucose metabolism, it was observed early on that ^{18}FDG is taken up more rapidly by some types of tumor cells than by the surrounding tissue, and ^{18}FDG imaging became a widely used diagnostic and staging tool in oncology and other medical fields. It is still frequently used in research for the quantification of brain glucose metabolism as well. ^{18}FDG is a substrate for the same carrier protein that transports glucose into brain tissue. It is also a substrate for hexokinase, the enzyme that metabolizes glucose, and is phosphorylated into ^{18}FDG-6-PO4. ^{18}FDG-6-PO4 does not follow further steps of glucose metabolism. It does dephosphorylate, but at a rate that is very slow compared to the forward process, and ^{18}FDG-6-PO4 is treated as a trapped state. Here, K_{in} represents the steady-state phosphorylation rate of ^{18}FDG. This is proportional, not identical, to the rate of these steps in brain glucose metabolism, owing to the fact that the transport and phosphorylation rates are different for the two compounds. When multiplied by a conversion factor accounting for this difference (1/LC, the “lumped constant” because it lumps two conversion factors together), K_{in}/LC times the plasma glucose

Telegram: @medical_k

www.konkur.in

concentration is taken as an estimate of brain glucose metabolism. As glucose is utilized throughout the brain, there are no reference tissues. The most comprehensive approach to estimating K_{in} with ^{18}FDG is to obtain arterial samples and fit the PET data to the 2TC irreversible model with arterial input or a modified version that accounts for the slow dephosphorylation, but this is rarely done in clinical research studies, where simplifications of both the blood input and the PET data acquisition are frequently employed. Simplification of blood input data can entail utilizing venous blood that has been “arterialized” by warming the site of the venous catheter to produce vasodilation and more rapid equilibration between arterial and venous ^{18}FDG concentrations, or even simpler, collecting only a small number of samples and using these to scale a standardized population input. PET data acquisition can be reduced by approximating K_{in} as the ^{18}FDG concentration in the brain at steady state divided by the area under the curve of the arterial plasma input; the image of the average ^{18}FDG concentration over a relatively short period of time, typically 30 minutes or less of acquisition starting between 45 to 60 minutes after a bolus injection, is used in this approach. Finally, the steady-state approach can be simplified even further by estimating a parameter called the standard uptake value (SUV), in which the area under the curve of the ^{18}FDG in blood is replaced by the injected radioactivity divided by the subject’s body weight. SUV is a widely used outcome measure in clinical scans but has come under criticism as a research tool because, without any direct assessment of the concentration of ^{18}FDG in blood, the method cannot account for differences across subjects or conditions in the rate of peripheral clearance of ^{18}FDG, and therefore can only provide information about relative metabolism across the brain within a scan.

RADIOTRACERS

Table 1.27–2 lists PET and SPECT radiotracers that have been successfully used in human subjects in recent years. Tracers for new targets and improved tracers for established targets are constantly under development; the table is intended to convey a sense of the resources available in 2021. Many more tracers have been proposed but have either failed to be adapted or have not yet progressed beyond testing in vitro or in preclinical species. The pharmacokinetic properties that lead to useful reversibly binding radiotracers are delicate and somewhat different than those that might make a compound suitable for *in vitro* binding experiments or as a therapeutic drug. In general, balance is required between a number of different properties in order for quantification to be reliable. For example, a prerequisite is that a tracer can be

Telegram: @medical_k

www.konkur.in

adequately supplied to brain tissues in order to provide a detectable signal. Several factors can affect this. The tracer will bind nonspecifically to plasma proteins in the blood. The protein-bound fraction (the unbound fraction is called f_P; $1 - f_P$ is the bound fraction) can be very high; for some radiotracers $1 - f_P > 99\%$. In some cases, this may prevent an adequate concentration of radiotracer from entering the brain for reliable image quantification. BBB penetrability is an issue that must be addressed in the *in vivo* setting that does not arise in cell cultures or *in vitro* assays utilizing brain tissue. A property related to this is lipophilicity. High lipophilicity generally improves the potential of a compound for BBB penetration, but it also leads to high nonspecific binding. If the nonspecific binding is too high relative to specific binding, the specific binding signal will be difficult to separate from the background, leading effectively to low BP_{ND} and unreliable quantification. Thus lipophilicity must have an intermediate value (log P in the range of 1.5 to 4) to balance between the need for brain penetrance and the undesirable effect of high nonspecific binding. Also related to BBB penetrability is the fact that some radiotracer candidates are substrates or weak substrates for P-glycoprotein (P-gp) or other efflux mechanisms that actively prevent brain entry; this can be hard to predict prior to *in vivo* testing. Another property that needs to be considered is the relationship between the affinity of the tracer for its target and the target density. As $BP_{ND} = f_{ND}B_{MAX}/K_D$, it can be seen that for a given target availability and f_{ND}, BP_{ND} varies directly with affinity. If BP_{ND} is too low, specific binding cannot be reliably measured relative to nonspecific binding (Fig. 1.27–11). Conversely, if the target density is very high, a high-affinity tracer may not reach a washout phase within a reasonable time frame, and parameter estimates will not be stable—small perturbations of the data late in the scan will lead to large changes in outcome measures (Fig. 1.27–11). Targets that are distributed very heterogeneously in the brain may require multiple radiotracers, with moderate affinity tracers for high-B_{MAX} regions and high-affinity tracers for low-B_{MAX} regions. Some tracers that appear promising in development may turn out to be too far to one end or the other of this spectrum to be useful in humans: either BP_{ND} too low everywhere or washout too slow everywhere. Another phenomenon that can limit the usefulness of a radiotracer is the discovery that *in vivo*, its selectivity for the primary target molecule compared to a secondary target is less than predicted *in vitro*. In general, tracers are screened *in vitro* for binding affinity to many brain proteins, but there have been cases where the *in vitro* affinity for a primary target is several hundredfold greater than for another protein, but *in vivo,* the affinities are found to differ by much less and binding to the secondary target

Telegram: @medical_k

www.konkur.in

presents a confound for quantification. Finally, a tracer may appear to have high potential according to all of the above criteria and then turn out to have a radiolabeled metabolite in the blood that crosses the BBB and makes quantification difficult or impossible.

Chemists working in radiotracer development can control some of these parameters, but much of the process is trial and error. Development might entail starting with an initial pharmacophore or a molecule known to have specificity for the target and then iterating through the sequence of devising a radiolabeling procedure, testing the result *in vitro*, testing in preclinical species, altering the molecule to improve properties based on test results, and repeating until a suitable candidate has strong enough potential for human testing. This process can be long and arduous, often taking years to arrive at a suitable radiotracer for a given target. Some recent work has focused on ways to streamline the process or on the development of a rational approach to predicting the quantitative potential of new tracers early in their development.

NEUROCHEMICAL IMAGING IN PSYCHIATRIC RESEARCH

As Table 1.27–2 demonstrates, radiotracers for imaging many different neurochemical systems have progressed as far as human imaging. Some of these are recently developed or have only been used in one or several studies, whereas dozens or even hundreds of studies of neuropsychiatric illnesses and other conditions related to brain function have been published using some of the more established tracers. Some of the most studied areas are schizophrenia and related conditions, major depression and other mood and affect disorders, substance and alcohol abuse and addiction, and more recently, Alzheimer disease and other dementias, but many more have been investigated. Some of these extensively studied areas and some well-replicated results are described here. This section is not intended to be a comprehensive review of all neuroimaging results in psychiatry but rather a selective sample to convey the nature of the research, some of the more well-established or informative results, and cases illustrating the capabilities as well as limitations of radiotracer imaging.

FIGURE 1.27–11. Time to peak-specific binding in simulated 2TC time–activity curves. These simulated curves were all created with the same input function and the same K_1, k_2, and k_4 values; they differ only in k_3, which is proportional to B_{AVAIL}. They illustrate the fact that the time of the peak-specific binding increases with increasing B_{AVAIL}. In the **upper left panel** ($BP_{N\ D}$ = 0.2), the majority of the activity is attributable to the C_{ND} curve, so that it will be difficult to distinguish C_T from C_{ND}, and BP_{ND} will be difficult to estimate accurately; the signal-to-background ratio is too low. In the **lower right panel** (BP_{ND} = 35), the peak-specific binding occurs so late in the scan that small perturbations of the last several data points could lead to large differences in estimated V_T or BP_{ND}. The **other two panels** (BP_{ND} = 5, 10) illustrate cases where parameter estimation would be robust, both because C_S comprises a large part of C_T, and peak-specific binding and a washout phase are reached during the course of the scan. *Dashed curves* are C_{ND}, *dotted curves* are C_S, and *solid curves* are C_T.

Dopamine

The dopaminergic system is one of the most extensively studied neurotransmission systems with both PET and SPECT imaging. Studies have examined receptor and transporter availability as well as transmitter synthesis, storage, and release capacity in cohorts from a broad range of patient populations. Several tracers have also been developed for intracellular

Telegram: @medical_k

www.konkur.in

enzymes involved in the signaling pathways of dopamine receptors, such as phosphodiesterase 10A (PDE10A). Because all antipsychotic drugs block dopamine D2 receptor transmission to some degree, and because of the role of dopamine transmission in functions such as attribution of salience to environmental stimuli or fine-tuning of working memory, dopaminergic dysfunction is considerably implicated in schizophrenia, and there have been a particularly large number of imaging studies characterizing different aspects of the dopaminergic system in patients with schizophrenia. Another area that has produced many imaging studies of the dopaminergic system is substance dependence. Many drugs of abuse induce the synaptic release of dopamine. This is especially true of drugs such as cocaine and amphetamines that act directly on dopamine terminals but is also true for other substances such as alcohol or nicotine that act indirectly. Because of this, and because of dopamine's roles in motivation, identification of rewarding stimuli, and reinforcement of rewarding behaviors, dopaminergic dysfunction has been implicated in drug abuse and addiction, and this has been an area of focus for imaging.

D1 Receptor Availability. Dopamine D1-like receptors are distributed throughout most of the brain, with a high concentration in the striatum and low to moderate concentration in the frontal cortex. D1 concentration in the cerebellum is below the detectable level with currently available tracers, and the cerebellum is treated as a reference tissue. Because of the involvement of cortical dopaminergic function in cognition and working memory, there has been great interest in assessing cortical D1 in conditions where these are affected, especially schizophrenia. There are two PET radiotracers that have been most frequently used to assess D1 receptor availability. These are [^{11}C]NNC112 and [^{11}C]SCH23390. Neither tracer can distinguish between D1 and D5 receptors. The signal-to-noise ratio, embodied in BP_{ND} values, is approximately threefold higher for [^{11}C]NNC112 than for [^{11}C]SCH23390. Also, the rapid peripheral metabolism of [^{11}C]SCH23390 has made it difficult to measure arterial plasma concentration reliably, so [^{11}C]SCH23390 is used exclusively with reference tissue methods, whereas [^{11}C]NNC112 can be used with both arterial input and reference tissue methods. Several studies have been performed to examine D1 availability in patients with schizophrenia. The studies utilizing [^{11}C]NNC112 have found increased cortical D1 in antipsychotic drug-free patients and especially patients without prior history of antipsychotic drug treatment compared to demographically matched control subjects, whereas the studies utilizing [^{11}C]SCH23390 have found decreased D1. Initially, it was thought this might reflect differences in tracer properties,

Telegram: @medical_k

www.konkur.in

but subsequent studies from both sets of investigators, comparing subsamples of the original cohorts who had been administered both tracers, have yielded results in the same directions as originally reported, suggesting this may be more related to population heterogeneity than to the tracers. During the first decade of the 2000s, several investigators demonstrated that the selectivity of both [^{11}C]NNC112 and [^{11}C]SCH23390 for D1 compared to serotonin 5-HT_{2A} receptors is approximately 10-fold rather than the 100-fold difference measured in vitro and that 25% to 35% of cortical BP_{ND} is attributable to 5-HT_{2A} binding for both tracers. Investigators presented some evidence that 5-HT_{2A} binding probably did not contribute to group differences in the schizophrenia studies, but unless more D1 selective radiotracers are developed, future studies will need to account for this factor when interpreting their results.

D2/D3 Receptor Availability. Dopamine D2-like receptors are heterogeneously distributed, with a high concentration in the striatum, and low concentration in the thalamus, midbrain (substantia nigra and ventral tegmental area, SN/VTA), and medial temporal cortical regions (amygdala, hippocampus) and very low concentration in the frontal cortex. These receptors are among the most studied with imaging, and many tracers have been developed. Widely used tracers are [^{11}C]raclopride for PET and [^{123}I]IBZM for SPECT. Both are suitable for striatal imaging but do not have high enough BP_{ND} for imaging outside the striatum. The cerebellum is frequently used as a reference tissue for each, and neither tracer distinguishes between D2 and D3 receptors. Several higher affinity tracers have been developed for extrastriatal imaging, including [^{18}F]fallypride and [^{11}C]FLB457 for PET and [^{123}I]epidepride for SPECT. [^{11}C]FLB457 can only be used quantitatively in the cortex and limbic regions as striatal binding does not reach equilibrium within a suitable time frame for ^{11}C imaging. Also, unlike most other tracers for D2-like receptors, specific binding of [^{11}C]FLB457 is detectable in the cerebellum. [^{18}F]fallypride, with its more long-lived radioisotope, can be used to simultaneously image the striatum and extrastriatal regions, though cortical BP_{ND} is still very low, and striatal imaging requires lengthy scanning of at least 3 to 4 hours. Specific binding in the cerebellum has also been detected with [^{123}I]epidepride, which is chemically similar to [^{11}C]FLB457. The long half-life of ^{123}I allows simultaneous striatal and extrastriatal imaging, but again, with very long scan times in excess of 4 hours. In addition, some investigators have detected radiolabeled metabolites of [^{123}I]epidepride in the brain. None of these high-affinity tracers can be used

Telegram: @medical_k

www.konkur.in

to distinguish between D2 and D3 receptors. [^{11}C]-(+)-PHNO is an agonist radiotracer that is strongly D3-preferring. Estimates of its in vivo D3:D2 selectivity range from 20- to 50-fold. D3 receptors are much less widely distributed and in lower concentrations than D2 receptors, but the D3-preferring nature of [^{11}C]-(+)-PHNO has allowed noninvasive in vivo characterization of D3 receptors for the first time. Binding is quantifiable in the striatum, the globus pallidus, the thalamus, the SN/VTA, and the hypothalamus. Dorsal striatum BP_{ND} is attributable mostly to D2 binding, SN/VTA and hypothalamus BP_{ND} are attributable mostly to D3 binding, and globus pallidus, thalamus, and ventral striatum BP_{ND} represent a mixture of both receptor subtypes. The cerebellum is used as a reference tissue.

D2 Receptor Availability in Schizophrenia

Studies of striatal D2 receptor availability in schizophrenia have been mixed, with meta-analyses suggesting that striatal D2-like receptor availability may be slightly elevated, if at all. Most of these studies were performed with [^{11}C]raclopride or [^{123}I]IBZM. One recent study also failed to detect a difference in striatal [^{11}C]-(+)-PHNO BP_{ND} between patients with schizophrenia and matched control subjects. Studies have also been published assessing extrastriatal D2 availability in schizophrenia using [^{18}F]fallypride, [^{11}C]FLB457, and [^{123}I]epidepride imaging. Individual studies have reported differences between patients and controls in several brain regions such as the temporal cortex, anterior cingulate, or thalamus, but these have not been seen consistently across studies or even go in opposite directions, suggesting that observed changes were either state dependent or due to population heterogeneity. In summary, the imaging literature to date suggests that dopaminergic dysfunction in schizophrenia is not likely mediated through receptor expression levels but rather through either pre- or postsynaptic phenomena.

D2 Receptor Availability in Substance Dependence

In substance dependence, a very different picture has emerged in which studies have consistently shown decreased striatal D2 availability in subjects who are dependent on a variety of substances, including cocaine, methamphetamine, alcohol, or heroin. An exception is cannabis use, in which such differences have not been detected in several studies using [^{11}C]raclopride in moderate users or in one study that imaged heavy users with [^{11}C]-(+)-PHNO.

www.konkur.in

Dopamine Release, Synthesis, and Storage Capacity. Many studies have used imaging methods to indirectly assess aspects of dopamine transmission. These include studies measuring ΔBP_{ND} of a receptor-binding tracer to infer levels, or changes in levels, of synaptic dopamine following pharmacologic challenges and metabolism studies using mainly [^{18}F]DOPA to assess presynaptic dopamine tone. In theory, any radiotracer that binds to receptors should be sensitive to changes in the synaptic concentration of the endogenous neurotransmitter, but for reasons that are not yet well understood, radiotracers for D2-like receptors have turned out to be the most sensitive. Thus, studies examining dopamine transmission have mainly used [^{11}C]raclopride or [^{123}I]IBZM. More recently, several studies have been published using [^{18}F]fallypride or [^{11}C]FLB457 to examine extrastriatal dopamine transmission, or [^{11}C]-(+)-PHNO, which provides another perspective due to its agonist and D3-preferring properties. Two of the most widely used pharmacologic compounds for increasing synaptic dopamine are dextroamphetamine (d-AMPH) and methylphenidate (MPH). d-AMPH causes dopamine to be extruded from intracellular synaptic vesicles and to be released in synapses by reversing the direction of action of the dopamine reuptake transporter (DAT). ΔBP_{ND} in the striatum between a baseline scan and a post–d-AMPH scan shows decreased binding ($\Delta BP_{ND} < 0$) consistent with competition at the receptors between the radiotracer and dopamine. The d-AMPH paradigm has been carefully validated; preclinical testing has demonstrated that measured ΔBP_{ND} is strongly correlated with released dopamine levels measured by microdialysis, that the measured levels are d-AMPH dose dependent, and that the d-AMPH effect is negated ($\Delta BP_{ND} \sim 0$) when dopamine is depleted prior to administration of d-AMPH, that is, the effect requires the presence of dopamine. There is some question as to whether, in addition to competition between the radiotracer and dopamine, the d-AMPH effect is mediated by other processes such as trafficking of receptors between the cell surface and cytoplasm because the decreased BP_{ND} is sustained for at least several hours longer than the dopamine surge following administration, but nonetheless ΔBP_{ND} following d-AMPH has been accepted as a reliable indicator of the capacity for dopamine synthesis, storage, and release. Microdialysis results from nonhuman primates show increased extracellular concentration of dopamine following d-AMPH of 1,000% or more and suggest that in the dose range administered to human subjects, dopamine release is high, but the effects on BP_{ND} are still small, with striatal ΔBP_{ND} in the range of 10% to 20% for [^{11}C]raclopride, [^{123}I]IBZM, and [^{18}F]fallypride. There is some evidence that dopamine may compete more

Telegram: @medical_k

www.konkur.in

effectively with agonist tracers than antagonists. Studies examining d-AMPH–induced dopamine release with [^{11}C]-(+)-PHNO or with [^{11}C]NPA, another agonist radiotracer that is not D3 preferring, found a larger magnitude ΔBP_{ND} than when the same subjects were scanned with [^{11}C]raclopride. This effect may be due to the agonist and dopamine competing for the same subset of receptors that are G-protein coupled and therefore in a high-affinity state for agonist binding, whereas the antagonist tracer binds with equal affinity to coupled and uncoupled receptors. This interpretation, however, is somewhat speculative and has yet to be rigorously demonstrated as the cause of the difference in tracer responses to dopamine release. MPH blocks reuptake through the transporter, so that released dopamine accumulates in the synapse and extracellular space. The magnitude of accumulated dopamine concentration following MPH is less than the amount released following d-AMPH, but the effect is still reliably detected with imaging and MPH challenge has also been widely used as a measure of presynaptic dopamine tone. Because radiotracers for D2-like receptors are sensitive to binding competition from endogenous dopamine, and there is a sustained, low baseline level of dopamine binding to receptors, there is some question as to the extent to which apparent baseline BP_{ND} is reduced by baseline dopamine. Depletion studies, in which preadministration of a compound that pharmacologically prevents dopamine synthesis or vesicular storage, are designed to unmask the contribution of baseline dopamine to apparent BP_{ND}. The tyrosine hydroxylase inhibitor α-methyl-para-tyrosine (AMPT) prevents dopamine synthesis and causes depletion of dopamine stores when administered over a period of 48 hours or more; AMPT has been used in human subjects to unmask baseline occupancy of D2 receptors by dopamine.

DOPAMINE TRANSMISSION IN SCHIZOPHRENIA. Studies using the d-AMPH challenge have consistently shown greater dopamine release (larger magnitude of ΔBP_{ND}) in patients with schizophrenia compared to matched control subjects. These have been observed at the level of the whole striatum, using [^{123}I]IBZM or [^{11}C]raclopride imaging. Studies using the AMPT depletion paradigm have found elevated baseline dopamine at the level of the whole striatum using [^{123}I]IBZM and, more recently, specifically in the associative striatum (caudate and precommissural putamen), using [^{11}C]raclopride imaging. These studies suggest that in humans, baseline occupancy of D2 receptors by dopamine is in the range of 10% to 20%. One study in which a small cohort of patients was imaged with both d-AMPH and AMPT challenges showed a high correlation between these, that is, greater AMPH-induced dopamine release was associated with greater baseline dopamine binding as

Telegram: @medical_k

www.konkur.in

inferred from AMPT unmasking. Thus imaging measures of dopamine transmission have consistently found elevated presynaptic tone in the striatum in schizophrenia. This is also in accord with [^{18}F] DOPA imaging in patients with schizophrenia and prodromal subjects at high risk for schizophrenia which have shown elevated K_{in} compared to matched controls in patients and intermediate elevation in prodromal subjects, with an association between the magnitude of [^{18}F] DOPA K_{in} and the likelihood of progression to psychosis in the prodrome. Conversely, one study used the d-AMPH paradigm in conjunction with [^{11}C]FLB457 imaging and found blunted dopamine release in patients with schizophrenia in the cortex and midbrain, in line with theoretical models of cortical hypodopaminergic transmission in schizophrenia. It has yet to be demonstrated that the two phenotypes, increased release in the striatum and decreased release in the cortex, occur in the same patients.

DOPAMINE TRANSMISSION IN SUBSTANCE DEPENDENCE. In contrast to patients with schizophrenia, in substance-dependent subjects, reduced dopamine release relative to matched controls has been most frequently observed following either d-AMPH or MPH administration. This has been observed in cocaine users, heroin users, heavy cannabis users, and alcohol-dependent subjects. One study also used the AMPT depletion model to show that baseline dopamine levels were reduced in cocaine users. Combined with observations of reduced D2-like receptor availability, the imaging literature suggests an overall reduced function or blunting of the dopaminergic system in substance dependence. These studies cannot address the question of whether low dopamine function is a predisposing factor or consequence of drug use, but one recent study using a nonhuman primate model of cocaine dependence found that presynaptic vesicle availability in dopamine terminals, as measured with the VMAT2 radiotracer [^{11}C]DTBZ, is lowered following chronic cocaine administration, suggesting a direct role for cocaine itself in the observed reduction of dopamine tone in users.

Dopaminergic Target Engagement. As far back as the late 1980s and early 1990s, PET studies were published using ΔBP_{ND} to infer receptor occupancy by commonly used antipsychotic drugs. It was shown, using [^{11}C]raclopride, that haloperidol (Haldol) and sulpiride (Dogmatil, Dolmatil, Eglonyl, Espiride, Modal, Sulpor) administered at therapeutic doses occupied between 75% and 90% of D2-like receptors and, using [^{11}C]SCH23390, that binding of both drugs to D1-like receptors was below detectable levels. The atypical antipsychotic clozapine (Clozaril) was shown to occupy ~50% of D2-like receptors and ~40% of D1-like receptors. These papers also were the

Telegram: @medical_k

www.konkur.in

first to demonstrate a direct link between extrapyramidal symptoms (EPS) and the level of D2 receptor occupancy, showing a threshold for the appearance of EPS at approximately 80% occupancy. Since that time, receptor occupancy has been characterized for many antipsychotic drugs as well as drugs from many other classes. Studies using [^{11}C]raclopride have repeatedly shown some widely used atypical antipsychotics such as risperidone (Risperdal) or olanzapine (Zyprexa) occupy 70% to 80% of striatal D2-like receptors in patients on stable doses and have also replicated earlier results that D2 occupancy by therapeutic levels of clozapine is lower than for other antipsychotics. In addition, risperidone, olanzapine, and clozapine have all been shown to occupy a greater percentage of serotonin 5-HT_{2A} receptors than dopamine D2 receptors using radiotracers for 5-HT_{2A}. Studies measuring striatal and extrastriatal occupancy of D2-like receptors by the partial agonist antipsychotic aripiprazole (Abilify) using [^{18}F]fallypride have demonstrated very high occupancy, ~90% at stable doses, without EPS, consistent with the expectation that partial agonists should support higher levels of D2 receptor blockade without EPS than antagonists.

Serotonin

The serotonergic (5-HT) system has also been widely studied with neuroimaging. The involvement of 5-HT in major depression and other mood disorders has led to an extensive body of imaging studies measuring the availability of receptors and reuptake transporters in those conditions, but serotonergic indices have been characterized across a wide spectrum of neuropsychiatric and related conditions.

5-HT_{1A} Receptor Availability. 5-HT_{1A} receptors are distributed throughout the brain, with the highest concentration in the insula and medial temporal cortex, high concentration in the cingulate, and moderate concentration in the prefrontal cortex and posterior cortex (parietal and occipital cortices). The receptors are also found in the dorsal raphe nuclei (DRN), where they act as inhibitory autoreceptors. DRN concentration is low but still of particular interest because of the role of 5-HT_{1A} autoreceptors in the regulation of serotonin transmission, as evidence from preclinical studies and other sources suggests that the mechanism of selective serotonin reuptake inhibitors (SSRIs) may involve desensitization of 5-HT_{1A} autoreceptors in DRN over the first several weeks of treatment, leading eventually to increased serotonin transmission. [*carbonyl*-^{11}C]WAY100635, usually abbreviated as [^{11}C]WAY100635, a selective 5-HT_{1A} receptor antagonist, has been the most

Telegram: @medical_k

www.konkur.in

widely used radiotracer for this target. The cerebellum is frequently used as a reference tissue with [^{11}C]WAY100635, but there is detectable specific binding in the cerebellar vermis, so the reference tissue must be defined to exclude that part of the cerebellum. [^{11}C]WAY100635 is difficult to produce due to a long and complicated synthesis procedure, and quantification is also difficult due to rapid peripheral metabolism and very low signal in the cerebellum, so there have been numerous attempts to develop modified versions and alternatives. Many of these use ^{18}F as the radiolabel and have run into problems with radiolabeled metabolites in the brain or uptake of [^{18}F]fluoride ion in the skull bone. Most recently, a new ^{11}C radiotracer, [^{11}C]CUMI101, has been introduced but has yet to be widely adopted. Thus despite the difficulties associated with its use, most published studies to date in patient populations have been performed with [^{11}C]WAY100635.

5-HT1A RECEPTOR AVAILABILITY IN DEPRESSION. There have been a large number of studies examining 5-HT_{1A} availability with [^{11}C]WAY100635 in major depression disorder (MDD) and related mood conditions. The majority of these have reported decreased BP_{ND} in the DRN and many other brain regions in MDD patients compared to matched controls; a few have reported no differences between groups. A small number of investigators, however, report increased binding in DRN and other regions when using the outcome measure BP_F, derived as V_S/f_P. BP_F is a form of the binding potential that uses nonprotein bound tracer in arterial plasma as the reference value rather than the nondisplaceable concentration in the brain used with BP_{ND}. There has been debate as to whether these exceptional findings are due to methodologic differences, differences in patient samples, or a combination of these. Studies using BP_{ND} with cerebellum as reference tissue may be biased by group differences in cerebellum binding of the tracer or by group differences in f_{ND}. Conversely, arterial plasma and f_P are challenging to measure and may contribute variability to data leading to discrepant results. Some evidence suggests that [^{11}C]WAY100635 is a weak substrate for P-gp. Possible group differences in P-gp activity have not been investigated in MDD to date, but if they exist, they might bias plasma-based outcome measures more than BP_{ND}. Thus, despite the importance of understanding the role of 5-HT_{1A} availability in MDD, there are currently controversies in the field that may only ultimately be resolvable with the development and use of more quantitatively reliable radiotracers for this target.

Telegram: @medical_k

www.konkur.in

Serotonin Reuptake Transporter Availability. Serotonin reuptake transporter (SERT) is heterogeneously distributed in the brain, with the highest concentration midbrain, high concentration in the striatum, amygdala, and thalamus, moderate concentration in the cingulate and hippocampus, and low concentration in the frontal cortex. The cerebellum is treated as a reference tissue for SERT tracers. The first radiotracer used to image SERT was [^{123}I]β-CIT. This tracer has an affinity for both SERT and the DAT and was thus not suitable for imaging SERT in the striatum where DAT concentration is high. Effectively, [^{123}I]β-CIT could only be used for SERT measurement in the midbrain. Subsequently, several PET radiotracers were developed for SERT imaging. The first of these, developed in the early 1990s, was [^{11}C]McN5652, which has a relatively low signal-to-noise ratio but is suitable for imaging in the midbrain and striatum. [^{11}C]DASB was developed in the late 1990s and has BP_{ND} values that are nearly double those of [^{11}C]McN5652 but are still very low in the prefrontal cortex. [^{11}C]DASB has become the most widely used radiotracer for SERT imaging. More recently, higher affinity tracers such as [^{11}C]AFM and [^{11}C]HOMADAM have been developed that may provide reliable quantification in the cortex, but studies using these have not yet been widely reported. SERT availability, measured with imaging, has been interpreted as a marker of 5-HT innervation and the integrity of the serotonergic system.

SERT AVAILABILITY IN MDMA USERS. 3,4-methylenedioxymethamphetamine (MDMA, ecstasy) releases 5-HT and increases its synaptic concentration by binding to and reversing the direction of action of SERT. MDMA has been used as a recreational drug due to its euphoria- and empathy-inducing qualities. Animal studies performed in the late 1980s indicated MDMA produced neural toxicity and reduced SERT at doses comparable to those of recreational users, raising the possibility that MDMA use could lead to reversible or even permanent neural damage. Initial studies performed in the late 1990s of SERT availability using [^{11}C]McN5652 found dramatically lowered BP_{ND} in MDMA users compared to matched control subjects. Several subsequent studies using [^{11}C]McN5652 did not replicate the dramatic result observed in the first study but did show moderately decreased BP_{ND}, in the range of 20% to 30%, in current MDMA users that appeared to be reversible both in cross-sectional studies that included former users, as well as in correlations, with the duration of abstinence or amount of use, in another study. Since that time, at least eight studies have been performed using [^{11}C]DASB in current and former MDMA users. These have consistently shown moderate decreases in cortical SERT availability in recently abstinent

Telegram: @medical_k

www.konkur.in

current MDMA users. One study examining former users found no difference compared to matched controls, suggesting the cautious interpretation of reversibility of MDMA-related neurotoxicity. An interesting aspect of this set of findings is that reported [^{11}C]DASB BP_{ND} values in the prefrontal cortex range from approximately 0.05 to 0.15 in healthy controls; these are usually considered well below the limit of quantitative reliability, but nonetheless, the result that there is reduced cortical SERT in recently abstinent MDMA users has been repeatedly replicated.

Serotonin Release, Synthesis, and Storage Capacity. Attempts to indirectly measure 5-HT release through competition with radiotracers following stimulant challenges have not been as successful as they have been for dopamine. The options for experimental design are more limited because strong 5-HT—releasing agents such as fenfluramine or MDMA are not suitable for human administration, and studies using human subjects have had to rely on SSRI administration to increase 5-HT levels, which likely leads to more modest effects than compounds that release 5-HT directly. But studies in rodents and nonhuman primates using fenfluramine to release 5-HT failed to consistently demonstrate the sensitivity of most 5-HT_{1A} and 5-HT_{2A} tracers available in the first decade of the 2000s to 5-HT, despite microdialysis evidence that extracellular 5-HT levels rise dramatically in response to the pharmacologic challenge. Several more recently developed tracers demonstrated sensitivity to changes in 5-HT levels in nonhuman primate models. These include two radiotracers for the 5-HT_{1B} receptor, [^{11}C]AZ10419369 and [^{11}C]P943, and [^{11}C]CIMBI-36, an agonist tracer for 5-HT_{2A} receptors. All three have proven sensitive to 5-HT release by fenfluramine with robust ΔBP_{ND} following fenfluramine administration. Results from the small number of studies performed in humans to date have been more mixed, with minimal response to SSRIs. One study did show a robust decrease of [^{11}C]CIMBI-36 binding in response to dAMPH.

The only currently available approach for reducing 5-HT levels to unmask possible baseline binding to receptors is rapid tryptophan depletion (RTD). Tryptophan is the precursor of 5-HT. The only source of tryptophan is dietary, and by having subjects ingest preparations that have high concentrations of other amino acids but not tryptophan, plasma levels decrease rapidly, leading, in turn, to reduced 5-HT in the brain. Behavioral studies have shown that RTD induces symptoms of depression in remitted depression patients. Glucose metabolism as measured with PET and FDG, cerebral blood flow measured with PET and ^{15}O water and neural activity measured with fMRI all suggest a detectable effect of RTD on brain function. Neurochemical imaging with PET

Telegram: @medical_k

www.konkur.in

has been more equivocal. Studies using [^{11}C]WAY100635 or [^{11}C]DASB failed to detect effects at 5-HT$_{1A}$ receptors or SERT. Two studies using the 5-HT$_{2A}$ tracers [^{11}C]MDL100907 or [^{18}F]Setoperone detected paradoxical effects, in which tracer binding was slightly reduced, rather than increased, in several brain regions following RTD. More recent studies with [^{11}C]P943 and [^{11}C]CIMBI-36 have also failed to definitively detect the effects of RTD on tracer binding.

Serotonergic Target Engagement. PET imaging has been used to establish SERT occupancy necessary for SSRI efficacy. These studies have been remarkably consistent across patient groups, drugs, and radiotracers in demonstrating that therapeutically effective SSRI doses attain 80% or greater occupancy of SERT. Studies have included patients with MDD, panic disorder, obsessive-compulsive disorder, and other conditions and have used both [^{11}C]McN5652 and [^{11}C]DASB as radiotracers. Tested drugs have included citalopram (Celexa), fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), venlafaxine (Effexor), and others. These findings provide a quantitative dimension to the understanding of SERT blockade as an antidepressive mechanism and a benchmark for drug development and clinical trial design. An interesting related set of studies provide an instructive example of the application of imaging studies in drug development. The long latency to therapeutic effects of SSRIs is believed to be related to a period of reduced 5-HT release following an initial transient increase due to inhibition of serotonergic cell firing in the DRN caused by stimulation of 5-HT$_{1A}$ autoreceptors. The inhibition was thought to subside over the course of several weeks due to the desensitization of 5-HT$_{1A}$ autoreceptors. Thus a strategy for reducing the latency would be to block 5-HT$_{1A}$ receptors in the DRN. But while this might reduce autoinhibition in the DRN, systemic administration of a 5-HT$_{1A}$ antagonist would also block postsynaptic 5-HT$_{1A}$ receptors in the terminal fields, possibly interfering with antidepressant activity. Pindolol (Visken) is a β-adrenergic receptor blocker that is also a weak partial agonist at 5-HT$_{1A}$ receptors, and in the 1990s, some preclinical and postmortem data indicated that it might bind preferentially to DRN autoreceptors, suggesting that augmentation of SSRI treatment with pindolol might decrease the latency and increase the efficacy of SSRIs. Double-blind, placebo-controlled clinical trials showed mixed results, with some reporting beneficial effects and others not. In the early 2000s, several PET studies were performed to measure occupancy of pre- and postsynaptic 5-HT$_{1A}$ receptors by pindolol using [^{11}C]WAY100635 imaging. These studies showed that at the

Telegram: @medical_k

www.konkur.in

doses of pindolol administered as augmentation therapy in the clinical trials, probably less than 30% of DRN 5-HT_{1A} receptors were occupied, calling into question whether or not the tested doses provided enough blockade of autoreceptors to be effective. In the particular case of pindolol, higher doses could not be tested due to adrenergic effects, but these studies demonstrated the key role that imaging can play in quantifying target engagement by therapeutic agents. Among the several PET studies measuring pindolol occupancy, the most comprehensive one did observe higher occupancy in DRN than in the cortex. Theoretical models have been suggested, but the mechanism for this difference has never been carefully characterized.

NEUROINFLAMMATION IMAGING IN PSYCHIATRY

Imaging of neuroinflammatory markers, initially studied in neurologic and neurodegenerative diseases, has more recently been widely applied in psychiatry as well, motivated by various lines of evidence such as increased expression of inflammatory cytokines in schizophrenia and depression. Microglia are the resident immune cells in the brain, and 18 kDa translocator protein (TSPO) is a mitochondrial protein highly expressed in activated microglia and reactive astrocytes. Many tracers have been developed for TSPO imaging (Table 1.27–2), and this is the neuroinflammatory target that has been most extensively imaged. The protein is not exclusive to activated microglia, but elevated TSPO has still been interpreted as indicative of increased activated microglia. Support for this interpretation has come from studies in humans and nonhuman primates in which administration of the inflammatory agent lipopolysaccharide caused increased TSPO radiotracer binding. The first PET tracer for TSPO was [^{11}C]PK11195, and many early studies used this radioligand. [^{11}C]PK11195, however, has a low signal-to-background ratio, and this motivated the search for better tracers for this target. Many new tracers were developed, all of which were discovered to be sensitive, to varying degrees, to a single nucleotide polymorphism (rs6971). Research participants have been found to have different binding affinities of these second-generation tracers for TSPO according to whether they have two copies of the major allele (high-affinity binders, HABs), are heterozygous for the major and minor alleles (mixed affinity binders, MABs), or homozygous for the minor allele (low-affinity binders, LABs). For some second-generation tracers, like [^{11}C]PBR28, specific binding is so low in LABs that it is virtually undetectable. The strategy adopted by most researchers has been to perform genetic prescreening, exclude LABs from their studies, and treat HAB or MAB group membership as a factor in statistical models. As there is no obvious

Telegram: @medical_k

www.konkur.in

reference tissue, most investigators report V_T as the outcome measure. Some studies, especially earlier [^{11}C]PK11195 studies, have also reported BP_P or BP_{ND}, derived directly from ratios of the estimated rate constants from the 2TC fits. As described above in the section on kinetic models, these should be interpreted cautiously.

TSPO in schizophrenia and psychosis. Some of the earliest studies using [^{11}C]PK11195 reported higher BP_P or BP_{ND} throughout the cortex in patients with schizophrenia than in matched controls. Many more recent studies with second-generation tracers did not replicate those results. Meta-analyses of studies utilizing second-generation tracers in schizophrenia and other psychotic disorders have found either globally lowered V_T in patients or no difference between patients and controls. Given the better imaging properties of the second-generation tracers and the more reliable outcome measure V_T, the available data do not support the hypothesis of elevated TSPO in psychotic disorders.

TSPO in major depression. Studies in MDD have established a stronger link between TSPO binding and the illness than in schizophrenia. To date, seven studies comparing patients with MDD to matched controls have been performed. Six of these, mostly using second-generation tracers, have found elevated binding in the patients throughout the cortex. Additional findings among the individual studies included associations of TSPO binding with peripheral proinflammatory markers or duration of untreated illness and predictive value of TSPO binding for treatment response to anti-inflammatory drugs.

TSPO in post-traumatic stress disorder (PTSD). Imaging markers of neuroinflammation have not been extensively studied in PTSD yet, but an intriguing result has been reported. Contrary to hypotheses that stress-related disorders are associated with brain neuroimmune activation, patients with PTSD were found to have lower [^{11}C]PBR28 V_T than matched controls in prefrontal-limbic brain regions, with V_T negatively associated with both symptom severity and plasma C-reactive protein levels. These results were also consistent with postmortem data showing lower TSPO expression in females with PTSD than in controls. The study requires replication, but the differences in TSPO imaging results among PTSD, MDD, and psychotic disorders suggest very different involvement of the neuroimmune system in different psychiatric disorders.

Other targets for neuroinflammation imaging. The limitations of TSPO imaging have spurred the quest to develop radiotracers for other targets associated with neuroinflammation. Among these, the ones that have

Telegram: @medical_k

www.konkur.in

progressed the farthest are cyclooxygenase 1 and 2 (COX-1, COX-2), both of which have roles in inflammatory processes. COX-2 has low basal levels but rapidly increases in response to acute inflammatory conditions and is expressed both in microglia and neurons. The tracer [^{11}C]MC1 is specific for COX-2, but the low basal levels are difficult to detect and quantify. COX-1 is constitutively expressed in all tissues, with predominant brain expression in microglia. The ability to quantify baseline binding may make COX-1 a more desirable target for detecting chronic inflammation in psychiatric populations. [^{11}C]PS13 is a COX-1 tracer that has a heterogeneous binding distribution in the brains of healthy human volunteers, with the highest V_T in the hippocampus, occipital cortex, and sensorimotor cortex, consistent with known mRNA expression from postmortem brains. While still in the early exploratory phase, COX-1 imaging with [^{11}C]PS13 is likely to be tested as a paradigm for probing neuroinflammation in psychiatric populations in the near future.

FUTURE DIRECTIONS

The field of radiotracer imaging with PET and SPECT continues to grow and expand, with the number of peer-reviewed publications using these methods increasing annually. Progress in certain areas, both in the technology and the biologic science, may lead to expanded utility and adaptation of imaging. The manufacture of scanners or cyclotrons that are less expensive or more portable would facilitate even wider use. Some manufacturers have already developed lines of lower-cost PET instruments, for example, by utilizing BGO detector crystals, which have some less optimal properties but are also less expensive than LSO and other state-of-the-art scintillators. At the other extreme, manufacturers are continuing to make major technologic advances in their high-end scanners, leading to finer spatial resolution, higher sensitivity, and better signal-to-noise properties in reconstructed images. It can be expected that these improvements in image quality will translate into more precise results in research imaging as these instruments come into wider use. The most immediate way to expand the scientific questions that can be addressed with PET or SPECT is the development of tracers for more currently inaccessible target molecules or processes. Despite numerous attempts, progress has been slow in developing tracers for the glutamatergic and GABAergic transmitter systems, but clearly, direct observation of the major excitatory and inhibitory neurochemical systems would benefit all brain research. The library of tracers for human imaging of other transmitter systems such as the cholinergic and opioid systems has broadened

Telegram: @medical_k

www.konkur.in

considerably in recent years, and it can be expected that these will lead to studies providing new insights into psychiatric illnesses. Recent developments in alternative therapeutic targets in schizophrenia and depression will require new imaging paradigms to confirm mechanisms of action. Finally, it is possible that eventually, neurochemical information currently obtained by PET and SPECT radiotracer imaging will be replaced by less invasive methods, for example, by the development of neurochemical probes that can be detected with MRI. But for the foreseeable future, PET and SPECT neuroimaging methods remain essential translational tools for understanding the brain in health and disease and for informing the drug development process.

1.28 Functional Brain Connectivity and Psychopathology

Deanna M. Barch, Ph.D.

Since the advent of modern "biological psychiatry" in the 1950s, much work on understanding the etiology of mental illness has focused on identifying the neural mechanisms that contribute to the development and maintenance of varying forms of psychopathology. This work has been aided by advances in novel neuroimaging technologies, such as the use of SPECT, PET, and MRI for the assessment of structural and functional characteristics of the human brain. The focus of this chapter will be on the use of measures of human brain functional connectivity and the ways in which understanding brain connectivity can inform the general understanding of the mechanisms that lead to the development and maintenance of various forms of psychopathology. The chapter begins with a brief history of the development of methods to measure and understand human functional brain connectivity. Next, the chapter provides a brief overview of the currently available methods for studying functional brain connectivity, with some discussion of their relative pros and cons. An overview of the current knowledge about core "intrinsic" functional brain connectivity networks in humans is also provided. Finally, the chapter selectively describes some of the work using functional brain connectivity to understand the neurobiology of mental illness, with a specific focus on psychosis and depression, as these are two facets of psychopathology with perhaps the largest existing literature on functional connectivity impairments.

In terms of brain function, historically, much of the functional neuroimaging work in psychopathology has focused on the use of either SPECT/PET or fMRI. These approaches provide indirect estimates of neural activity through the measurement of either glucose or oxygen metabolism (PET), blood flow (SPECT), or the measurement of blood oxygen level–dependent (BOLD) activity. The initial studies addressing questions about the neural mechanisms of psychopathology primarily used task-based PET or fMRI to assess differential activation of brain regions while participants performed various cognitive, affective, or social tasks. These studies have been essential for the development and testing of hypotheses about which brain regions may be affected in different manifestations of mental illness, under the inference that abnormal BOLD activity during performance of cognitive or affective tasks

Telegram: @medical_k

www.konkur.in

indicates abnormal underlying neuronal processes. As some examples, this research has led to the development of theories about the role of the dorsolateral prefrontal cortex (DLPFC) in cognitive dysfunction in psychosis, the role of the amygdala in depression, the role of the amygdala and insula in at least some anxiety disorders, and the role of striatal mechanisms in addictive disorders.

Both the basic and translational research on task-related brain activation has been hugely informative in terms of the current understanding of the neural substrates of particular cognitive and effective processes and how these may go awry in psychopathology. However, over time, it has become clear that rarely does any particular task activate only a single brain region, and rarely is any particular domain of psychopathology associated with abnormal activation in only a single brain region. Further, basic neuroscience research has long made it clear that activity in any individual brain region (or any individual neuron!) is the result of inputs from and outputs to different areas of the brain. Such realizations led to a shift in focus to questions regarding neural circuits rather than a focus only on specific brain regions. More specifically, this shift has been to questions about the relationship *between* and *among* different brain regions in producing successful cognitive and affective function in health and the ways in which abnormalities at the level of circuits contribute to the development and maintenance of particular dimensions of psychopathology. Questions regarding the role of the DLPFC in cognitive dysfunction in schizophrenia provide an excellent case study in this regard. Much of the early work on DLPFC dysfunction associated with cognitive impairment in psychosis focused almost exclusively on the DLPFC itself. However, what if, for example, the abnormal activity observed in the DLPFC during a cognitive control task was actually the result of faulty inputs from another brain region(s)? In other words, what if the DLPFC itself functioned normally in schizophrenia, but the information it received was leading to the observed abnormalities? Alternatively, what if the problem was not in the activity within any specific brain region but rather in the connections among or the ability to coordinate activity among brain regions? The growing work on the role of brain oscillations in coordinating activity among and between neural networks is consistent with such hypotheses that localize impairment in psychopathology at the circuit level of function rather than within specific individual brain regions. Further, in many ways, it is easier to connect circuit-level hypotheses with the larger literature on impairments at other levels of analysis in psychopathology (e.g., neurotransmitter availability, receptors, E-I balance). Such impairments are frequently not regionally specific and involve processes and mechanisms that would reasonably be

Telegram: @medical_k

www.konkur.in

expected to alter inter-regional communication, either within or between cortical regions or between cortical and subcortical regions.

THE ADVENT OF STUDYING FUNCTIONAL CONNECTIVITY

The ability to examine these types of questions has been propelled by the development of functional connectivity methods for use in humans. Originally, the concept of functional connectivity was applied to simultaneous recordings of neuronal spike trains, which are thought to contribute to the functional connectivity observed in humans using noninvasive neuroimaging methods. A main inference of functional connectivity is that if two regions have highly correlated neuronal activity (i.e., have high functional connectivity), then they are more likely to engage in a common set of processing mechanisms. If so, then functional connectivity provides a tool for understanding which brain regions may be communicating during the completion of cognitive or affective demands and, therefore, what brain circuits support performance and ability in different domains of cognition, emotion, and/or social processing.

RESTING-STATE FUNCTIONAL CONNECTIVITY

A major breakthrough in the development and application of functional connectivity methods for humans came in 1995 when Biswal and colleagues reported that spontaneous activity from regions in the right and left motor cortices were highly correlated even while an individual was resting, suggesting functional connectivity between these brain regions even when the individual was not performing a task. Interestingly, this correlated activity was observed in the spontaneous low-frequency fluctuations of the BOLD signal (0.01 to 0.10 Hz), a frequency band that has often been discarded as noise in task-based studies, though such correlations can be seen at other frequencies as well. This work spurred a major field of exploration of what is now referred to as resting-state functional connectivity. Importantly, this resting brain state activity is thought to consume a major portion of the body's energy (~20%), despite the brain only being 2% of the body's total mass. Further, changes in metabolism due to engagement in a specific task are typically less than 5%, which suggests that ongoing resting-state activity may provide as rich a source, if not richer, of disease-related variability than changes observed due to task performance. In addition, there is also robust work demonstrating that a large portion of the trial-to-trial variability in task-related activity reflects coherent and organized spontaneous fluctuations in

Telegram: @medical_k

www.konkur.in

brain activity, providing another piece of evidence that this is a meaningful source of variation in human brain function.

RESTING-STATE FUNCTIONAL CONNECTIVITY NETWORKS

One of the key aspects of resting-state functional connectivity that has spurred interest in this aspect of brain function is the realization that *resting-state functional connectivity* reveals intrinsically organized networks of brain regions that are consistently functionally connected, even in the absence of task-induced perturbations in ongoing brain activity. This has been supported by numerous “network” mapping studies that have identified consistent, robust, and reproducible networks of brain regions that show coordinated activity at rest. Among others, these include the default mode network (DMN), the frontal–parietal network, the cingulo-opercular network, and the dorsal attention network, to name but a few. One recent example of this is shown in Figure 1.28–1, where 356 regions (“parcels”) identified as having highly homogenous patterns of resting-state functional connectivity were grouped into 12 resting-state networks that map nicely to networks identified in previous resting-state studies. Such networks are robustly identified across varying methods for assessing functional connectivity, are robustly identified across individuals, though they show important individual differences in the size and location of particular regions, and emerge at least in part early in the course of life as early as birth. Importantly, many of these networks map closely or at least partially to networks that have been identified in task-based studies, providing validation to the functional meaningfulness of this coordinated activity.

Telegram: @medical_k

www.konkur.in

FIGURE 1.28–1. Functional connectivity networks derived from resting state data. The **top row** is a lateral view of the brain, and the **bottom row** is a medial view of the brain. The colored "parcels" were derived from a boundary identification approach using a "watershed by flooding" algorithm to identify boundaries in the gradients of change in whole-brain maps of functional connectivity. The community structure of the parcels derived from this boundary mapping was generated using an InfoMap algorithm. (See eBook for color images.) (From Gordon EM, Laumann TO, Adeyemo B, Huckins JF, et al. Generation and evaluation of a cortical area parcellation from resting-state correlations. *Cereb Cortex.* 2016;26(1):288–303, by permission of Oxford University. doi: 0.1093/cercor/bhu239.)

Such functional connectivity networks have their basis in part in structural connectivity but are not isomorphic with regions that show direct structural connectivity. As such, the mapping of resting-state networks to known task networks has led to the hypothesis that resting-state networks reflect, in part, organized interactions that arise partly from a history of coactivation over development, though, as noted above, key components of this organization are present as early as birth. Such networks are now frequently referred to as "intrinsic" connectivity networks, given that they are not dependent on the performance of a particular task for identification, are present even at rest, and are relatively consistent across task and environmental states. Recent major projects to study the human functional and structural connectome across multiple scales, modalities, and ages—the Human Connectome Projects Across the Lifespan—have corroborated the presence of these core networks in the human brain. Moreover, the results of the Human Connectome Project have confirmed and extended current knowledge about the critical relationship between individual variation in functional brain connectivity and individual variation in a range of behaviors relevant to mental health and both negative and positive life outcomes across the lifespan.

Telegram: @medical_k

www.konkur.in

Although in principle, any human brain network is relevant to the understanding of psychopathology, several of the most commonly identified networks are particularly relevant to the functions and processes often found to be impaired in psychopathology. For example, both the *frontal–parietal* and the *cingulo-opercular* networks are ones that have been consistently associated with a variety of cognitive control functions. The frontal–parietal network includes dorsal regions of both the lateral prefrontal cortex and parietal cortex, while the cingulo-opercular network includes the dorsal anterior cingulate (dACC), bilateral dorsal anterior insula, and sometimes both thalamic regions and anterior prefrontal regions. As will be discussed in more detail below, these networks have been found to be abnormal in populations with known impairments in cognitive control, such as schizophrenia, or in emotion regulation, such as major depression. The *dorsal* and *ventral attention* networks have also been associated with cognitive function, though more so top-down and/or stimulus-driven attention functions. The dorsal attention network is closely aligned with the frontal–parietal network in that it includes not only both dorsal, frontal, and parietal regions but also more dorsal supplementary motor and eye field areas. The ventral attention system includes the temporal–parietal junction and the ventral lateral prefrontal cortex (VLPFC), and has been associated with attention to salient events in the environment, often activated when events in the world that disrupt ongoing processing occur. Altered connectivity has been associated with anxiety disorders under the hypothesis that it could contribute to altered attention to threat-relevant stimuli in anxiety disorders.

The *DMN* has been associated with a variety of functions, but in particular, it may be associated with attention to internal emotional states and the ability to distinguish or shift between internal and external modes of attention. Further, there is a large body of literature showing that the DMN decreases activity during engaged task states and some hints that a failure to “shut down” the DMN may impair cognitive function. The DMN (see Fig. 1.28–1) includes a wide variety of regions, but most notably medial prefrontal, medial posterior cingulate, and precuneus regions. Further, a number of studies have suggested that there may be multiple DMN subnetworks that may subserve somewhat different functions). Increased connectivity among DMN regions has been associated with rumination in major depression. The *salience* network is one that has been identified somewhat more recently than some of the other networks and includes more rostral regions of the anterior cingulate and insula than typically associated with the cingulo-opercular network (see Fig. 1.28–1), though both have strong connectivity with limbic and subcortical regions. Connectivity of the salience network has been associated with

Telegram: @medical_k

www.konkur.in

anxiety and arousal and is hypothesized to be a network of regions that serve to process and coordinate reactions to salient events in the environment.

MODALITIES FOR ASSESSING RESTING-STATE FUNCTIONAL CONNECTIVITY

Resting-state functional connectivity in humans can be assessed using a variety of methods. By far, the most common is to use fMRI with a focus on spontaneous fluctuations in BOLD-related activity. This approach is noninvasive and provides good-to-excellent spatial resolution, depending on the pulse sequences used, but it is inherently limited by the fact that BOLD-related signals are indirect measures of neural activity (i.e., reflecting a compensatory blood flow response in reaction to neural activity that alters local magnetic homogeneity) and by the fact that BOLD signals are slow and temporally extended over time. Resting-state functional connectivity can also be measured using EEG or magnetoencephalography (MEG), which can provide much finer-grained temporal resolution and the ability to resolve connectivity at different frequencies, though these methods can be limited in their ability to localize signals (i.e., EEG) or to address deep sources of activity in regions such as the striatum or thalamus (i.e., MEG). Functional connectivity can also be assessed using more invasive techniques, such as electrocorticography (ECoG), which involves the placement of grids of electrodes subdurally. Such an approach has the obvious advantage of direct mapping to the electrical activity generated by neuronal activity along with good spatial localization but is limited to use in populations in need of intracranial recordings for medical reasons.

Further, although much of the focus on functional connectivity has been on data acquired while participants are resting quietly with their eyes closed or open, numerous studies have now demonstrated that very similar results can be derived from data acquired during the performance of specific tasks or even watching movies, though with some caveats. One such approach is to use data acquired during the performance of a task but to try to remove the deterministic influence of the task structure on BOLD activity through regression methods and then base the functional connectivity analyses on the residuals from the regression. Results from such studies can be very similar to results from traditional resting-state studies. However, the degree to which this is true may depend on the number of different task states over which the data is integrated. Doing this for only a single task state is essentially functionally equivalent to the data generated using psychophysiologic interaction analysis approaches (PPI), which focus on comparing connectivity

Telegram: @medical_k

www.konkur.in

differences in one task state versus another task state. Further, there is some evidence in the literature that prior "states" or performance of specific types of tasks can influence subsequent assessments of resting-state connectivity. As such, integrating over several task states may be more effective at eliminating deterministic or residual effects of any one task state and thus increase generalizability and similar to resting-state connectivity. Another approach that has been increasing in popularity has been to examine functional connectivity while people watch movies, with evidence that this can perform as well as rest data in predicting behavior. Not surprisingly, such an approach is particularly attractive for special populations who may have difficulty resting quietly, such as children.

FIGURE 1.28–2. Dimensions characterizing functional connectivity analysis. The **bottom row** illustrates the dimension from more hypotheses driven to more data-driven approaches to the analysis of functional connectivity data. The **middle row** illustrates the dimension of analysis approaches more focused on characterizing association versus those attempting to determine causality or directional relationships. The **top row** illustrates the dimension of analysis approaches focused on static estimates of connectivity in a single session versus approaches more focused on the dynamics of change within a session or across sessions.

METHODS FOR ANALYZING RESTING-STATE FUNCTIONAL CONNECTIVITY

As is true for most neuroimaging methods, the use of resting-state functional connectivity data introduces many choice points for the researcher, primarily in terms of how functional connectivity should be calculated, how to identify different brain regions, and how noise should be handled. Each of these choices will influence the structure and quality of the data, but there is no clear consensus about a “best” method for all resting-state studies, only trends of commonly used approaches in the literature. A review of all possible variations or choices relevant to these issues is beyond the scope of this chapter and has been reviewed elsewhere. The focus of this chapter now turns to some of the choices most relevant to understanding the current literature on psychopathology. For most studies of psychopathology, the main goal of resting-state functional connectivity analyses is to assess variations in the relationships between different brain regions, either due to an interest in a specific, a priori region and its connectivity or to better understand disruptions in functional networks. As such, one dimension (see Fig. 1.28–2) along which characteristics analysis approaches is from relatively more a priori and hypothesis driven to relatively more data driven. Along this dimension, the three most common analysis techniques are a region of interest (ROI) or a priori network-based analyses, seed/ROI to whole-brain connectivity analysis, and independent component analysis (ICA) or other clustering methods. All three of these methods have pros and cons, and it is up to the researcher to decide which analysis will allow them to most accurately test their research question at hand.

ROI–ROI or Network-Based Connectivity

ROI to ROI or network-based analyses typically take as their starting point a specific set of regions or a specific network of regions already identified and characterized in the literature and focus on extracting the time series from these regions and analyzing the connections among those specific ROIs or among the regions in that specific network. As an example, one might wish to test the hypothesis that a particular dimension of psychopathology is associated with abnormal connectivity between two specific regions (e.g., medial prefrontal and precuneus regions from the DMN) or with abnormal connectivity among all or some of the regions associated with the DMN. For example, prior work has examined whether connectivity among or between regions in the frontal–parietal network, the cingulo-opercular network, or the default-mode network is altered in schizophrenia and whether it relates to

Telegram: @medical_k

www.konkur.in

variation in cognitive function. As another example, Perino and colleagues examined whether connectivity among and between the dorsal and ventral attention systems predicts anxiety in youth. Of note, recent research suggests that there may be important individual differences in the size and location of regions within these networks and that it is possible with sufficient data to reliably assess person-specific regions and networks, an approach that may enhance connections to behavior and psychopathology.

ROI/Seed-Based Connectivity

Another common approach is to start with a particular ROI or “seed” and examine connectivity between the seed and the rest of the brain, or at least a subset of the brain. Seed-based connectivity is a flexible method that can be performed, if so desired, but is more commonly used to understand the functional connectivity maps for specific regions of interest. There are numerous examples of this in the literature, such as work looking at the connectivity of the amygdala, or subregions of the amygdala, in relation to depression. Seed regions can also be used to identify functional networks, assuming that the seed region is a robust member of a specific network. However, just because many regions are strongly connected with, say, the DLPFC does not necessarily indicate that those regions form a unitary network. In the case of seed-derived functional networks, it is important to verify that most other nodes are functionally connected to one another as well as to the seed. Taken together, one of the biggest advantages of ROI–ROI, network, or seed-based connectivity methods is that they allow for a direct test of specific research questions, making interpretation of findings in such studies relatively straightforward, modulo all of the potential interpretive caveats that arise in any functional connectivity study.

Importantly, however, this advantage to ROI or seed-focused studies may also contribute to some of the drawbacks of such studies. ROI/seed-based studies allow researchers to make specific predictions about relationships between certain regions or networks of the brain and to test those questions directly. However, by preselecting an anatomical region as the seed for all other correlations, researchers can introduce a bias in their data. There is no perfect way to provide the most accurate and reliable time series for the functional area of interest in all subjects. Consider the possibility that functional areas from two different networks could sit side by side in the brain, such that the inclusion of several voxels from the wrong region could result in connectivity maps that reflect two different functional networks. Add on top of that the consideration that at least some clinical populations may also have anatomical abnormalities that could make the identification of regions

Telegram: @medical_k

www.konkur.in

challenging. However, as noted above, increasing evidence suggests that it is possible to reliably identify individual-specific brain regions based on their patterns of functional connectivity, which helps to address some of these issues. Further, seed or ROI-focused studies may also suffer from the "streetlamp" problem, such that a researcher is biased to find significant results in a priori regions simply because those are the ones examined, and the researcher does not know whether even stronger or more consistent results might have been generated through the use of a different set of regions.

Another limitation of seed-based connectivity approaches is that they provide a univariate analysis of what is, in reality, a multivariate system. In such ROI or seed-based connectivity analyses, the time series of one or more regions is correlated with the time series of one or more other regions or voxels in an effort to understand pairwise relationships. What is being ignored in this process are the complex interactions that lead to the observed pairwise relationships, such as modulations of the connectivity of that pair of regions or voxels by other connections. Therefore, seed-based connectivity analysis not only restricts the anatomical definition of functional networks, as described above, but interpretations of these functional networks do not take into account the full complexity of the system in which the network is embedded.

Independent Components Analysis

A common alternative to ROI or seed-based connectivity analysis is ICA, which is a multivariate data-driven approach to identifying functional networks of the brain. ICA is an algorithm that takes the entire set of BOLD data and decomposes it into spatially segregated, maximally statistically independent components. In doing so, ICA addresses several of the limitations associated with ROI/seed-based connectivity that were discussed above. Namely, ICA does not require the definition of a priori regions, resolving the potential bias of selecting nonoptimal voxel clusters or of looking only at certain connections. ICA also takes into account the complexity of multivariate data since the components identified by ICA are determined using the entire BOLD data set, which includes information about the time series from all voxels.

Not surprisingly, ICA also introduces several limitations that, similar to seed-based connectivity, have the potential to bias the data. Most notably, ICA identifies components of the data, but it is up to the researcher to determine what each component represents. For example, researchers must decide which components are noise and which components represent functional networks, though strategies exist for helping investigators to accomplish this, such as automated identification of previously validated noise components.

Telegram: @medical_k

www.konkur.in

Finally, the interpretation of ICA data is not always as straightforward as the interpretation of seed-based results. Specifically, the metric of ICA is the magnitude of the component, not the magnitude of a specific pairwise relationship. The magnitude of a component can be reduced for a number of different reasons, including variations in spatial distribution, reduced variability in signal, or reduced correlations among time series across regions, and it is not always clear which of these is driving the results.

Association versus Directionality

Another dimension (see Fig. 1.28–2) on which the analysis of resting-state data can vary is the degree to which the methods focus on simply characterizing association versus attempting to identify causal or directional associations. By far, the most common approach to the analysis of resting-state data is to simply use full correlations or ICA, which do not presume any directionality to the associations, and which capture covariance due both to direct connections between regions and to shared variance with other regions. At the opposite end of the spectrum are approaches such as dynamic causal modeling, Granger causality, and lagged time series analyses, which attempt to establish temporal or causative directionality from the patterns of covariance, though there are challenges to the use of this method with resting-state fMRI data. Somewhat in between these two extremes is the use of partial correlations, which attempt to isolate the direct associations of connectivity between regions or voxels, partially out the covariance due to shared connections with other regions.

Static versus Dynamic Assessments

Yet another dimension along which analysis of resting-state data can vary is a focus on a static estimate of a pattern of functional connectivity in an individual at one point in time versus dynamic variations in connectivity "states" over time. A number of studies have now begun to examine how patterns of connectivity among brain regions may vary over time and be classified into a limited set of connectivity "states" or patterns of connectivity. These state patterns may also vary across clinical populations, either in terms of the number of states achieved, the amount of time spent in different states, or the speed with which transitions between states occur.

Network Approaches to Functional Connectivity

As a complement to seed/ROI-based and data-driven approaches, researchers are increasingly applying tools from network science to

Telegram: @medical_k

www.konkur.in

understand brain organization, primarily through the use of graph theory. When adopting a graph theory approach, investigators have examined variations in several graph properties, including global and local efficiency, small-worldness, and participation coefficients. Global efficiency measures a brain network's functional integration by indexing how easy it is for information to be communicated across brain regions in a network (e.g., across regions in the DMN). Local efficiency measures how well a brain region's neighbors continue to communicate with each other following the removal of that region ("node" in graph theory terminology) and therefore represents something like the fault tolerance of a network. Participation coefficients indicate the number of different networks with which a particular brain region communicates, providing information about how important that region is in overall brain communication. Regions with high participant coefficients are often referred to as "hubs" and are thought to be particularly important for information transfer. The hubs that have been identified in the human brain include the DLPFC, the precuneus, and the insula, among others, and those that are particularly highly connected to each other are referred to as the "rich club." Graph theory approaches have been used to examine brain organization in a number of forms of psychopathology, but perhaps most frequently in schizophrenia, as will be discussed in more detail below.

BENEFITS AND CHALLENGES IN APPLYING RESTING-STATE FUNCTIONAL CONNECTIVITY ANALYSES TO THE STUDY OF PSYCHOPATHOLOGY

Studies of resting-state functional connectivity have not only shaped the way that human brain activity and organizations are understood but also have had important implications for research in clinical populations. One potential advantage of examining resting-state data over task-based data in individuals with psychiatric impairments is that it may not be as complicated by task performance as task-based imaging data, which has proved to be a difficult confound in studies comparing healthy individuals and various patient populations. Primarily, a concern of task-based studies is often whether the differences in observed BOLD activity between controls and patients might be due to differences in the ability to complete the task rather than due to inherent problems using those brain regions since modulation of task difficulty often influences BOLD activity within subjects. This has led many researchers into a challenging situation of designing tasks that are difficult enough for healthy controls to yield variability in BOLD signal and performance but easy enough for patients to learn and perform reliably. In addition, this task

Telegram: @medical_k

www.konkur.in

performance confound has shaped the recruitment strategies of researchers who tend to focus on higher-functioning patients who can tolerate a cognitive or effective task within the scanner. Because of this, the majority of task-based fMRI studies in schizophrenia may be biased by the use of populations of higher-functioning patients and, therefore, may not always generalize to more symptomatic individuals. Therefore, resting-state functional connectivity potentially represents an opportunity to assess neurobiologic abnormalities in a wider range of individuals with schizophrenia.

However, it is also important to keep in mind that resting-state studies come with their own particular set of challenges when using such data to understand the neural mechanisms of psychopathology. The first and foremost challenge is the pernicious confound introduced by participant movement, which is often greater among clinical populations. Movement can introduce all sorts of artifacts and confounds into resting-state data and, if not properly addressed during processing, can lead to spurious conclusions about the nature and source of connectivity changes in clinical populations. For example, one of the effects of movement is to increase the magnitude of connections among regions that are close together but to decrease the strength of connections among more distant regions, a confound referred to as *distance-dependent movement artifact*. The existence of such artifacts challenges the interpretation of studies claiming to find global reductions in long-range connections coupled with increased local connectivity in clinical populations when movement confounds have not been sufficiently addressed in the data. Another potential challenge is variation in factors such as arousal/sleepiness, respiratory rate, and eyes open versus closed state, all of which can also modulate patterns of resting-state functional connectivity to some extent. Further, there are additional challenges if one wants to use such measures in longitudinal studies, for example, work trying to predict conversion to illness, treatment response, or longitudinal course or change over time. One needs to be able to distinguish actual change from the unreliability of measurement. This latter concern is relevant to any neuroimaging measure, though, not just functional connectivity.

Insights from Resting-State Functional Connectivity Studies in Psychopathology

To date, there are now thousands of resting-state functional connectivity studies that have been conducted in various populations with different aspects of psychopathology. As such, it is well beyond the scope of this chapter to review all of these studies. However, to illustrate some of the insights gained from using resting-state functional connectivity to study psychopathology, this

Telegram: @medical_k

www.konkur.in

chapter will selectively review studies focused on the two domains with arguably the largest resting-state literature—schizophrenia and major depression. The specific focus will be to identify areas where there is starting to be a convergence of results that have been replicated across studies and which point to clear pathways or directions for future research.

Functional Connectivity Abnormalities in Schizophrenia Spectrum Disorders

To date, there are over 500 empirical studies examining various aspects of functional connectivity in schizophrenia spectrum disorders, with the vast major conducted in individuals with *Diagnostic and Statistical Manual of Mental Disorders–fourth edition* (DSM-IV) or fifth edition (DSM-5)-diagnosed schizophrenia. These studies have used a range of methods and approaches and thus have generated quite a diversity of findings. However, there are areas with increasingly consistent results that point to clear and compelling aspects of altered functional connectivity in individuals with schizophrenia.

Altered Thalamic Connectivity. A strong focus on functional connectivity in schizophrenia is consistent with long-standing hypotheses about schizophrenia as a “disconnection” syndrome, where impairments in cognition and behavior occur because of a failure of coordinated action across multiple brain regions. As many researchers have noted, versions of this hypothesis were put forth as early as the work of Wernicke and Bleuler. Further, theories about abnormalities in connections among brain regions have also played a central role in more modern theories of the pathophysiology of schizophrenia. One such prominent theory, put forth by Andreasen and colleagues, suggested that schizophrenia involves a disruption in the integration of cortical–subcortical–cerebellar circuits, a hypothesis termed “cognitive dysmetria.” Alterations in the structure and function of the thalamus are prominent in schizophrenia literature.

Telegram: @medical_k

www.konkur.in

FIGURE 1.28–3. Patterns of altered thalamic connectivity in schizophrenia. Unpublished data showing regions (in *red*) where healthy individuals show greater thalamic connectivity than individuals with schizophrenia and regions (in *blue*) where individuals with schizophrenia show greater thalamic connectivity than healthy individuals. The regions showing decreased thalamic connectivity in schizophrenia include the cerebellum, striatum, dorsolateral prefrontal cortex, and the dorsal anterior cingulate. The regions showing increased thalamic connectivity in individuals with schizophrenia include motor and somatosensory cortices, visual cortex, and anterior temporal poles. (See eBook for color images.)

As shown in anatomical studies of primates, the thalamus is topographically organized into parallel pathways connecting specific thalamic nuclei to different regions of cortex brain regions, helping to form parallel loops for various types of information processing between subcortical and cortical regions. In particular, the medial dorsal and anterior nuclei of the thalamus project to the DLPFC. A large and consistent body of evidence has now shown connectivity from bilateral thalamic regions, medial dorsal and anterior nuclei in particular, to bilateral DLPFC, dACC, parts of the striatum, and bilateral cerebellum. In a number of studies, these patterns of decreased connectivity have also been coupled with increased connectivity between the thalamus. These patterns of altered connectivity are illustrated in Figure 1.28–3, which shows regions showing reduced thalamic connectivity in

Telegram: @medical_k

www.konkur.in

schizophrenia in blue and those showing increased connectivity in red. Like the published literature, individuals with schizophrenia in this sample show reduced thalamic connectivity with bilateral prefrontal and parietal cortices, the ACC, and bilateral striatum and cerebellum. In contrast, they show increased connectivity bilaterally with motor, somatosensory, and visual cortices.

Similar patterns of altered connectivity are seen in individuals at both clinical and genetic high risk for schizophrenia and even to some extent in other disorders characterized by psychosis, such as bipolar disorder. Further, among individuals at high clinical risk, the patterns of altered thalamic connectivity are most pronounced among those who subsequently converted to a full-blown psychosis diagnosis. In addition, studies of structural connectivity are also starting to support altered thalamic (especially medial dorsal) to prefrontal connectivity, including reduced fractional anisotropy of the anterior limb of the internal capsule. Importantly, reduced connectivity between the thalamus and the DLPFC predicts cognitive impairment. These robust and consistent findings across studies of altered thalamic connectivity are fully consistent with the idea that coordination among these brain regions is disrupted in individuals with schizophrenia spectrum disorders. Further, the relationship of this impaired thalamic connectivity with cognitive function is in line with the idea that thalamocortical networks are critical for organizing brain oscillations important for effective cognitive function and that disruptions in such circuits due to impairments at other levels of analysis (e.g., E-I balance) may significantly impair large-scale brain function.

A variety of aspects of the results regarding thalamic connectivity suggest that it needs to be given major weight as a potential biomarker for the risk of psychosis. The first is the fact that such results have been found even among individuals who have never taken medications. The second is the fact that it is present across the course of the disorder and even in those who share the risk of psychosis via either clinical symptom manifestation of genetic risk. As such, the next important step will be to relate thalamic connectivity to other early indicators or risk markers for the development of psychosis. Such markers would include the evidence for increased presynaptic dopamine availability in the striatum, as well as altered glutamate levels in the thalamus.

Altered Default Mode Connectivity. Many researchers have been interested in the idea that individuals with schizophrenia might have alterations in the connectivity of the DMN. As described above, one of the major functions ascribed to the DMN is attention to internal emotional states. A number of researchers have hypothesized that this attention to internal

Telegram: @medical_k

www.konkur.in

states must be dampened when individuals need to engage in specific tasks or attend to the external world and that this leads to the reduced activity of the DMN typically seen when individuals engage in a focused cognitive task. Thus, the interest in the DMN from the perspective of schizophrenia is the idea that some of the altered perceptual experiences that individuals with schizophrenia might have, or even some of the delusional material, might reflect *enhanced* attention to internal thoughts, feelings, and experiences, due to altered connectivity as well as activity of the DMN. Further, it has been hypothesized that a failure to suppress DMN activity during cognitive task performance may be one of the mechanisms leading to disrupted cognitive function in schizophrenia.

Although such hypotheses are intriguing, the empirical literature on abnormalities in default mode connectivity in schizophrenia as a broad disorder is actually quite mixed, with relatively little consistent evidence for clear disruptions in default mode connectivity. However, one of the challenges in this literature may be that many of the studies have simply focused on comparing individuals with schizophrenia, regardless of symptom profile, to healthy controls. Given the fact that symptom profiles and severity can vary widely across individuals with the same diagnosis and across time in the same individuals, it is critical to also examine default mode connectivity in relation to variations in the severity of specific symptoms. For example, a growing body of work links auditory hallucinations to altered connectivity of the temporal–parietal junction and cortical midline structures that are part of the DMN (anterior and posterior cingulate, precuneus), as well as to disrupted connectivity between default mode and language network regions. The direction of the relationship is such that the presence of auditory verbal hallucinations tends to be associated with reduced connectivity among these default mode structures. This is perhaps not the direction one would have predicted under the hypotheses that auditory hallucinations reflect abnormal attention to internal states due to hyperconnectivity or hyperactivity of default mode regions, but are consistent with the idea that disruptions in networks thought to be important for monitoring internal states are present among individuals with hallucinations.

Graph Theory Analyses of Functional Brain Connectivity in Schizophrenia. Earlier, this chapter described the application of graph theory approaches to understanding functional brain connectivity as a means of summarizing major properties of brain organization. Such approaches have been increasingly applied to study functional (and structural) brain connectivity in schizophrenia. Although the findings have been somewhat

Telegram: @medical_k

www.konkur.in

mixed and complex, an emerging theme is that individuals with schizophrenia show reductions in both global and local efficiency, particularly when examining specific networks. The networks most frequently associated with reduced global and/or local efficiency tend to involve the anterior cingulate and/or insula (i.e., the cingulo-opercular network) or frontal regions (i.e., the frontal–parietal network). Such findings are consistent with a large body of other work using ROI-based or ICA-based methods that have also identified reduced functional connectivity in or between frontal–parietal and cingulo-opercular networks in schizophrenia. Interestingly, reductions in both the local and global connectivity of the frontal–parietal and cingulo-opercular networks have also been associated with impaired cognition in schizophrenia, suggesting the functional relevance of these network alterations.

There is also intriguing evidence that individuals with schizophrenia show impaired function and connectivity of “hub” regions in the brain, particularly those that are thought to be part of the “rich club” of highly interconnected hubs. More specifically, individuals with schizophrenia show significant reductions in the connections among regions characterized as hubs, including the insula, the superior frontal cortex, the precuneus, and the superior parietal lobule. However, they do not show reductions in the connections between these hub brain regions and nonhub regions (referred to as “feeder” connections) or in the connections among nonhub regions. Importantly, for some regions, such as the anterior insula, individual differences in the degree of hubness, as indexed by participation coefficients, also predict the level of cognitive impairment in schizophrenia. As a piece of converging evidence, numerous studies have also shown reduced gray matter volume in at least some of these hub regions, including the anterior insula.

Summary of Schizophrenia Functional Connectivity Literature. As noted above, there is now a very large literature on functional connectivity in schizophrenia, and some of the findings are mixed, including the results regarding default mode connectivity. However, several findings stand out as consistently replicable. By far, the most robust set of findings is of reduced thalamic connectivity with frontal, cingulate, striatal, and cerebellar regions, a result that is strongly consistent with long-standing theories about schizophrenia as a disconnection syndrome. In addition, there is a growing literature suggesting reduced global and local efficiency in schizophrenia, particularly in frontal–parietal and cingulo-opercular networks, as well as evidence for reduced connectivity of hub regions in this illness, both of which predict cognitive function. It is highly likely that these two sets of findings are related, as the large-scale thalamic disconnectivity seen in schizophrenia may

Telegram: @medical_k

www.konkur.in

contribute to reductions in the efficiency with which networks can process and transfer information and may also interfere with the ability of hub regions to communicate information across networks. In many cases, these impairments are present at the start of the illness or even before the start and are more prominent among those individuals who go on to develop full-blown psychosis. Thus, these findings converge to suggest that abnormalities in functional connectivity may be a key component of the pathophysiology of psychosis and a promising avenue for future biomarker and intervention work.

Functional Connectivity Abnormalities in Major Depression

Like the literature on schizophrenia, there are now a burgeoning number of empirical studies examining various aspects of functional connectivity in major depression, using a variety of different analytic approaches. Again, like the schizophrenia literature, there is diversity in the findings, which may relate to methodology, stage of illness, and medication factors. However, there are several emerging trends that provide important clues about the ways in which altered functional brain connectivity may be contributing to the development and/or maintenance of mood disorders.

Amygdala Connectivity and Emotion Regulation. The amygdala is a subcortical structure that has received massive research attention because of its role in fear conditioning, threat sensitivity, and generally responding to salient events in the environment. In addition, numerous studies have shown that poverty, stress, and trauma influence the development, function, and structure of the amygdala. Further, a number of investigators have suggested that such alterations in amygdala structure/function are a mediating mechanism linking early adversity to later negative mental health outcomes. Importantly, these findings in humans are consistent with a large animal literature also showing detrimental effects of stress and maternal care on amygdala function and structure, as well as behavior.

The amygdala shows a normative pattern of both positive and negative connections with other regions of the brain. Figure 1.28–4 illustrates the typical pattern of amygdala connectivity found in both children and adults, using a sample of school-aged children and adolescents. As can be seen, the amygdala shows positive resting-state functional connectivity with other regions in the medial and anterior temporal lobes, including the hippocampus, as well as the ventral medial prefrontal cortex (at age 10+ for this region). These regions showing positive connectivity with the amygdala are also important for emotion and stress responsivity. In some studies, the amygdala has been found to couple with other regions in the salience network, including

Telegram: @medical_k

www.konkur.in

ventral regions of the anterior cingulate (ventral medial prefrontal cortex, as in Fig. 1.28–4) and ventral regions of the insula and anterior temporal poles. In contrast, as shown in Figure 1.28–4, the amygdala also shows negative functional connectivity—anticorrelation—with bilateral dorsal prefrontal and parietal regions, as well as the dorsal anterior cingulate. These regions showing negative correlations with the hippocampus and amygdala are the same regions that are activated in studies of emotion regulation and overlap in large part with regions that are part of the frontal–parietal and cingulo-opercular networks. Importantly, these "anticorrelations" are thought to indicate top-down regulation of emotion and stress responsivity occurring in amygdala regions, suggesting a critical role for the integrity of these connections between the amygdala and frontal–parietal and cingulo-opercular networks in mood and effective function.

FIGURE 1.28–4. Patterns of amygdala connectivity. Unpublished data showing regions (in *light gray*) demonstrating positive functional connectivity with the amygdala and regions (in *dark gray*) showing negative functional connectivity or "anticorrelations" with the amygdala. The regions showing positive functional connectivity with the amygdala include the hippocampus, the ventral medial prefrontal cortex, and the anterior temporal poles. The regions showing negative functional connectivity with the amygdala include the dorsolateral prefrontal cortex.

Telegram: @medical_k

www.konkur.in

Importantly, several studies have shown that early life stress and/or maternal deprivation are associated with altered connectivity between the amygdala and ventral medial prefrontal cortex and pregenual anterior cingulate, as well as other regions, connections that are thought to be critical for effective emotion regulation. Further, patterns of altered amygdala connectivity with components of both the salience network and the frontal–parietal and cingulo-opercular networks have also been found in individuals with major depression. The results have been somewhat variable across studies, but one of the more consistent findings has been reduced connectivity between the amygdala and various regions of the prefrontal cortex, including dorsolateral prefrontal, rostral prefrontal, and ventral prefrontal regions, as well as part of the anterior cingulate. As noted above, one hypothesis is that such reduced amygdala to prefrontal/cingulate connectivity reflects impaired top-down regulation of emotion processing and that such reduced connectivity contributes to emotion regulation difficulties in this form of psychopathology. Interestingly, these patterns of altered connectivity have been found across the life span, including among individuals with depression who are children, adolescents, young and middle-aged adults, and older adults, suggesting that altered amygdala to prefrontal/cingulate connectivity may be a life span characteristic of depressive disorders. Further, such connectivity alterations are present even in those who are at risk of the development of depression by virtue of having a mother with depression, suggesting that such connectivity disruptions precede the onset of manifest illness and might even be part of the pathophysiologic pathway. For example, among preschool children with early signs and symptoms of depression, reduced connectivity between the amygdala and medial prefrontal cortex is associated with impaired emotion regulation and increased negative emotionality (see Fig. 1.28–5).

Default Mode Network Connectivity and Rumination. The second area of consistent findings of altered connectivity associated with major depression is in the domain of DMN connectivity. As described above, one of the major functions ascribed to the DMN is to modulate attention to internal emotional states and to govern self-referential processing. Phenomenologically, one of the major characteristics of depression is a preoccupation with negative mood, negative self-evaluation, and frequently a ruminative style of coping with negative events and thoughts. It is not surprising, then, that research points to an *increase* in connectivity among default mode regions in major depression, especially those forming the more anterior part of the DMN, including the dorsomedial prefrontal cortex. Interestingly, work has also shown an increase in connectivity between the dorsomedial prefrontal cortex and the rostral anterior insula, part of the salience network, among individuals with major depression. This increased connectivity between parts of the DMN and the salience network has been interpreted as potentially reflecting an overly strong integration or dominance of DMN activity overactivity related to attention to salient events, potentially contributing to a negative evaluation bias in regard to salient information in the surrounding environment.

A number of studies have also found evidence for increased connectivity of the subgenual prefrontal cortex with the DMN. The subgenual prefrontal cortex is a brain region that has received consistent attention in the literature on mood disorders, as studies have demonstrated that it shows glial cell reduction, altered metabolism, and reduced volume and/or thinning among individuals with MDD, again across the life span. It has been hypothesized that the subgenual prefrontal cortex is important for mechanisms of behavioral withdrawal and effective negative appraisal, with activation of this region associated with conserving resources (i.e., withdrawal), promoting safety-oriented behaviors, and experiencing guilt. Importantly, research has shown that the degree of hyperconnectivity between the subgenual prefrontal cortex and the DMN predicts the level of rumination among individuals with depression. This work has led to the hypothesis that this overly strong integration serves to link the self-referential processing supported by the DMN with the negative affectivity and withdrawal supported by the subgenual prefrontal cortex, leading to a cycle of rumination and impaired emotion

Telegram: @medical_k

www.konkur.in

regulation among individuals with MDD. As with disrupted amygdala connectivity, such default mode alterations are present even in those who are at risk of the development of depression by virtue of having a family history of depression, again suggesting that such connectivity disruptions precede the onset of manifest illness and might even be part of the pathophysiologic pathway.

Striatal Connectivity and Anhedonia. In recent years, a growing number of studies have been examining functional connectivity correlates of anhedonia both within depression and transdiagnostically. Anhedonia is defined as either a reduction in the ability to experience pleasure or a reduction in the ability to anticipate pleasure. Much of this work has focused on connectivity from regions in the striatum, such as the nucleus accumbens or caudate, with either whole networks (e.g., default mode, cingulo-opercular, salience, etc.) or specific regions in these networks (e.g., the pregenual cingulate of the DMN, the DLPFC in the frontal–parietal to network). This focus on the striatal connectivity has been driven by the evidence suggesting that functional activity and connectivity of the striatum may be important for understanding individual differences in reward responsivity, a construct central to thinking about anhedonia. In individuals with major depression, the findings have been somewhat mixed, but a number of studies have found decreased connectivity of the striatum with other networks, including the default mode, frontal–parietal, and cingulo-opercular networks, to be associated with greater anhedonia.

Summary of Functional Connectivity Literature in Major Depression. As with the literature on functional connectivity in schizophrenia, the literature on connectivity in depression is large and somewhat mixed. However, several findings again stand out as somewhat replicable. The first is evidence of altered connectivity between the amygdala and prefrontal/cingulate regions that are part of the frontal–parietal and cingulo-opercular networks. These connections are thought to be crucial for top-down emotion regulation and control over regions such as the amygdala, which are important for responding to stress and salient environmental events. These connectivity alterations are present in individuals experiencing various forms of early stress or trauma, are present across the life span in individuals with major depression, and are present even among those at risk of depression. As such, that may represent an important clue as to the etiologic pathway linking stress and trauma to subsequent development of emotion dysregulation and mood pathology. The second area of relatively consistent results is evidence for increased connectivity of the DMN, including links between the subgenual

Telegram: @medical_k

www.konkur.in

prefrontal cortex and other regions of this network. This increased connectivity has been specifically linked to rumination among individuals with major depression and may reflect an overly tight integration between brain regions supporting self-referential processing and those influenced by negative effect processing and withdrawal. A third area is evidence for a link between disrupted striatal connectivity with default–model, frontal–parietal, and cingulo-opercular networks and anhedonia in depression and transdiagnostically, though more work is needed to establish the robustness and replicability of such findings.

CONCLUSION

The goal of this chapter was to provide a brief overview of the current state of the field in terms of methods for assessing the human functional connectome, the existing knowledge about the core intrinsic functional connectivity networks present in the human brain, and the ways in which connectivity abnormalities in these networks are relevant for understanding the pathophysiology of major mental illnesses. Although in many ways, this field is still in its infancy, the remarkable consistency and robustness of the identified functional brain networks across imaging modalities, functional connectivity methods, and populations attest to the importance and relevance of understanding their impact on human behavior. Work from the Human Connectome Projects across the lifespan has confirmed that individual variation in intrinsic network connectivity relates to a wide range of both positive and negative traits and characteristics in humans. Further, this work has shown that core aspects of the brain's functional organization arise early in life, though with developmental evolution across the lifespan. Further, the work selectively reviewed in this chapter illustrates that there are robust, replicable, and differentiable alterations in functional connectivity associated with different forms of psychopathology. This includes robust evidence for altered thalamic connectivity associated with psychosis, impairments in global and local efficiency of frontal–parietal and cingulo-opercular networks in relation to cognitive function in psychosis, and alterations in the hub structure of regions such as the anterior insula in schizophrenia. In major depression, there is consistent evidence for the altered amygdala to prefrontal–cingulate connectivity relevant for understanding emotion regulation, as well as evidence for increased default mode connectivity in relation to rumination. The next key steps, several of which are ongoing, are to examine the role that these connectivity alterations play in the development of psychosis and depression, or specific symptom dimensions, as well as the degree to which

Telegram: @medical_k

www.konkur.in

connectivity can be modified by treatment and whether it serves as a mediator of symptom improvement. Further, it will be crucial to link alterations at this neural circuit level of analysis with alterations at other levels of analysis, such as genes, gene expression, neurotransmitter signaling, and/or cellular architecture.

1.29 Neuropsychiatry of Self

DAVID R. VAGO, PH.D., DEBRA A. GUSNARD, M.D., AND DAVID A. SILBERSWEIG, M.D.

This chapter is intended to provide an overview of considerations for what may be regarded as a translational science of self and its relevance to psychiatry. Conceptual issues are discussed from both historical and theoretical perspectives to inform our current understanding of the self. Evolutionary, neurobiologic, and clinical perspectives inform the phenomenology and function supporting the act of being a self in the world. A single paradigm for research on "self" does not exist, as it is not necessarily a unitary phenomenon. Diverse disciplines inform the study of the individual (qua self) and its varied representations and relevance uniquely. However, conceptual convergence in this scientific enterprise addressing self "issues" continues to emerge along with signs of where a more advanced program for a science of self may be heading. Implications for a critical interdisciplinary analysis of self on the field of psychiatry and into the nature of consciousness are provided.

INTRODUCTION

Stated simply, self-representation is central to human behavior in health and disease. That is, an individual's abilities to experience and recognize their physical and mental being as distinctly their own and to act on various kinds of self-knowledge are critical for their being able to organize and regulate their own behavior and engage in social relationships. Until recently, the importance of self-representation and the value of its study for understanding consciousness and clinical health and well-being have been generally underappreciated in scientific circles. But this has begun to change as clinical and psychological disciplines concerned with various disorders bearing on aspects of self-representation have started to collaborate and communicate more directly. Philosophers, religious scholars, computational cognitive scientists, and neuroscientists are

Telegram: @medical_k

www.konkur.in

improving methods and technologies that can be applied to the explanatory gaps found between objective, observable properties, first-person experience, and biophysical systems embedded in particular contexts. This chapter aims to clarify the various models of the self that have been developed from diverse academic disciplines, with the goal of informing an integrated, comprehensive approach to clinical treatment and neuropsychiatric research. The multifaceted nature of the self, with its profound impact on individual well-being and collective human flourishing, holds an essential place in our understanding of consciousness and evolution of the human race.

Historically, the relative dearth of scientific studies targeting self-representation has been largely a consequence of the fact that unlike most other domains in science where commonly agreed upon and well-elaborated conceptual frameworks guide investigation and constrain the interpretation of data, the scientific investigation of the self has not been grounded by a universal framework and, as a consequence, has been a relatively fragmented enterprise. Yet, there is increasing acceptance that a science of self-representation provides insights critical for understanding a fundamental human nature of consciousness. In this view, forms of self-representation involve operations that support the distinguishing and recognition of an individual's spatiotemporal perspective *as* their own as well as an individual's self-specifying sense of ownership and agency in relation to their own mental and bodily states. Many models of self-representation and conscious experience have been proposed and are now currently contributing to the paradigmatic development of a coherent scientific approach to the expressly multidimensional self.

One general distinction is made between substantialist and nonsubstantialist theories that affirm or deny the existence of a material self, respectively. Substantialist theories see the self as the subject of experience with specific physical (e.g., biologic) properties that support conscious states. Nonsubstantialist theories describe a self as consciousness itself, devoid of any particular material properties. Nonsubstantialist theories that propose a "nonself" stem mostly from Indian Buddhist traditions. These traditions propose any self-identification with material substance (e.g., body, brain) is an illusion and the cause of our mental suffering. One common feature of substantialist theories of self-representation and their constitutive operations is the naturalistic emphasis on neural processes to support the conscious experience of

Telegram: @medical_k

www.konkur.in

self. Although neurobiologic evidence has been rapidly accumulating, there are also clear reasons not to overemphasize a view limited exclusively to the brain or “brain in isolation” but rather emphasize a theoretical grounding from an interdisciplinary and complex systems perspective instead.

FIGURE 1.29–1. The life mask and skull of Phineas Gage. Note damage to the frontal region. “A famous case illustrating the result of frontal lobe damage involves Phineas Gage, a 25-year-old railroad worker. While he was working with explosives, an accident drove an iron rod through Gage’s head. He survived, but both frontal lobes were severely damaged. After the accident, his behavior changed dramatically. The case was written up by J. M. Harlow, M.D., in 1868, as follows: [Gage] is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts his desires… His mind was radically changed, so decidedly that his friends and acquaintances said he was ‘no longer Gage.’” (Warren Anatomical Museum Collection, Center for the History of Medicine in the Francis A. Countway Library of Medicine, Harvard University.)

Specific historical understandings of the self have evolved in tandem with advancements in scientific methodologies. These developments have enabled an increasingly accepted line of inquiry that links self-representation, functional brain anatomy, and theories of neural networks. For instance, pioneering work in functional anatomy carried out by Franz Joseph Gall and J. C. Spurzheim in the late 18th and early 19th centuries provided early insights into the distribution of mental abilities across different brain areas. This foundational research paved the way for

Telegram: @medical_k

www.konkur.in

subsequent phrenologic theories advanced by Pierre Flourens and other prominent neurophysiologists. Early brain lesion studies by Paul Broca and Carl Wernicke described a variety of aphasias that led to connectionist models of localized function. The case of Phineas Gage, a railroad worker suffering from orbitofrontal cortex (OFC) damage (see Fig. 1.29–1), provided profound insight into our understanding of frontal lobe function in emotional expression and regulation. Equally impactful was the case of H. M., who underwent the removal of a significant portion of his hippocampus and adjacent tissue to address intractable seizures. This case became a landmark in shedding light on the specific brain structures responsible for memory functions. Earlier, Karl Lashley published *Brain Mechanisms and Intelligence* (1929) and argued a theory of localization focused on a principle of equipotentiality. Lashley reasoned that complex functions "are largely carried out in independence of structural differentiation." Split-brain studies performed by Roger Sperry and colleagues in the 1960s on individuals who had undergone separation of their two cerebral hemispheres by corpus callosotomy for intractable epilepsy revealed significant disconnection of the perceptions and decisions of one hemisphere from the other. These findings, among other functional neurologic case studies, contributed to deflating the notion of a necessary unity and coherence in self-representation and the recognition that the normal experience of such unity masks underlying modular neural organizational processes that may be subject to disruption and scientific manipulation.

Recent transdisciplinary collaborations have stimulated new thinking and inherently different, though still functionalist, perspectives on considerations of self-representation. For example, cognitive and computational neuroscientists, neuropsychiatrists, and cognitive behavioral neurologists sometimes work with philosophers of mind and religious scholars to refine and clarify concepts enhancing the design and interpretation of experimental studies. Many contemporary models posit that the self exists beyond some individual entity and elaborate upon the phenomenology and conscious experience of being a self, the relation of self and others, the self-organization of living things, and the naturalistic substrates in the brain and body that support an existence of the self situated in the world. The perspectival perspective emphasizes the viewpoint-dependent nature of our self-concept and identity. This perspective holds that the way we understand and experience our self is

Telegram: @medical_k

www.konkur.in

inherently shaped by various contexts, such as cultural, social, and even moment-to-moment situational factors. Other theories emphasize an embodied perspective on our self-representation, which is constructed through how we move through space, including our physical interactions, and even biologic states like hunger or fatigue. One model by Christoff and colleagues (2011) proposes that the reafferent–efferent processes of sensorimotor integration and homeostatic regulation implement a self-specific, agentive perspective at the bodily level of perception and feeling without the need for conceptual processing. Here, a distinction is made between self-specific and self-related representations of self. Processes that are self-specific are intrinsically related to the agent's own action without an explicit self-concept (e.g., the self is specified through interaction with the world) whereas self-related processes involve evaluation of some feature of oneself in relation to one's perceptual image or mental concept one's self-identity. The first-person experience of what it is like to be a self in the world is also described by Francisco Varela and other phenomenologists as "direct knowledge" supported by a science of mind embodiment that incorporates the experience of being there. Philosophers such as Martin Heidegger, Edmund Husserl, and Maurice Merleau-Ponty established phenomenology as a philosophical tradition and analytical account of the self through direct experience that does not exist in separation from the stream of consciousness and is nonconceptual and prereflective in nature. A number of representational systems and theories from this perspective have been proposed. Thomas Metzinger (2010) attempts to provide a synthesis of these perspectives through his phenomenal self-model (PSM). The Projective Consciousness Model proposed by David Rudrauf, Karl Friston, and colleagues (2017) builds upon a perspectival phenomenological structure supporting consciousness with a free energy minimization model of active inference describing the modulation of cognitive and affective dynamics to control the embodied agentic self. A global workspace model was proposed by Bernard Baars (2005) that attempts to account for both phenomenal and access forms of consciousness. Metzinger's PSM theory of subjectivity, Karl Friston's free energy principle theory, and Anil Seth's utilization of hierarchical Bayesian inference have all contributed to philosophical and computational understandings and ontologic claims about the nature of the self. Scientific inquiry into the nature of self-representation is clearly broadening across levels of description (from psychological and

Telegram: @medical_k

www.konkur.in

behavioral levels of description to computational, neurophysiologic, and systemic levels of description) and in terms of relevant capacities that change across human development and may exist in other animal species as well.

HISTORICAL CONSIDERATIONS

The Hindu Vedic and Buddhist texts dating back between 500 to 1000 BCE all describe insight into the nature of self as the ultimate form of salvation. The Hindu scripture, the Bhagavad Gita, written around 500 BCE, says, “True knowledge of the self does not lead to salvation: it is salvation.” The founder of the Sōtō school of Zen, Dōgen Kigen, claimed, “To study the Way is to study the self. To study the self is to forget the self. To forget the self is to be enlightened by all things. To be enlightened by all things is to remove the barriers between one’s self and others.” Vedic descriptions of the self and the soteriologic aspects of self-reflection describe an immutable self (Sanskrit, ātman) akin to the soul, while the Buddhist descriptions, similar to Dōgen, further elaborate upon the nondual nature of the self, its impermanency, and how mental suffering manifests through attachment to the illusory concept of self, self-identity, and the distorted interpretation of the world through the lens of mental habits and social conditioning.

Although extensive work had been done through the soteriologic lens of Hindu philosophy and Buddhist spiritual teachings, socially accepted intellectual interest in the self has clearly varied across time due to societal and cultural forces. For example, in the West, before the decline of the Middle Ages and the attendant decline of religion as the dominant organizational culture, emphasis was placed on the concept of community rather than on self in all aspects of social life. The significance of the community tended to overshadow the significance of individuals and their personal interests, which were viewed by the dominant culture as arising from a human nature that was inherently biased and “selfish.” Ideally, self-interest was to be suppressed in the interests of the common good and spiritual attainments. Major shifts in social thought began to occur with the dawning of the Renaissance in the 14th century with its greater focus on the personal and temporal, which was then followed by the Enlightenment period in the 18th century with its emphasis on rationality, systematized thinking, and science. During these periods, the individual, personal

Telegram: @medical_k

www.konkur.in

identity, and personal expression became increasingly valued. Descartes (1637) proposed that the self is not identical to one's body or, indeed, to any physical thing. Instead, he famously concluded that the essential self —that claims, "I exist"—is a nonphysical, conscious thing—creating a Cartesian duality of immaterial and material. "Cogito, ergo sum; I think therefore I am." Technologic developments also played a role. Interestingly, it has been suggested that one of the more significant technologic developments in this regard was the rise of the glass industry in Western Europe and the establishment of mirrors as a common commodity. The widespread availability of mirrors provided individuals for the first time in human history with a stable and accurate representation of their own faces, which allowed them to regard themselves in a different way and encouraged greater self-inspection, including more frequent introspection. Since then, political and economic changes, as well as the rise of capitalist societies, have promoted a veritable culture of individualism, particularly in North America and Western Europe. Such forces have all contributed to a modern intellectual climate that has made the concept of the individual and the nature of the self and subjectivity available for consideration and conceptual elaboration as never before through a scientific lens.

Conceptualizations of self have been far from homogeneous as discussions in the modern era have unfolded, however. One of the fundamental questions targeted in the intellectual debate has, in fact, been whether there is such a thing as the self, adding support to nonsubstantialist, nonself theories. David Hume, in his *Treatise on Human Nature* in 1739, notoriously stated that, when he looked inside himself, he could find many perceptions but nothing linking them together. Introspection, Hume concluded, reveals only a continuously changing flux of sensory, emotional, cognitive, and other bodily processes. Since Hume's denial of the self, other influential philosophers, including Friedrich Nietzsche in the German tradition and Ludwig Wittgenstein in the analytical tradition, have also argued that the self is most reasonably understood to be a fiction that may have some utility for those using the term but that it has no actual substance or basis in reality, that "the self [is simply] a center of narrative gravity," as Daniel Dennett, the American philosopher has famously put it. The French novelist and philosopher Jean-Paul Sartre summarizes this incommensurability by stating we are "condemned" to believe in the self.

Telegram: @medical_k

www.konkur.in

For some scientists, the very term “self” has been associated with this problematic notion of an entity within the brain controlling brain processes and behavior. For example, the term “homunculus” is used to describe maps in the brain that correspond to sensory input and motor output for different parts of the body. These are often portrayed as distorted human figures, where the size of each body part is proportional to the amount of brain area. Yet, the presence of a homunculus does not explain the subjective nature of experience and inadvertently supports Cartesian dualism—the idea that the mind and the body are separate entities. Many scientists have focused on the processes supporting an individual organism’s subjectivity and sense of personal-state ownership via consideration of biologic and evolutionary pressures. Neuroscientists Rodolfo Llinás and Walter Freeman, for example, have both used the term “self” to refer to that locus of properties that permit a mobile organism to sustain its viability *as* an individual organism. Autopoiesis, or “self-production,” is a concept introduced in the 1970s by the biologists Humberto Maturana and Francisco Varela to describe a sytem capable of reproducing and maintaining itself and distinguishing it from nonself. Varela suggested that the human organism should be considered an autopoietic entity where mental processes are intrinsically linked to bodily ones. For example, emotions are not just abstract experiences but have physiologic components that influence the entire organism. Similarly, the way we perceive and engage with the world is informed by our embodied and enactive experiences, which in turn are shaped by our cognitive and emotional states. This creates a circular or recursive relationship between the body and mind, typical of autopoietic systems. Niklas Luhmann’s autopoietic sociologic theory (1995) further distinguishes between society and functionally differentiated social systems that are interconnected through complex communication, suggesting group dynamics may contribute to self-identity at individual and collective levels. Though the details of their formulations differ, many theories consider the self from a comparative perspective and regard the primary *need* for a “self” to be related to action or mobile organisms’ capacities for goal-directed behavior in an environment. That is, in contrast to organisms incapable of active movement, mobile organisms need to be able to predict the effects of their actions on their environment. Otherwise, the outcomes of their actions would be purposeless and potentially dangerous. They need to be able to “own” their behavior (though this need not be conscious) and

Telegram: @medical_k

www.konkur.in

distinguish their behavior's effects from effects attributable to other forces in their environment.

Such basic biologic processes have also been distinguished from more complex cognitive processes that help elicit a self-narrative over time. Evolutionary theory and the field of paleoneurology have described the evolution of biologic processes to support the demands of survival for Homo sapiens. For example, specific basic and core architecture has been described to evolve through layers of complexity (e.g., proto- and core-self) with unique regulatory neurophysiology. With the advent of complex cognition in human evolution, pressures for reasoning, problem solving, and learning influenced the development of the frontal lobe and capacity for reflection. Theoretical neuroscientists like Endel Tulving have attempted to understand consciousness through the perspective of conscious self-awareness and memory. For example, Tulving (1983) describes his theoretical position of self-knowing as autonoetic consciousness. Tulving defines this awareness of episodic events as a veridical part of one's own past existence. Karl Friston and Patricia Churchland extend and elaborate on the idea of the self-concept as something fundamentally rooted in memory, or the "mnemonic concept." In their framework, the self is not just a static concept or identity but a dynamic, self-organizing biologic system. This system functions as a complex array of organizational tools that serve to bring coherence to the various operations of the brain, including planning, decision making, and perception. In essence, they propose that the self acts as a kind of internal coordinator, working to align different cognitive processes into a unified, coherent experience. This approach sees the brain as an adaptive system constantly seeking to reduce uncertainty and inconsistency. The self, in this model, helps to navigate this uncertainty by "coherencing" or synchronizing various neural and cognitive processes. Bridging the gap between biologic systems and first-person phenomenology, Francisco Varela (1971) advocated for a neurophenomenological perspective that accounts for an emergent, multilayered self, arising from the dynamic interactions between brain, body, and environment and not merely through neural computations within the brain. This is in line with his broader framework of enaction, which postulates that organisms enact or bring forth their worlds through their actions and perceptions. Within these opportunities for investigation at the first-, second-, and third-person perspectives of observation, cognitive science, neuroscience, and the

Telegram: @medical_k

www.konkur.in

cross-disciplinary field of neuropsychiatry are integrating the neurophysiologic substrates supporting the range of self-representation with the evolutionary, therapeutic, and transformative value of contemplative traditions.

Developmental approaches to healthy, age-appropriate, psychological functioning contribute greatly to our understanding of the genetic, sensory–motor, and behavioral evolution of the self as a function of individuals' embeddedness in social structures. Current conceptions of self and its role in human culture, society, developmental, and clinical health are very relevant to an understanding of the progressive evolution of the human mind and partial fulfillment of its fate as a uniquely self-aware and self-conscious species (Homo sapiens).

MULTIDIMENSIONALITY OF SELF-REPRESENTATION

In scientific literature, over 25 notions or aspects of the self have been specified, including the cognitive self, conceptual self, core self, minimal self, ecologic self, embodied self, emergent self, the material self, social self, interpersonal self, and others. William James made the distinction between self-as-subject (the I-self) and self-as-object (the Me-self) as two separable but intimately interrelated aspects of the self. He also identified subcomponents in which the self-as-subject included self-agency (the sense of ownership of one's thoughts and actions), self-awareness (an appreciation of one's internal states, needs, thoughts, and emotions), self-continuity (the sense that one remains the same person over time), and self-coherence (a sense that one is a single, coherent, bounded entity). Components of his self-as-object included what he referred to as the "material me," the "social me," and the "spiritual me," which were conceptualized as aggregates of various kinds of knowledge about the self that one acquired by adopting an observer's perspective, the details of which also had the potential for coming into conflict with each other.

While details of the Jamesian framework have been challenged, his general distinctions have remained a viable heuristic for much subsequent research in this area. Until recently, more empirical attention had been devoted to the latter, the self as an object of one's knowledge and evaluation, because of the relative ease with which it and its derivatives (e.g., individuals' "self-concepts" and "self-esteem") are able to be queried and articulated by investigators and study participants. The more implicit

Telegram: @medical_k

www.konkur.in

and thereby elusive cognitive processes that define the individual as a subject have only recently gained increasing emphasis in theories and studies of self-development. This has happened largely because of advances in interdisciplinary collaboration, experimental paradigms, methods, and technology, facilitating insight into neurophysiologic and psychosocial mechanisms supporting the complex ways individuals think and act.

Shaun Gallagher (2013), for example, proposed a pattern theory of self to organize these dimensions further through situated, extended, narrative, psychological, intersubjective, minimal experiential, and minimal embodied aspects of self-processing. In those areas of scientific discourse, clinical health, and philosophy where progress has been made, it has become increasingly clear that a single discrete referent for the concept “self” does not exist, nor does a unitary, fixed, or independent self within the world of phenomenology. There is also no property of the concept “self” that is present in all instances of “self” processing and absent in all instances of “nonself” or “other” processing. Properties or characteristics by which “self” is sometimes defined (e.g., being a particular kind of mental phenomenon or having a particular kind of function) do not apply to all instances in which the concept is used, and none is unique to it.

Work that has been undertaken from comparative evolutionary and human developmental perspectives is particularly useful in illustrating this with regard to notions of the changing self. Importantly, both of these perspectives are grounded in considerations of the biology and adaptive functioning of organisms. Across the animal kingdom and in human ontogeny, self-representational processes that are operationalized in the nervous system clearly vary in their degrees of complexity and in the self-representational phenomena that they support. Yet it is also the case that, from these evolutionary and developmental perspectives, “self” may be regarded as the set of mechanisms or means by which individuals (and, more specifically, their nervous systems) organize their perceptions, plans, and decisions, allowing them to act as a coherent, embodied whole rather than as a group of independently operating systems with competing interests. It is, in fact, when such coherence significantly breaks down that self-pathology is thought to exist, and affected individuals (if they are capable of sufficient insight) may actually report that aspects of their experience or behavior seem “foreign” to them or unmanageable by them.

www.konkur.in

Comparative Evolutionary and Paleoneurologic Perspectives

Scientists who study various animal species are among those that have been interested in the question of how organisms represent themselves to themselves. Because such scientists consider the conservation or loss of certain bodily structures and capacities across species (in this case, conservation or loss of organisms' capacities to recognize aspects of themselves as being or belonging to themselves), they are often able to offer physiologic (proximate) and evolutionary (ultimate) explanations for "why" such capacities exist.

In contrast to organisms of greater complexity, simple vertebrates are observed to be very limited in their self-representational capacities. In these simple animals, such capacities are confined to mechanisms that coordinate visceral and other internal signals with perceptions of the outside world that allow them to distinguish the boundaries of themselves or the effects of their own actions from other phenomena in the environment and generate responses that enable their survival (e.g., an appendage withdrawal when a noxious stimulus is perceived to have impinged upon it). At this simple level, the coordination of responses is automatic and implicit. There is no conscious awareness of a "self" who is the subject of experience or the agent of the action.

The centralization of such coordinated, even if limited, processing is the neurobiologic foundation upon which higher levels of self-representation rest. One widely recognized view on the interdependent relationships between this implicitly coordinated reflexive processing that subserves basic survival functions of the individual organism and the computationally more sophisticated reflective processing that is associated with self-awareness has been provided by Antonio Damasio and Jaak Panksepp. While both scholars agree on the importance of emotion in constituting a foundational, primitive aspect of the self, Panksepp's work focuses on the primal, universal aspects of emotion that are conserved across species as the basis for more complex, secondary emotions found in humans more uniquely. Damasio, on the other hand, tends to focus on the complex interplay between emotion and cognition, especially as it pertains to human consciousness and decision making. In Damasio's model, the "proto-self" is the most basic level of self-representation which consists of a collection of distributed neural patterns that preconsciously map the body's internal state and serves as the foundation for more complex forms of self, such as the "core self" and "autobiographical self." Panksepp does

Telegram: @medical_k

www.konkur.in

not use the term, “proto-self,” but describes primal emotions that are hardwired into subcortical regions of the brain that interact with sensory-motor input and output, influencing behavior and physiology. The multilayered models of the self proposed by Panksepp and Damasio offer a nuanced understanding of the self that integrates biologic, psychological, and social dimensions that map complex aspects of self that have developed in humans layered upon more basic nonconscious processes that arise from interactions of the body with the environment.

The paleoneurology literature also suggests points of human evolution in which anatomical changes to the brain coincide with the emergence of complex social phenomena like language development, tool use, and cognitive skill development. Brain changes and associated functional advances are implied through morphologic changes found in skull casings from early hominid ancestors. Aside from current human cranial capacity (~1,350 to 1,400 cm^3) being three times the size of our earliest hominid ancestors (~450 cm^3 for australopithecines), the anterior frontal cortex has been found to be twice greater in relative size than other parts of the frontal lobe in our closest ancestors, chimpanzees and bonobos. As described later, the anterior or frontal polar cortex (FPC, Brodmann area 10) is uniquely involved in higher-order, complex cognitive processing (e.g., prospective memory, meta-cognition) and is uniquely positioned to facilitate more complex self-reflective processes. Aspects of the frontal pole’s organization vary slightly across hominid species, including the relative width of its cortical layers and the space available for connections. BA10 is larger in humans than in apes, both in absolute terms and relative to the rest of the brain. Horizontal spacing distance between neurons has been observed to be 30% larger in the human frontal pole than in other species, suggesting more opportunities for complex dendritic branching and interconnectivity across frontal structures. Other perspectives from comparative biology have questioned the social brain hypotheses, suggesting ecologic factors, rather than social complexity, best predict brain size across the evolution of primate species. DeCasien and colleagues (2022) provide modern insights from comparative biology and emphasize that a proportionally large human prefrontal cortex may not represent an adaptive specialization; rather, its role in integrating with wider distributed neural networks may be more relevant for understanding the unique evolution of the self.

www.konkur.in

Human Developmental Perspective

Developmental approaches to healthy, age-appropriate, psychological functioning contribute greatly to our understanding of the genetic, sensory–motor, and behavioral evolution of the self as a function of individuals' embeddedness in social structures. Researchers in child and adolescent development describe human beings not as unitary but as integrated multidimensional beings whose capacities underlying self-identity emerge and mature over time and in relation to others. This social-developmental perspective contends that our sense of self is not formed in isolation but at least partially through our social roles and how others see us. Concepts like Charles Cooley's "looking-glass self" fall under this category, emphasizing the role of social validation and feedback in the formation of self-identity. The socially constructed aspects of the self are dependent upon one's social roles in societal systems and other aspects of social identity.

Some developmental theorists have invoked William James' framework for considering the complexity of self-representation that fluctuates between increasingly differentiated and integrated perspectives emerging in childhood through adolescence. Self-as-subject and Self-as-object are two general domains of self-representation proposed by James and are considered crucial for healthy development. Specifically, the structure and content of *what* individuals say they think about themselves or how they act in the world at any developmental stage depend on the acquisition of specific cognitive and self-specifying abilities. These learned persepctives influence how individuals are able to implicitly demonstrate and explicitly report on what they reflectively know about themselves across stages of development. For example, one piece of evidence concerning the development of I-self, or self-as-subject, is that infants show relatively long fixation durations between 0 and 2 months of age, whereas they show relatively short fixation durations from 2 to 6 months of age. This may reflect a genetically programmed sensitive period in which the infant automatically (rather than effortfully) learns how to fixate on and differentiate selected objects first (e.g., caregiver's face); followed by a period in which they learn to shift their attention to other objects nearby in time and space and thereby begin linking sets of experiences together. The me-self, or self-as-object, begins to take over more considerably by age 2 through the development of representational constructs. Young children between the ages of 2 and 4 are able to construct separate

Telegram: @medical_k

www.konkur.in

attributes of themselves that may be physical (e.g., “I have blonde hair”), social (e.g., “I have three brothers”), or psychological (e.g., “I am happy”). However, they are unable to coordinate two such constructs into a coherent self-portrait, in part because of working memory limitations at that age that prevent them from holding several features in mind simultaneously. They are also unable to acknowledge the possibility that they (or others) can possess opposing attributes (e.g., good and bad) or different emotions of the same valence, such as mad and sad, or opposite valence, such as happy and sad, at the same time. It is not until middle childhood, between the ages of 7 and 9, that children acquire the ability to integrate positive and negative concepts about the self and become less likely to engage in the kind of all-or-none thinking about self that they display earlier.

Similarly, while even infants are capable of perceiving that other individuals (particularly their significant socializing agents) have reactions toward them, it is not until early to middle childhood that children acquire an ability for mentalization—a cognitive appreciation for the perspective of others and recognition that others have a particular viewpoint and are actively evaluating them and their behavior. As this perspective-taking and mentalizing ability develop, it begins to function as a guide for children so that they are able to identify more with what others expect of them and are increasingly capable of regulating their own behavior. Consistent with Erik Erikson’s concept of *psychosocial identity* introduced in his seminal work, “Childhood and Society” (1950), Roeser and Peck (2009) describe self-identity developmentally in a relational context between an individual’s intra-individual self-identity structure and the extra-individual self-identity structures to which they are currently exposed. In their Basic Levels of Self (BLoS) model, this relational identity refers to specific self-other part-processes within the larger set of multilevel systems (body, mind, social and physical worlds) within which every human being negotiates their particular lifepath. It is not until adolescence, however, that perspective-taking goes beyond recognition of others’ expectations for the self and extends to sophisticated abilities for evaluating the self independently and abstractly. It is during this developmental phase that dramatic increases in introspection are observed, which in some individuals appear to be associated with enhanced vulnerabilities to depression or social anxiety. The Basic Levels of Self-in-Context (BASIC) Model further expands upon the developmental changes in self from the vantage point of individuals’

Telegram: @medical_k

www.konkur.in

selves/identities—where selves/identities are defined as multilevel phenomena involving individuals' embodied ways of being in their physical and social worlds given the affordances and constraints of those worlds, their habitual states of awareness, and their complex system of psychological representations of self, social others, and the world.

Recent developmental cognitive neuroscience studies have similarly described adolescence as a period of profound social cognitive change. Given the emphasis during this period on developing self-identity, self-consciousness, and social relations as an independent person in society, the changes in the developing brain provide clues that identify neural correlates for the self. In terms of brain development, numerous neuroimaging studies have revealed differences in the density of white and grey matter between the brains of prepubescent children and adolescents (12+ years old). In terms of cortical grey matter density, sensory and motor brain regions are found to mature earliest, with frontal and parietal cortex peaking around 12 years old. Adolescents consistently have a higher volume of white matter and a lower volume of grey matter in the frontal cortex and parietal cortex compared with prepubescent children. The increase in white matter continues through the 20s and has been interpreted as reflecting continued axonal myelination and synaptic proliferation. A sharp acceleration in grey matter loss between childhood and adolescence has been consistently found in the dorsal lateral prefrontal cortex (dlFPC) and the parietal cortex, suggesting synaptic pruning in those areas. Other studies of adolescents versus adults during mentalizing and self-knowledge retrieval tasks find that the dorsal medial prefrontal cortex (dmPFC), and specifically FPC, is more active in children than in adults, suggesting this region is heavily involved in developing self-other relations but requires less engagement as these functions become more routine later in development.

Despite the general utility of the Jamesian framework and proposed developmental approaches, there is no clear consensus on a standard developmental taxonomy of self-representational phenomena at this time. This is particularly apparent in research on adult populations, where debates about self and its conceptualizations are, at times, still fairly contentious. Self-identity across the lifespan is thought to be highly influenced by experience in the context of societal and cultural pressures. Significant coordination among the comparative evolutionary, human developmental, contemplative, and traditional (adult human) investigative

Telegram: @medical_k

www.konkur.in

approaches will likely provide a broadly applicable theoretical framework for research on “self” into the future.

CLINICAL PERSPECTIVE

In her 1961 work, “Seduction of the Minotaur,” French-Cuban-American essayist Anaïs Nin describes, “We don’t see the world as it is, we see the world as we are.” An essential text from the Buddhist canon, The Dhammapada, also describes, “Our life is shaped by our mind, for we become what we think.” Both perspectives allude to perception and thought content that has the potential to influence biologic dispositions and significantly contribute to personality characteristics, enduring behavioral traits, and habits. For example, an emerging area of investigation on mindsets has demonstrated that particular ways of perceiving and thinking contribute to core assumptions and expectations we maintain about ourselves and how we interact with the world. These mindsets contribute to the placebo and nocebo effects with a strong influence on health outcomes and associated neurophysiology. For instance, the influence of the placebo effect—triggered by a specific mindset and mental approach to ailments, exercise, and the prospect of recovery—has been demonstrated to account for 43% to 71% of meaningful clinical improvements in a range of conditions. These include pain management, anxiety and depression relief, respiratory and cardiovascular issues, treatment of neurodegenerative diseases, bolstering of immune function, postsurgical recovery, and even in reducing premature mortality. Similarly, negatively-oriented mindsets and associated habitual thought processes contribute to self-identity schemas that can have a negative impact on mental health.

Much of the earliest work encouraging scientific investigation of self-representation arose in the clinical context of treatment for adolescent and adult patients with psychiatric disorders. Sigmund Freud was most prominently recognized for his contribution of the tripartite model of the human psyche. Freud’s personality theory (1923) saw the psyche structured into three parts, the id, ego, and superego, all developing at different stages in our lives. These are implicit systems without neurophysiologic correlates and are directly related to the development of self-identity based on childhood experiences. In essence, the self was described to be composed of (1) the id, a primitive and instinctual part of

Telegram: @medical_k

www.konkur.in

the mind that contains sexual and aggressive drives and hidden memories, (2) the superego, a moral conscience, and (3) the ego, a realistic part that negotiates between the desires of the id and the superego. Freud's theory helped create a psychoanalytic technique for dismantling self-relations to improve mental illness in adulthood. Heinz Hartmann (1946) built upon Freud's ego psychology and proposed innate capacities of ego that facilitated an individual's ability to adapt to their environment. These included cognitive, perceptual, and motor coordination. Under normal conditions, which Hartmann called "an average expectable environment," these capacities developed into ego functions with autonomy from the libidinal and aggressive tendencies. Heinz Kohut, an Austrian-born American psychoanalyst, helped further craft psychodynamic theory for the treatment of psychopathology, emphasizing an understanding the self that focuses on its developmental aspects and the role of interpersonal relationships. Although his work evolved over time, by 1962 he had outlined several key components that contribute to the formation of healthy self-object relations. In Heinz Kohut's self psychology, the term "self-object" refers to a person or symbolic representation that serves specific psychological functions for the self, particularly in the realms of validation, care, and support. In essence, self-objects are those entities in our external environment—usually significant people like parents, caregivers, teachers, mentors, and later in life, peers and romantic partners—whose functions and responses are essential for developing and maintaining our sense of self. Kohut argued that self-objects are crucial especially during the formative years for providing the experiences that lead to a cohesive, healthy self. These experiences generally fall under three categories: (1) Mirroring: Self-objects in the form of parents or caregivers reflect back the child's own sense of worth and value. This mirroring validation gives the child a sense of vitality and effectiveness. (2) Idealizing: In this function, the self-object acts as a figure of strength and calm onto which the child can transfer feelings of fear or instability. The child idealizes this powerful, nurturing figure and seeks to be like them, absorbing their qualities into their own sense of self. (3) Twinship (or Alter Ego): Twinship self-objects are those with whom individuals feel a deep sense of similarity or likeness. These relationships often serve to confirm one's own sense of being and of belonging to a community. Importantly, the need for self-objects doesn't entirely vanish as we grow older. Adults also seek self-object experiences,

Telegram: @medical_k

www.konkur.in

often through intimate relationships, friendships, or mentorship, to maintain a cohesive sense of self and to repair disruptions in their self-cohesion. Kohut's theory had revolutionary implications for psychotherapy, suggesting that therapeutic success often hinges on the therapist becoming a self-object for the patient—providing the mirroring, idealizing, and twinship experiences that might have been missing or flawed in the patient's earlier life. Object relations theorists such as Margaret Mahler (1897–1985), Melanie Klein (1896–1971), and Otto Kernberg (1928) were also responsible for developing ego psychology and recognized the importance of early object relations and stages of self-development. Object-relations theorists recognized the centrality of the early mother–infant relationship for personality development, the development of an internal representation of self and others, and for the early understanding of interpersonal relationships. Carl Jung, a Swiss psychiatrist and psychoanalyst who founded analytical psychology, described the self as not just the conscious ego, but as a larger, overarching structure that includes both conscious and unconscious elements. The self, in Jung's framework, serves as the central organizing principle of the total psyche, striving for wholeness and integration. In seminal works like "Man and his Symbols" (1964) and "Memories, Dreams, Reflections" (1962), Jung described the self as inclusive of the conscious mind (ego), the unconscious that contains weakness, desire, and instinct (shadow), the inner contrary gender characteristics (animus), the social mask or facade one assumes in public (persona), and innate, unconscious universal patterns or images that shape human experience (self-archetypes). Last, Jung described a collective unconscious dimension of the self, which reflects a reservoir of archetypes and collective experiences that have accumulated over the course of human history.

The rise of behaviorism and cognitive psychology in the mid-20th century had a significant impact on cognitive and behavioral theories that explained psychopathology. Aaron Beck, one of the founders of Cognitive Behavioral Therapy (CBT), conceptualized the role of "schemas" in shaping one's self-concept and, ultimately, one's emotional and behavioral responses. In Beck's model (1979), "self-schemas" refer specifically to the durable reified cognitive structures that contain our beliefs about ourselves. These enduring self-schemas influence how we interpret experiences, what we pay attention to, and how we react emotionally and behaviorally. A healthy self-schema helps a person adapt effectively to life

Telegram: @medical_k

www.konkur.in

challenges, whereas maladaptive self-schemas can lead to emotional distress and dysfunctional behavior. Beck proposed that psychopathological self-schemas are enduring and dysfunctional cognitive structures that contribute to the onset and maintenance of psychological disorders. For example, in depression, these schemas might consist of persistent, ruminative beliefs like “I am worthless,” “I am unlovable,” or “I am not good enough.” These schemas become activated by specific situations that are perceived as threatening or confirmatory of the maladaptive beliefs. Once activated, they bias cognitive processing, leading to distortions in perception, memory, and thought, which in turn maintain or exacerbate emotional distress, maladaptive behavior, and lasting depressive attitudes and dispositions. There is now clear evidence that psychopathology is particularly vulnerable to negatively oriented mindsets that perpetuate negative self-schemas. Treatment of psychopathology through CBT involves identifying these dysfunctional self-schemas and cognitive distortions, challenging them, and replacing them with more adaptive beliefs and thought patterns about the self and the world.

Although much research has emerged in the last century to delineate the clinical relevance of the self and how it is represented and embodied in the context of mental illness, the influence of cognitive schemas, mindsets, and mindful awareness has only recently been leveraged in the context of therapy to facilitate a de-reified and more adaptive form of self-representation.

Brain Networks Supporting Self-Representation and Self-Transformation

A significant amount of PET and fMRI data have emerged from functional imaging studies specifically targeting various properties of the self, implicating coordinated activity in a network of specific frontoparietal association cortices (see Gusnard, 2005).

Vago and Silbersweig (2012) proposed a systems-based neurobiologic model for self-transformation that focused on frontoparietal cortices supporting the reduction in emotion dysregulation and the development of a sustainable healthy mind through changes in self-representation, including self-awareness, self-regulation, and self-transcendence (S-ART). The S-ART model describes transformative changes in the self through systematic training of the mind using specific meditation

Telegram: @medical_k

www.konkur.in

techniques and mindful awareness. Such techniques facilitate insight and familiarity with the conditions which cause (and remove) distortions or biases in the individual's construction of their external or internal experience through interoceptive attention, cognitive and emotional regulation, and prosocial development. Meta-awareness is described as a fundamental mechanism by which the individual gains awareness and control over pathologic thought processes common to emotion dysregulation and most mental illnesses. Meta-awareness is a combination of reduced reactivity to and disidentification from one's internal experience, improving the maladaptive emotional and cognitive processes. Specific resting-state networks (RSNs) were identified as comprising different aspects of the self in action or "selfing" (see Fig. 1.29–2), including networks supporting enactive experiential, phenomenological, narrative, and integrated self-related processes.

Enactive experiential brain regions are described as supporting early, prereflective, nonconceptual processing of the world. The self-specifying sensory–motor convergence proposed to contribute to enactive self-processing is localized to a distributed set of interconnected spinothalamocortical regions (including the periaqueductal gray [PAG], midbrain colliculi [MC], thalamus, hypothalamus, and posterior insular cortex [PIC]), all of which are known to be closely involved in monitoring (orienting and tracking), deciphering, and controlling interoceptive feedback at a nonconscious level. Frontal eye fields (FEF) and pre- and supplementary motor areas (PMA/SMA) were also described as critical to enactive self-processing. Experiential phenomenological self-processing involving the sense of being the immediate subject of experience without reflection or evaluation is described to involve primary sensory cortices (S1), the dorsal lateral PFC (dlPFC), dorsal anterior cingulate cortex (dACC), precuneus, and temporoparietal junction (TPJ). Together, these regions are believed to facilitate "executive" monitoring, vigilance, and alertness—monitoring performance or arousal levels and maintaining response readiness. The narrative self refers to the empirical or autobiographical construction of self-identity proposed by Daniel Dennett (1992), and also described in the pattern theory, to highlight the continuity over time as it extends in a coherent way into the future and reflectively into the past. The brain regions that have come to be most identified with the narrative self comprise the default mode network (DMN), an RSN that consistently incorporates the ventral posteromedial cortex (vPMC),

Telegram: @medical_k

www.konkur.in

including posterior cingulate cortex (PCC) and retrosplenial cortex (RSC), ventral medial prefrontal cortex (vmPFC), posterior inferior parietal lobe (pIPL), hippocampus, and lateral temporal lobe. Sometimes referred to as the hippocampal–cortical memory system, the DMN has occasionally been reported to also include the dorsomedial/rostromedial PFC (including BA 8, 9, and 10), rostral anterior cingulate cortex (rACC, or anterior medial PFC), insular cortices, and temporal pole. The DMN and other RSNs were first described in early functional connectivity studies of passive resting states using fMRI to probe spontaneous low-frequency (<0.1 Hz) blood oxygen level–dependent (BOLD) fluctuations that demonstrate consistent spatially and temporally coherent connectivity among large-scale functional brain networks. It has been hypothesized that DMN regions—especially the vmPFC—support the introspective self-reflective and evaluative mental processes that are characteristic of resting-state mind-wandering conditions. This conception of the core DMN as a "self-making" network is reinforced by findings that these regions are among the brain's most highly integrated and play a major role in processing autobiographical events and representations of individuals, including oneself. Jonathan Smallwood and Jonathan Schooler (2015) propose mind wandering involves engagement of episodic and emotional processes supporting the narrative self in addition to *perceptual decoupling*, in which attention is disengaged from perception during periods of self-generated or internally directed cognition.

The final network proposed by Vago and Silbersweig to support the integration of self-related informational processing is the frontoparietal control network (FPCN) (rostral frontopolar PFC [FPC], right ventrolateral PFC [vlPFC], dmPFC, dorsal anterior cingulate cortex [ACC], dlPFC, anterior insular cortex [AIC], lateral cerebellum, and anterior inferior parietal lobe [aIPL]). Some central executive and FPCN regions often overlap with other RSNs and are depicted in Figure 1.29–2 as cross-modal areas. The FPCN has been described as a hub and supervisory attentional gateway coordinating information processing between RSNs. Described to specifically facilitate relational binding and controlling stimulus-independent and stimulus-oriented cognition, the FPCN is uniquely situated to integrate information coming from other RSNs and facilitate global reorganization or plasticity among networks. Both global reorganization and integration across networks appear to support self-transformations and improved clinical health outcomes. For example,

Telegram: @medical_k

www.konkur.in

FPCN-DMN connectivity has correlated with improved clinical outcomes in support of mindfulness meditation training and psychedelic-assisted psychotherapy. Studies of mindfulness-trained individuals, including a seminal paper by Norman Farb and colleagues (2007), found unique engagement of experiential self-networks and suppression of DMN regions supporting a narrative self-focus. A number of meta-analyses have identified mindfulness-mediated targeted activity, related morphologic changes, and functional connectivity changes to the FPCN, associated regions, and their interaction with the DMN.

FIGURE 1.29–2. Functional networks shown to support different aspects of the self in action or "selfing." Functional networks originally described by Vago and Silbersweig, 2012 include an experiential enactive self (EES) network, experiential phenomenologic (EPS), narrative self (NS), and integrative frontoparietal control network (FPCN), each of which involves parcellation nodes previously identified in resting-state networks. The self-specifying sensory–motor convergence proposed to contribute to EES is localized to a distributed set of interconnected spinothalamocortical regions (including the periaqueductal gray [PAG], midbrain colliculi [MC], thalamus, hypothalamus, and posterior insular cortex PIC]), all of which are known to be closely involved in monitoring (orienting and tracking), deciphering, and controlling interoceptive feedback at a nonconscious level. Frontal eye fields (FEF), pre- and supplementary motor areas (PMA/SMA) are also described as critical to EES processes. The EPS involves the sense of being the immediate subject of experience without reflection or evaluation, and is described to involve primary sensory cortices (S1), the dorsal lateral PFC (dlPFC), dorsal anterior cingulate cortex (dACC), precuneus, and temporoparietal junction (TPJ). Together, these regions facilitate "executive" monitoring, vigilance, and alertness—monitoring performance or arousal levels and maintaining response readiness. The NS refers to the empirical or autobiographical

www.konkur.in

construction of self-identity mostly supported by the default mode network (DMN), a resting state network that consistently incorporates the ventral posteromedial cortex (vPMC), including posterior cingulate cortex (PCC) and retrosplenial cortex (RSC), ventral medial prefrontal cortex (vmPFC), posterior inferior parietal lobe (pIPL), hippocampus, and lateral temporal lobe. Sometimes referred to as the hippocampal–cortical memory system, the DMN has occasionally been reported to also include the dorsomedial/rostromedial PFC (including BA 8, 9, and 10) rostral anterior cingulate cortex (rACC, or anterior medial PFC), insular cortices, and temporal pole. The FPCN supports the integration of self-related information processing and includes the rostral frontopolar PFC (FPC), right vlPFC, dmPFC, dorsal ACC, dlPFC, AIC, lateral cerebellum, and anterior inferior parietal lobe (aIPL). Some central executive, FPCN, and DMN regions often overlap in functional parcellations with other RSNs identified by Yeo et al. 2011 and are depicted in figure as cross-modal areas. (Adapted from Vago DR, Silbersweig DA. Self-awareness, self-regulation, and self-transcendence (S-ART): a framework for understanding the neurobiological mechanisms of mindfulness. *Front Hum Neruosci.* 2012;6:296. doi: 10.3389/fnhum.2012.00296. Schizophrenia and Other Psychiatric Disorders

Neurologic syndromes, severe psychiatric illness, and known structural brain lesions have also contributed to illustrating many of the phenomena that will need to be explained by any scientific formulation of neural substrates of self-representation. In psychiatry, beyond depression, schizophrenia may be viewed in part as a disorder of the self. This is presumably because symptoms observed in patients with schizophrenia, such as auditory hallucinations ("voices" that likely represent patients' own inner speech), delusions (that commonly involve patients' own identities and powers), thought withdrawal and insertion (delusions regarding ownership and control of patients' own thought processes), and negative symptoms (that include deficits in emotional responsiveness, spontaneous speech, and volition) typify dysfunction of some of the traditional subject and object conceptions of the self already noted.

In the very earliest days of psychiatry, Emil Kraepelin (1896, 1913) claimed that disunity in schizophrenic patients' consciousness ("an orchestra without a conductor") was a core feature of the illness and that this disunity was linked to "a peculiar destruction of the psychic personality's inner integrity, whereby emotion and volition, in particular, are impaired." Such a framing of a core dysfunction in schizophrenia is striking for its resonance with current thinking from dynamical systems

Telegram: @medical_k

www.konkur.in

and theoretical neuroscience perspectives that consciousness, including aspects of self-representation, fundamentally depends on the brain's *capacity to "properly" integrate and coordinate* information within and across widely separated brain regions.

Several other psychiatric disorders exhibit features that current thinking (according to DSM-5 diagnostic criteria) would suggest involve critical dysfunction of some aspect or aspects of self-representation. Examples include anorexia nervosa (with its disturbance in the way in which one's body weight or shape is experienced), various dissociative disorders (with their losses of continuity in subjective experience, such as fragmentation of identity, depersonalization, and derealization and/or inability to access information or control mental functions that normally are amenable to such access or control), social anxiety disorder (with its marked fear or anxiety of social situations in which the individual is exposed to possible scrutiny by others), and various personality disorders, notably borderline personality disorder, with its pattern of instability of self-images, affects, and interpersonal relationships. This nosologic "list" is likely to become more refined and expanded as research progresses and the current understanding of the neural bases of self-representational capacities increases.

Neurologic Syndromes

Seizure disorders have been shown to present with experiences of depersonalization and derealization, or even autoscopy, suggesting self-representation may be disrupted by focal or global electrical disruption. Epilepsy with "ecstatic auras" have been described as experiences of intense feelings, including bliss, joy, and heightened self-awareness. This unique seizure disorder has been associated with abnormalities in the anterior temporal pole (TP) and AIC. This region has also been implicated in representing the "sentient self" or interoceptive awareness. Some patients who are known to have sustained brain damage, usually as a result of a cerebrovascular accident, display dissociations between aspects of their behavior and their reported experiences or stated beliefs about themselves. For example, there are patients with alien limb and alien hand syndromes who, by definition, exhibit movements of all or a portion of one of their upper extremities that are dissociated from their stated intentions and are often in conflict with those of their opposite extremity. The patients react with surprise and concern at such

Telegram: @medical_k

www.konkur.in

movements. These involuntary movements are not spontaneous but are in response to stimuli in patients' peripersonal space. The qualities of these movements are different depending on the location of their brain lesions. Patients with damage to the medial surface of the frontal lobe, for example, typically display intermanual conflict or grasping, groping movements of the hand represented by the lesioned cortex, and an inability to release grasped objects. Patients with parieto-occipital lesions, by contrast, display involuntary movements that involve avoidance of contacts so that the affected hand and limb often levitate away from support surfaces. Damage to the precuneus and surrounding lateral and medial parietal structures appears to be critical to the control of goal-directed visually guided reaching in humans as well as motor, sensory, or visual field–related disorders like optic ataxia and ability to perceive the visual field as a whole as seen in simultagnosia.

In addition to neurologic disorders that exhibit dissociations between self-perceived will and purposive action, there are other disorders that involve an apparent lack of self-awareness with regard to some acquired impairment of the body that is clearly apparent to observers. In some cases, this lack of awareness is associated with unshakeable false beliefs about the alteration in their bodies or their impairments. The syndrome of unilateral spatial neglect, for example, is seen in a heterogeneous group of patients who have suffered damage, usually to the right parietal lobe (right frontal and left parietal variants are uncommon). Though specific symptoms and their severity vary, all patients exhibit some failure to detect or respond to stimuli on the side opposite to the brain damage. Along with this, patients may have an isolated delusion where they deny ownership of the limb or entire side of the body represented by the lesioned cortex. At the same time, they continue to retain awareness of subjective sensations such as whether they are tired or hungry and continue to have normal autobiographical memory.

Patients who have sustained brain injuries in various locations (again, typically in the right hemisphere) may also remain unaware of and deny their handicaps (anosognosia). This is seen acutely in 20% to 30 % of cases of hemiplegia/hemiparesis after stroke but can occur with virtually any neurologic impairment, including bilateral cortical blindness, prosopagnosia (face blindness), amnesia, aphasia, or apraxia, as well as in cases of multiple impairments where lack of awareness may be for all or limited to just one of the impairments. The amputation of a limb

Telegram: @medical_k

www.konkur.in

represents a serious disruption of body integrity and is associated with postamputation “phantom limb” pain. Almost all amputees report ongoing awareness of a phantom limb, with 60% to 80% complaining about phantom limb pain, a painful sensation perceived in the amputated limb and thus located outside the physical borders of the body. Such denials of one’s own impairments do not appear to be directly related to sensory loss but rather to damage to higher-level cognitive processes, including attentional mechanisms, which likely disrupt some capacity for self-monitoring. Nonlocalizability (except to the right hemisphere) also suggests a disturbance of a brain “dynamical” mechanism (e.g., an integrative mechanism, such as one that permits the coordination of sensory information with other processes that support spatial or bodily representations) as its basis. Such attentional and “dynamical” mechanisms need not be mutually exclusive.

There are also patients who exhibit dissociations between their behavior and reported sense of themselves of another sort. These patients have often been characterized as having disorders of self-regulation. Adult patients with acquired lesions involving the prefrontal cortex, particularly the ventromedial region, often exhibit changes in their ability to control their behavior. While in testing situations, they can verbalize norms for acceptable social behavior, in actual practice, they behave in ways that conflict with their reportable knowledge. It is as if, despite knowing “the rules,” they are unable to implement them. Such patients often appear impulsive, socially insensitive, and as if their decision making, particularly in social contexts, is impaired. They are commonly described by those familiar with them as having undergone a “personality” change. This was seen in the case of Phineas Gage, mentioned earlier, who sustained a traumatic injury to his OFC (see Fig. 1.29–1). When the prefrontal damage is of childhood onset, affected individuals exhibit defective social and moral reasoning as well, suggesting that capacities for acquiring knowledge of complex social conventions and making moral judgments have also been impaired. Such “moral self-effect” changes that shift characteristics like social reasoning, honesty, empathy, or virtuous behavior have been suggested to constitute the greatest weight and importance to self-identity in comparison to other aspects of change to mental life (e.g., memories, preferences, desires).

These various clinical syndromes demonstrate some of the ways in which impairments in capacities for self-representation manifest

Telegram: @medical_k

www.konkur.in

themselves and result in the disunity of functioning that is perceptible to the subject in some cases and only to outside observers in others. Patients' verbal reports and clinical observations of patients' behavior are clearly limited in what they can contribute to the development of a taxonomy of self-representation functions and underlying mechanisms, however. Although a pattern of self-specific neural substrates appears to be emerging (see Brain Networks Supporting Self-Representation and Self-Transformation), more experimental work is needed with neurologic cases and those not afflicted to better characterize the instantiation of such impaired aspects of self-representation in nervous systems and elucidate an even wider variety of pathology involving the disordering of aspects of human subjectivity and behavior.

Split-Brain Studies

Some of the most significant data providing conceptual traction on the issue of self-representation in the human nervous system arose from the aforementioned ground-breaking studies of patients who had undergone complete transection of the corpus callosum for the treatment of medically intractable epilepsy that were first undertaken in the 1960s. Functional specializations of the two cerebral hemispheres (e.g., the dominant role of the left hemisphere in supporting most language functions) were the most widely reported findings of the initial studies that were conducted by Roger Sperry and for which he won a Nobel Prize in 1981. Sperry used several ingenious tasks to investigate the lateralization of brain function. The experiments all involved presenting tasks separately to the two cerebral hemispheres in each experimental subject. For example, after blindfolding one of the subject's eyes, subjects would be asked to fixate with the seeing eye on a point in the middle of a screen to the left or right of which a stimulus would subsequently be presented for less than one-tenth of a second. This very short duration ensured that there would not be time for subjects to move their eyes and permit the visual information to "spread" across both left and right visual fields and, therefore, across both sides of the brain. Analogous procedures were used for presenting unseen tactile stimuli to one or the other of the subjects' hands or auditory and olfactory stimuli to only one side of their brains. The subjects would then be asked to name the various stimuli. Because language is largely processed in the left hemisphere, it was only when stimuli were presented so that processing occurred in the left hemisphere that subjects were able

Telegram: @medical_k

www.konkur.in

to name the stimuli (i.e., because of fiber crossing, this would occur when stimuli were presented to subjects' right visual fields or right hands). It was also observed that when subjects were presented with a stimulus first in one of the two visual hemifields and then the other, they responded in the second case as if they had never seen the stimulus before. But when the stimulus was represented to the original hemifield, subjects were able to recognize it as the one they had seen before. Other examples of the separability of processing in the two hemispheres were seen in related experiments where different objects would be placed in each of the participants' hands at the same time and then placed for retrieval in a pile of test items. Each hand was observed to search out its own object, rejecting the other item for which the other hand was searching.

Besides revealing specialization of the two hemispheres, these studies also showed that a manipulation (in this case, a disconnection of the two hemispheres) was able to result in a real-time separability of aspects of an individual person's consciousness. Long-term observations of such patients showed that each disconnected hemisphere possesses not only a separate sensorimotor interface with the environment, with its own perceptual, mnestic, and linguistic repertoires, but also its own characteristic likes and dislikes and styles of decision making. Researchers involved in conducting experiments with such patients also reported that the experience of "interacting" with each of the separated hemispheres in individual patients felt akin to interacting with a distinct personality.

Recognizing that the partially disconnected right hemisphere demonstrates awareness in the absence of an ability to express such awareness verbally has provided additional evidence that language is not necessary for human consciousness. Also, while the normal experience of consciousness is often thought to be inherently unified, it now appears that normal consciousness may be fundamentally "dual" (if not "multiple"). That is, it is grounded in parallel processes in the two hemispheres that tend to interact and accommodate the resources of each other in most settings, but whose partially separable workings may sometimes be in evidence, as in the common human experience of subjective conflict.

And, despite the fact that the two cerebral hemispheres in a single split-brain individual clearly exhibit signs of distinctiveness in processing styles that occur in parallel, other mechanisms exist for "driving" coherence in the nervous system in natural settings. For example, there are also

Telegram: @medical_k

www.konkur.in

pathways at levels below that of the corpus callosum that indirectly connect the two hemispheres via the cerebellum, brainstem, and the thalamus. These may facilitate interhemispheric cooperation for compatible stimuli in the two visual fields and the typically observed unity in motor responses. Findings such as these and others from real-world settings that appear to engage other compensatory processes have led increasing numbers of theoretical neuroscientists and others to begin viewing the brain and its operations as a kind of "complex adaptive system," subject to self-organizing principles and dynamics similar to those observed in other domains.

Distinguishing Self from Nonself

It is critical for the integrity and survival of all mobile organisms that they be able to distinguish "self" from "nonself" and act on the basis of such a distinction. The evolution of nervous systems from the simplest vertebrates to humans has resulted in marked increases in complexity and diversity of capacities for achieving various forms of such "self-recognition." Brains, and the nervous systems of which they are a part, are thus being increasingly viewed as inherently dynamical. Their ongoing activity, the patterns of communication between brain areas residing in such activity, and adaptive "problems" they "solve" likely subserve various forms of self-representation. For example, the fundamental problem of distinguishing self from nonself exists for all mobile organisms. It has been studied in lower animals as well as humans. One well-studied animal model is that of the electric fish. Studies of this animal have been useful for identifying strategies that a relatively simple sensorimotor system may use for solving the inverse problem of determining which of all the patterns of neural activity in its sensory system represent those arising from environmental events (nonself). All such strategies are made possible by the animal's movement and exploration of its environment, which result in modification of the kind of sensory information that it acquires and help constrain the solutions to this problem.

Some of the modifications that help obtain such a solution arise from nervous systems' determination of different temporal relationships between, and integration of, sensory afferent and motor efferent signals. As a result of interaction with the environment, an organism must constantly integrate efferent and afferent signals to distinguish between reafference—afferent signals arising as a result of the organism's own

Telegram: @medical_k

www.konkur.in

efferent processes (self)—and exafference—afferent signals arising as a result of environmental events (nonself). This functional yet implicit self–nonself distinction specifies the self as a bodily agent. Internal reports of an organism's own movements are referred to as corollary discharge signals. Corollary discharge information informs sensory areas about the upcoming movements and allows them to prepare for the sensory consequences of the movement. These prediction signals arising from the motor system and their comparison with sensory signals are thought to play a major role in neural processes that permit the separation of self-generated movements from movements caused by another individual (passive movement) or from other activity that is going on in the environment. That is, well-established theoretical frameworks (called feed-forward models) have been developed for computational considerations of processes describing such action execution and motor control by nervous systems. In these frameworks, at least one kind of neural signal that is thought likely to be a component of this preparatory activity for movement execution is one *predicting* the sensory consequences of the movement.

Sarah-Jayne Blakemore, Daniel Wolpert, and Chris Frith conducted a now-classic experiment (2000) in which normal subjects underwent self-produced tactile stimulation and robotic stimulation using the same stimulus (a sinusoidal movement having a particular amplitude and frequency of a piece of soft foam across the right palm). In a related experiment, subjects underwent the same kind of stimulation, but it was achieved via a robotic interface that the subjects manipulated with their own left hands and into which different time delays were introduced (between when the subjects moved their left hand and produced the stimulation on their right palm). Under these controlled conditions, subjects rated the self-produced tactile stimulation as significantly less tickling and pleasant than that produced by the robot. They also reported a progressive increase in the tickling and pleasant sensation as the temporal delay increased from no delay to a 200-ms delay. Such data are consistent with the feed-forward model's hypothesis of perception of self-produced tactile stimulation being able to be attenuated due to precise sensory predictions. A follow-up neuroimaging study of the self versus robotic stimulation comparison supported this by showing that there was relatively attenuated activity in the parietal operculum (secondary somatosensory cortex) and anterior cingulate cortex (ACC) in the self-condition.

www.konkur.in

In similar experiments as well as those using other designs, individuals with delusions of control have been shown to differ in their responses from individuals without such delusions. Other designs include the “rubber-hand illusion,” an established method for manipulating the sense of body(part) ownership, where subjects see feedback of their own hand movement or that of an experimenter’s hand making similar movements. In such experiments, individuals with delusions of control have found it more difficult than control subjects to distinguish sensations arising from self-generated actions from those arising from actions that were not self-generated. They also required greater temporal discrepancies between such actions to distinguish between actions arising from themselves and those not arising from themselves. These and other results have suggested that some component of the feed-forward modeling process for making such discriminations is impaired in these individuals.

Self versus Other: Perspective-Taking and Mental State Attribution

In human beings, there is another set of functions by which an individual’s experience of self may be uniquely characterized. These involve the manipulation of perspective-taking and mental state attribution. First- versus third-person perspectives are quite different from each other. First-person perspective refers to the centralization of the subjective multimodal experiential space around one’s own body, while third-person perspective refers to a variety of processes that all include ascribing mental states to others and shared experience with others.

Individuals may adopt first- versus third-person perspectives with regard to movement through or location in space. Spatially, an individual is situated in what is called an egocentric reference frame, where locations of objects are represented relative to that individual’s body. However, when individuals try to understand what someone else sees, for example, they need to be aware that others’ percepts are actually different from their own, *and* they need to be able to perform the mental computation that permits reorienting the egocentric reference frame and centers it on that other person’s body. Electrophysiologic studies in primates have yielded much data on the role of the posterior parietal cortex, including the precuneus, in multisensory integration and spatial coordinate transformations for this purpose. These processes are also required for converting sensory input centered on an organism’s body into motor output directed at objects located in an allocentric reference frame that

Telegram: @medical_k

www.konkur.in

references object–object relations with internal coordinates that are independent of an organism's body. In human brain imaging studies, the posterior parietal cortex, usually on the right side, has routinely been activated when people have been asked to execute tasks that involve adopting a third-person perspective.

The capacity to be aware that others have mental states that are different from one's own is critical for individuals' ability to participate successfully in human social interaction. Much of human cooperative behavior depends on the ability and motivation to exchange information, the recognition that others lack important knowledge, have beliefs that are false, or have intentions that complement or conflict with one's own. Human social interaction is also supported by individuals' abilities to understand the emotional and affective states of selves and others. Abilities to reflect on one's own feelings as well as to be empathic, feel sympathy, and have compassion for others contribute to moral decision making and help promote social cohesiveness. Cognitive empathy or mentalizing is often characterized uniquely from affective empathy and is more often associated with shared experience through perspective-taking. The cognitive form has been measured by items describing the understanding of others' feelings (e.g., "I'm able to recognize, before many other children, that other people's feelings have changed"), and affective empathy by items about sharing others' feelings (e.g., "When somebody tells me a nice story, I feel as if the story is happening to me"). Powerful position and status among peers are increasingly important for adolescents, and both forms of empathic ability have been shown to also contribute to increasing and maintaining social status.

Research using neuroimaging techniques has shed light on the neural mechanisms underlying the process of understanding others' mental states, a key aspect of perspective-taking. These studies often distinguish between tasks and stimuli related to the self and those that are not. Notably, evaluating one's own personality traits, physical features like facial appearance, or tasks that require interpreting emotions or mental states, consistently activate certain brain regions. These include the medial prefrontal cortex (mPFC), the precuneus, the posterior cingulate cortex (PCC), the temporoparietal junction (TPJ), and the temporal pole (TP) (see Fig. 1.29–2). For example, self-face recognition and mental state attribution in comparison to other familiar faces has been found to have particular neural substrates supporting this process, including the

Telegram: @medical_k

www.konkur.in

middle and superior frontal gyri in the right hemisphere. The mPFC has shown activation when subjects have been asked to perform various acts of self-evaluation. For example, mPFC and experimental tasks have included asking subjects to make trait judgments about themselves ("does this word [e.g., friendly, unhappy, industrious] apply to you") and make preference judgments ("which do you prefer—item 1 or item 2").

These data support a model developed by Gordon Gallup Jr. (1982) that posits that self-awareness and mental state attribution are part of a shared neurocognitive suite of processing and that neural architecture implicated in processing knowledge about the self is called upon when inferring knowledge in others. Gallup devised mirror recognition tasks in nonhuman primates as a distinguishing factor for self-awareness capacity. Other studies have focused on distinguishing self from nonself through identifying a social network of functioning that includes mentalizing and empathic behavior. Brain areas that are involved in mentalizing include TPJ, TP, AIC, precuneus, dmPFC, while the ACC, inferior frontal gyrus (IFG), posterior superior temporal sulcus (pSTS), and inferior parietal lobe (IPL) have been implicated more with prosociality, empathic concern and experience sharing. Imagined self-action relative to imagined experimenter action strongly activates IPL (including TPJ), somatosensory cortex, and precuneus. The dmPFC has also shown activation when subjects have been asked to assess what others think or feel, as in so-called theory-of-mind (ToM) tasks. ToM refers to the cognitive ability to attribute mental states, such as beliefs, desires, and intentions, to oneself and others and to understand that others have mental states that are different from one's own. The right IPL is more often associated with ToM, whereas the left IPL is more often involved in representing one's own mental states. The posterior IFG has been shown to be involved in emotional judgment and has been suggested to play a role in emotion recognition, predicting emotion, affective empathy, and mirroring action.

Cognitive studies and functional imaging experiments targeting empathy have also been done. Experimental work on this issue has shown that the same network of brain regions is often engaged when subjects experience something (e.g., pain) *and* when they observe someone else appearing to be in the same experiential state (e.g., when shown pictures of others in pain). Such data again support the view that certain brain networks *share* in representing self and others' states and, in this case, account for humans being able to achieve empathic

Telegram: @medical_k

www.konkur.in

understanding. Brain networks that have been identified in such contexts include but are not limited to portions of PFC, medial parietal cortex, portions of the ACC, and insula. Yan Fan and colleagues (2011) found that the dACC and anterior midcingulate cortex (aMCC) were recruited more frequently in the cognitive–evaluative form of empathy, while the right AIC was found to be involved in the affective–perceptual form of empathy only, and the left AIC was found to be active in both forms of empathy. Tania Singer and Claus Lamm (2009) propose the AIC serves a dual role, a primary mapping of internal states with respect to the self and the predictive representations or simulation of how the same emotional stimuli feel to others.

A growing number of behavioral and neurophysiologic studies demonstrate shared representations between perception, action, and predicted action. There is evidence that perception of an action activates motor representations to the degree that the perceived and the represented action are similar. As such, these representations may be shared between individuals through a theoretical mirror neuron system. Indeed, a mirror neuron system has been identified in the ventral premotor cortex and posterior parietal cortex of the macaque monkey that fires both when it carries out a goal-directed action and when it observes the same action performed by another individual. This common coding reflecting shared representations between self and others helps clarify the meaning of a given object, action, or social situation that may be common to several individuals and therefore activate corresponding distributed patterns of neural activation in similar brain networks of perception–action and inference across individual brains. This shared-representation explanation is also consistent with, though not completely explained by, the tenets of “simulation theory,” which is a framework for describing how individuals understand others’ behavior and subjective states. Identical circuitry for “sharing” or “simulating” others’ experiences is unlikely to be the sole mechanism underlying abilities to appreciate and recognize others’ subjective states as such, however. Being empathic also requires maintaining a separateness of oneself from another so that one can act. In settings such as psychotherapy, for example, both must occur for progress to be made. Thus, mechanisms underlying personal agency likely need to be integrated with those that underlie this kind of equivalence between self and other to accomplish this in practice.

Telegram: @medical_k

www.konkur.in

Current evidence suggests that the relatively primitive capacity to recognize features of one's physical self, such as features of one's face or body, is limited to a small set of primate species, including humans. The behavioral mirror self-recognition test has been evidence of such self-recognition capacity. More cognitively abstract forms of self-awareness, such as introspection and mental state attribution, are likely unique to humans. Interestingly, von Economo neurons (VENs) and fork cell neurons (FNs), two morphologically "atypical" types of neurons found predominantly in the AIC and ACC in humans, and some nonhuman primates (e.g., great apes, gibbon, rhesus) have been identified as unique to primates who have self-awareness and capacity for self-reflection. While their exact function has yet to be clearly elucidated, the VENs and FNs have been uniquely associated with the evolutionary development of self-reflective and socially relevant forms of subjective awareness. They uniquely provide connections between cognition and internal homeostatic bodily states implicated in this unique human capacity. The precuneus has also been implicated in self-specified conscious awareness, agency, visuospatial imagery, sensory integration, and episodic memory retrieval. It is heavily interconnected with visuospatial areas in the inferior and superior parietal areas, extensively with dlPFC, premotor areas, and subcortical regions like the thalamus, striatum, claustrum, and brainstem. Interestingly, the precuneus and surrounding posteromedial areas are among the brain structures with the highest resting metabolic rates displaying transient decreases in tonic activity during engagement in non–self-referential goal-directed actions. As one progressively lowers conscious awareness toward states of sleep, drug-induced anesthesia, and vegetative states, the metabolic rate linearly decreases its metabolic output.

Although a neural network supporting social cognitive processes for self–nonself distinctions is gaining more traction in the science of self and social cognition (see description of S-ART model earlier), it remains unwarranted at this juncture to describe any of these brain regions as uniquely self-specific, given the wide range of other cognitive processes these regions support in other contexts. It does shed light on one aspect of self-awareness in which the self is seen as an object, not as the agent or knowing subject. In a large meta-analysis conducted by Dorothée Legrand and Perrine Ruby (2009), self-specific brain regions and networks of brain regions have been identified for self-representation;

Telegram: @medical_k

www.konkur.in

however, they emphasized a framework for describing self-processing as a product of more general evaluative mechanisms that, taken separately, are not self-processing specific, but in their aggregate are self-defining. More specifically, they proposed that these mechanisms together operationalize a subjective perspective and permit relating represented objects to a representing subject. Their proposal aligns in several respects with other investigators' emphases on aspects of agency, underscoring the role of functional processes that effectively integrate an individual's motor activity with its predicted sensory consequences in the course of acting in the world.

Another attempt at a broad theoretical framework has used a different approach with potential applicability beyond the human species, approaching the problem of self-recognition specifically. Matthew Apps and Manos Tsakiris (2014) focused on the relatively low-level problem of how the brain processes incoming visual, auditory, somatosensory, or interoceptive input as "self" ("me") and distinguishes it from "nonself" ("not-me"), allowing recognition of an individual's physical self (face, body and movement, and voice) as their own. They describe how the recently developed "free-energy principle" (itself an attempt at a unifying theory of the brain viewed as a self-organizing biologic system developed by Karl Friston and colleagues) can be used to explain many of the current findings in self-recognition research and also relate to higher cognitive processes of self-awareness. Though the details of their theoretical account (particularly the Bayesian principles and mathematical descriptions upon which it is based) lie outside the purview of the present chapter, the basic notion is that there are mechanisms by which the brain optimizes predictions about the sensory consequences of events occurring in the environment (including the results of subjects' own actions) in order to minimize the amount of "free-energy" (i.e., "surprise" or deviation from expectation) and engender states of high predictability. Anil Seth and Karl Friston (2016) expand on this concept to explain how prediction is continually updated through sensory input and how Bayesian principles may further explain our active inferences, hypotheses, or beliefs as neuronally encoded probability distributions. They apply these principles to predictive coding in the context of interoception, in particular, and suggest perceptual predictions arise from agranular motor cortices and are updated based on prediction errors and sensory input. Apps and Tsakiris also argued that several of the brain regions identified by others

Telegram: @medical_k

www.konkur.in

for so-called self-processing could be interpreted as participating in the mechanisms of minimizing prediction errors and integrating multisensory information for recognizing the “self” versus “nonself” that are critical to their account. Like Legrand and Ruby, they propose that there are general mechanisms underlying the defining of a particular sense of self that are not self-processing specific but are grounded in the operations of brain regions whose dynamic and coordinated activity are what are, in fact, responsible for such self-definition. Clearly, additional work will be required to disambiguate self-other distinctions to more dynamic notions of self-*processing* (i.e., *how* such representations are constructed).

The Self as Agent

With modern scientific discussions of self moving away from a relatively “static” concept to more dynamical, process-based accounts, there are new considerations of self as an agent promoting investigations that target *experiences* of agency (e.g., experiences of mental causation or of being the “source” of intentions and motor commands) or the actual *structure* of agency (the organizational relationships among perception, an intention or goal, planning or selecting a movement consciously or unconsciously, and a motor command that may or may not require subsequent monitoring for reaching its goal). Experiences of agency represent individual agents and their actions as being in a certain way. For example, normal individuals do not simply find themselves walking toward a stairway and then, on the basis of this, acquire a belief that they must be intending to go down the stairs. Rather, the experience is of walking toward the stairway in order to go down the stairs. Individuals usually experience a sense of purposiveness with their actions, which may be related to intentions that are conscious or not. When there is no awareness of a prior intention, it is still the case that normal individuals’ actions involve experiences of having acted in the service of a goal and thus having implemented an intention that they experience as their own. In normal individuals, the sense of intention and of being the “owner” and source of their actions is typically very strong. Normal individuals tend not to doubt that their actions are self-generated. There is now a variety of data on how normal individuals experience their actions as self-generated and the form that this self-generation takes.

Research has investigated the experience of agency by probing awareness. In one study, subjects were typically asked to draw a straight

Telegram: @medical_k

www.konkur.in

line on a computer screen while they were unable to see their arm or hand. They would be given false feedback about the trajectories of their movements so that they would have to make significant deviations from straight movements in order to reach their goal. However, when asked about their experiences, subjects' verbal reports indicated that they had been unaware that they were making deviant movements. Other experiments involved discrepancies in the timing between expected and actual movements with similar results. Investigators also determined thresholds for the degrees of discrepancy that could exist before individuals reported awareness of a discrepancy when they were asked. When they were not asked, subjects appeared not to notice even when the degrees of discrepancy were higher than these thresholds. Thus, it appears that there are aspects of their own movements about which even normal individuals are unaware. In addition, individuals may be more aware of movements they *intend* to make than those they actually make in particular settings.

Disorders of agency are also described as disorders of volition—that is, the psychiatric or neurologic conditions where individuals' own actions are either denied having been self-generated or are reported as feeling as if they have not been self-generated. Drug- or trauma-induced dissociative experiences similarly result in an experience of disconnection from one's own action, thoughts, feelings, memories, or sense of identity. Agency is also reduced or experienced as illusory during an out-of-body experience in which there is a feeling of disembodiment (location of the self outside one's body), the impression of seeing the world from a distant and elevated visuospatial perspective (extracorporeal egocentric perspective), and the impression of seeing one's own body (or autoscopy) from this elevated perspective. These dissociative and out-of-body experiences demonstrate how multisensory afferent signals interact with body representations to generate a sense of body ownership, and efferent signals may modulate this sense of ownership through the sense of agency. There is some evidence that the sense of agency originates in neural processes responsible for the motor aspects of action, including visual and proprioceptive/kinaesthetic information that provides information about movement in space. Studies of self-attribution of action and ownership most consistently activate a right frontoparietal network, including the superior parietal cortex, the inferior parietal cortex, and the insular cortex. Yet, dysfunction of the TPJ leads to the related failure to

Telegram: @medical_k

www.konkur.in

integrate multisensory information from one's own body, also resulting in a disrupted sense of agency. Thus, there appears to be a fundamental relationship between brain activity in frontoparietal regions and conscious perception of one's agentic self that can be modulated by the dissociative experience. These data suggest interpretation of dissociative experiences by the individual may contribute to expanding consciousness beyond normal limits of perception and boundaries of bodily ownership or becoming constricted and fear-inducing through traumatic forms of dissociative experience. Future research may better distinguish between drug-induced dissociation and that which is associated with post-traumatic stress. More clarity may thus be provided on dissociation as a potential defensive mechanism for the organism with psychotherapeutic implications.

Sense of Agency and Voluntary ("Willful") Action

There are common human intuitions as well as folk-psychological beliefs that intentions and thoughts *cause* human action. As already noted, however, scientific accounts of intention and its relationship to action reject dualistic accounts, where the "mind" is thought to cause changes in the body, resulting in action. In the reductionist scientific view, both conscious experience ("thought") and action are *results* of brain activity. Despite the inherent challenges in identifying organized relationships in neural processes that instantiate this process, some investigators have specifically attempted to identify neurophysiologic mechanisms for the human experience of agency.

A classic study by Benjamin Libet and colleagues (1983) has been commonly cited as evidence that consciousness (specifically, individuals' experience of the intention to move) is not the initial cause of behavior and that behavior occurs instead as the result of a chain of events initiated by nonconscious brain events. Libet monitored subjects' electroencephalogram (EEG) and muscle activity while subjects performed simple finger movements and asked them when they were aware of the "urge" to move. Though subjects did consistently anticipate the starting time of the movement by over 50 ms, there were signs of preparatory brain activity for this movement that preceded these "awareness judgments" by several hundred milliseconds. Many authors have had concerns about some of the technical details of this experiment,

Telegram: @medical_k

www.konkur.in

however, and have consequently also disagreed that the results of this study support the idea that “free will” does not exist.

Other investigators have undertaken experiments based on the Libet paradigm to pursue this issue further. These experiments are notable in two respects. First, the basic result that the generation of action (from the beginning of preparatory brain activity to the onset of muscular activity) extends over time and has a phase that is unavailable to awareness has been replicated. However, the details of the relationships among brain activity, conscious intention, and action have also been determined to be more complex than initially surmised. What is now recognized is that action generation is not a “simple” process. That is, it is not simply an underlying neural process of preparation to move and its execution that may (or may not) be experienced. Rather it now appears that the brain processes of preparation, execution of movement, and conscious experience of these phenomena each have several components.

The actual structure of agency itself is thought to depend upon particular organizational relationships among several variables, including intention or goal, action selection, a motor command, and its outcome. Models have been proposed for this structure, with a particularly notable one being a “comparator model” formulated by Daniel Wolpert and colleagues in the 1990s. This model and its derivatives were originally articulated as models of motor control. An important question, however, is whether or not the sense of agency associated with or emerging from this structure depends solely upon comparing the degree of matching between *predicted* and actually experienced consequences of movement (so that sense of agency is strong when there is a close match between predicted and actual sensory consequences of an action and is reduced or absent when the match is poor). Such an account would necessarily imply that the sense of agency occurs *after* an action has been performed and information about its sensory consequences becomes available. While the “comparator model” and its retrospective account of agency have received significant behavioral and neuroimaging support (recall the “tickling” and “rubber-hand illusion” experiments, as examples), other experimental data challenge the notion that sense of agency is *fully* explained by such an account.

The sense of agency may also be generated *prospectively* via the process by which intentions (here defined as prospective signals involved in action preparation) are transformed into specific actions to reach

Telegram: @medical_k

www.konkur.in

desired effects. In a variant of the Libet paradigm, for example, they stimulated the motor cortex using TMS and observed that, relative to the nonstimulated condition, the perceived time of movement was only slightly delayed (~75 ms) while signs of initiation of the movement (muscular activity) were more significantly delayed (~200 ms). Such data support the idea that awareness of initiating a movement is not derived from any sensory signals arising from the moving limb (because such signals are not available until after the limb has started moving). Rather awareness appears to be linked, at least in part, to some signal that precedes the movement. Additional behavioral and neuroimaging experiments by this group have shown that sense of agency is also able to be modulated by subliminal priming maneuvers that affect the fluency of action selection processes (i.e., the sense that something may or may not be "wrong" when selecting or following a course of action). Thus, at least under certain circumstances, individuals' sense of agency may be more an effect of such prospective signals than an effect of the consequences of the movements themselves.

As previously noted, prediction signals are crucial in the nervous systems of organisms that are capable of movement. For human beings, who are capable of both voluntary and involuntary movement, being able to compare signals that predict the likely effects of commands arising from the motor system with sensory information acquired during movement is particularly important for adjusting movements easily and checking whether movements are being completed as planned. That is, such a system includes both feed-forward (prediction) and feedback (signal comparison) components. Haggard and colleagues (2005) suggest, however, that even earlier prospective signals involving action *selection* (and action programming) may participate along with these prediction signals and signal comparisons in acting as cues that have a role in the experience of agency. Additional research will be required to further clarify the details of these processes and the circumstances under which each may have a particularly important role.

Self-Transcendence: Nondualistic Notions of Self and Spiritual Self-Development

The ultimate experience in being human is often described by the empowerment that is experienced in connection with some force greater than our individual self. The self is thus transcended and no longer

Telegram: @medical_k

www.konkur.in

conceptually or dualistically represented in space and time. In *Varieties of Religious Experience* (1902), William James wrote, “we can experience union with something larger than ourselves and in that union find our greatest peace.” Some models of self that are rooted in a developmental perspective have focused on this uniquely human characteristic underlying self-transcendence at the top of a hierarchical structure and part of personal growth.

Self-transcendence has been used to describe contextually similar phenomenology, arising spontaneously, in connection with religious or other culturally embedded rituals, as part of meditation, yoga, or other mind–body practice, and in pharmacologically induced states such as those influenced by psychedelic pharmacy. In addition to James’ description of self-transcendence as a “religious” or “mystical” experience, self-transcendence has been operationalized in a myriad of ways, including hypoegoic states, transpersonal experiences, unitary experiences, spiritual experiences, sacred moments, epiphanic experiences, ecstatic experiences, anomalous experiences, nondual awareness, near-death experiences, persistent nonsymbolic experiences, among others. David Yaden and colleagues (2017) define self-transcendent experiences (STEs) as experiences of unity with other people or one’s surroundings, involving the dissolution of boundaries between the sense of self and “other.” Such transient mental states of decreased self-salience involve a positive relationship between self and other that transcends self-focused needs, increases prosocial dispositions (e.g., compassion, empathy, and forgiveness), and increases the frequency of nondual (subject-object) phenomenological experience. Schoenberg and Vago (2019) further elucidate states and stages of self-development common to training across styles of meditation and other mind–body practices, including yoga breathwork, bodywork, and movement-based practices. Briefly, the first stage is “neurovisceral integration” in which autonomic, attentional, and affective systems are regulated through improved inhibitory tone. A continuum of contemplative exercises that focus attention on cardiorespiratory regulation and musculoskeletal strengthening facilitate the relaxation response to arise more readily, improve embodied awareness of interoceptive experience, and gradually improve the capacity for strengthening inhibitory processes across systems. This stage of improved parasympathetic control through integration of body awareness with body movement is essential for

Telegram: @medical_k

www.konkur.in

preparing the mind for sustained concentration. The second stage is described as “concentration practices” characterized by training the mind with stable concentration and/or flexible open, receptive attention. Inhibitory control processes engage negative feedback circuits that interrupt ongoing behavior. Inhibitory circuits and coordination with frontoparietal networks facilitate rapid toggling between resources supporting conceptual, sensory, and nonconscious processes driving contextually specified demands of the situation. The next two stages of “insight” and “nondual” practices serve to integrate more abstract contemplative practices for ordinary and extraordinary insight into the nature of self, mental habits, and self-transcendence. The ultimate stage termed “unified compassion practices” describes a concrete understanding of ultimate reality where one’s formal practice transforms into everyday living, integrating the preceding tiers and insights. This is described as the highest state and stage of development where altruistic motivations for compassionate action, service to others, and unconditional love are more readily experienced. This state is similarly described in contemplative pedagogy as psychological fulfillment characterized by an “unconditional compassion or love for the world, joined with perfect insight or wisdom.”

The hypothesis here, common to many contemplative spiritual traditions, is that normal waking consciousness is a construction that we “live through” that is obfuscating with respect to the world as it truly is. That is, there is a gap between “the world as we construct and perceive it” and the “world as it truly is.” The spiritual path, from a contemplative or pharmacologically induced vantage point, is a means of reducing this gap by “cleansing the doors of perception” such that we can “see the world as it is and know it again for the first time.” While both contemplative, mind–body practices and psychedelics may disrupt self-consciousness and underlying neural processes in a phenomenologically similar fashion, there are unique differences reported, and each experience of self-transcendence is likely to involve unique mechanisms.

Psychedelics

Psychedelics are a pharmacologic technology with a mixed history, venerated as sacred medicines and vilified as narcotics with no medicinal value; yet, the profound effects on consciousness and self-representation are very well documented.

Telegram: @medical_k

www.konkur.in

Psychedelic compounds fall into two general categories: tryptamines and phenethylamines. Lysergic acid diethylamide (LSD), psilocybin, and its metabolite psilocin are classic tryptamines. *N*,*N*-dimethyltryptamine (DMT), 5-methoxy-DMT (5-MeO-DMT), ibogaine, and bufotenine are also examples of tryptamine compounds. Phenethylamine hallucinogens are amphetamine analogs such as 2,5-Dimethoxy-4-iodoamphetamine (DOI) and 2,5-Dimethoxy-4-methylamphetamine (DOM, also known as "serenity, tranquility, and peace" or STP), 2,5-dimethoxy-4-bromophenethylamine (2C-B), and mescaline. The two classes of psychedelics are structurally distinct but produce hallucinations and other psychedelic effects via serotonin-2A receptor stimulation. They are distinct structurally and mechanistically from other drugs that are often also considered hallucinogens, such as cannabinoids, N-Methyl-D-Aspartate (NMDA) glutamate receptor antagonists (ketamine, phencyclidine [PCP], dextrorphan, nitrous oxide), and kappa-opiate receptor agonists (salvinorin-A). Although structurally related, the phenethylamine hallucinogens are structurally and mechanistically distinct from the so-called "entactogenic" drugs like 3,4-Methylenedioxymethamphetamine (MDMA), which produce stimulant effects, feelings of relatedness, and elevated mood but do not produce hallucinations. Although the neurophysiology is still being characterized, it is clear that most of the classic psychedelic tryptamine compounds are agonists or partial agonists at brain serotonin 5-hydroxytryptamine 2A (5-HT_{2A}) receptors widely distributed across cortical networks, with particular importance on those expressed on apical dendrites of layer 5 pyramidal cells. There is considerable evidence demonstrating correlations between 5-HT_{2A} receptor occupancy across the FPCN-DMN and subjective intensity of psychoactive effects. Much of the self-transformative effects of psychedelics are proposed to be due to the increased excitability and neuroplastic action of 5-HT_{2A} activation, including dendritic arborization, complexity, spine growth, synapse formation, increases in brain-derived neurotrophic factor, and an increased rate of learning/extinction. Other pharmacodynamics have been identified, including activation of 5-HT_1 and 5-HT_{2C} receptors, increases in glutamate availability, agonistic and antagonistic activity at the D1 and D2 dopamine receptors, anticholinergic, kappa-opioid agonists, and activation of tryptophan metabolic pathways in the gastrointestinal tract.

Telegram: @medical_k

www.konkur.in

In 1938, while working at Sandoz laboratories, Albert Hofman synthesized the first tryptamine psychedelic, LSD, from the ergot fungus and later reported on its profound psychological effects in 1943. Shortly thereafter, the Swiss pharmaceutical company Sandoz chemicals and the National Institute of Mental Health began researching and supporting the promising therapeutic effects of LSD and the similar serotonergic psychedelic, psilocybin, as Delysid and Indocybin, respectively. These pharmaceuticals were investigated as psychiatric treatments for a variety of diseases, including end-of-life anxiety, traumatic stress, depression, and alcoholism. In 1952, Charles Savage published the first study using LSD for the treatment of depression. The word “psychedelic” was first coined by psychiatrist Humphrey Osmond in a New York Academy of Sciences meeting in 1957, drawing from the Greek words for “mind” or “soul” (psychē) and “to manifest” (delos), suggesting these drugs make manifest latent aspects of the mind. During the period of time between the 1950s and mid-1960s, approximately 1,000 clinical research studies were published on the benefits of psychedelics in psychiatric treatment, and a number of other therapeutic mechanisms were proposed. For example, one popular psychological theory described that psychedelics may weaken psychological defenses, allowing personal conflicts to surface and be worked out with a therapist. The dynamics underlying psychological processes experienced in the context of psychedelic psychotherapy were well documented by two prominent psychiatrists, Hanscar Leuner (1962) and Stanislav Grof (1972). They suggested ego-dissolution as key to the psychodynamic therapeutic process through integrating increased sensory and basic emotional activity with regression of ego functions as they emerged through autobiographic memories and autoproduction of symbolic imagery. Grof professed that the use of psychedelics in proper treatment contexts can be a revolutionary tool for psychiatry, similar to what the microscope is for biology and medicine or the telescope is for astronomy. Savage (1962) also proposed that psychedelics allowed the individual to let go of the ego, with or without volition, and experience intense existential or peak moments that facilitate long-term positive effects on behavior and attitude. One must also consider how this sense of ego or consciousness dissolution relates to similar phenomenology found in brain-lesioned patients or as might occur with meditation. Evidence for the temporary suspension of effortful cognition or spontaneous thought brought on through psychedelics or meditation may

Telegram: @medical_k

www.konkur.in

prove to be similar to the phenomenology experienced through unique agnosias or lesion-induced deficits such as athyhormia, a disorder of motivation. Initial studies have begun to explore the use of psychedelics as potential therapeutic aids for brain damage and dysfunction; yet, distinctions between these states have yet to be clarified.

Due to a combination of factors, including social stigma, poor translation of benefits, and recreational use and misuse by high-profile researchers, psychedelics became an illicit substance by 1971. After decades of prohibition, growing failures of conventional mental health care, pioneering work of the Multidisciplinary Association for Psychedelic Science (MAPS), and research from a few labs at prominent universities, a new wave of psychedelic research emerged (See Nutt & Carharhart-Harris, 2021). Models for how psychedelics function and contribute to mental health are currently evolving and describing self-related insights uniquely induced by specific chemical variants of hallucinogenic pharmacology, with targeted dose-related effects and integration with psychotherapy and other psychiatric treatment modalities. Some of the most prominent theories supporting clinical outcomes focus on increased 5-HT_{2A} receptor excitability and plasticity, increased integration, and decreased modularization of brain networks. Most recently, a randomized controlled trial investigating psilocybin versus escitalopram for treatment-resistant depression found the antidepressant response to psilocybin was rapid, sustained, and correlated with decreased DMN and FPCN modularity.

Many leaders in psychiatry now value the therapeutic potential of psychedelics in proper psychotherapeutic contexts and with proper support and training for providers. New protocols that mix psychotherapy with supervised psychedelic treatment are at various stages of randomized clinical trials. Yet, there is some cautious criticism of the growth in the industry. There are now more than 50 publicly traded companies related to the development of the administration of psychedelic-like drugs in the United States alone, with a market of $2 billion in 2020 to projected growth of over $10 billion by 2027. With the expansion of research, large growth in the psychedelic industry, and deregulation at federal levels, global brands promise a psychiatric revolution in treatment and mental health outcomes over the next decade. As of April 2021, there are more than 80 psychedelic clinical trials registered through ClinicalTrials.gov investigating either psilocybin, LSD,

Telegram: @medical_k

www.konkur.in

or MDMA with clinical psychiatric patients. These studies include treatment for anorexia, headache, obsessive-compulsive disorder, caregiver burnout, PTSD, depression, and addiction. Dosage titration has been key to this process, and data are emerging in support of such protocols across the neuropsychiatric spectrum. The “psycholytic” method uses lower doses and frequent sessions to enhance the standard psychotherapeutic process. Low-dose psychedelics, also referred to as “microdosing,” are beginning to show potential for well-being enhancement in nonclinical samples. The “psychedelic” method uses higher doses in fewer sessions to induce a mystical experience and moments of intense catharsis, enabling participants to work through and integrate difficult feelings and situations, thereby reducing anxiety and depression. As therapeutic mechanisms emerge with more clarity, and newer protocols also emerge with specific cocktails of tryptamine or phenethylamine psychedelics, the self and how it may be transformed through a neuropsychiatric lens will clearly be impacted.

FUTURE DIRECTIONS

Through growing interdisciplinary approaches, the science supporting the nature of the self and its clinical relevance to psychiatry is developing rapidly. Future translational science will leverage the results of studies emerging from neuroscience, computational and cognitive science, along with the insights from other diverse disciplines. Conceptual issues are discussed here from both historical and theoretical perspectives to inform our current understanding of the self using evolutionary, neurobiologic, and clinical perspectives. Representative scientific work provides some of the conceptual convergence in this scientific enterprise with its diverse moves toward more dynamical and multidimensional considerations of a socially and otherwise “systemically” embedded self, along with signs of where a more advanced program for a science of self might be heading.

Novel psychotherapeutic approaches introducing mindfulness, psychedelic drugs, and plant-based entheogens in appropriate therapeutic contexts provide the opportunity to advance both the science of mental health and the therapeutic relevance of the mind in and of itself. Mindfulness-oriented therapies include a focus on context, processes, and functions by which a person relates to their internal experience rather than focusing on the content of those thoughts. Mindfulness training is being

Telegram: @medical_k

www.konkur.in

used in the context of a new wave of behavioral and cognitive psychotherapy (e.g., mindfulness-based cognitive therapy) to improve clinical outcomes (e.g., depression, anxiety, pain). These new mindfulness-oriented therapies (e.g., mindfulness-based cognitive therapy, acceptance and commitment therapy, and mindfulness-oriented recovery enhancement) are referred to as third-wave therapies, supporting an evolution of traditional cognitive behavioral treatments. Psychedelic medicine is demonstrating effectiveness in augmenting the therapeutic process, offering direct insight and STEs in which to resolve maladaptive mental habits and integrate the dissolution of self-other boundaries that may improve prosocial relations with others. Yet, major challenges remain, such as scaling treatment approaches given the intensive time invested in therapist-guided treatment and the cost-prohibitive issues associated with the use of medicine that remains illegal under most international conventions. Augmentation approaches that utilize both psychedelics and mindfulness in psychiatric contexts are likely to leverage a science of self for therapeutic purposes. One recent review describes the potential synergistic effects psychedelics and mindfulness-based interventions may have through common contextual, methodologic, experiential, neurobiologic, and clinical outcomes, as well as an emphasis on insight into the nature of the self.

Brain–computer interfaces (BCIs) are promising technologies for extending the self, supplementing and augmenting cognition, remote communication and control, and social integration with games and entertainment. A powerful communication tool between users and systems, BCI promises to transcend boundaries of self-other relations, improve physical limitations found in neurologic disorders or deficits, and will likely provide a research platform from which to better understand consciousness and self-representation. Brain stimulation and physiologic sensor technology are transforming health care and the limitations of our own biology. Altering brain network dynamics and peripheral physiology through repetitive transcranial magnetic stimulation, transcranial direct current stimulation, focused ultrasound, and vagus nerve stimulation will continue to improve therapeutic opportunities and change our perception and limitations of self-functioning.

Neuroimaging and big data science methods for assessing anatomical and functional connectivity now exist in data-rich and open science collaborative networks, but they are continuing to undergo development,

Telegram: @medical_k

www.konkur.in

particularly in terms of the speed and accuracy with which the imaging data may be acquired and processed and how patterns are identified to predict outcomes through the use of machine learning analytics. Researchers and computational neuroscientists are also beginning to use this kind of data to assess patterns of connectivity disturbance and network breakdown in various developmental, degenerative, and mental disorders during passive resting states. These studies are providing preliminary markers for what constitutes robust versus disordered patterns of brain network activity, which also have implications for our understanding of neural (information) processing and self-representation. These brain network and other brain dynamical approaches are highly sophisticated and currently relatively labor-intensive techniques, however, so their ramifications for furthering the understanding of self-processing remain in their infancy.

So, while understanding “the self” in all the various and nuanced ways in which that term is used provides challenges, continued pursuit of the scientific agenda on self-processing within the limits and with some of the caveats outlined in this chapter holds promise for continued progress to enrich the understanding of mechanisms underlying many psychiatric disorders. The next generation of neuropsychiatric studies will rely heavily on clarifying some of the pertinent issues that have been identified as limitations and on new emerging technologies and methods that capture dynamic complex neural dynamics and associated physiologic and embodied phenomena underlying the nature of suffering for the human mind and some of its remediation. There is clearly increasing emphasis on mechanistic and therapeutic considerations of self-representation and associated processing for psychiatry, including insight into the experiential, autobiographical, introspective, and integrative aspects of self-experience from the third-person perspective of naturalistic science and through the phenomenology of first-person experience. Indeed, adaptive self-transformative processes across contexts of human experience may be critical to the therapeutic lens by which psychiatric treatment advances. As methods and current technologies improve, progress will be made in identifying potential biologically based diagnostic and therapeutic targets and strategies for those suffering from mental illness and clarifying our understanding related to the nature of mind and consciousness.

1.30 Learning Theory and Psychosis, Anxiety, and Addiction

PHILIP R. CORLETT, PH.D.

Associative learning theorists concern themselves with how humans and other animals learn and use information about the relationships between events. Ivan Pavlov is perhaps the most famous learning theorist; his empirical studies of anticipatory learning about food rewards in dogs gave us a framework to examine how relationships between environmental stimuli (lights, tones) and salient events (food, electric shocks) are acquired. In a curious mistranslation from his original Russian, we call this process conditioning and the cues conditioned stimuli (they ought to have been conditional, as the salient events were conditional upon those cues).

Conditioning has obvious relevance to psychiatry (which is broadly considered as the study and treatment of mental illness, emotional disturbance, and abnormal behavior), given that conditioning guides behavior and emotions—abnormal conditioning may portend emotional disturbance, abnormal behavior, and thus mental illness. Anxiety and addiction have been studied most extensively from a learning theory perspective. More recently, psychosis has been likewise investigated in learning theory terms. Given that learning theory is inherently translational studying mental illnesses from this perspective may portend a translational or reductionist understanding of mental illness. We will review the impact of learning theory on our understanding of psychosis, addiction, and anxiety. Furthermore, we shall conclude by highlighting how computational neuroscience and, thereby, computational psychiatry are grounded in learning theory.

Pavlov himself appreciated the role of conditioning in mental illness. Toward the end of his career, he sought to explain hysteria and neuroses in conditioning terms. He attributed emotional perturbations to dysfunctions in the low-level first signaling system that dealt with unconscious, preverbal associations. The verbal, second signaling system Pavlov considered to be unique to humans, and he asserted that

Telegram: @medical_k

www.konkur.in

dysfunction in the second signaling system led to psychosis. This distinction—between simple associations and complex propositions continues to be a focus of contemporary learning theory, and it may have relevance to mental illness. In the first part of this chapter, we will review the history of associative learning and learning theory addressing the development and history of learning theory.

A BRIEF HISTORY OF LEARNING THEORIES

Learning theory is sometimes referred to as associative learning theory, its currency being associations between mental concepts, although this is the subject of ongoing debate. Proponents of learning theory are sometimes called associationists.

Associationism began with Plato. Aristotle developed the concept and outlined the first associative learning theory by expounding the laws of association: **The law of contiguity**; things that occur close to each other in space or time are associated in mind. **The law of frequency**; the more often two things occur together, the more strongly they will be associated. If you think of Oliver Hardy, it is rather difficult not to think of Stan Laurel. **The law of similarity;** thoughts about one thing will trigger thoughts of similar things. **The law of contrast**, on the other hand, recollecting something will also trigger its complete opposite. When thinking of the tallest person you know, you may suddenly recall the shortest one as well.

Although John Locke is considered the first to discuss the role of improper association of ideas in mental illness, David Hartley believed that the principles of association were the fundamental operations of cognition and a means through which to relate psychology and physiology. In a neural doctrine inspired by Newton, Hartley argued that neural vibrations passing from the representation of one idea to another formed the physiologic basis for their association (preempting the contemporary Hebbian notion of neurons firing together and wiring together). Hume added cause and effect (contiguity in time) as a law of association. British empiricist philosophers rejected Descartes's notion of innate faculties. At birth, they thought of the mind as a tabula rasa—a blank slate—that accumulated ideas via sensory experience and built more complex ideas from simpler ones through the laws of association.

Pavlov was perhaps the first experimental associationist. He explored the physiologic and psychological mechanisms of association. He

Telegram: @medical_k

www.konkur.in

developed paradigms for presenting associations to experimental animals and tracking their learning, as well as theories for explaining how the cortex and subcortex underpinned that learning. Pavlov's work provided a framework for broad experimental exploration, some of which indicated that mere contiguity was not sufficient for learning. For example, Leon Kamin blocking effect. When a novel cue (e.g., a tone) is paired with a stimulus (e.g., a light) that already predicts an outcome (electric shock)—the pretrained cue—the light–"blocks" new learning about the novel cue—the tone; clearly a problem for contiguity-based theories of association.

Blocking requires that associative learning is sensitive to surprise—the degree of predictability of one associate to another modulates the formation of new associations. Hebb and Hartley's physiologic explanations of learning are driven by contiguity and hence cannot explain blocking. It seems error correction– earning from mistakes–is crucial to the formation and updating of associations. For example, an algorithm was developed to solve engineering problems using a simple connectionist neural network learned via error correction; the networks represented their inputs and outputs across distributed nodes. Associations or connections were formed and strengthened between nodes. The weights of connections between particular nodes were updated using the mismatch between the desired output from a given input and the output that actually occurred. By reducing this error signal, the network's responses to particular inputs improved—the network learned associations.

A similar algorithm was proposed to explain conditioning in rodents by Robert Rescorla and Allan Wagner. Here, environmental stimuli engender a set of expectations about potential subsequent states of the world by exciting representations of those states (e.g., the availability of food or the presence of a predator). Any mismatch, or prediction error, between those expectancies and actual experience, is used as a teaching signal to update future expectancies by changing the associative strength. They explain Kamin blocking in terms of a lack of prediction error. The outcome is already completely predicted by the pretrained cue. When the novel cue is added, there is no prediction error and hence no new learning.

Attention is also critical for associative learning. Associationists theorize that attention changes associability—the readiness with which an event or its representation (cue, outcome) can enter into associative relationships. Some theorists argue that cues that are predictably associated with

Telegram: @medical_k

www.konkur.in

important outcomes are more associable. On the other hand, stimuli with an uncertain predictive history also garner attention. Hence, cues whose outcomes were surprising in the past are allocated more attention and learned more readily. These theories are incompatible, but they are both supported by behavioral evidence. Attention must be important to association formation in different ways under different circumstances. Theories have reconciled these observations by positing a role for both confirmation and violation of expectancy in associative learning; the occurrence of an event that matches an active expectancy amplifies its representation in short-term memory, increasing the likelihood that it will be consolidated within long-term memory. By contrast, when an unexpected event violates the active expectancy, an orienting system is activated, which resets short-term memory (dropping active expectancies) and engages an orienting response, permitting the acquisition of new explanatory associations. Using both of these mechanisms, organisms learn associations between stimuli, events, thoughts, and percepts to build an internal model of their environment from which to make predictions.

Note the increasing cognitive complexity of the models beyond the formation of simple links between representations. This has been the cause for some to reject any role of associations in predictive learning and the formation of causal beliefs. Many such critics favor a propositional alternative in which directional links between concepts are formed and used to make predictive and causal inferences. Indeed, some comparative psychologists imbue the humble laboratory rat with rational inferential abilities. For some, the causal models used in inferential learning are innately specified. The British empiricist philosophers and later the behaviorists were opposed to any innate endowment; indeed, the demise of behaviorism was confirmed by Chomsky's scathing critique of Skinner's behaviorist analysis of language (and behaviorism in general) that denied any innate linguistic representations. However, across species, there are clearly certain associations that are easier to learn, some of which appear to be evolutionarily prepared and endowed upon young organisms from birth. One can conceive of mechanisms through which preparedness could be learned very early on through environmental interaction. Much more probable is the sort of neo-constructivist approach whereby a set of genetically conferred allowable connections is endowed,

Telegram: @medical_k

www.konkur.in

and then the weights of those connections are influenced by sensory experience.

We suggest that the principles of contiguity, similarity, and prediction error drive association formation and, like the British empiricists, more complex cognitive structures emerge by combining these simple representational units. There is some evidence for such an approach in human causal learning; subjects learn new causal models (propositional knowledge structures that they use to learn about causes) by minimizing prediction errors within and across possible causal models, that is, associative links can be used to form more complex causal representations and the principles of associative learning (namely minimizing prediction error) may aid decisions about which structures to impose on an inference task. We note, too, that simple connectionist architectures in which Widrow–Hoff/Rescorla–Wagner-like error-correcting mechanisms are embedded often demonstrate rather complex emergent properties akin to reasoning and inference. In some of the earliest computational models of cognition, McCulloch and Pitts elaborated upon Gottfried Leibniz, the 17th-century philosopher who attempted to create an alphabet of human thought, each letter of which represented a concept and could be combined and manipulated according to a set of logical rules. Their building block was the proposition—the simplest possible statement, either true or false. From there, they employed the fundamental operations of logic, like the conjunction (“and”), disjunction (“or”), and negation (“not”), to link propositions into increasingly complicated networks. McCulloch–Pitts networks have also been combined with Widrow–Hoff error correction in a foreshadowing of propositional causal model theory.

Causal model theories also highlight an important new direction in cognitive science, the rise of Bayesianism. Thomas Bayes was a British mathematician whose doctrine of probabilities (published posthumously in 1873) has had a striking impact on science in recent years. The theorem embodies a formal approach to reasoning about data using hypotheses and captures the probabilistic nature of many of the tasks faced by organisms; we believe a Bayesian approach to the mind and brain might bridge David Marr’s levels of analysis and achieve what Fodor thought to be impossible, a consilient understanding of cognition and its implementation in the brain. To wit, the problem faced by an organism is to predict its environment and respond appropriately. The organism’s brain

Telegram: @medical_k

www.konkur.in

does this by minimizing its uncertainty about subsequent inputs by forming and maintaining a set of prior expectancies (predictive associations) about incoming stimulation.

Such prediction error minimization is even manifest in the signaling properties of single neurons that shuttle ion channels and receptors into and out of their membranes to modulate the cell's receptivity to incident stimuli. It is also embedded in the hierarchical neuroanatomy of the brain, in which stimuli enter through sense organs, and their neural representations are communicated through the brain. Top-down expectations are communicated from areas with more abstract representations downward through the hierarchy. Any mismatch between prior expectation and current input (prediction error) needs to be dealt with. It is either canceled by the top-down expectancy or propagated and used to update subsequent expectations with new learning. The neuroanatomy and neurochemistry of backward and forward connections across cortical layers are exquisitely suited to this approach. Such a Bayesian analysis of the neurobiology of vision predicts various qualities of receptive fields in the visual cortex, such as "end stopping." Even the retinal protein signaling cascades involved in signaling light incident on the eye have been subjected to Bayesian analysis with favorable results.

The task of visual perception, conceived of as unconscious inference about current inputs based on a world model, embodies similar Bayesian principles. Indeed, the various visual illusions to which we are susceptible profoundly illustrate the overriding role of prior visual experience and expectancies on current perception. Pavlov believed that Helmholtz's unconscious inferences were aligned with his conditioned responses, an assertion realized at the algorithmic level by the use of similar Bayesian formalisms to explain Kamin blocking, perceptual learning, and visual perception. Indeed, color-after effects in the visual system appear to be influenced to some degree by selective learning. They are subject to Kamin blocking, underlining the crucial role of learning across cognitive, perceptual, and neural systems.

Taken together, these theories conceive of perception, cognition, learning, action, and belief as processes of inference about latent causes, latent causes that unite environmental stimuli and neural responses, cues and outcomes, choices and rewards. These latent causes form the basis of the associations on which associative learning theories are and, by extension, minds are predicated. Disruptions to these processes of

Telegram: @medical_k

www.konkur.in

inference can lead to perturbed world models, percepts, beliefs, and actions. In the remainder of this chapter, we shall use learning theory to explain the symptoms of psychosis, addiction, and anxiety.

Psychosis

Psychotic symptoms involve a profound departure from consensual reality, manifest as perceptual experiences (hallucinations) and beliefs (delusions) that others in one's culture do not share. We will address one of the cardinal delusions, which occurs both after neurologic injury and as a symptom of psychiatric illness. The Capgras delusion, originally termed the illusion of doubles is the belief that familiar individuals (usually family members) have been replaced by imposters. While the individual confronting the sufferer looks very much like the familiar person, they are described as subtly different in appearance, and crucially, the sufferer reports lacking the feeling of emotional recognition that characterizes our experience of those familiar to us.

First, we will explain delusions using learning theory as a theoretical framework that bridges mind and brain, perception and belief. The unit through which this bridging takes place is the association. The following processes are central to our general explanation of delusions; first, the notion of expectation and that, through experience, we learn to expect a certain set of circumstances. Second, the consequences when these expectancies are violated are either to ignore or discard the dissonant experience or to embrace it and incorporate it into our world model, engendering an updated set of expectancies. That is, when confronted with someone whose features very much resemble a loved one, we expect to feel a sense of familiarity. The absence of such a feeling induces a prediction error that demands explanation.

Absent but expected events are crucial in the phenomenology of psychosis. They contribute greatly to the feeling of delusional mood or atmosphere that attends the formative stages of delusions. In learning theory, too, absent but expected events garner new learning. Indeed, events that involve updating a causal belief about an absent but expected event engender a prediction error brain signal in the same circuit engaged when we learn beliefs about events that were actually experienced.

This error signal guides the Capgras sufferer toward a particular conclusion; that a replica has replaced their loved one. Our learning

Telegram: @medical_k

www.konkur.in

model challenges the strict distinction between perception and belief and, therefore, the necessity for two factors to explain delusions.

The prediction error model provides little insight into the exact form that the new learning will take; the particular beliefs it will reinforce. The simplest associative learning models argue that the belief formed will track the evidence experienced; that the weight given to a particular belief will be proportional to the prediction error that it minimizes. Nearly all delusions are socially relevant: they are ideas about oneself and one's relationships with others. Their content is crucially related to the individual's specific fears, needs, or security.

Also important are the particulars of past and present experiences, including personal and cultural context. Associations made in early childhood are likely critical to the specific content of delusions, though in many cases, those experiences will be difficult to identify. A recent review of associative learning mechanisms of synesthesia (associations across sensory modalities, e.g., people for whom "A" is red): though some of those people recall a red A in a much-loved set of letter magnets, for many others, it is reasonable to think that early childhood experience included this pairing. With regard to the cultural context, it was common during the cold war for persecutory delusions to involve KGB agents; now, they more commonly involve the CIA. Delusions also keep up with technology and popular culture: delusions of reference have evolved from worries about monitoring via radio and then satellite to worries about monitoring via the internet; five years ago, our patients were in The Matrix, and now they are in Transcendence associated with the delusional mood is perhaps best explained in terms of the Truman Show starring Jim Carey —in which the protagonist discovers that his life is a reality TV show and everything, every social interaction, and seemingly insignificant event, is arranged for him by a director and cast. Such experiences (perceiving others as actors wearing masks) predate the movie. However, it has become the framework through which many patients explain their delusions.

Historically, associative learning research has also failed to consider mental representations of causality, that is, going beyond how correlations are represented to try to understand how people make causal attributions. For example, how do people learn about and represent foods causing allergies or drugs causing side effects? Also, these causal relationships can be complex. For example, in the case of foods causing allergic

Telegram: @medical_k

www.konkur.in

reactions, do two foods that cause allergies interact to cause a stronger allergy? As described above, individuals bring a rich set of expectancies regarding causal interactions to bear on the causal relationships with which they are confronted and, in the presence of competing candidate causes, they make all kinds of inferences about those candidates and how they might interact. There may be minimization of prediction error within a causal model (when learning about particular cues) as well as across causal models (when forming beliefs about causal mechanisms) as beliefs form. When research subjects see implausible candidate mechanisms but strong covariation between candidate cause and effect, executive prefrontal brain regions are activated, including the left dorsolateral prefrontal cortex (DLPFC) and the anterior cingulate cortex (ACC). These regions have been shown to respond to prediction errors. A note about laterality: Devinsky has postulated, after Ramachandran and Blakeslee and according to our own data, that the right DLPFC is responsible for signaling when events have violated expectations and that the left DLPFC is responsible for generating explanations for those expectancy violations and producing the delusional narrative. In Fugelsang and Dunbar's data, the combination of an implausible theory and strong evidence in favor of that theory drives the "explanation generator" (left DLPFC) more robustly, as do delusional mood experiences during delusion formation.

One remarkable feature of delusional beliefs is their elasticity: they expand and morph to include new contradictory data. The person with Capgras, claiming their spouse is an imposter, might respond to other family members who greet the spouse warmly by saying, "*of course, they hug her [the impostor spouse]–they're in on it!"* This can be particularly difficult to understand, as the patients can often learn about other new things (they don't have an all-encompassing deficit in learning). How can associative learning, and in particular prediction error, account for delusion formation and maintenance account for elasticity?

Given their explanatory utility, delusions are rehearsed extensively. When delusions are questioned, *bringing them to mind* may actually serve to reinforce rather than disrupt the memory.

In summary, then, delusions form in response to aberrant prediction errors that imbue stimuli, thoughts, and percepts with inappropriate salience. Delusions formed to explain these experiences relieve the uncertainty associated with the prodromal "delusional mood." These

Telegram: @medical_k

www.konkur.in

beliefs are maintained in memory more strongly through cycles of recall, reactivation, and reconsolidation-based strengthening. Confronted with contradictory evidence, people are more likely to discount the evidence than relinquish the belief (whether or not it is a delusion).

In light of these challenges, we think it prudent to briefly review the burgeoning literature on belief updating in people with delusions and psychosis more broadly. This has, until recently, focused on potential biases and heuristic accounts of how people with delusional beliefs behave. For example, hasty decision-making, when confronted with evolving evidence, has been termed a jumping to conclusions (JTC) bias. Rigid anchoring of one's belief in the face of contradictory evidence is a BADE. The advent of formal computational modeling—wherein we write a generative model of participant beliefs and convolve the model with their behavior, estimating the model parameters and comparing them between groups (with and without delusions, for example). This work allows us to assess features of belief updating that may not be immediately visible from a heuristic stance. For example, JTC and promiscuous belief updating may be conceived of as a strong prior belief in environmental volatility—people with delusions (particularly paranoia) expect that reward learning tasks have an unstable generative process, and as such, they switch choices even after being reinforced. They also fail to update that volatility belief in light of the evidence they are experiencing—manifesting as a slower learning rate from volatility. Relatedly, in the perceptual domain, people with hallucinations and delusions are less sensitive to increases in volatility and thus stick with their prior perceptual beliefs—compared with healthy voice-hearers who have the string priors but can update them with alacrity when the task changes. Furthermore, even in the context of the same task, people with schizophrenia engage in "all or none" belief updating—they both jump to conclusions on some trials and fail to jump at all on others in the same session. The circumstances that lead to such updating and the mechanisms that govern are worthy of much more attention from theorists and experimentalists alike. The picture is much more complex than strong or weak priors, slow or fast updating, and it likely varies both with the task at hand, as well as the state and trait features of the participants. There is no brain region that stores our prior beliefs and no monolithic update mechanisms.

Hallucinations

Telegram: @medical_k

www.konkur.in

Hallucinations (percepts without external stimulus, often auditory and verbal in patients with schizophrenia—auditory verbal hallucinations, AVH) may be explicable in terms of aberrant associative learning. Horace Barlow, after Helmholz, pointed out the similarities between Pavlovian conditioning and the unconscious inference processes that underpin perception.

Statistical regularities abound in the world around us, and many of them are actually or potentially important for our survival. Barlow suggested that perception also adapted to statistical regularities of the environment and that, indeed, all learning can be regarded as the internalization of environmental regularities, for it is driven by the statistically regular occurrence of reinforcement following particular sensory stimuli or self-initiated actions. Helmholtz argued that perception results from the interaction of apperception–the immediate impact of sensory messages–with remembered ideas resulting from past experience. He wrote of perceptions that *"… by their peculiar nature they may be classed as conclusions, inductive conclusions unconsciously formed.*" Thus he held the view that experience of the environment was internalized or remembered and provided the basis, together with current sensory messages, for the statistical conclusions—mostly valid—that constitute our current perception of the world. These conclusions constitute symbolic working models based on the associative structure of objects and events in the environment and are therefore expressions of environmental regularities. This is similar to Tolman's notion of cognitive maps. Can those models be misappropriated to give rise to perception without stimulus?

We highlight the "*conditioned hallucination*" research, published most extensively by Douglas Ellson in the 1940s. Here, subjects believed they were undergoing a test of auditory acuity: every time they saw a lightbulb illuminate, they would be presented with an auditory stimulus. After a series of pairings between tone and light, the light was presented. Subjects reported continuing to perceive the tone. Patients who hallucinate are more susceptible to this effect, suggesting a common mechanism between pathologic and conditioned hallucinations. At first, it seems conditioning theories might have some difficulty explaining the phenomenology of AVH—for example, why are they voices rather than other sounds? Theorists like Chris Frith have proposed self-monitoring theories whereby AVH arise as a result of misattribution of inner speech to

Telegram: @medical_k

www.konkur.in

an external source. Can we reconcile prediction error and conditioning with this notion of source monitoring?

In perhaps the paradigmatic example of computational neuroscience, Wolfram Schultz has demonstrated in a series of studies that the prediction error signals that drive conditioning are generated in midbrain dopamine neurons. The signals are communicated to the striatum and prefrontal cortex via glutamate corelease, where they have a role in ascribing salience to coincident stimuli, thoughts, and percepts and determining agency for important events. Peter Redgrave argued that the dopamine signals in VTA do respond to expectancy violations. However, their role in the behavior is one of agency attribution—did I cause that surprising event to happen with my actions and is it something I want to happen again? This is achieved by discerning whether the VTA prediction error was coincident with forward models of action, reverberating representations of intended actions in the striatum. When predictions and prediction errors are disrupted, agency for actions can be misattributed externally, leading to delusions of control (feeling that one's actions are under the control of an external agent). Since speech is a motor act, it too may be generated and attributed via prediction error mechanisms, and through similar mechanisms, inner speech may be externalized.

In terms of the Bayesian brain theory, slower neuromodulators like acetylcholine and dopamine gate the impact of a particular prediction error on new learning and future percepts. It has much in common with associability in earlier learning theories or attention in more common parlance. Hallucinations may arise top-down due to higher precision-weighting of predictions such that they shape expectations in a sort of listening attitude. Exactly how that expectation more commonly gives rise to voices than other sounds remains to be established. There are some intriguing findings from functional neuroimaging studies of patients who hear voices. First, in a predictive learning task, aberrant resting activity in the auditory cortex and thus weakened responses to unexpected speech were observed in patients with auditory hallucinations. Similarly, the connectivity between Wernicke's area and Broca areas is disrupted during inner speech perception in patients who hear voices. Specifically, there is reduced input from temporal to frontal language areas in schizophrenia patients with AVH, suggesting that Broca activity may be less constrained by perceptual information received from the temporal cortex that could, in turn, prime increased top-down efforts from Broca area. Indeed, it has

Telegram: @medical_k

www.konkur.in

been suggested that reduced perceptual input triggers top-down influences in perception. With regard to speech processing, an fMRI study showed that only Broca area (BA44) was activated by unintelligible speech presented at low signal-to-noise ratios, whereas an extended frontotemporal network (Wernicke areas) was active during intelligible speech at high signal-to-noise ratios. The agency mechanism hypothesized by Redgrave and Gurney has yet to be examined in the context of speech studies in patients with schizophrenia. However, there is evidence for auditory cortex prediction error dysfunction and evidence (in healthy controls) that striatal prediction errors can train perceptual expectations in the auditory cortex. Given the growing role that linguistic representations, like propositions, have in associative learning, the links between voice-hearing and conditioning bear further investigation.

The predictive processing account of psychosis posits that hallucinations—percepts without an external stimulus—arise when prior beliefs are overweighted relative to sensory evidence so that expectations override inputs and prediction errors are discarded. According to some models, this weighting is based on the relative precision of the incoming data relative to prior beliefs. If the incoming data are less precise (i.e., they have a higher inverse variance), then inference will conform to prior beliefs, and hallucinations will result. Empirical data support this hypothesis: Participants who hallucinate tend to evince overweighting of prior beliefs in experimental tasks. For example, they can be more readily conditioned to hallucinate an absent tone on the basis of previous conditioning that tones are predicted by salient visual checkerboard stimuli. Ongoing work aims to delineate the underlying mechanisms of prior overweighting in order to better deliver pharmacologic and psychological treatments for hallucinations.

Negative Symptoms

Under a conditioning account, the negative symptoms of schizophrenia (like anhedonia, amotivation, and alogia) might occur when predictions are unreliable and sensory data are noisy. This would lead to a state in which decisions are difficult, and ultimately, actions are fruitless. One can easily imagine how such a situation would lead, for example, to the apathy and a-motivation that are debilitating, strongly associated with poor functional outcomes, and particularly poorly treated with current pharmacotherapies. Furthermore, some current pharmacotherapies

Telegram: @medical_k

www.konkur.in

interact with the specification of reward predictions and prediction errors to exacerbate negative symptoms iatrogenically, which may explain some of the unpleasant side effects of these drugs like weight gain and sexual dysfunction.

Learning theory may further shed light on the relationships between psychotic symptoms. Philosophers and clinicians have challenged the notion that delusions are even real beliefs, equating them with “empty speech acts” without manifest conviction. That is, patients with delusions espouse their beliefs verbally but do not act upon them in a manner consistent with such fantastical or terrifying claims; for example, a patient may claim that their food is being poisoned, but they will nevertheless eat it. This is termed double bookkeeping. Of course, some patients do act on their delusions with disastrous consequences, both suicidal and homicidal. The cognitive neuropsychiatric account of delusions is committed to conceiving delusions as a broken form of belief, but belief nevertheless. One answer is that even those without delusions fail to act consistently on their beliefs. Perhaps a more satisfactory explanation is that motivation plays a crucial mediating role, dictating whether we act upon our beliefs or not. Given that patients who have delusions in the context of schizophrenia often have co-occurring negative symptoms, including motivational deficits, double bookkeeping may represent a confluence of delusions and negative symptoms.

ADDICTION

Laboratory animals will self-administer drugs and learn the cues and actions that predict drug access. Those cues drive subsequent drug-seeking, even after periods of abstinence. Thus, associative models of addiction in animals have face and construct validity for human drug abuse. However, clinical research determining how human subjects learn about drug-predicting stimuli is lacking. First, there are ethical considerations when administering drugs to human subjects. Furthermore, it is difficult to know exactly what might serve as a drug-predicting cue to a human addict, for example, the places in which drugs were procured or consumed, the sight and smell of drugs and drug paraphernalia, or even the friends with whom drugs have been taken. In one study, smokers recorded the place, situation, and feeling experienced during smoking.

Telegram: @medical_k

www.konkur.in

Different contexts were associated with differing degrees of craving and enjoyment.

But how does this learning take place? Thus far, with a few notable exceptions, clinical research into cue processing in addiction has focused on exposing drug users to generic cues associated with drug use, such as stimuli from the International Affective Pictures System or dramatized video representations of cocaine consumption. However, conditioning histories are unique to each subject, and hence, these standard pictures will vary in their relevance to subjects (for example, a cocaine user may not snort their cocaine from a mirror). Nevertheless, stimuli related to the abused substance evoke neural activation in the striatum of smokers, alcoholics, and cocaine users, exactly as one would predict from the preclinical literature and from an aberrant learning and memory model of addiction (note, however, that one should be careful of making reverse inferences with functional imaging data; merely observing striatal activation in a subject does not mean that the subject was necessarily experiencing reward, motivation or engaging in learning).

Positron emission tomography (PET) scans with radiolabelled tracers sensitive to dopamine binding reveal dopamine release in the dorsal striatum in cocaine users in response to cocaine-associated cues. Alcoholics too release dopamine in the striatum in response to alcohol cues, particularly in situations when alcohol was expected but not delivered. Such expectancy violations or prediction errors may provide a strong impetus to drug-seeking and may drive new learning of Pavlovian cue-drug associations and the instrumental actions involved in drug procurement.

Learning to predict important environmental events and therefore behave adaptively toward natural rewards, aversive experiences, and other salient shifts in environmental contingencies are highly conserved across phylogeny. Drugs and drug-predicting stimuli appear to usurp the systems responsible for such adaptive anticipation, driving behavior toward anticipation and consumption of drug rewards and biasing memory consolidation toward associations between cues, drugs, and the actions that procure them, perhaps by spuriously elevating reward prediction error signals in the midbrain, striatum, and frontal cortex. These aberrant errors may drive addiction-related plasticity toward a particular behavioral repertoire, but once strongly consolidated, this learning becomes

Telegram: @medical_k

www.konkur.in

insensitive to updating and is maintained despite large discrepancies between expected and experienced reinforcement.

During the earliest phases of drug use, individuals appear to show sensitized responses to all salient events but with repeated drug use, and hence conditioning, behavioral repertoires become more and more focused on the procurement and consumption of drug rewards. This conditioned attentional orienting response (CAOR) is elicited by initial sensory processing of the cues and engenders a shift in the focus of attention toward the spatial location of drug-predicting cues. It is speculated further that the CAOR gates other drug-associated conditioned responses and Pavlovian-to-instrumental-transfer (PIT)—the energizing effect of drug-predicting cues on drug-seeking behavior, which support and constitute drug-seeking and drug-taking.

In a series of studies with smokers, Hogarth, Dickinson, and Duka have established the utility of eye-tracking as an outcome measure in studies of predictive learning in addiction. They trained a set of novel arbitrary visual cues as discriminative stimuli. That is, subjects were trained that instrumental key-press responses in the presence of these stimuli were always rewarded with smoke delivery. In a subsequent test phase, they found that subjects demonstrated preferential attention to those stimuli relative to cues that did not predict smoke delivery. There are competing theories of the role of attentional allocation in conditioning and suggestions from Hogarth and colleagues that attentional biases may differ depending on the stage of drug use and abuse.

Folk Psychology conceives of drug use as a bad habit, something in which addicts indulge despite an expressed desire not to. Preclinical behavioral neuroscience supports this conception of addiction. As described above, ascertaining whether a behavior is goal-directed or habitual involves a simple yet elegant procedure—if behavior is governed by the incentive value of a reward, then devaluing that reward (by, for example, prefeeding to satiation or associating reward consumption with gastric illness) will decrease the vigor with which an organism engages in reward-seeking behaviors. However, if behavior is habitual, it is no longer governed by a representation of reward value. Instead, it involves reflexive responses to environmental cues previously associated with drug use; hence devaluing the drug reward has no effect on behavioral choice or vigor, and the organism continues to engage in reward-seeking. Although much of this work has been conducted in rodents, recent reports

Telegram: @medical_k

www.konkur.in

have confirmed similar behavioral and neural processes are involved in human habit learning. That is, with overtraining, devaluing a particular food will not prevent human subjects from engaging in the instrumental action that procures that food, and such behavior is associated with activation in the dorsal caudate and putamen the regions aligned with habitual responding in laboratory animals.

To date, no studies have examined the neural mechanisms of associative learning where drugs are the reinforcers. However, studies using monetary outcomes associated with previously neutral cues have revealed neural differences between addicted individuals and nonsubstance-abusing controls. These studies indicate a more global dysfunction in learning and memory suggestive of rapid habit learning and insensitivity of actions to their consequences. For example, in a financial investment game, smokers' brains compute a fictive error signal (indicating what they would have won had they chosen an alternative option). However, they do not use that signal to guide their choices in the same way nonsmokers do. Likewise, alcoholics learning action choices generate striatal prediction errors, but those errors appear to not be communicated to the frontal cortex effectively such that they are not used to update action choices. Interestingly, in this study, the degree of frontostriatal dysconnectivity predicted current alcohol craving in the problem-drinking group. Of course, these effects with monetary rewards may indicate a relative lack of salience of monetary reinforcers when compared with drugs, but, nevertheless, they implicate associative learning dysfunction in the pathology of addiction. Furthermore, these studies suggest an insensitivity to the consequences of actions in addicts that resonates with the theoretical conception of habitual responding.

Some learning-based treatments for addiction have emerged. Psychotherapies based upon cue reactivity involve repeatedly exposing a client to the sights, smells, or paraphernalia associated with a substance in the absence of actual consumption, thus attenuating the power of those cues to elicit an expectation of drug effects. In other words, they no longer readily predict a "high" is coming, so the cue-drug associations are extinguished. Such therapies are often effective in the therapeutic setting, but they can fail to transfer to the real world outside of the clinic. That is, they are context-dependent.

ANXIETY

Telegram: @medical_k

www.konkur.in

Watson and Rayner (1920) originally argued that phobias are associative fears that develop when a neutral stimulus is paired with a traumatic event. They conditioned a phobia in their subject, Little Albert (a 9-month-old boy), by pairing a loud and frightening gong with the presence of a rat. It is said that the boy became afraid of white furry animals subsequently, and that fear even generalized to Santa Claus—whose beard was white and fluffy.

One criticism of conditioning theories, though, is the observation that many people with phobias do not appear to recall a specific conditioning episode. It is possible that simply observing others experiencing trauma or behaving fearfully could be sufficient for some phobias to develop. Such vicarious conditioning of a fear of snakes fear has been observed in primates. Laboratory-reared monkeys without initial fear of snakes watched unrelated monkeys reacting fearfully to snakes. The observers rapidly acquired an intense fear of snakes. This vicarious conditioning also occurred via watching videotapes of model monkeys behaving fearfully. This has interesting implications for human susceptibility to vicarious conditioning from watching movies and TV.

However, many individuals who actually have traumatic experiences do not develop phobias. There may be a genetic vulnerability rendering some individuals more susceptible than others. There are also relevant differences in life experiences that may occur before, during, or following a fear-conditioning experience, and they can affect how much fear is experienced, acquired, or maintained over time.

Latent inhibition is a conditioning phenomenon in which prior exposure to a conditioned stimulus before it is ever paired with an unconditioned stimulus retards subsequent conditioning. Children who have had more previous nontraumatic encounters with a dentist are less likely to develop dental anxiety if subsequently traumatized at the dentist's office. Likewise, monkeys that had previously seen a conspecific unafraid of snakes did not acquire that fear when they subsequently observed it.

Instrumental learning (learning to make responses rather than passively experience contingencies) is also relevant to fear conditioning and anxiety. As we have discussed so far, Pavlovian conditioning elicits fear in response to situational cues. That fear response then mediates avoidance responses. The avoidance response is maintained, according to two-factor theory, by escape from the conditioned stimulus and by an immediate reduction in its fear-eliciting properties. These ideas aided the

Telegram: @medical_k

www.konkur.in

development of behavior therapy, particularly exposure and response prevention approaches.

In addressing pathophysiologic and potentially therapeutic processes, we should also consider what happens after fear learning. Extinction refers to the well-demonstrated effect that if a conditioned predictor that engenders a response is presented alone (without the salient outcome), then response strength will decline over successive trials until the stimulus no longer elicits a response. Exposure to the cue without the traumatic outcome should allow the anxious response to extinguish, which is the basis for exposure-based treatments for anxiety.

Despite this success, conditioning as an explanation of how phobias develop has come under fire: basic conditioning theory predicts that fear should decrease over successive nonreinforced presentations of the cue. However, the opposite is often true. When someone with an established spider phobia subsequently comes into contact with spiders without traumatic consequences, fear should extinguish. Instead, spider fear increases, and it incubates. Incubation may proceed through memory reconsolidation. Reconsolidation occurs when memories are recalled into a labile state, integrated with new information, and consolidated once more. This process depends on prediction error and evokes competing processes: on the one hand, there is extinction initiated by a negative prediction error signal and engendering competing learning that overrides the original memory. On the other hand, the positive prediction error response to predictive cues leads to the reminder-based strengthening of the belief. The precise balance between these processes is driven by the magnitude, sign, and timing of the accompanying prediction error signal. Incubation may occur because of this reminder-based reconsolidation. That is, fear memories strengthen because they are reactivated, ruminated upon, reconsolidated, and laid down more strongly.

Although exposure and other interventions based on conditioning have already proved successful, it is clear that therapeutic interventions are relatively simplistic and do not incorporate, for example, the possibility for incubation. Of course, therapists already try to discern cues (e.g., in exposure therapy), but realizing that such cues might also trigger incubation and understanding the role of reconsolidation in fear memory maintenance might add to and improve our therapeutic arsenal. For example, although reconsolidation might contribute to fear of memory

Telegram: @medical_k

www.konkur.in

maintenance, it can be blocked pharmacologically and psychologically and might therefore be employed therapeutically.

SYNTHESIS AND FUTURE DIRECTIONS

Associative learning lends itself to the burgeoning field of computational psychiatry in which patients' behavioral and brain responses can be compared to and combined with algorithmic predictions of optimal performance in order to characterize which processes are related to (or are perhaps responsible for) their psychopathology. If we can characterize the underlying psychological and neural mechanism of those processes, and we can ameliorate those deficits through behavioral and pharmacologic means, it stands to reason that computational modeling (of behavioral and brain responses) in individual psychiatric patients could perhaps be used to divert patients toward particular treatment approaches that address their specific deficits. Thus far, goal-directed and habitual behavior has largely been modeled in terms of model-based and model-free reinforcement learning, respectively. These computational approaches capture the initial flexibility and outcome sensitivity (model-based/goal-directed) and its transition to inflexible stimulus-driven responding (model-free/habitual). However, many do not appreciate that, in order for these models to work, they necessitate an assumption that agents have complete knowledge of the task and environmental contingencies. This is not realistic. Rather than assuming that our subjects will learn associations (e.g., between stimuli-actions and outcomes), they instead learn beliefs or causal hypotheses—that the same causal factor leads to the stimuli and outcomes and that actions influence those factors. Hence transfer occurs because of the agent's assumptions about common causes between the factors generating the relationships between Pavlovian cues and outcomes and the factors influencing whether (and which) actions lead to outcomes. Similar latent cause models have been applied to Pavlovian conditioning and attentional allocation. Furthermore, these latent cause models can discern goal-directed and habitual behavior. We can apply these models to the behavioral and neural data generated in our studies to discern the representational structures and processes that are guiding learning in clinical disorders.

1.31 Neuroscience of Substance Use Disorders

KHALED MOUSSAWI, M.D., PH.D.

"Drug addiction" will likely remain in the current vernacular, but it fails as a medical term because it is laden with semantics and negative stigma. In particular, it is impossible to ascribe a precise point at which drug misuse can be classified as drug addiction. Likewise, "drug dependence" fails as a medical term for a disorder because dependence can be a normal physiologic response to a substance. Substance use disorder (SUD), as defined in DSM-5, solves these issues by combining the DSM-IV categories of substance misuse and dependence into a single disorder measured on a continuum from mild to severe. In DSM-5, each specific substance (hereafter referred to as "drug") class (e.g., alcohol, stimulants) is addressed separately, and diagnostic criteria are provided for three distinct drug-related phenomena: SUD, substance intoxication, and substance withdrawal. Although disorders with the majority of drugs are diagnosed based on the same overall criteria (Table 1.31–1), it is increasingly clear that chronic exposure to different drugs produces different patterns of neuroadaptations.

Clinically, severe SUD is defined as meeting six or more of the DSM-5 criteria listed in Table 1.31–1. From a neurobiologic perspective, severe

Telegram: @medical_k

www.konkur.in

SUD is a relapsing CNS disorder characterized by craving and compulsive drug seeking and taking, along with negative emotional states (e.g., dysphoria, anxiety, irritability) when access to the drug is prevented. Neural adaptations persist beyond detoxification and are responsible for craving and relapse when an individual has drug access. Research over the last four decades has significantly advanced the understanding of the neurobiology underlying SUD, which has led to improved treatments. Through the use of increasingly sophisticated experimental methods in laboratory animals and humans, detailed information from molecular to behavioral levels exists on the neural pathways that underlie each phase of the addiction process. Although animal models cannot fully reconstitute psychiatric disorders in humans, studies in laboratory animals permit investigation of specific elements of SUD. As neuroscience and psychiatry have evolved, these elements have become more concrete and tractable.

Telegram: @medical_k

www.konkur.in

Table 1.31–1.
Generic Diagnostic Criteria for Substance Use Disorder, DSM-5

1. Drug is taken in larger amounts or over a longer period than intended.
2. There is a persistent desire or unsuccessful effort to reduce drug use.
3. A great deal of time is spent in activities necessary to obtain, use, or recover from the drug.
4. Craving, or strong desire or urge to use the drug.
5. Recurrent drug use resulting in a failure to fulfill major obligations at work, home, or school.
6. Continued drug use despite persistent of recurrent social or interpersonal problems caused or exacerbated by drug use.
7. Important social, occupational, or recreational activities are given up or reduced because of drug use.
8. Recurrent drug use in situations where it is physically hazardous.
9. Continued drug use despite knowledge of having a persistent or recurring physical or psychological problem that is likely to have been caused by or exacerbated by the drug.
10. Tolerance: either a need for increased amounts of drug to achieve intoxication or desired effects, or a markedly diminished effect with continued use of the same amount of drug.
11. Withdrawal: either experiencing a drug withdrawal syndrome or taking drug to relieve or avoid the withdrawal syndrome.

As described in the DSM-5, SUDs comprise a collection of cognitive, behavioral, and physiologic symptoms suggesting that an individual continues to misuse drugs in a pathologic pattern despite adverse consequences. SUD diagnostic criteria (see Table 1.31–1) can be roughly grouped into four categories:

1. Impaired control (criteria 1 to 4)
2. Social impairment (criteria 5 to 7)
3. Risky use (criteria 8 and 9)
4. Pharmacologic (criteria 10 and 11)

PHASES OF THE ADDICTION PROCESS

The distinction between drug use, misuse, and SUD is critical to understand. Drug use includes legal use of substances such as caffeine, nicotine, and alcohol, as well as medically prescribed use of drugs such as benzodiazepines, marijuana, and opioid painkillers. Drug misuse includes illicit drug use or when a psychoactive drug is taken for nonmedical use. It is estimated that 15% to 16% of the U.S. adult population engage in drug misuse at some point in their lives. Of those, approximately 3% go on to develop SUD. Implicit in this is the idea that drug use (drug exposure) is required for the expression of SUD, wherein increasing levels of drug consumption lead to compulsive drug use despite adverse consequences.

The transition from casual drug use to SUD has been neurobiologically conceptualized as a shift from impulsive to compulsive use and hedonic dysregulation driven by a transition from positive to negative reinforcement mechanisms. Reinforcement is a motivational process by which a response-contingent delivery or removal of a stimulus increases the probability of a subsequent response. There are two forms: positive reinforcement, which is associated with euphoria (e.g., initial drug “high”), and negative reinforcement, which is associated with cessation of an aversive state (e.g., drug withdrawal). Casual drug users who go on to develop SUD display characteristics of impulse control disorders, in which there is an increasing sense of tension or arousal before the impulsive act, followed by a sense of relief or pleasure when the act is committed. Impulse control disorders are thought to involve positive reinforcement mechanisms. In contrast, individuals who meet criteria for SUD display characteristics of compulsive disorders, in which there are feelings of anxiety and stress before engaging in a compulsive and repetitive behavior, followed by relief from stress when the compulsive behavior is enacted. Compulsive disorders are thought to involve negative reinforcement mechanisms and habitual, automatic behaviors. When viewed within this psychiatric-motivational framework, the development of SUD can be described as a three-stage cycle: binge/intoxication, withdrawal/negative affect, and preoccupation/anticipation (Fig. 1.31–1). Impulsivity is most evident in the early stages, whereas compulsivity dominates in later stages. The transition from substance use to SUD

Telegram: @medical_k

www.konkur.in

involves pathologic neuroplasticity at each stage within neural circuits that regulate affective state, motor patterns, and cognition.

Binge/Intoxication

Initial drug use may begin in vulnerable individuals. However, it is difficult to study this early stage of substance use because what constitutes vulnerability and reasons for initiating drug use vary between individuals and across cultures. Furthermore, only a small subset of people (20%) who use drugs casually will develop SUD, indicating that the increased vulnerability to SUD is not universal. Indeed, the DSM-5 provides diagnostic criteria for drug intoxication that are separate from those of SUD. Whether or not a person tries a drug and what the hedonic valence of initial intoxication will be is influenced by a confluence of genetic factors, innate traits (e.g., decisional and motor impulsivity, sensation seeking, negative urgency, risk-taking), social and environmental influences (e.g., socioeconomic status, education, stress, exposure to adversity like trauma and abuse, peer pressure, drug availability), and psychiatric comorbidities (e.g., depression, anxiety). Despite these complexities, recent studies have begun to identify some of the critical behavioral and biologic markers that may predict a propensity to SUD. Animal models have been developed that reflect the innate or environmental factors thought to contribute to acquisition of drug taking. These models continue to be tested in behavioral paradigms that reflect the binge/intoxication stage of the SUD cycle (Table 1.31–2).

FIGURE 1.31–1. Diagram showing the neurocircuitry of the addiction cycle divided into three stages: binge/intoxication (*dark gray*); withdrawal/negative affect (*white*); and preoccupation/anticipation (*light gray*). The neurocircuits involved are also color coded, with the basal ganglia, including the nucleus accumbens (NAc), dorsal striatum (DS), globus pallidum (GP), and thalamus (Thal) as key elements of the binge/intoxication stage; the extended amygdala, including the central nucleus of the amygdala (AMG), bed nucleus of the stria terminalis (BNST), and a transition area in the shell of the nucleus accumbens (NAc) as key elements of the withdrawal/negative affect stage; and the frontal cortex and allocortex, including the prefrontal cortex (PFC), orbitofrontal cortex (OFC), hippocampus (Hippo), and insula (Insula) as key elements of the preoccupation/anticipation stage. Molecular, synaptic, and neurocircuitry neuroadaptations combine to render the four key elements of the transition to addiction: increased incentive salience, decreased reward, increased stress, and decreased executive function. Neuropsychopharmacology. 2014;39:254–262, Springer Nature. doi:10.1038/npp.2013.261.)

Withdrawal/Negative Affect

As substance use progresses toward SUD, periods of chronic drug use are typically followed by periods of abstinence and increasingly severe somatic and/or psychological withdrawal signs. People with SUD have described withdrawal states as a “hunger” or a primary need that is only satisfied by taking more drug (i.e., negative reinforcement). As drug use escalates and becomes compulsive in nature, neuroadaptations develop and result in executive dysfunction (e.g., decreased inhibitory control) and increased motivation for drugs that outweigh the motivation for natural rewards. Motivation is defined as the biologic, emotional, social, and cognitive forces that activate behavior, and it can be modulated by drug-induced changes in hedonic and affective states that occur with the transition from substance use to SUD. This has been conceptualized in the opponent process theory of motivation (Fig. 1.31–2). According to Solomon and Corbit (1974), “hedonic, affective, or emotional states are automatically opposed by CNS mechanisms which reduce the intensity of hedonic feelings, both pleasant and aversive.” Positive hedonic responses to drug use (i.e., euphoria, reward) occur shortly after taking the drug, correlate closely with the intensity, quality, and duration of the drug, and show tolerance. Upon drug withdrawal, negative affective states are unmasked. These are slow to develop, slow to decay, and grow in magnitude with repeated exposure to drug. In the context of SUD, opponent processes begin early in drug taking and reflect compensatory changes in the neural circuitry that controls reward and stress responses.

Temporal dynamics of affect. *Psychol Rev.* 1974;81(2):119–145. doi:10.1037/h0036128)

Preoccupation/Anticipation

Periods of drug withdrawal are followed by instances of craving and relapse, whereby various triggers such as stress, exposure to the drug itself, or previously drug-paired environmental cues reinstate drug seeking and drug taking. The subjective experience of craving frequently precedes relapse. Craving can be defined as an acquired desire characterized by wanting/anticipating drug use. Its importance is exemplified by its inclusion in the DSM-5 criteria for the diagnosis of SUD (see Table 1.31–1). In studies of people with psychostimulant use disorder, increasing levels of craving have been associated with increasing levels of anxiety, irritability, restlessness, increases in heart rate, nausea, and other

Telegram: @medical_k

www.konkur.in

symptoms that overlap with stress-related arousal and are transiently relieved with drug use.

The objective measurement of craving in the laboratory has historically presented a major challenge for researchers; however, animal models provide a variety of objective and quantifiable indices of drug-taking and drug-seeking behavior from which neurobiologic substrates of craving may be deduced. The best empirical model to study mechanisms of drug-seeking and drug-taking behavior is self-administration (intravenous [IV], vapor, or oral routes), an established operant procedure for measuring the reinforcing effects of drugs. Drug self-administration in animals meets face, construct, and predictive validity criteria. Animals contingently administer drugs akin to human drug users. IV and inhalation routes allow for rapid drug delivery to the brain and therefore are highly reinforcing. Drug self-administration studies in animals are also widely used for preclinical evaluation of putative pharmacotherapies for the treatment of SUD. Preclinical studies suggest that the underlying mechanisms and neural circuits mediating the reinforcing effects of drugs in animals overlap substantially with those mediating the drug-related effects in humans. These studies have also increased the understanding of the normal function of the neural substrates of reward-related behavior.

Clinical interventions have been successful at getting SUD patients off drugs while minimizing withdrawal symptoms (detoxification). However, clinical interventions to maintain abstinence in those patients have been of limited efficacy. Therefore, the study of the neurobiologic substrates of relapse has received particularly intense focus because this point in the cycle of SUD underlies the chronicity of the disorder, and preventing relapse is critical for successful treatment approaches. Drug self-administration paradigms have been adapted to model relapse by focusing on the reinstatement of operant behavior (i.e., lever pressing or nose poking) previously associated with drug delivery. “Reinstatement”—a common abbreviation for “reinstatement of drug-seeking behaviors”—is an animal model of drug craving and relapse. In this procedure, laboratory animals are trained to self-administer a drug of abuse and then put through either extinction training, in which operant responding is no longer paired with drug delivery, or abstinence. When predetermined criteria of operant responding under extinction conditions is achieved, the animals are tested for reinstatement of drug-seeking behavior by the presentation of a drug prime, discrete cues, contextual cues, or a stressor. Although

Telegram: @medical_k

www.konkur.in

reinstatement models in animals can be further refined to more closely approximate relapse in humans, they possess good face and construct validity for modeling the activation of drug craving and relapse produced by various stimuli in drug-dependent humans.

THEORIES OF ADDICTION

A number of theories have been proposed to explain the development and maintenance of SUD. Given the heterogeneity of the disorder (e.g., contributions of genes, environment, and the drugs themselves), it is likely that aspects of each theory are applicable under given conditions. The major theories are summarized below and framed in the context of the SUD cycle described above and in Figure 1.31–1. It is important to note that *these theories are not mutually exclusive* but rather tend to emphasize particular aspects of the SUD cycle. There is a general consensus that positive reinforcement kicks off the cycle and leads to the initial repetition of drug taking that eventually becomes habitual and compulsive.

Psychomotor Stimulant Theory

Addictive drugs share common features: they cause psychomotor activation, are reinforcing, and elicit approach behaviors. Seminal work done in the 1960s to 1980s demonstrated that the mesocorticolimbic dopamine system is a major neural substrate of the natural approach system. In this theory, people initiate and maintain drug-taking behavior because drug-induced dopamine release has reinforcing effects and activates motor systems that result in repetitive drug “approaches.”

Incentive Sensitization Theory

This theory builds upon the psychomotor stimulant theory of addiction in that drugs are hypothesized to hijack neural systems (e.g., mesocorticolimbic dopamine system) that normally motivate animals to approach salient stimuli that are important for preservation of the species (e.g., scent of prey). Contexts, cues, and other stimuli—including drugs of abuse—that activate these neural systems become tagged with incentive salience (motivational importance, “wanting”). This theory posits that repeated exposure to drugs of abuse results in persistent neural adaptations in these systems such that the animal becomes

Telegram: @medical_k

www.konkur.in

hypersensitive to drugs and to any cues that have become associated with the drug. Thus, as SUD develops, a person's motivational focus narrows to drug seeking at the expense of natural reward seeking. A key aspect of this theory is that sensitization of neural systems that control incentive salience (drug "wanting") is independent of changes in neural systems that control reward (drug "liking"). Finally, proponents of this theory argue that the systems that mediate incentive salience are distinct from those controlling drug withdrawal–induced negative hedonic states.

Aberrant Learning Theory

The increase in the incentive salience of drugs and drug cues at the expense of natural rewards is explained in the context of aberrant learning. As with incentive sensitization theory, this theory holds that repeated exposure to drugs heightens responsiveness to drug-associated cues by modulating neural systems that control normal responses to nondrug-associated cues. This aberrant learning process is thought to represent changes in associative brain structures such that drug seeking and taking becomes automatic or habitual. Evidence supports the idea that this is mediated by a gradual shift from ventral to dorsal striatal mechanisms. An important aspect of this theory is that the sensitized responsiveness to drugs and drug cues is immune to punishment, resulting in a core symptom of SUDs: continued drug use despite adverse consequences.

Frontostriatal-Dysfunction Theory

This theory incorporates mechanisms to explain the clinical observation that people with SUD tend to have poor impulse control by proposing that repeated drug exposure leads to alterations in cortical and limbic circuits such that an individual displays pathologic responses to drugs and drug cues while simultaneously displaying impaired inhibitory, "top-down" executive control over drug-taking behavior. This leads to loss of impulse control, poor decision making, heightened responsiveness to drug-associated cues, and compulsive drug use.

Hedonic Allostasis Theory

This theory is rooted in the opponent process theory of motivation and postulates that initial drug misuse is motivated by the positive

Telegram: @medical_k

www.konkur.in

reinforcement obtained from the drug's rewarding effects, whereas chronic drug misuse is motivated by the negative reinforcement resulting from the recruitment of stress-related systems and emergence of hypernegative hedonic and emotional states referred to as "hyperkatifeia." This chronic drug-induced allostatic hedonic state reflects a persistent change in the animal's normal reward set point. Hedonic allostasis contributes to compulsive drug taking through negative reinforcement mechanisms that involve circuits connecting cortical, striatal, and thalamic regions.

BRAIN PATHWAYS IN ADDICTION

There is considerable evidence from animal models and human studies that all drugs of abuse converge on a common circuitry in the brain's limbic system. Synthesizing (and simplifying) decades of work, there are three primary circuits upon which chronic exposure to all drugs of abuse acts. First, chronic exposure to addictive drugs causes a homeostatic impairment of the dopamine system, in which natural rewards (e.g., food, water, sex, social companionship) become less effective at increasing dopamine release in a typical fashion. These homeostatic changes are thought to contribute to negative affective states observed between periods of drug taking or during periods of drug withdrawal and abstinence. It is also observed that chronic, intermittent drug exposure can sensitize the dopamine system, such that exposure to the drug or drug-associated stimuli elicits greater increases in dopaminergic transmission. This sensitization of dopamine responses can persist long after drug taking ceases and may relate to drug craving and relapse. A second neural circuit common to all drugs of abuse involves the extrahypothalamic actions of corticotropin-releasing factor (CRF). Acute drug withdrawal activates CRF-containing neurons in the amygdala, which project to numerous forebrain and brainstem regions discussed below. The stress-like effects of CRF are thought to contribute to the negative affective and somatic symptoms that occur upon drug withdrawal. Another adaptation common to chronic exposure to most drug classes is reduced activity in various brain networks (e.g., salience, reward, executive, memory, habit). Of particular relevance is cortical "hypofrontality," in which there is reduced basal activity of cortical neurons and a decreased ability of natural rewards to activate certain cortical regions such as the prefrontal cortex, ACC, and orbitofrontal cortex. These cortical regions

Telegram: @medical_k

www.konkur.in

control executive function, working memory, attention, and behavioral inhibition through glutamatergic projections to the nucleus accumbens and ventral tegmental area (VTA). Chronic drug-induced neural adaptations in these frontal cortical regions and their glutamatergic outputs are thought to contribute to both impulsive and compulsive aspects of SUD.

Neural Pathways Underlying Acute Drug Reward

The DSM-5 separates substance intoxication, withdrawal, and SUD into distinct diagnostic categories. Intoxication comprises four criteria (Table 1.31–3), two of which include feelings of euphoria that occur during or shortly after substance ingestion. Although effects other than euphoria can certainly be reinforcing, this section will focus on brain pathways known to play a role in the acute rewarding effects of drugs of abuse. It is this feature of intoxication that is thought to reinforce drug taking and lead to SUD in vulnerable individuals.

Table 1.31–3.
Generic Diagnostic Criteria for Substance Intoxication, DSM-5

A. Recent ingestion of substance.
B. Clinically significant problematic behavioral or psychological changes that develop shortly during or shortly after substance ingestion.[a]
C. A minimum number of physiological/psychological symptoms that are substance-specific.[a]
D. The signs or symptoms are not attributable to another medical condition and are not better explained by another mental disorder, including intoxication with another substance.

[a]DSM-5 includes euphoria for cannabis, inhalants, opioids, and stimulants.

The discovery in the 1950s that rats would learn to press a lever to self-deliver electrical stimulation into specific brain regions (an operant behavior known as intracranial self-stimulation [ICSS]) allowed for the discovery of neural circuits involved in reward function. The efficacy of ICSS to produce brain stimulation reward is quantified by measures such as the minimum frequency of electrical stimulation that supports operant responding. Although brain stimulation reward involves multiple brain regions, the most sensitive site—defined by the lowest stimulation

Telegram: @medical_k

www.konkur.in

thresholds—is within the medial forebrain bundle at the level of the lateral hypothalamus. The medial forebrain bundle connects the VTA to the basal forebrain and carries ascending norepinephrine and dopamine monoaminergic fibers (Fig. 1.31–3). Acute administration of most drugs of abuse decreases brain stimulation reward thresholds (i.e., increase reward), whereas chronic administration increases reward thresholds during withdrawal (i.e., decrease reward). In summary, these early studies provided strong support for monoaminergic neurotransmission as a critical substrate of the reinforcing effects of drugs of abuse.

Emerging data is accumulating that mesolimbic dopamine pathway activity is required for the primary reinforcing effects of psychostimulants but has a more enabling function for other drug classes. These differences are due to the varied pharmacologic mechanisms of action of each drug class. Psychostimulants such as cocaine and amphetamine block monoamine reuptake transporters at nerve terminals to directly increase levels of dopamine and other monoamines, whereas other drugs indirectly activate mesocorticolimbic pathways (Fig. 1.31–4). Opioids, such as oxycodone and heroin, act on μ-opioid receptors in the VTA to decrease the activity of inhibitory GABA interneurons, which results in a greater release of dopamine in forebrain regions. Other drugs, including nicotine and cannabinoids, activate their respective receptors, which cause disinhibition or excitation of dopamine neurons. Drugs with more complex pharmacologic profiles, including alcohol, also lead to increased dopamine release, albeit through actions at a variety of receptor subtypes, including serotonergic, glutamatergic, and GABAergic receptors. While somewhat controversial, there are also theories that the rewarding effects of some of these substances (e.g., opioids, phencyclidine, alcohol, benzodiazepines) may be regulated by actions directly upon the medium spiny neurons of the nucleus accumbens, independent of dopamine.

The mesocorticolimbic dopamine pathway is consistently identified as a common neural substrate of all drugs of abuse. Indeed, studies in rodents have shown that all drugs with addictive potential increase dopamine release in forebrain structures such as the nucleus accumbens (see

Telegram: @medical_k

www.konkur.in

Fig. 1.31–3). The majority of dopamine cells reside in the ventral mesencephalon, particularly the VTA, and project to forebrain regions, including the nucleus accumbens, prefrontal cortex, and amygdala. As an example of the importance of this pathway in acute drug reward, it has been shown that lesioning the VTA or nucleus accumbens prevents the self-administration of drugs in rodents. Also, drugs like cocaine, heroin, or alcohol are self-administered directly into the VTA, while inhibition of dopamine neurons in the VTA suppresses drug self-administration. In general, repeated exposure to nondrug rewards (e.g., food) activates the mesocorticolimbic dopamine pathway in a consistent manner that does not result in abnormal (too much or too little) dopamine release. In contrast, drugs of abuse “hijack” this pathway such that acute drug ingestion produces dramatic and supranormative increases in dopamine release, with subsequently profound and long-lasting adaptive changes following repeated exposure to the drug and intervening withdrawal periods. The last several decades of research have identified multiple roles for dopamine: it stamps in salience to stimuli in the environment and promotes behavioral activation and performance of goal-directed behavior. The time course of dopamine signaling is also a key factor. Rapid, phasic dopamine neuronal firing encodes the reward experience and value and is necessary to learn the association of predictive stimuli with rewards and punishers. On the other hand, tonic firing of dopamine neurons determines the overall motivational state in responding to learned cues.

Telegram: @medical_k

www.konkur.in

FIGURE 1.31–4. Simplified schematic of converging acute actions of drugs of abuse on the VTA–NAc pathway. Stimulants directly increase dopaminergic transmission in the nucleus accumbens (NAc). Opiates indirectly increase dopaminergic transmission in the NAc by inhibiting GABAergic interneurons in the ventral tegmental area (VTA), which disinhibits VTA dopamine (DA) neurons. Opiates also act directly on μ-opioid receptors on NAc neurons. μ-Opioid receptors, like D2 dopamine receptors, signal via the inhibitory G-protein Gαi; hence, the two mechanisms converge within some NAc neurons. The actions of other drugs of abuse remain more conjectural. Nicotine seems to activate VTA dopamine neurons directly via stimulation of nicotinic cholinergic receptors on those neurons and indirectly via stimulation of its receptors on glutamatergic nerve terminals that innervate the dopamine cells. Alcohol promotes GABAA receptor function, which may inhibit GABAergic terminals in the VTA and hence disinhibit VTA dopamine neurons. It may similarly inhibit glutamatergic terminals that innervate NAc neurons. Many additional mechanisms (not shown) are proposed for alcohol. Cannabinoid mechanisms are complex and involve activation of CB1 receptors (which, like D2 and μ-opioid receptors, are Gαı linked) on glutamatergic and GABAergic nerve terminals in the NAc, and on NAc neurons themselves. Phencyclidine (PCP) may act by inhibiting postsynaptic NMDA glutamate receptors in the NAc. Finally, there is some evidence that nicotine and alcohol may activate endogenous opioid pathways and that these and other drugs of abuse (such as opiates) may activate endogenous cannabinoid pathways (not shown). PPT/LDT, peduncular pontine tegmentum/lateral dorsal tegmentum. (Reprinted from Nestler E. Is there a common molecular pathway for

Telegram: @medical_k

www.konkur.in

addiction? *Nat Neurosci*. 2005;8:1445–1449, Springer Nature. doi: 10.1038/nn1578.)

The nucleus accumbens is a small subcomponent of the ventral striatum that is a substrate for both dopamine-dependent and dopamine-independent drug reinforcement. The nucleus accumbens receives information related to hedonic states from glutamatergic afferents originating in the amygdala, frontal cortex, and hippocampus and converts it to motivational action via connections with the extrapyramidal motor system. Glutamate neurotransmission is tightly regulated: too much or too little can have deleterious effects (e.g., cytotoxicity), whereas stimulus-dependent changes in glutamatergic transmission are necessary for learning and behavioral engagement. Indeed, a long-standing concept is that the nucleus accumbens is a "motivation to movement interface." The nucleus accumbens itself can be subdivided into core and shell regions whose functional connectivity and neuronal phenotypes reflect this functional integration of motivation to movement. The shell has an important role in acute drug reward, motivated behavior, behavioral sensitization, and changes in affective state. The core is a central portion of the ventral striatum and is a functional continuation of the neighboring, motor-related dorsal striatum.

Neural Pathways Underlying Tolerance and Withdrawal

When drugs are used repeatedly over time, tolerance may develop. Tolerance is defined as a reduced sensitivity to the drug effects (e.g., euphoria) such that a higher dose of the drug is required to achieve the same level of response achieved initially. Importantly, the development of tolerance is not equivalent to addiction. In the context of addiction, tolerance engages mechanisms that serve to oppose reward and, paradoxically, reinforce drug-seeking behavior. Opponent process theory has been used as a framework to understand tolerance and the transition from occasional drug use to addiction: immediate rewarding effects of a drug are followed by delayed aversive effects that are due to drug-dependent recruitment of opponent processes (see Fig. 1.31–2). These aversive effects emerge in force during drug withdrawal and include acute and protracted aversive states, including anxiety, anhedonia, irritability, and depressed mood that resemble MDD. The mechanisms underlying tolerance to drugs and opponent processes occur at the molecular,

Telegram: @medical_k

www.konkur.in

cellular, and circuit levels and can be classified as within- or between-system adaptations.

A primary example of a “within-system” neural adaptation to chronic drug administration is hypofunction of the mesocorticolimbic dopamine system during withdrawal, which leads to decreased motivation for nondrug-related stimuli and increased sensitivity to, and motivation for, the misused drug (see Fig. 1.31–3A). Consistent with hypofunction of mesocorticolimbic dopamine systems, psychostimulant withdrawal in humans is associated with fatigue, depressed mood, and sluggishness, and in animals is associated with decreased motivation to work for natural rewards and decreased locomotor activity. Similarly, withdrawal from chronic opioids essentially unmasks all the neural adaptations the brain produced in its attempts to equilibrate in the presence of drug. Consequently, neural circuits regulating everything from gastrointestinal function to affective states are instantly unbalanced, and an opioid withdrawal syndrome emerges. One cause of affective withdrawal signs, such as anxiety, dysphoria, depression, and irritability, is thought to be the reduction in dopamine neuron firing and dopamine release in efferent targets such as the nucleus accumbens.

Despite the long tenure as the “reward centers” of the brain, increasing evidence supports the idea that the nucleus accumbens and ventral pallidum are bivalent structures that process positive and negative environmental stimuli into either approach or avoidance behavior. Electrophysiologic data collected over the last several years have shown that the nucleus accumbens may encode aversive states via increases in firing rates of intrinsic medium spiny neurons and that individual nucleus accumbens neurons can track the hedonic valence of a stimulus by varying their firing-rate response to it. In the ventral pallidum, appetitive versus aversive stimuli are encoded by different neuronal populations, namely GABA versus glutamate neurons, respectively. This has important ramifications for understanding addiction since drugs of abuse provide hyperbolic positive (drug “high”) and negative (drug withdrawal, “crash”) emotional signals to the nucleus accumbens and pallidum, and since drug addiction is characterized by insensitivity to aversive outcomes.

Between-system neuroadaptations also contribute to tolerance and withdrawal syndromes. These involve neurochemical systems different from those directly targeted by drugs of abuse, such as norepinephrine, CRF, orexin, dynorphin, substance P, vasopressin, neuropeptide Y (NPY),

Telegram: @medical_k

www.konkur.in

endocannabinoids, orphanin, and many others. The extended amygdala, which is composed of the central nucleus of the amygdala, bed nucleus of the stria terminalis (BNST), and a medial portion of the nucleus accumbens shell, represents a common anatomical substrate that integrates stress and reward systems to produce drug withdrawal—induced hyperkatifeia and promote negative reinforcement processes associated with the development of SUD (see Fig. 1.31–3A). Engagement of the extended amygdala is one mechanism by which the brain attempts to restore normal function despite the chronic presence of drug. The stress peptide CRF mediates stress responses of both the HPA axis and the extended amygdala, and CRF is released during withdrawal from all major drugs of abuse. In summary, drug withdrawal is associated with within-system decreases in mesocorticolimbic dopamine activity and between-system recruitment of stress-like neurotransmitter systems.

Chronic exposure to drugs of abuse increases the activity of CRF and dynorphin systems within mesocorticolimbic and extended amygdala circuits. In general, CRF and dynorphin produce states that have characteristics of both withdrawal and stress. Dynorphin binds to and activates κ-opioid receptors (KORs), and CRF binds to and activates CRF type 1 and 2 receptors (CRF_1-R, CRF_2-R) in the brain. KOR activation in mesolimbic structures, including the VTA and nucleus accumbens, decreases dopamine transmission, whereas the effects of CRF are more complex. On balance, evidence supports a serial CRF to dynorphin directional relationship between the two stress peptide systems such that stress triggers CRF release, which then functions to increase dynorphin release and subsequent activation of the KOR system within neural stress circuits. Withdrawal from drugs of abuse can be conceptualized as a stressor that causes a dysphoric state encoded by CRF and dynorphin release. This is supported by studies showing that CRF infusions into the VTA can trigger reinstatement of drug seeking—perhaps through activation of dopamine neurons—and CRF antagonists reduce stress-induced but not drug-induced reinstatement of drug seeking. Similarly, KOR antagonism blocks the development and expression of cocaine withdrawal–induced anhedonia and attenuates the expression of nicotine and morphine withdrawal signs in rats. KOR-induced dysphoria is thought to enhance the rewarding valence of drugs of abuse—although empirical evidence centers primarily on psychostimulants. This role of KORs in addictive behavior has been expanded to include a role in stress-induced

Telegram: @medical_k

www.konkur.in

reinstatement of drug seeking. In rodents, KOR antagonism and genetic deletion of the dynorphin gene block stress-induced, but not cocaine prime-induced, reinstatement of drug seeking.

Neural Pathways Underlying Substance Use Disorder

Impaired Control (Impulsive → Compulsive Use). Repeated exposure to drugs results in potentiation of the pathway between the prefrontal cortex and D1-receptor–expressing medium spiny neurons in the ventral striatum. This is thought to underly the invigoration of drug-seeking behaviors after repeated drug exposure. Another aspect of the development and progression of SUD is the transition from voluntary (goal-oriented, model-based) to habitual (model-free) and compulsive drug use with repeated drug exposure. Recent data show this is encoded through drug-dependent transitions from ventral to dorsal striatal control over drug-seeking and drug-taking behaviors (Fig. 1.31–5). This has been demonstrated in stimulants, nicotine, and alcohol SUDs. The basic organization of cortical inputs to the striatum comprises a functional gradient from limbic to associative to motor domains. A similar gradient is found in the midbrain to nucleus accumbens connections. There is topographical organization such that a medial (i.e., shell) to lateral (i.e., core/dorsal striatum) series of projection loops allows emotion-based information from limbic-associated structures to transfer to motor-related areas of the basal ganglia. It has been conceptualized that the nucleus accumbens (ventral striatum) is an especially critical substrate for the rewarding drug effects that contribute to the development of SUDs, whereas the dorsal striatum is an especially critical substrate for the motor habits that maintain SUDs. This phenomenon of a transition from voluntary to habitual drug use as SUD develops was shown to be associated with increased activity in the orbitofrontal to medial dorsal striatum circuit, which is thought to reflect the overestimation of drug value relative to associated adverse outcomes. Such findings are broadly consistent with functional neuroimaging studies in humans showing increased dopamine release and cue reactivity in the dorsal striatum in patients with alcohol or stimulant SUD, but increased dopamine release and cue reactivity only in the ventral striatum in subjects who use drugs recreationally.

In summary, the connections among prefrontal cortex, the striatum, and midbrain dopamine neurons are organized in an ascending spiral that

Telegram: @medical_k

www.konkur.in

creates a feed-forward organization from reward-related regions of the striatum to cognitive and motor areas. Importantly, the neural networks underlying the transition from voluntary to habitual drug use are drug dependent. For example, it has been shown in heroin self-administration studies that information in ventral medial cortical to ventral and dorsal striatal circuits may be processed in parallel rather than in a spiraling, feed-forward series.

Craving. Drug craving is an important construct in addiction, and it is now included in the DSM-5 as a clinical symptom of SUD. Craving can be defined as an acquired desire characterized by wanting to use drug in that moment. Drug craving is evident after chronic drug use, along with the associated increased salience of drug and drug cues. Clinical studies show that acute increases in anxiety or distress that occur during periods of drug abstinence or withdrawal do not in themselves predict drug relapse as proposed in models of negative reinforcement. Rather, concomitant increases in aversive states and drug craving predict subsequent drug taking and relapse.

Craving is difficult to study in animal models of SUD as it is a highly personal and subjective, emotion-based state. Recent advances in neuroimaging techniques and ecologic momentary assessment approaches to studying craving and drug use episodes in real time in individuals with SUD have allowed identification of neural circuits involved in craving. While activity in different brain networks is reduced in SUDs in a nondrug context (e.g., salience, reward, executive, memory, habit networks), exposure to drug cues results in a significant increase in neuronal activity of these circuits, which is referred to as cue reactivity and has been shown to be correlated with craving. Similarly, stress-induced craving activates the different brain circuits.

FIGURE 1.31–5. Diagram of the organization of striatonigralstriatal (SNS) projections that comprise spiraling limbic–motor loops. The colored gradient in rostral and caudal schematics of the striatum illustrates the organization of functional corticostriatal inputs (*white* = limbic, *light gray* = associative, *black* = motor). The shell receives forebrain input primarily from the amygdala, hippocampus, and cortical areas 25 and Ia. The core receives input from the entire orbital and medial prefrontal cortex (OMPFC). The dorsolateral prefrontal cortex (DL-PFC) projects to the central striatum and premotor and motor cortex project to the dorsolateral striatum. Midbrain projections from the shell target both the ventral tegmental area (VTA) and ventromedial substantia nigra pars compacta (SNc) (*white arrows*). Midbrain projections from the VTA to the nucleus accumbens shell form a "closed," reciprocal SNS loop (*white arrow*). Projections from the medial SN feed forward to the nucleus accumbens core forming the first part of a spiral (*dark gray arrow*). The spiral continues through the SNS projections (*light gray arrows* and *dotted arrows*) with pathways originating in the core and projecting more dorsally (*black*

Telegram: @medical_k

www.konkur.in

arrows). In this way, ventral striatal regions influence more dorsal striatal regions via spiraling SNS projections. Magnified oval region shows a hypothetical model of the synaptic interactions of SNS projections in reciprocal versus feed-forward loops. The reciprocal component (*white arrows*) of each limb of the SNS projection terminates directly (a) on a dopamine cell, resulting in inhibition. The nonreciprocal, or feed-forward, component (*dark gray arrow*) terminates indirectly (b) on a dopamine cell via a GABAergic interneuron (*light gray cell*), resulting in disinhibition and facilitation of dopaminergic cell burst firing. IC, internal capsule; S, nucleus accumbens shell; SNr, substantia nigra, pars reticulata. (Reprinted from Haber SN, Fudge JH, McFarland NR. Striatonigrostriatal pathways in primates form an ascending spiral from the shell to the dorsolateral striatum. *J Neurosci.* 2000;20(6):2369–2382. doi:10.1523/JNEUROSCI.20-06-02369.2000. Relapse. A major problem in the treatment of SUD is relapse to drug use even after periods of abstinence. Unlike craving, which is difficult to model in laboratory settings, the phenomenon of relapse is well modeled in laboratory animals using the reinstatement procedure (described above). Evidence from animal studies suggests that neural circuit changes associated with drug- and cue-induced reinstatement after extinction of operant responding for drug are linked to glutamatergic projections from the prefrontal cortex to the nucleus accumbens core, dopamine projections from the VTA to the medial prefrontal cortex, and GABA projections from the nucleus accumbens to the ventral pallidum. In contrast, stress-induced reinstatement of drug-seeking depends more on activation of CRF and norepinephrine systems within the extended amygdala.

Drug-Primed Relapse. Small doses of a misused drug (often called “priming”) can initiate subjective states of drug desire that prompt renewed drug consumption in humans. Early studies indicated that dopamine neurons in the VTA and glutamatergic neurons in the prefrontal cortex (prelimbic, anterior cingulate, media) that project to the nucleus accumbens shell and core, respectively, play critical roles in cocaine- and heroin-induced reinstatement of drug seeking. Indeed, a key feature of the circuitry underlying cocaine and heroin seeking is enhanced glutamate release into the nucleus accumbens core by afferents from the prelimbic cortex. Inhibiting α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA)-type glutamate receptors or activating presynaptic GluR2 autoreceptors in the nucleus accumbens core blocks both cocaine- and

Telegram: @medical_k

www.konkur.in

cue-induced cocaine seeking. Dopamine transmission within mesocorticolimbic circuitry is also required for drug-primed relapse as blockade of dopamine D1 receptors in the medial prefrontal cortex decreases reinstatement. Additional brain areas have been implicated in drug-primed reinstatement through reversible, pharmacologic inactivation studies. These include the ventral subiculum, ventral pallidum, and central and basolateral amygdala.

Converging evidence from all domains of neuroscience research on addiction highlights the point that the actions and consequences of different drug classes can be distinct from one another. As a case in point, the neural circuitry that underlies heroin-primed reinstatement of heroin seeking has both distinct and overlapping components. Compared to cocaine-primed reinstatement, a more diffuse circuit appears to be engaged during heroin-primed reinstatement because inactivation of multiple cortical and limbic structures abolishes reinstatement of heroin seeking. Some of these heroin-specific brain regions include the substantia nigra, BNST, and mediodorsal thalamus. Furthermore, dopamine has distinct roles. It has been shown that blockade of D1 or D2 dopamine receptors in the nucleus accumbens prevented heroin- and cocaine-primed reinstatement of drug seeking.

Conditioned Cue–Induced Relapse. In the animal model of conditioned cue–induced reinstatement of drug seeking, several lines of research have implicated corticostriatolimbic pathways in the development and maintenance of drug–cue associations that drive drug-seeking behavior after periods of withdrawal. Of particular interest has been the amygdala, which is well established as a critical structure in the learning of affectively relevant stimuli for both appetitive and negative reinforcers. Studies have found that permanent excitotoxic lesions or temporary pharmacologic inhibition of the basolateral amygdala does not affect cocaine taking during daily cocaine self-administration but abolishes the reinstatement of cocaine seeking produced by drug-paired cues long after the cessation of drug self-administration. Additional studies have demonstrated that amygdala modulation of conditioned-cued reinstatement is dopamine dependent. Blockade of dopamine D1 receptors in the amygdala blocks cue-induced reinstatement, whereas increasing dopamine signaling in the amygdala during cue presentation potentiates cocaine seeking.

Telegram: @medical_k

www.konkur.in

Discrete subregions of the prefrontal cortex (anterior cingulate and prelimbic cortex) and striatum are also involved in conditioned cue-induced reinstatement. Pharmacologic inactivation of the dorsal medial prefrontal cortex, the lateral orbitofrontal cortex, or the nucleus accumbens core attenuates cue-induced cocaine seeking. Similarly, lesions or inactivation of the ventral pallidum inhibits relapse to drug seeking. The amygdala, prefrontal cortex, ventral pallidum, and nucleus accumbens core circuitry in the animal model of cue-induced relapse shows striking homology with data from humans. Brain imaging studies in cocaine-dependent human subjects have shown that cocaine-paired cues increase metabolic activation of the amygdala, the anterior cingulate region of the cortex, the nucleus accumbens, and the orbitofrontal cortex.

While limited in scope, imaging studies on the neural circuitry of cue-induced relapse in humans have generally found overlapping patterns of brain activation of cortical and limbic structures across various drugs of abuse, including methamphetamine, alcohol, opioids, and nicotine. In rodent models, the amygdala is necessary for both heroin- and methamphetamine-paired cue-induced relapse in animal models. However, a more diffuse circuitry is engaged during heroin-paired cue reinstatement, suggesting mechanistic differences that can be best parsed out in animal models.

In humans, craving and relapse can occur after prolonged periods of abstinence. For unknown reasons, drug craving waxes and wanes over time. In an attempt to account for temporal oscillations of craving and the persistent capacity for relapse, it was hypothesized that cue-induced drug craving progressively increases over time during abstinence and can remain high over several months (>6 months). This effect was first described in the context of alcoholism and was called the “alcohol deprivation effect.” More recently, this effect has been more broadly conceptualized as “incubation of drug craving” and can be modeled in rodents, as shown by time-dependent increases in cue-induced cocaine or heroin seeking that occur after withdrawal from the drug. Many of the same brain regions implicated in cue-induced reinstatement of drug seeking (discussed above) also contribute to incubation of drug craving. In the first few days of withdrawal, the number of silent synapses increases; these synapses contain NMDA but not AMPA glutamate receptors and hence are not active under normal synaptic transmission conditions. However, these silent synapses are then “filled” with the high-conductance

Telegram: @medical_k

www.konkur.in

calcium-permeable AMPA glutamate receptors resulting in potentiation of glutamatergic synapses in the ventral striatum medium spiny neurons. This finding of increased expression of calcium-permeable AMPA receptors is one of the most robust drug-induced adaptations associated with incubation of craving. In addition, increased neuronal activity has been demonstrated in the ventral medial prefrontal cortex, nucleus accumbens core, and central nucleus of the amygdala when drug craving —as assessed in reinstatement tests after 1 or 30 days of drug withdrawal (extinction)—is measured.

Stress-Induced Relapse. Stress plays a role in all facets of drug misuse and SUD. People with SUD have an increased behavioral sensitivity to stress, even after prolonged abstinence, which supports the clinical relevance of negative emotionality and hyperkatifeia for relapse. By definition, stress is the nonspecific response of an organism to any demand (stressor) placed upon it that requires adaptation. Stressors typically engage the HPA axis to produce physiologic and emotional responses. The biologic effects of stress are relatively hardwired and can be measured objectively, whereas emotional effects can depend on an individual's perception of their ability to cope with the stressor and are, therefore, more subjective. A popular conceptualization of stress is that it is a constellation of negative, depressive-like emotions (anhedonia, anxiety, irritability, feeling overwhelmed) that should be avoided, although stimuli that would seem to qualify as stressors can be experienced as positive or even thrilling (e.g., new job, skydiving). Controlled laboratory studies in patients with SUD have shown that drug craving can be elicited by stressors and that this stress-induced response predicts relapse. The fact that the same stressor may trigger pleasure in one individual but aversion in another has made it very difficult to develop blanket "antistress" pharmacotherapeutics as a panacea for addiction treatment.

Part of the circuitry required for drug-primed or conditioned cue–induced reinstatement of drug seeking is also necessary for stress-induced reinstatement, including the prelimbic cortex and nucleus accumbens, as well as structures within the extended amygdala. Inactivation of BNST and central, but not basolateral, amygdala attenuates stress-induced reinstatement. For intermittent footshock-induced reinstatement, studies indicated a role of CRF and glutamate in the VTA and a role of CRF projections from the central amygdala to the

Telegram: @medical_k

www.konkur.in

BNST. Central infusions of CRF produce reinstatement, whereas CRF receptor and ionotropic glutamate receptor antagonists block stress-induced reinstatement of cocaine and heroin seeking, as do noradrenergic α_2-receptor agonists.

Numerous other neurotransmitter systems known to play a role in stress responses likely contribute to stress-induced relapse. For example, enhanced vulnerability to stress during withdrawal and protracted withdrawal may be due in part to a hypodopaminergic state in the mesocorticolimbic system. Drug dependence and early drug withdrawal have been associated with decreased dopamine levels and dopamine receptors in limbic areas such as the nucleus accumbens. Reduced tonic dopamine levels during withdrawal may provide a better contrast, or "signal-to-noise ratio," to a phasic dopamine signal in response to a stressor. As discussed earlier, the neuropeptide dynorphin is increased with chronic drug administration and acts at KORs on dopaminergic nerve terminals to decrease dopamine release. This raises the possibility that chronically elevated dynorphin expression and release could contribute to drug withdrawal–induced hypodopaminergic state and increased stress sensitivity. Consistent with this, blockade of KORs in the VTA with the selective antagonist nor-BNI decreases swim stress–induced reinstatement of cocaine seeking in rats. A summary schematic of the shared and distinct neurocircuitry for the reinstatement of drug-seeking behavior produced by conditioned cues, drug priming, and stress is illustrated in Figure 1.31–6.

CELLULAR AND MOLECULAR SUBSTRATES OF ADDICTION

Defining SUD as a relapsing CNS disorder accompanied by adaptations in the brain that persist beyond detoxification and are responsible for continued drug use, craving, and relapse require identifying and understanding such neural adaptations. This has proven to be difficult, as chronic exposure to drugs of abuse elicits a plethora of cellular and molecular adaptations that vary depending on the type and route of administration of the drug, the brain region studied, developmental history, and biologic sex, to name a few. A current struggle is understanding how different drug classes (e.g., psychostimulants and opioids) can produce similar behaviors but seemingly different molecular and cellular

Telegram: @medical_k

www.konkur.in

adaptations. Following are a few representative examples of drug-induced neuroadaptations and current theories on their functional significance. This is a rapidly changing field of study with extraordinarily high stakes: development of effective SUD treatments.

Gene Expression

The majority of studies examining drug-induced molecular changes have focused on the mesocorticolimbic system (VTA, nucleus accumbens, prefrontal cortex) and the consequences of altered dopamine signaling. As discussed above, a common initial action of all drugs of abuse is an increase in extracellular dopamine levels in the nucleus accumbens. Dopamine binds to and activates D1- or D2-like G-protein–coupled dopamine receptors, which leads to either stimulation or inhibition, respectively, of adenylate cyclase and cyclic adenosine monophosphate (cAMP) production. As a molecular second messenger, cAMP has multiple intracellular effects, including activation of cAMP-dependent protein kinase A (PKA) and subsequent phosphorylation of an activating site on cAMP response element-binding protein (CREB), a transcription factor (Fig. 1.31–7). As such, a reliable acute effect of most drugs of abuse is modest D1-receptor–mediated CREB phosphorylation in the nucleus accumbens. More importantly, for the development of SUD, chronic administration of drugs of abuse produces compensatory adaptations in cAMP-PKA signaling pathways. Repeated exposure to cocaine, amphetamine, or opioids significantly induces CREB activity in the nucleus accumbens, whereas alcohol and nicotine reduce CREB phosphorylation in this region. Drug-induced modulation of CREB activity is not limited to the nucleus accumbens. For example, acute morphine binds to inhibitory μ-opioid receptors and inhibits CREB phosphorylation in the locus coeruleus, a brain region important for opioid physical dependence and withdrawal. This inhibition undergoes tolerance with chronic morphine exposure due to compensatory upregulation of adenylate cyclase–mediated cAMP production and activation of PKA. Upon morphine withdrawal, this upregulated cAMP/PKA pathway results in a spike in CREB activation, which is thought to contribute to withdrawal signs. Finally, there is evidence that chronic administration of several drugs of abuse activates CREB in the VTA, an effect that directly impacts dopamine synthesis and excitability of VTA dopamine neurons. CREB induces expression of tyrosine hydroxylase (TH), the rate-limiting enzyme

Telegram: @medical_k

www.konkur.in

in dopamine biosynthesis, in the VTA. Despite increased TH gene expression in the VTA, decreased levels of TH protein and/or activity have been reported in VTA nerve terminals in the nucleus accumbens under certain experimental conditions. Decreases in TH protein levels could mediate chronic drug-induced hypodopaminergic states and emergence of negative affective states.

Although CREB phosphorylation is a transient effect on the order of minutes, repeated brief activations of CREB trigger numerous changes in the neuronal transcriptome that, in turn, cause significant alterations in the physiology of individual cells as well as the circuits in which they are embedded. Some examples of CREB-regulated genes that likely play important roles in SUD include other transcription factors such as c-Fos, intracellular messengers (e.g., adenylate cyclase VI. VIII), neurotransmitter biosynthetic enzymes (e.g., TH), peptide neuromodulators (e.g., CRF and somatostatin), growth factors (e.g., brain-derived neurotrophic factor [BDNF]), opioid peptides (e.g., dynorphin and enkephalin), and neurotransmitter receptor subunits (e.g., GluR1) (see Fig. 1.31–7). The behavioral effects of chronic drug-induced activation of CREB in the nucleus accumbens tend to be similar across drugs. Increased CREB activity in the nucleus accumbens decreases behavioral responses to cocaine, opioids, and alcohol, whereas decreased CREB activity increases such responses. This finding, which has been observed in many experimental systems with a variety of methods, has led to the hypothesis that nucleus accumbens CREB activation is a molecular opponent process engaged to counteract the continued presence of drug. In support of this hypothesis, CREB-induced dynorphin activates KORs on VTA dopamine neurons and their nerve terminals, resulting in decreased dopaminergic tone and opposition of drug reward in the presence of drug or production of negative affective states in the absence of drug (i.e., withdrawal).

Telegram: @medical_k

www.konkur.in

FIGURE 1.31–7. Simplified depiction of how extracellular signals influence gene transcription via CREB. Phosphorylation of CREB at ser133 increases its transcriptional activity and target gene expression. CREB activity can be attenuated by phosphorylation of CREB at ser142. Within the nucleus accumbens (NAc), neurons expressing Gαs-coupled receptors (e.g., dopamine D1) activate adenylate cyclase (AC), whereas neurons expressing Gαi/o-coupled receptors (e.g., dopamine D2) inhibit AC. Exposure to drug-induced increases in dopamine in the NAc can also trigger activation of MAPK- and calcium- (Ca^{2+}) sensitive signal transduction pathways. For clarity, cross-talk between second messengers is not included. *Black lines* signify activation; *gray lines* signify inhibition. (Reprinted with permission from Muschamp JW, Carlezon WA, Jr. Roles of nucleus accumbens CREB and dynorphin in dysregulation of motivation. *Cold Spring Harb Perspect Med*. 2013;3(2):a012005.© Cold Spring Harbor Laboratory Press. doi:10.1101/cshperspect.a012005.)

In addition to CREB activation, drugs of abuse activate other transcription factors, including members of the Fos protein family (c-fos, FosB, Fra-1, and Fra-2) and NAC-1 in the nucleus accumbens. Direct involvement of these gene products in acute drug reward is doubtful, as this depends upon more immediate signaling events associated with

Telegram: @medical_k

www.konkur.in

dopamine and opioid receptor stimulation. ΔFosB, a highly stable form of FosB, has been shown to accumulate over time with repeated administration of virtually all classes of drugs of abuse. Animals in which ΔFosB is activated have been shown to have exaggerated sensitivity to the rewarding effects of morphine and cocaine. This has led to the hypothesis that ΔFosB may be a sustained molecular “switch” that helps to initiate and maintain a state of addiction. As with CREB, ΔFosB itself does not contribute to cellular functioning but facilitates transcription of numerous genes that encode proteins involved in neural plasticity. Taken together, the current understanding of how drugs of abuse modulate gene expression comes primarily from studies that focus on one drug class (e.g., psychostimulants or opioids). A postmortem study in people with cocaine and heroin use disorder showed that out of approximately 39,000 gene transcripts that were investigated in the nucleus accumbens, only 25 genes had altered expression in both cocaine and heroin users. For about half of these genes, the drugs had opposite effects on expression.

A final example of how drugs of abuse regulate gene expression is the finding that drugs of abuse upregulate BDNF in the VTA, nucleus accumbens shell, and amygdala, where it is thought to act as a “proaddictive” modulator. BDNF promotes presynaptic axonal branching and organization as well as postsynaptic dendritic arborization, number, size, and motility of dendritic spines and enhances the synthesis of synaptic proteins. BDNF is increased by acute drug administration, but BDNF protein levels continue to increase in the nucleus accumbens during withdrawal from cocaine self-administration, with maximum levels observed after approximately 30 days of withdrawal. BDNF can remain elevated for months. The temporal pattern of BDNF accumulation maps onto the phenomenon of incubation of drug craving (as discussed above in Conditioned Cue–Induced Relapse), and intra-VTA or nucleus accumbens shell BDNF injections cause delayed and long-lasting increases in cocaine seeking after withdrawal. However, it has been shown that BDNF projections from the prefrontal cortex to the nucleus accumbens reduce vulnerability to cocaine seeking. This provides another important example of how the behavioral effects of proteins and other modulators depend on the neural circuits within which they act.

Neuronal Morphology and Synaptic Plasticity

Telegram: @medical_k

www.konkur.in

In addition to dopamine- and opioid receptor–mediated changes in gene expression within mesocorticolimbic pathways after repeated drug exposure, the transition from drug use to addiction involves persistent restructuring of cortical circuitry. Drug-induced structural plasticity includes changes in the size of cell bodies and changes in dendritic arborizations or spine morphology. The most consistent and recognizable cellular adaptations observed are morphologic changes in dendritic spine density. These changes are most likely due to drug-induced regulation of genes that encode cytoskeleton regulatory proteins, including decreased levels of Homer 1 and postsynaptic density 95 (PSD95), both of which are scaffolding proteins associated with the postsynaptic actin cytoskeleton. In addition, morphine and cocaine have been shown to decrease RhoA, Rac1, and cell division cycle 42 (Cdc42), which are small GTPases that regulate the actin cytoskeleton.

Telegram: @medical_k

www.konkur.in

FIGURE 1.31–8. Morphine and cocaine have opposite effects on structural neuroplasticity in the nucleus accumbens (NAc) and medial prefrontal cortex (mPFC). **A:** Groups of rats were trained to self-administer morphine or cocaine intravenously for several weeks. The control groups were given daily intravenous infusions of vehicle for the same period of time. After 1 month of withdrawal from the drugs, the rats' brains were processed using the Golgi staining procedure. Rats that were exposed to cocaine showed increased dendritic branching and increased spine density in both NAc medium spiny neurons and mPFC pyramidal neurons. By contrast, rats that were exposed to morphine had both reduced dendritic branching and reduced spine density in these brain regions. **B:** A summary of changes in spine density and dendritic branching that occur after exposure to cocaine or morphine relative to controls. A dissociation between the effects of cocaine and morphine was also observed in the orbital prefrontal cortex (oPFC) and in the primary somatosensory cortex (S1). (From Badiani A, Belin D, Epstein D, Calu D, Shaham Y. Opiate versus psychostimulant addiction: the differences do matter. *Nat Rev Neurosci*. 2011;12:685–700, Springer Nature. doi: 10.1038/nrn3104.)

A current paradox in addiction research involves the generalization that opioids decrease, whereas psychostimulants increase, the number and complexity of dendritic spines on neurons in the nucleus accumbens, medial prefrontal cortex, and on hippocampus pyramidal neurons

Telegram: @medical_k

www.konkur.in

(Fig. 1.31–8). Likewise, opioids decrease, whereas psychostimulants increase, the soma size of VTA dopaminergic neurons. These changes appear to normalize within 2 weeks after the last drug exposure. One hypothesis toward reconciliation of these different cellular effects of opioids and psychostimulants involves the finding that both repeated morphine and cocaine administration increase actin cycling. This can theoretically lead to increases or decreases in spine density, but more importantly, it is associated with greater plasticity in responses to drug-induced changes in glutamate release.

Despite the apparent opposite effects of different drug classes on neuronal morphology and synaptic strength, an implicit assumption has been that neuroadaptations that occur independently of drug class are particularly important for core elements of SUD that exist across drug classes. Relapse is a core element of SUD, and it has been shown that, regardless of drug class, cue-induced reinstatement is accompanied by a rapid, transient synaptic potentiation of glutamatergic synapses in the core of the nucleus accumbens, especially on D1-receptor–expressing neurons. In addition, enlargement of dendritic spine heads and increases in AMPA-mediated glutamatergic transmission are observed. In addition, the extracellular matrix constitutes an environment replete with neurotransmission modulators—many of which are likely involved in addiction. As one example, matrix metalloproteinases (MMPs) are a family of extracellular proteases that strongly modulate synaptic plasticity. Drugs of abuse and reinstatement of drug-seeking rapidly induce MMP activity and subsequent enlargement of dendritic spine heads and increased synaptic strength in the nucleus accumbens core. Likewise, inhibiting MMP activity prevents reinstatement to drug seeking. Finally, a relatively consistent finding is that drug seeking is associated with increased glutamate release in the nucleus accumbens. The mechanisms underlying enhanced glutamate release include downregulation of cystine–glutamate exchange in glia, decreased signaling through presynaptic metabotropic glutamate receptors (mGluRs), and reduced elimination of glutamate through glutamate transporters.

Epigenetics

Epigenetics can be broadly defined as a series of biochemical processes through which changes in gene expression are achieved throughout the life of an animal without a change in DNA sequence. Epigenetics is a

Telegram: @medical_k

www.konkur.in

means through which environment and genes can interact to produce enduring structural and functional changes underlying experience-dependent neuronal development and plasticity, as well as addiction-related behaviors. DNA is organized into chromatin, and the fundamental unit of chromatin is the nucleosome, which consists of DNA wrapped around a core group of histones. Epigenetic mechanisms control internucleosome spacing and the degree to which they are condensed, which is a determinant of gene activity. Heterochromatin refers to the condensed, inactivated state, which does not allow gene transcription, and euchromatin refers to the activated, open state, which allows individual genes to be transcribed. There are three major types of epigenetic regulation: histone modifications (e.g., acetylation and methylation), DNA methylation, and regulatory noncoding RNAs.

Telegram: @medical_k

www.konkur.in

FIGURE 1.31–9. A: Epigenetic mechanisms implicated in acute and chronic drug effects on gene priming and desensitization. Many epigenetic changes are latent, meaning that they are not reflected by stable changes in steady-state mRNA levels. Instead, such changes alter chromatin structure, so that a later drug challenge induces a given gene to a greater (primed) or lesser

Telegram: @medical_k

www.konkur.in

(desensitized) extent based on the epigenetic modifications that are induced by previous chronic drug exposure. A, acetylation; M, methylation; P, phosphorylation; pol II, RNA polymerase II. (A, from Robison AJ, Nestler EJ. Transcriptional and epigenetic mechanisms of addiction. *Nat Rev Neurosci*. 2011;12:632–637, Springer Nature. doi:10.1038/nrn3111.) **B:** The complex interactions between micro RNA 212 (miR-212), cAMP response element-binding protein (CREB), methyl CpG-binding protein 2 (MeCP2), and brain-derived neurotrophic factor (BDNF) and their putative effects on cocaine intake. The *black outlined circle* implies that CREB signaling protects against the development of escalating cocaine intake, whereas the *dotted circle* implies that MeCP2-BDNF signaling promotes escalation of intake. *Light gray arrows* indicate a stimulatory relationship, whereas *dark gray lines* indicate an inhibitory relationship. Cocaine is shown to activate both CREB and MeCP2-BDNF signaling, and the balance between these two pathways, coordinated by miR-212, likely regulates escalation of cocaine intake in extended access rats, and perhaps vulnerability to cocaine addiction. (B, from Jonkman S, Kenny PJ. Molecular, cellular, and structural mechanisms of cocaine addiction: A key role for microRNAs. *Neuropsychopharmacology.* 2013;38:198–211, Springer Nature. doi:10.1038/npp.2012.120.)

Epigenetics likely plays a major role in addiction. Repeated exposure to drugs of abuse or other environmental insults can engage epigenetic processes in early life (or adulthood). These epigenetic processes act at specific genes or sets of genes resulting in stable changes in gene expression or changes in the inducibility of other genes that can lead to addiction in vulnerable individuals (Fig. 1.31–9A). It is also possible that drugs or other environmental insults produce epigenetic changes in gametes, which can be passed on to offspring and increase their vulnerability to SUDs. There is increasing evidence supporting this idea of transgenerational epigenetic inheritance of vulnerability to addiction, but it remains controversial. As such, two salient examples of epigenetic changes are described below.

Histone Acetylation. Histone acetyltransferases (HATs) and deacetylases (HDACs) catalyze acetylation and deacetylation of histones, respectively. Acetylation promotes decondensation of chromatin and—in general—increases gene activity. The bulk of addiction research on histone acetylation has been with psychostimulants, which increase total cellular levels of acetylated histones in the nucleus accumbens. The c-Fos gene promoter is acetylated briefly after drug treatment, with no observable chronic changes, which is consistent with the rapid on–off expression pattern of c-Fos mRNA. In contrast, BDNF promoters become

Telegram: @medical_k

www.konkur.in

acetylated only after chronic cocaine, which is consistent with the accumulation of BDNF protein only after chronic cocaine and during withdrawal. However, most genes that show altered histone acetylation in response to cocaine do not exhibit changes in mRNA expression expected with hyper- or hypoacetylation. Furthermore, the behavioral effects of histone acetylation are difficult to parse out because each gene promoter has multiple sites at which epigenetic regulation can occur.

Micro RNAs. Micro RNAs (miRNAs) are small, noncoding RNA transcripts (~22 nucleotides) that bind to target mRNAs and either inhibit their translation or induce their degradation. To date, hundreds of miRNAs have been identified, and each miRNA can potentially target hundreds to thousands of mRNA transcripts. In a series of studies focused on the miRNA miR-212 (Fig. 1.31–9B), it was shown that extended access to cocaine self-administration in rats increases levels of miR-212 in the striatum. Experimenter-controlled overexpression of miR-212 in the striatum reduces the motivation to self-administer cocaine, specifically in rats given extended access to the drug, but had no effect on self-administration of cocaine in rats with restricted drug access. CREB increases the expression of miR-212, which can, itself, dramatically increase CREB activity in the striatum. Although BDNF is a CREB target gene (see above), elevations in miR-212 actually repress BDNF expression in the striatum. Taken together, the epigenetic regulator, miR-212, is increased with chronic cocaine self-administration, activates CREB, and suppresses BDNF. These findings suggest that miR-212 may protect against the development of cocaine addiction.

SEX DIFFERENCES IN SUBSTANCE USE DISORDERS

In humans, there are numerous sex differences in almost every facet of SUD (see Table 1.31–4). For most drugs, men consistently have higher rates of use, misuse, and dependence compared to women, with an overall odds ratio of 2:1 (men:women). However, these differences have been declining. For example, the alcohol misuse rate in women is rapidly approaching the rate in men. This suggests that many of the population sex differences in SUDs could be cultural rather than biologic in nature. Having said that, clinical and preclinical studies reveal significant sex

Telegram: @medical_k

www.konkur.in

differences related to the interaction of gonadal hormones with the stress and mesolimbic dopaminergic systems. Accumulating evidence suggests that women progress from substance use to SUD faster than men, a phenomenon termed “telescoping.” In animal models of SUD, sex differences have been found in drug sensitivity and self-administration behaviors. Repeated drug exposure, especially psychostimulants, enhances incentive sensitization to a larger extent in females compared to males. In general, females are more vulnerable than males to the reinforcing effects of psychostimulants, opioids, and nicotine during each phase of the addiction cycle: acquisition, maintenance, escalation, and relapse.

Table 1.31–4.
Summary of Human Studies on Sex and Ovarian Hormone Influences on Drug Misuse

Dependent Measure/Phase	Drug	Finding[a]
Subjective effects	Cocaine	Women ↑↑ nervousness
		Women ↓↓ euphoria and dysphoria
		↑↑ high during follicular
	Amphetamine	↑↑↑ euphoria and high during follicular
		↑ pleasant stimulation with estrogen
Levels/patterns of use	Cocaine	No sex difference in total levels
		Women ↓ abstinence
	Opioids	No sex difference in total levels
		No sex difference in patterns of use
Relapse	Cocaine	Women ↑ cue reactivity
		Women ↑↑↑ craving during abstinence

↑ Small, ↑↑ Moderate, ↑↑↑ Large effect.

[a]Adapted from Lynch WJ, Roth ME, Carroll ME. Biological basis of sex differences in drug abuse: preclinical and clinical studies. *Psychopharmacology*. 2002;164:121–137, Springer Nature. doi: 10.1007/s00213-002-1183-2.

The biologic mechanisms that underlie sex differences in substance use and SUD are still being elucidated. While the basic neural systems involved in positive and negative reinforcement processes that contribute to SUD development are similar in males and females, sex differences have been described in the organization and connectivity of these systems. When thinking about how sex can influence SUD, it is important to keep in mind that sex differences can occur at behavioral and/or neural levels. Given that rigorous examination of the role of sex in SUD is relatively recent, there are still many gaps in the current knowledge. It has

Telegram: @medical_k

www.konkur.in

become clear that factors such as drug type, experimental paradigm, animal species, and estrous cycle contribute to behavioral and neurobiologic responses to drugs of abuse. As such, much of the data currently available are widely variable. Following are two relatively robust examples of putative mechanisms underlying sex differences in substance use and addiction.

Activational Effects of Gonadal Hormones

Evidence from both preclinical and clinical studies demonstrates that fluctuations in gonadal sex hormones, particularly estrogen and progesterone, over the course of the female reproductive cycle (Fig. 1.31–10) play important roles in sex differences in the response to drugs. For example, several of the reinforcing effects of amphetamine, such as euphoria and increased energy, are potentiated in women during the follicular phase compared to the luteal phase and are positively correlated with estrogen levels. Consistent with this, administration of exogenous estrogen during the follicular phase enhances the subjective effects of psychostimulants in women. In contrast to the potentiating effects of estrogen, progesterone levels are negatively correlated with the subjective effects of psychostimulants. Furthermore, administration of exogenous progesterone during the follicular phase decreases many of the positive subjective effects of cocaine. The use of animal models allows a more precise examination of the effects of gonadal hormones on behavior because gonadectomy can eliminate the source of hormones, which can then be reintroduced with experimental control of dosing and timing. Using these methods, it has been shown that ovariectomy reduces cocaine self-administration, and exogenous estrogen treatment is sufficient to facilitate acquisition of cocaine, morphine, and heroin self-administration in ovariectomized rats. Interestingly, there is no effect of castration on acquisition of cocaine self-administration in male rats.

www.konkur.in

FIGURE 1.31–10. Gonadal hormone fluctuations throughout the female reproductive cycle. **A:** Changes in levels of estrogen (E2) and progesterone (Prog) as a function of days from the preovulatory luteinizing hormone (LH) surge for the human menstrual cycle. The *shaded bar* separates the periovulatory phase from the follicular and luteal phases. **B:** Changes in levels of estrogen and progesterone throughout the phases of the rat estrous cycle. The *shaded bars* separate the successive estrous cycle phases diestrus (DIE), proestrus (PRO), estrus (ESTR), and metestrus (MET) to identify the start and end of each phase. (From Lynch WJ, Roth ME, Carroll ME. Biological basis of sex differences in drug abuse: preclinical and clinical studies. *Psychopharmacology*. 2002;164:121–137, Springer Nature. doi:10.1007/s00213-002-1183-2.)

Sex Differences in Dopamine Signaling. In a second example of a possible mechanism underlying sex differences in addiction, the number and function of midbrain dopamine neurons have been reported to be sexually dimorphic. For example, women have been reported to have a greater capacity for dopamine synthesis and reuptake through the

Telegram: @medical_k

www.konkur.in

dopamine transporter (DAT) relative to men. Gonadal hormones can regulate the density of dopamine terminals in the nucleus accumbens and dorsal striatum and the rate of firing of dopamine neurons. The density of dopamine terminals impacts basal dopamine tone, which has been shown to fluctuate in females over the course of the reproductive cycle but is relatively stable in males. For example, female rats show higher firing rates and more burst firing in dopamine neurons during the estrous cycle. There is also evidence that—regardless of the estrous cycle—females show greater basal and cocaine-stimulated dopamine release and reuptake compared to males.

CURRENT TREATMENTS

Treatment of SUD occurs in three phases: detoxification, initial recovery, and relapse prevention. After detoxification, the goal of the initial recovery phase is to learn to tolerate craving induced by external or internal cues and to learn new patterns of behavior that help the individual avoid relapse. The goal of relapse prevention treatments is for the individual to develop long-term strategies that allow them to replace addictive behaviors with new, healthy behaviors. Treatments can be pharmacologic, behavioral, social, and/or cognitive. There is a general consensus among clinical and preclinical investigators that the most effective treatments will be based on scientific evidence that comes from the understanding of basic neural mechanisms underlying SUD.

Telegram: @medical_k

www.konkur.in

Evidence-based clinical interventions may be understood as effective interventions according to the neurobiologic substrates targeted during the engagement process and early recovery treatment of those with SUDs (Table 1.31–5). For example, medication interventions are designed to ameliorate allostatic states associated with chronic substance exposure and the development of physiologic dependence and withdrawal syndromes. As such, stabilization of these systems includes the improvement of withdrawal symptoms, substance craving, and hyperarousal associated with early abstinence. This translates clinically to improved individual capacity for executive functioning and impulse regulation, learning and attention, lowered stress and cue reactivity, and social normalization.

Psychosocial interventions may be similarly conceptualized based on the components of their structure (see Table 1.31–5). Psychosocial interventions include both community-based interventions such as education about SUDs and their treatments, access to exercise programs as a component of health and wellness, and mutual help peer support programs aimed at supporting abstinence (e.g., the 12-step model of recovery founded as Alcoholics Anonymous), as well as professional interventions delivered by trained clinicians such as motivational interviewing, cognitive behavioral relapse prevention, and positive reinforcer contingency management. For instance, education is a prevention and treatment modality that instructs individuals about risk factors for SUDs and also provides a basic understanding of SUD as a brain-based illness that may be arrested with abstaining from substance use. As such, it will primarily assist individuals in making healthy choices, promoting healthy social networks, and avoiding the use of substances as a means of coping with stressors. It will not have much impact on altering reward-seeking behavior and related incentive salience, nor will it help to stabilize withdrawal syndromes. An engagement intervention, known as motivational interviewing, refers to a trained process of dialogue with an individual to help that person better define their goals, values, and current incentivized behavioral patterns, with a goal of assisting that person in focusing on incentivized behaviors congruent with their goals, and diminishing incentivized behaviors (such as substance misuse) resulting in consequences that are inconsistent with personal goals and values. While motivational interviewing may successfully engage an individual in planning for change, it is unlikely on its own to significantly alter subjective

Telegram: @medical_k

www.konkur.in

reward-driven behavior and/or stress reduction, and thus motivational interviewing best serves as a platform to support engagement in other therapies, such as cognitive behavioral relapse prevention or contingency management, which are more specifically aimed to alter these aspects during the abstinence recovery phase of treatment. Interestingly, mutual help peer support may provide the broadest neural substrate “coverage” in recovery by virtue of its being a socially facilitated system of training the individual to understand addiction cues (“people, places, and things”), avoid occasions of substance use, develop healthier alternatives for stress reduction and natural reward, and integrate meaningful social connection into planned recovery and meaningful life pursuits.

Neuromodulation, defined as an intervention that changes neuronal activity in brain circuits, is emerging as a promising therapeutic approach for SUD. Neuromodulatory tools include invasive approaches like deep brain stimulation (DBS) and noninvasive approaches like transcranial magnetic stimulation (TMS) or transcranial direct current stimulation (tDCS). TMS is currently FDA approved for the treatment of nicotine use disorder.

Below are two clinical vignettes of opioid and stimulant SUD and the clinically recommended treatments currently available.

Telegram: @medical_k

www.konkur.in

A 23-year-old single woman with no children, working part-time in a retail department store, and on the weekend as a dancer, presents for first-time treatment of heroin use disorder with IV drug self-administration. She has a significant history of childhood and adult sexual trauma. She began using substances at age 14 with cigarette smoking, drinking with friends episodically, and using marijuana regularly. At age 18, her boyfriend introduced her to using illicit prescription opioids, first orally and then intranasally. At age 19, he left the relationship, and she experienced opioid withdrawal for the first time. This led her to increasingly risky drug-seeking behaviors, including dancing at a strip club, and at age 20, she was introduced to IV heroin use. She has maintained a daily intake of 1 to 2 g IV for 3 years and has not had any medical or mental health care. She presents for treatment in the context of severe weight loss and having been assaulted two nights ago. She is in early opioid withdrawal and has been smoking marijuana for relief. She is a one-pack-per-day cigarette smoker.

Treatment approach: This young woman has multiple life-threatening problems related to her SUDs: lack of stable housing, injection drug use, malnutrition, and sexual assault. The first step in treatment is securing environmental safety through residentially contained housing to support engagement in health care and prevent access to substances and dangerous peers. The severity of early opioid withdrawal symptoms will not be adequately diminished by cannabis use, and consideration of agonist stabilization as a medication-assisted treatment (i.e., buprenorphine or methadone maintenance) would be recommended to engage her in care and to reduce opioid craving that would drive her to leave the residential setting. Treatment with naltrexone is not appropriate in the first 7 to 14 days after the last opioid use to reduce the risk of withdrawal symptoms. Effective care must also be comprehensive and would include assessment of depression and PTSD as well as medical assessment of nutritional status, infection (endocarditis, HCV, HIV, sexually transmitted diseases), and smoking cessation. Women's peer support would provide important social structure for breaking dangerous behavioral patterns and optimizing reproductive health. Vocational counseling is necessary to support independent recovery in a safe manner. In the setting of injection opioid use disorder, best

Telegram: @medical_k

www.konkur.in

practices would include a component of contingency management to incentivize recovery-oriented behaviors and training and access to intranasal naloxone rescue in the event of future relapse and opioid overdose.

Telegram: @medical_k

www.konkur.in

A 55-year-old divorced man and father of three adult children is referred by his primary care provider for stabilization of cocaine use disorder. He has been followed medically for treatment of recurrent sinus and upper respiratory infections and was ultimately found to have nasal perforation associated with intranasal cocaine use. He owns a plumbing business that has been successful and flourished over the past 20 years. He presents with significant grief, depressed mood, and passive thoughts of suicide in the context of the recent loss of his homosexual partner of 5 years, with whom he has been using cocaine 3 days per week on average. His family is unaware of his loss and drug use, and he lacks any personal support. Recently, he has been using online sites for rapid “hookups” with other men who use cocaine, and he has begun to experience financial strain in supporting some of these evenings. His last cocaine use was 1 week ago, and he presents with severe cravings. He does not use other drugs, has never injected any drugs, and drinks alcohol infrequently.

Treatment approach: In this case, in addition to counseling immediate disengagement with potentially dangerous online partner-seeking sites and assessing his environmental safety, the most imminent risk of harm in his bereaved, early abstinent state is that related to suicidal ideation, which could progress at any time to suicidal planning and suicidal behavior. Careful assessment of the need to hospitalize or otherwise admit him to a residential treatment setting is appropriate, as SUDs are associated with significantly increased suicidality. While there are currently no specific medication-assisted treatments for cocaine or other stimulant use disorders, aggressive treatment of dysphoria/depression, a hallmark of early stimulant abstinence, is warranted; consideration of bupropion would be optimal due to its weak dopaminergic activity, which may contribute to amelioration of cocaine craving. Culturally sensitive therapy addressing “coming out” and recent complicated bereavement is essential for recovery, and mutual help peer support would provide social support that facilitates coping and healing. Although family education is typically an integral component in care, some aspects concerning this case would suggest caution and consideration that the individual be further along in his recovery process prior to integrating family directly into the treatment planning of his health care.

2

Neuropsychiatry and Behavioral Neurology

2.1 The Neuropsychiatric Approach to the Patient

FRED OVSIEW, M.D.

Psychiatry has eliminated the term “organic” from the official nomenclature, but the word persists in vernacular use because of the care of patients with identifiable, acquired brain diseases—such as those with epilepsy, movement disorders, traumatic brain injury, and dementia due to neurodegenerative disease—requires the physician to have a knowledge base and a familiarity with assessment and treatment methods not usually required for patients with primary psychiatric disorders. Patients with organic mental syndromes are common in clinical practice and often difficult to manage for the general psychiatrist, even with consultation from other specialists who may themselves not be experts in the mental and emotional phenomena accompanying brain disease.

Neuropsychiatry is the psychiatric subspecialty that deals with the psychological and behavioral manifestations of brain disease. Neuropsychiatry is closely allied with cognitive and behavioral neurology, the neurologic subspecialty that interests itself in psychological phenomena in patients with brain disease, especially cognitive phenomena. In addition to expert management of patients with organic mental disorders, from its clinical vantage point neuropsychiatry can offer a distinctive perspective on idiopathic psychiatric disorders, although later in this section the limitations on the usefulness of this perspective will be noted.

A few preliminary words about the history of neuropsychiatry and its terminology will help to sketch the neuropsychiatric perspective. The seemingly obvious view that neuropsychiatry is the offspring of psychiatry and neurology is historically mistaken. Psychiatry differentiated itself as a medical specialty in the early part of the 19th century; neurology did so somewhat later. Evidence is ample to show that

Telegram: @medical_k

www.konkur.in

early asylum physicians, the precursors of psychiatrists, considered their patients to be suffering from brain diseases, and moreover that a large proportion of their patients evinced organic disease, even with the limited tools of that time. General paresis of the insane (neurosyphilis, as it was later discovered to be), epilepsy, intellectual disability, and the complications of alcohol abuse were all common in the 19th-century asylum. Based on this evidence, one might say that general psychiatry, as it was understood for the larger part of the 20th century, derived from earlier neuropsychiatry.

An early neurology, on the other hand, took little part in the care of patients with major psychiatric disorders, at least those requiring hospitalization; but what would later become outpatient psychiatry—the care of patients with milder mood and anxiety disorders not requiring asylum management, for example—fell into the province of the early neurologists. The theories they deployed to understand their patients have fortunately been consigned to the dustbin of history. The mainstream of Anglo-American neurology was ill-equipped to give rise to scientific neuropsychiatry, and it was not until (as a convenient and meaningful landmark) Norman Geschwind in 1965 awakened interest in the continental tradition of a behavioral neurology *avant la lettre* that the contributions of John Hughlings-Jackson, Ludwig Lichtheim, Hugo Liepmann, Karl Wernicke, and others could provide impetus to the development of a clinical specialty devoted to the scientific understanding of the cerebral basis of mental and behavioral disorder.

To say that neuropsychiatry is devoted to the care of patients with brain disease is not to depreciate the role of psychological and social factors in the understanding of the genesis of symptoms or in the formulation of interventions to assist patients. On the contrary, patients with brain disease are often inordinately reactive to or dependent on influences from the outside world, notably the social world. To the extent that patients suffer from brain-based impairments in processing information from their environment, their need for assistance in dealing with instrumental and interpersonal tasks increases. Much of the brain, after all, is devoted to processing social information and devising ways of meeting internal needs in a social context. The neuropsychiatrist requires a detailed assessment of the patient's functional deficits and the contexts in which they arise.

To say that the neuropsychiatrist regards deficits, or for that matter intact behavior, as the manifestations of brain-based processes is not to imply that idiopathic psychiatric disorders occur in people with normal brains, nor that general psychiatrists are unaware of the cerebral origin of these disorders. On the contrary, the evidence for abnormal brain structure and function in major psychiatric disorders is unmistakable, and general psychiatrists often assert the neurobiologic nature of these illnesses. However, evidence for such assertions is often not demonstrable in the individual case, with all available laboratory investigations characteristically falling within the broad range of normal. Moreover, the neurobiologic abnormalities in question are believed to be, at least in large part and at least in most illnesses, genetic in nature and developmental in pathogenesis. The recognition and

Telegram: @medical_k

www.konkur.in

understanding of the mental consequences of acquired diseases of the brain, which form the bulk of the neuropsychiatrist's concern, are likely to require different tools from those required by the general psychiatrist treating idiopathic disorders. Although a bright line between the two situations is not possible and although many neuropsychiatrists maintain a lively interest in such disorders as schizophrenia and autism, the distinction supports the continued use of the term "organic" to refer to these acquired disorders with pathology identifiable at the bedside and by the clinical laboratory.

NEUROPSYCHIATRIC NEUROANATOMY

The "neuropsychiatric brain" is more complex than the "general-psychiatric brain." The latter is a soup of neurotransmitters, perhaps in "chemical imbalance," with considerable pharmacologic but little anatomic specificity. Although the benefits of psychopharmacological intervention are indisputable, the locus of these effects is rarely of concern to clinicians. A neuropsychiatric approach relies on greater differentiation among brain circuits and systems.

Lateralization

The two hemispheres differentially subserve many cerebral functions, although, in many instances, both hemispheres participate in naturally occurring behavior, albeit contributing differently to the complex outcome. Brain asymmetries arose early in vertebrate evolution, and the two hemispheres display regional lateral asymmetries in size and differentially innervate viscera and peripheral endocrine tissues. For example, pars opercularis of the third frontal gyrus (Broca area) and planum temporale (infolded cortex in the posterior portion of the Sylvian fissure) are typically larger on the left, with greater dendritic branching of the neurons therein. (For simplicity's sake, "left" and "right" here refer to the situation in the average dextral patient.) These cortical regions are parts of the substrate of language processing. The insular cortex of the right hemisphere regulates cardiac sympathetic drive, of the left hemisphere parasympathetic drive. In consequence, left hemisphere stroke involving insula produces more cardiac destabilization and morbidity than right, and lateralization of seizure discharges may have implications for autonomic function and unexplained sudden death in patients with epilepsy. Lateral differences in limbic (hypothalamic and amygdalar) regulation of sexual function also have clinical implications; for example, polycystic ovary syndrome in women may be more commonly associated with left-sided limbic epilepsy. The hemispheric side of the lesion also affects the immunologic consequences of brain injury.

Whether a single tag can accurately contrast the processing "styles" of the hemispheres across multiple functions—local versus global or linear versus context-dependent, for example—is doubtful. Although left lateralization of language and right lateralization of visuospatial function is widely recognized, lateral specialization in the prefrontal regions is less obvious but of clinical significance. Frontal lobe

Telegram: @medical_k

www.konkur.in

degeneration involving the right more than the left frontal lobe is particularly associated with disinhibition. Traumatic injury to the right hemisphere is more associated with depression and anxiety, to the left with anger and hostility. Women and sinistrals tend to show less lateralization of language (and perhaps of other functions) so that left hemisphere lesions are less likely to produce severe impairment.

Of considerable importance for neuropsychiatric practice is the question of lateralization of emotional processing. An array of evidence supports the notion of differential emotional valences in the two hemispheres. On this account, the left hemisphere is specialized for positive emotions, the right for negative emotions. Thus, it has been claimed that left hemisphere destructive lesions are associated with pathologic crying, right hemisphere ones with pathologic laughing; contrariwise, left hemisphere discharging lesions produce gelastic (laughing) epilepsy, right hemisphere ones dacrystic (crying) epilepsy. However, these associations have not been widely confirmed.

Much evidence favors assigning a prepotent role in emotional processing in general to the right hemisphere. Patients with right hemisphere damage appear to be more impaired at perceiving emotion, regardless of the valence or input medium. Lesions of the right hemisphere are associated with impairments in processing emotion in speech, a defect known as aprosodia. Patients may lack the capacity to modulate prosody so as to encode emotional information into speech or the capacity to recognize emotional intonations produced by others. Subtler clinically may be deficits in recognizing emotion in faces or visual scenes.

Fronto-Subcortical Circuits

The projection of the prefrontal cortex to subcortical structures in multiple closed loops is a crucial feature of behavioral neuroanatomy. The key concept is that, in each loop, a distinct region of the prefrontal cortex projects to a distinct portion of the striatum, then to an output nucleus of the basal ganglia, then in turn to a specific region of the thalamus, which in turn projects to the given area of cortex. Thus, a set of parallel (relatively) closed loops of fronto-subcortical connections process information in separate domains. In the motor system, the premotor cortex and supplementary motor area project primarily to the putamen, the output of which projects via ventrolateral globus pallidus and caudolateral substantia nigra pars reticulata (SNr) to ventrolateral/ventroanterior and centromedianum nuclei of the thalamus and then back to the originating cortical structures. Of particular interest to neuropsychiatrists are the loops involving dorsolateral prefrontal, medial and lateral orbitofrontal, and anterior cingulate cortex:

- Dorsolateral prefrontal cortex projects to dorsolateral caudate; projections from caudate go to dorsolateral globus pallidus and SNr. The output from basal ganglia flows primarily to ventrolateral and ventral anterior nuclei of the thalamus

Telegram: @medical_k

www.konkur.in

(but also to the dorsomedial nucleus of the thalamus), whence it projects to areas 9 and 46 of the dorsolateral prefrontal cortex.

- Lateral orbitofrontal cortex projects to ventromedial caudate, thence to the caudomedial aspect of SNr. The thalamic level of this loop is represented in ventral anterior and dorsomedial nuclei, whence projections arise back to the lateral aspect of area 12 in the orbitofrontal cortex.
- The medial orbitofrontal cortex loop features projections from the gyrus rectus and medial orbital gyrus to ventromedial caudate; output from the basal ganglia arises in SNr and flows to the dorsomedial nucleus of the thalamus as well as ventrolateral and ventral anterior nuclei, then back to the medial orbitofrontal cortex.
- The anterior cingulate cortex, in the dorsomedial aspect of the hemisphere, projects to the ventral striatum, including the nucleus accumbens and olfactory tubercle (termini of the mesolimbic dopamine system); with output from SNr flowing through the ventral anterior thalamus on its way back to anterior cingulate cortex.

Disruption of each of these loops produces a distinctive clinical syndrome. As is implied by the concept of a circuit, deficits similar to those produced by cortical damage can also occur with damage to the subcortical connections of the cortical region. Most naturally occurring lesions do not respect the anatomic boundaries, so clinical presentations are commonly mixed. Nonetheless, for analytic purposes, anatomic specificity is of interest and importance.

Interference with the loop involving the dorsolateral prefrontal cortex prominently produces executive cognitive impairment, with decrements in working memory, problem-solving, and related capacities. Damage to this loop commonly arises from traumatic brain injury, stroke, and basal ganglion degenerative diseases, such as Parkinson disease. Involvement of the white matter of the frontal lobes by small vessel disease commonly leads to interruption of cortico-subcortical connections in this circuit, resulting in the picture of subcortical dementia.

Damage to the orbitofrontal cortex and its connections produces impulsivity, disinhibition, dampening of the experience of emotion, irritability and lability of affect, poor judgment and decision making (especially in regard to social behavior), and insightlessness about these impairments. These impairments are generally seen with bilateral damage, although a unilateral right-sided injury may also produce them. As a neighborhood sign, damage may involve the olfactory nerve (which runs along the orbital surface of the brain) with consequent anosmia; at times, the only elemental neurologic sign. Cognitive function, as tested by the usual bedside or neuropsychological probes, may be unaffected even in the presence of devastating personality change. Trauma is a common etiology.

Damage to dorsomedial prefrontal structures may arise from a tumor or stroke. Abulia and apathy, disorders of initiation of action and the experience of motivation, are the result. Abnormalities of initiation of movement, with akinetic mutism as the most extreme state, may occur. The cingulate cortex is a structure of particular

Telegram: @medical_k

www.konkur.in

interest. Evidence from animal and imaging studies demonstrates its importance in orienting attention under conflicting stimulus demands, modulating focused problem-solving and monitoring performance to optimize reward. A cell type seen only in the cingulate cortex and fronto-insular cortex, the spindle cell (or von Economo neuron), appears in ontogeny only at age 4 months, concomitant with the infant's increasing capacity to focus attention. These cells appear to be specifically damaged in frontotemporal dementia. Interference with the output of the cingulate gyrus, namely by interrupting the cingulum—the procedure of cingulotomy—appears to be beneficial in a disorder of excessive attention, namely obsessive-compulsive disorder (OCD).

Limbic System

Le grand lobe limbique was delineated in the mid-19th century (by Broca of aphasia fame) as a ring of cortical and subcortical structures on the medial aspect of the hemispheres. Papez drew attention to the circuit formed by projections from the hippocampus via fornix to mamillary bodies of the hypothalamus, then to the anterior nucleus of the thalamus, then via anterior limb of the internal capsule to the cingulate gyrus, then back to the hippocampus via presubiculum, entorhinal cortex, and the perforant pathway. In addition to this "Papez circuit," the amygdala and its reciprocally connected orbitofrontal cortex are taken to form part of a limbic system, a term first used by MacLean.

The core limbic structures are characterized by rich reciprocal monosynaptic connections with the hypothalamus. These are (1) hippocampus, (2) amygdala, (3) piriform cortex, anterior to amygdala on the medial surface of the temporal lobe, (4) septal nuclei, in the medial wall of the hemispheres immediately rostral to lamina terminalis, and (5) substantia innominata in the basal forebrain. Paralimbic cortices reside in temporopolar, insular, and orbitofrontal regions, which have primary affiliations with the amygdala, and in parahippocampal, retrosplenial/posterior cingulate, and subcallosal regions, with primary affiliations with the hippocampus.

In the limbic system, broad and direct input from sensory cortices into the amygdala and hippocampus is extensively processed on its way to effector neurons in the hypothalamus that regulate autonomic and endocrine activity. In addition to this mediation of the regulation of the internal milieu, the limbic system gates the activity of the motor systems in the basal ganglia, regulating action in the external milieu. This occurs by prefrontal cortical integration of information in the limbic fronto-subcortical circuit, which reaches the cortex via projections from the ventral pallidum to the dorsomedial nucleus of the thalamus.

One reason for the central importance of the limbic system in neuropsychiatry is that the threshold for production of epileptic discharges is lowest in the amygdala and hippocampus. Thus most epilepsy in adults is limbic epilepsy. One consequence is the "voluminous mental state" first identified by Hughlings-Jackson. This refers to the range of experiential phenomena encountered as auras in limbic epilepsy: déjà vu, depersonalization/derealization, micropsia and macropsia, and so

Telegram: @medical_k

www.konkur.in

on. Such symptoms are seen not only in epilepsy but also in mood disorders and as putative pointers to limbic involvement in paroxysmal disorders not of clear epileptic nature, including those associated with borderline personality disorder and with childhood abuse. Their presence, therefore, does not unequivocally mark an epileptic phenomenon. Another reason for the centrality of the limbic system is that the hippocampus, in particular, has a crucial role in explicit memory, further discussed below.

Cerebellum

Anatomic evidence shows that cerebellar inputs access areas of the prefrontal cortex, with a relay in the thalamus. These areas of the cortex project reciprocally to the cerebellum, creating, as with the prefrontal-basal ganglia circuits previously discussed, a set of parallel (relatively) closed loops. These crossed connections from the cerebellar hemispheres and the further crossing of descending cerebrofugal long tracts mean that motor deficits manifest ipsilateral to lateralized cerebellar injuries. Additional reciprocal connections link the cerebellum with the hypothalamus monosynaptically and with other areas of the limbic system via a relay in basis pontis. The phylogenetically older vermis and fastigial nucleus can be differentiated from the neocerebellum of the cerebellar hemispheres and considered a “limbic cerebellum.”

Growing evidence of cerebellar contributions to cognition and affect comes from clinical data and neuropsychological studies. Interpretation of some of the data is uncertain, however, because many cerebellar patients have disorders that may not be limited to the cerebellum; for example, cerebellar degenerations may include cortical degeneration and tumors (and their treatment with radiation and chemotherapy) may have remote effects. Moreover, the phenomenon of crossed cerebellar diaschisis—the reduction in blood flow to connected neocortical areas after cerebellar damage—means that interpretation of deficits as due to abnormal cerebellar processing, as opposed to shut-down of cerebral cortical processing, is treacherous. Nonetheless, patients with stroke lesions clinically and by neuroimaging limited to the cerebellum may have deficits in executive cognitive function, memory, language, and visuospatial function. The data suggest that lateralized cerebellar damage is associated with the predicted lateralized cognitive phenomena (right cerebellar damage with language impairment, left with visuospatial impairment). Defects in affect regulation, with irritability and lability, are proposed to be associated with damage to the limbic cerebellum, notably the vermis.

Cerebral Cortex

The cerebral cortex develops through complex but increasingly well-understood processes of cell proliferation and migration, axonal projection, and dendritic proliferation and pruning. Abnormalities in these processes lead to cortical dysplasia, with clinical consequences including intellectual disability and epilepsy.

Telegram: @medical_k

www.konkur.in

Some 10% of intractable epilepsy may be due to such disorders, and increasingly migration abnormalities are recognizable by imaging prior to neuropathologic examination. Failure of normal pruning of synapses by elimination of dendrites is now known to be crucial in the pathogenesis of the fragile X syndrome and has been speculatively linked to schizophrenia. Rarely, cortical dysplasia may be present without epilepsy or intellectual disability; the neurobehavioral consequences of this abnormality are just coming under investigation.

The organization of sensory cortices follows a regular plan. Each primary sensory cortical area projects to unimodal association cortices specialized for the extraction of features in that particular modality; the unimodal association cortices are densely and reciprocally interconnected. For example, the visual association cortex has specialized regions for color, motion, and shape. Unimodal association cortices project in turn to heteromodal cortices which receive inputs from more than a single sensory modality. Heteromodal cortices are located in prefrontal, posterior parietal, lateral temporal, and parahippocampal regions. Unimodal cortices do not project to unimodal cortices in other modalities, only to the higher-level heteromodal cortices. Further, widespread hippocampal projections to the cortex arrive only at association cortices, not primary sensory cortices. These structural features amount to the isolation of sensory processing from top-down influences over the first several synaptic stages and presumably increase its fidelity to external phenomena.

Lesions of cortical association areas produce an array of behavioral and cognitive disorders of intriguing specificity. The specificity can be demonstrated by the occurrence of double dissociations: a lesion in area A produces a deficit in function X but not Y; a lesion in area B produces a deficit in function Y but not X. This pattern of findings provides crucial confirmation that the deficits arise not from task difficulty (if Y were simply more difficult than X, then Y would always be disturbed when X was disturbed) but from separable processing components. For example, some patients show a greater impairment for naming living things than for naming artifacts after a brain injury. However, occasionally patients show the opposite pattern, greater impairment in naming living things: a double dissociation. The explanation of the discrepancy thus cannot depend on insufficient processing resources but must reveal a property of the organization of the semantic system.

Cognitive disorders of the visual system can serve as a paradigm of the syndromes seen with damage to the association cortex. Lesions of the primary visual cortex (V1, or Brodmann area [BA] 17) produce cortical blindness in a quadrant, hemifield, or the entire visual field. Despite the genuine blindness, accuracy above chance in localizing visual stimuli can be achieved without awareness of vision, the phenomenon of blindsight, which testifies to subcortical visual processing inaccessible to consciousness. V1 projects to adjacent cortical regions (BA18 and BA19), which contain neurons that respond to specific features of visual stimuli such as color, movement, or shape. Lesions in these cortices produce deficits in the identification of these features. Thus arise syndromes such as central achromatopsia, demonstrated by the inability to sort (as well as to name)

Telegram: @medical_k

www.konkur.in

colors. The information transfer divides into dorsal and ventral streams, with the former specialized for localization of visual stimuli (“where”) and the latter for identification of the stimuli (“what”). Dorsal lesions involving the superior parietal lobule can produce impaired reaching under visual guidance (optic ataxia), a part of the Balint syndrome; the deficit testifies to the integration of visual information with motor output in the association cortex. Ventral lesions involving the inferotemporal cortex produce defects in recognition (agnosia). Agnosic patients are not only unable to name elements within the domain of agnosia but also unable to demonstrate their use or show recognition of the items in other nonverbal ways.

Central auditory disorders include cortical (or central) deafness; pure word deafness, the inability to recognize words presented in the auditory modality despite preserved visual-verbal function; and auditory agnosia, the inability to recognize words or complex sounds (e.g., the meaning of the ringing of a telephone). Central deafness requires bilateral lesions involving the primary auditory cortex in the superior temporal gyrus or auditory radiations in white matter. Patients with pure word deafness generally have bilateral lesions of the association cortex more anteriorly in the superior temporal gyrus, although unilateral left lesions, presumably disconnecting left from right cortices by subcortical damage, also are reported. The primary auditory cortex is partially spared in these cases. In agnosia for nonverbal environmental sounds, right-hemisphere damage is sufficient to produce the deficit. Amusia, the incapacity to recognize musical sounds, is associated with cortical damage, but the issue of laterality is complex, dependent in part on the preinjury level of musical skills.

White Matter and Cerebral Connectivity

Although the volume of the neocortex has increased over the course of phylogenetic history, the volume of white matter has increased disproportionately. In human beings, the white matter tracts occupy some 42% of the volume of the hemispheres. The great majority of these fibers serve cortico-cortical connectivity rather than projections between cortical regions and subcortical sites; for example, thalamic input is estimated to represent only 5% of the total input into the primary sensory cortex, remainder being from other cortical areas.

The fibers in white matter are of several types. First are the longer intrahemispheric fiber tracts:

- arcuate fasciculus, which connects superior and middle frontal gyri to the temporal lobe and (via a superior portion of the fasciculus called superior longitudinal fasciculus) the parietal and occipital lobes;
- uncinate fasciculus, which connects the orbitofrontal cortex to the temporal cortex and (via an inferior portion of the fasciculus called inferior occipitofrontal fasciculus) the occipital lobe;
- cingulum, which lies medially beneath the cingulate cortex in the cingulate gyrus and connects frontal and parietal lobes with the parahippocampal gyrus and

Telegram: @medical_k

www.konkur.in

adjacent structures.

Second are the long projection systems linking the cortex, subcortical nuclei, and lower portions of the neuraxis. The medial forebrain bundle is the primary connection between limbic structures and the brainstem and carries projections from the monoaminergic cells in the midbrain and pons. Others are the thalamic peduncle, with reciprocal fibers between the thalamus and parietal lobe, and the corticopontine and corticospinal tracts descending through corona radiata and internal capsule. Fibers from the prefrontal cortex descend into the anterior limb of the internal capsule so that lesions there may have predominant behavioral and a paucity of elementary sensorimotor effects.

Lacunes and degeneration of the white matter due to hypertensive small vessel disease (along with strokes, known as Binswanger disease) interrupt these cortico-cortical fibers and cortico-subcortical projections. The result of progressive loss of communication among cortical regions and between cortex and subcortical gray matter is the clinical state of subcortical dementia, which is prominently characterized by slowing of mental processing and failure of executive control processes. The latter may be explained in part by the preferential occurrence of lacunes in frontal locations but also by the impairment of connectivity.

Third, U-fibers are the short, juxtacortical fibers connecting adjacent cortical regions. These fibers are characteristically spared in Binswanger disease, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), and certain other disease processes.

Fourth are the many specific projection systems linking delimited regions, such as the mammillothalamic tract, which connects mamillary bodies with the anterior nucleus of the thalamus, and the fornix, which connects mammillary bodies with the hippocampus. Interesting neurobehavioral syndromes have been described related to rare cases of focal interruption of such pathways. For example, interruption of the mammillothalamic tract or of the fornix is implicated in amnesia.

Fifth, several pathways connect the two hemispheres, notably the corpus callosum but also anterior and posterior commissures and massa intermedia of the thalamus. Syndromes due to interruption of the smaller commissures have not yet been described, although the absence of massa intermedia is reported to be associated with schizophrenia in women, and anterior commissure and massa intermedia are larger in women than in men. Corpus callosum is congenitally absent in numerous neurodevelopmental syndromes, and its absence has been associated with schizophrenia. Congenital absence is not, however, associated with the interesting disconnection symptoms seen in lesional interruption of the callosum, such as by anterior or posterior cerebral artery stroke or by surgical callosotomy for control of epilepsy.

Two callosal disconnection syndromes are worthy of specific mention. After anterior cerebral artery occlusion with anterior callosal infarction, the right hemisphere is deprived of verbal information; left-hand apraxia is seen, and the patient cannot name unseen objects placed in the left hand. Reciprocally, the right

Telegram: @medical_k

www.konkur.in

hand shows constructional apraxia. This is termed the anterior disconnection syndrome. After occlusion of the left posterior cerebral artery with infarction of the left occipital lobe and splenium (posterior portion) of the corpus callosum, the language cortices of the left hemisphere lose access to visual information: The left visual cortex is damaged, as are the projections from the right visual cortex, which cross in splenium. Thus, reading becomes impossible, although other language functions are unaffected—the syndrome of alexia without agraphia.

Modulators of Brain States

This account of cognitive processing in the cortex will seem to many psychiatrists to leave out of consideration the matters with which they are most concerned, namely pervasive states of altered mood, drive, and behavior. That such states are behaviorally pervasive does not entail that they are anatomically global. The limbic structures discussed above provide in part the anatomic substrate for emotional states. Further, several systems with diffuse cortical projections have the capacity to modulate processing in widespread brain regions. These originate in:

- Intralaminar thalamic nuclei, which project to the cortex (especially prefrontal and cingulate cortex) and to the striatum;
- Histaminergic cells in posterior hypothalamus;
- Serotonergic cells in pontine raphe nuclei;
- Noradrenergic cells in locus ceruleus;
- Dopaminergic cells in the midbrain ventral tegmental area, giving rise to the mesocortical and mesolimbic systems;
- Cholinergic cells in basal forebrain nuclei, such as nucleus basalis of Meynert.

The last of these is of relevance to cholinesterase inhibitor treatment of dementia and the preceding three are of relevance to the treatment of mood, anxiety, and psychotic disorders. The hypothalamic histaminergic projections are involved in arousal. “Nonspecific” thalamic projections may have an important role in executive dysfunction seen after thalamic lesions.

Brain Networks

The description above of white matter tracts is an account of *structural* connectivity. Correlations of activity as measured by functional imaging yield patterns of *functional* connectivity. A finite number of circuits so-defined have been identified, some clearly of relevance to behavior:

- Default mode network (DMN): involving the medial prefrontal cortex, posterior cingulate cortex, precuneus, and angular gyrus
- Salience network: centered on anterior cingulate and anterior insular cortices, with nodes in the amygdala, ventral striatum, and thalamus
- Central executive network: linking dorsolateral prefrontal and parietal regions.

Telegram: @medical_k

www.konkur.in

These networks are also distinguished by atrophy patterns in neurodegenerative disease. In Alzheimer disease, the DMN shows atrophy corresponding to deficits in episodic memory. The salience network is affected by behavioral-variant frontotemporal dementia (bvFTD), with deficits in emotional and compartmental processing.

This way of looking at brain function—as the output of multiple regions organized as networks—begins to solve a problem posed by studies of lesion localization: not all cases have lesions in the presumed "right" location. The technique of lesion network mapping looks at the connectivity (as known from studies of the connectome of healthy control subjects) of each of the lesions in patients with a given disorder and then examines the overlap of those connectivity maps rather than the overlap of the lesions themselves. The technique has been used to show the underlying brain networks for disorders as various as hallucinations, movement disorders, depression, mania, free will, and criminal behavior.

An additional aspect of the network approach relates to individual differences in brain function. Studies of groups of affected subjects compared with healthy controls may reveal regions underlying a given function or deficit. Only large data sets of healthy subjects studied over time can reveal that different individual subjects perform the task by enlisting different networks, putatively reflecting different strategies in performing the task, different strategies that are trait-like and stable over time for each person. Individual differences in the organization of the language cortex are evident clinically in the unusual, but not negligible, occurrence of crossed aphasia (aphasia due to right hemisphere injury in a dextral), crossed nonaphasia (lack of aphasia in a dextral with a left hemisphere injury that "should" cause aphasia), and aphasic deficits anomalous in respect to the predicted effects of lesions in both dextrals and sinistrals. While this approach is in its early stages, the day may come when our understanding of the varying instantiation of function by brain networks is able to reflect the complexity of human behavior as studied in neuropsychiatry.

MODULARITY AND NEUROPSYCHIATRY

Focal behavioral syndromes compel attention to local processing in the brain and almost irresistibly suggest a particular model of brain organization. One imagines a box-and-arrow diagram in which each box—representing an elementary cognitive function—maps onto a specialized region of the cortex. Each area of the cortex has its job to do and a lesion of any area produces a distinctive, delimited, and predictable deficit.

This model raises the issue of the modular organization of the brain. The general topic of modularity in cognitive processing deserves further consideration because it is crucial to the theoretic perspective of neuropsychiatry, and in particular because it bears on the value of neuropsychiatric data for the understanding of idiopathic psychiatric disorders. Modularity in cognitive neuroscience refers to a brain

Telegram: @medical_k

www.konkur.in

organization characterized by multiple computational devices, each of which operates on characteristically encapsulated input with prewired (perhaps innate) rules, thus being rapid, efficient, and reliable. For example, elementary visual processing can be considered modular inasmuch as it utilizes restricted input with hardwired feature extraction (e.g., motion, color, shape). In another domain, consider that it is easier to teach an animal to associate a taste than a visual stimulus with the aversive effects of an ingested toxin. This finding implies domain-specific, innate learning constraints. The classic cognitive example of domain-specific prewiring is language, for example, Chomsky's observation that children generate language errors that they have never heard: "He bringed me here," the small child might say, although they have never heard an adult say "bringed." The implication is that a language-processing module possesses innate grammatical rules that have generated a grammatical form without an experiential foundation.

Evolutionary psychologists have forcefully argued the case for modular processing, as opposed to domain-general problem-solving devices. The core of the evolutionary argument is that cerebral organization is the result of natural selection operating on the adaptational fitness of mankind's Pleistocene hunter–gatherer ancestors. Domain-specific processing has advantages of speed and efficiency that necessarily lead to an advantage in fitness. The availability of pre-experiential information about the content of domain-specific processing carries a large advantage over the "combinatorial explosion" of informational possibilities requiring evaluation by a domain-general processor. For example, detection of cheating in social exchanges is an essential element of adaptation in a population group featuring cooperative behavior. Is it a function of a domain-general logical problem-solving device, or is there a cheater-detection module? Cross-cultural evidence shows that people are better at detecting violations of social exchange rules than at solving problems of equivalent logical complexity when posed in other terms, and focal lesions can differentially affect cheater detection. The implication is that prewired mechanisms, presumably located in a particular brain area, are "tuned" to recognize and reason about this adaptationally crucial behavior, just as innate mechanisms subserve language learning and toxin recognition. One of the strengths of the evolutionary approach is to direct attention to those processing domains, the modularity of which is plausible on adaptational grounds.

However, many of the "modules" that have attracted clinical interest are not plausibly directly the objects of natural selection. Reading and writing are clear examples. These have arisen too recently in evolutionary time to have been the product of natural selection and thus must depend on the workings of processors that are, at least to this extent, domain-general.

Moreover, much of the literature on modularity is written from a cognitive psychological or philosophical perspective, with less attention to the "wetware" (i.e., actual brain substance) implementing the processing devices. A foundation in cognitive neuroscience and evolutionary biology can enrich clinical theories, but it creates the potential for misunderstanding by clinicians interested in the functioning

Telegram: @medical_k

www.konkur.in

of patients with brain lesions. The modules of the evolutionary biologists and philosophically inclined cognitivists do not map directly to brain areas. One of the striking results of functional neuroimaging experiments is that, although the function under study is delimited, multiple areas of brain activation are found. Even functions that seem psychologically fundamental are not implemented in a simple way, and local processing components may be recruited into multiple networks subserving a variety of tasks. This seems to be the case with respect to the limited number of frontal sites involved in a wide range of executive tasks. The specialization of regions is dependent on input from other regions; specialization is not entirely dependent on intrinsic properties but partially on top-down influences.

The issue is not whether different cerebral regions carry out different modes of information processing. This is unquestionably so, and neither unreconstructed holists who believe in the equipotentiality of the cortex nor strict localizationists who believe only in fully autonomous processing devices figure on the current neuroscientific scene. The question is how regions are linked in carrying out tasks. Functions are implemented by networks, most or all of the nodes of which participate in multiple functional networks. This pattern of cerebral organization has been termed selectively distributed processing or sparsely distributed networks. Although cortical regions have specialized capacities for information processing, functions cannot be localized to regions (as Hughlings-Jackson explicitly warned a century and a half ago). It would be erroneous, for example, to believe that an area crucial for face recognition contained all of the neurons, and only neurons, that respond to faces.

Another critique of the modularity hypothesis crucial for neuropsychiatry derives from developmental psychology. Trenchant arguments contradict the assumption that a mapping of deficits to specific brain structures could be static over developmental time. On the contrary, how the brain performs cognitive tasks changes with development. Development entails changing patterns of interaction among brain components, and localization may alter as neurons and regions become “tuned” in responsiveness, based on their initial characteristic processing biases and their patterns of inputs and connectivity. This reorganization of cortical function could mean that the same behavior has different substrates at different developmental epochs. For example, in adult subjects with Williams syndrome, poor function at number processing and good language skills are characteristic; however, in infancy, the opposite pattern is seen. Whatever the fundamental processing disorder of genetic origin may be, it cannot be seen as having knocked out a module. A large expanse of nonlinear brain development lies between the gene and the clinical phenomena, an expanse that can be understood only with a better theory than neophrenology. The very development of modularity can be anomalous. Indeed, in the Williams syndrome cases, functional magnetic resonance imaging (fMRI) data disclose an anomalous, diffuse pattern of activation for music perception, an area of preserved or enhanced ability in these patients. Focal syndromes in adults provide an appropriate place to start formulating hypotheses,

Telegram: @medical_k

www.konkur.in

but a deficit seen in an idiopathic disorder cannot be assumed to have its basis in dysfunction in the same simple locus as a phenomenologically similar deficit seen after a focal brain lesion occurring in an adult.

Nothing in this line of argument diminishes the interest in focal neurobehavioral syndromes, which are clinical facts that have a substantial heuristic value for cognitive neurosciences. Neuropsychiatry, along with other brain specialties, has the task of importing into clinical theory the understanding of the mind and brain elaborated in cognitive neuroscience. The search for psychopathological understanding based on the identification of deficits in cognitive modules that are relatively well understood in normal subjects has been termed cognitive neuropsychiatry. This pursuit inevitably results in the deconstruction of the psychiatric diagnoses of the Diagnostic and Statistical Manual of Mental Disorders (DSM) or the International Statistical Classification of Diseases and Related Health Problems (ICD) into symptoms or syndromes because the standard diagnostic categories are generally based on folk-psychological notions (such as the division between “thought” and “affective” disorders).

Much of this section is devoted to the anatomical mode of thought practiced by neuropsychiatrists. However, some clinicians hope that neuropsychiatry will provide a localizing taxonomy of behavioral syndromes so that particular psychiatric disorders will carry the same localizing power as, say, the Babinski sign for the corticospinal tract: the nuclear syndrome of schizophrenia to the left temporal lobe, for example. From the contemporary cognitive neuroscience perspective just reviewed, this seems likely to be false hope. The Babinski sign is a limiting, not a paradigmatic, case of brain-behavior relationships. For the fullest understanding of complex mental syndromes, notably those traditionally in the realm of psychiatry, a more adequate theory of brain function is needed than can be offered by the localizationist tradition.

CLINICAL EVALUATION

The neuropsychiatric perspective places great reliance on information that can be gathered at the bedside. No practical inquiry and examination can include all possible items; rather, the clinician selects from a toolbox of probes of the history and the patient’s functioning in the examination room in order to confirm or refute hypotheses generated by the emerging clinical picture. Screening items should have high sensitivity but not necessarily high specificity. Beyond screening, elements of the history and examination that might potentially elucidate the nature of the disease process under consideration form the entire corpus of medical assessment.

The Neuropsychiatric History

The initial steps in screening for the presence of organic disease in patients with mental symptoms are easily taken. The physician should obtain a general medical

Telegram: @medical_k

www.konkur.in

history, including a history of diseases possibly relevant to the neuropsychiatric symptoms under consideration and a review of systems in potentially relevant areas. With a cognitively impaired or psychotic patient, such history-taking may be unreliable. An account from a family member or other informant and a review of medical records are almost always essential.

With virtually every patient, the clinician should inquire as to a history of (1) heart, lung, liver, kidney, skin, joint, or eye disease; (2) hypertension; (3) diabetes; (4) traumatic brain injury; (5) seizures, including febrile convulsions in childhood; (6) sleep disturbance; (7) unexplained medical symptoms; (8) substance use; (9) current medication; and (10) family history of neuropsychiatric disorder. The inquiry about these disorders in some settings can be quite general. For example, the question “Have you ever had heart problems?” along with a few questions in the review of systems may suffice to screen for heart disease in a young, apparently healthy patient. In other circumstances, more detailed information must be gathered.

The review of systems as well should vary according to the setting. Positive responses should lead to further inquiry. The clinician should be practiced at inquiring about:

- Constitutional symptoms: fever, malaise, weight loss, pain complaints;
- Neurologic symptoms: headache, blurred or double vision, impairment of balance, impairments of visual or auditory acuity, swallowing disturbance, focal or transient weakness or sensory loss, clumsiness, gait disturbance, altered urinary or defecatory function, altered sexual function;
- Paroxysmal limbic phenomena: micropsia, macropsia, metamorphopsia, déjà vu, jamais vu, forced thoughts or emotions, depersonalization/derealization, autoscopy, paranormal experiences such as clairvoyance or telepathy;
- Thyroid symptoms: heat or cold sensitivity, constipation or diarrhea, rapid heart rate, alopecia or change in the texture of hair;
- Rheumatic disease symptoms: joint pain or swelling, mouth ulcers, dry mouth or eyes, rash, past spontaneous abortions.

Birth History and Early Development

Because brain development starts before birth, so too does the neuropsychiatric history. The clinician should note:

- Maternal substance use, bleeding, and infections during the pregnancy;
- The course of labor;
- Fetal distress at birth, including Apgar scores if available;
- Perinatal infection or jaundice;
- Motor and cognitive milestones, such as the age at which the child crawled, walked, spoke words, spoke sentences;
- The infant’s temperament;

Telegram: @medical_k

www.konkur.in

- The child's school performance (including special education and anomalous profiles of intellectual strengths and weaknesses) is usually the best guide (absent psychometric data) to premorbid intellectual function.

The role of perinatal injury in cerebral palsy and intellectual disability has commonly been overestimated; in many instances, the developmental disorder was present in gestation prior to the perinatal misadventure, which may, in fact, have arisen from the pre-existing abnormality. However, perinatal injury, in particular hypoxic injury, is probably associated with later schizophrenia.

Head Injury and Its Sequelae

Head injury is a potential factor in late-onset mood and psychotic disorders, as well as cognitive impairment, epilepsy, and post-traumatic stress disorder (PTSD). The clinician should inquire about a history of head injury in virtually every patient. The nature of the injury should be clarified by eliciting the circumstances, including risk-taking behaviors that may have predisposed to injury and others who were injured in the same incident, often an emotionally powerful aspect of the event. Loss of consciousness is not a prerequisite to important sequelae; even a period of being stunned, "seeing stars," can presage later neuropsychiatric symptoms. The period of loss of consciousness, or coma, should be established, ideally with the assistance of contemporaneous medical records. The period of retrograde amnesia —from the last memory before the injury to the injury itself—and of anterograde amnesia—from injury to the recovery of the capacity for consecutive memory—should be noted.

Paroxysmal Disorders

Paroxysmal disorders of neuropsychiatric interest include epilepsy, migraine, panic attacks, and episodic dyscontrol of aggression. Taking a history of an episode has common features irrespective of the nature of the disorder. The clinician should track the chronology of the attack. This starts with the possible presence of a prodrome, a warning of an impending episode in the hours or days prior to one. The episode itself may be presaged by an aura lasting seconds to minutes. In the case of an epileptic seizure, this represents the core of the seizure itself and may carry important localizing information about the hemispheric side and site of the focus. The pace of buildup, from onset to peak of the ictus, is of differential diagnostic importance. For example, epileptic seizures begin abruptly; panic attacks may have a more gradual development to peak intensity. The mental and behavioral features of the ictus itself should be elicited in detail, if possible, from collateral informants as well as from the patient. The duration of the spell and the mode of its termination should be elicited. Inquiring whether the patient has just one sort of spell or more than one is an essential prelude to establishing the frequency of episodes, both at present and at maximum and minimum in the past.

Telegram: @medical_k

www.konkur.in

By interviewing the patient and collateral informants, information necessary to make a differential diagnosis can usually be elicited. The differential diagnosis between epilepsy and psychogenic nonepileptic seizures (PNES) can be difficult; but at times, if asked properly, the patient will make the diagnosis for the clinician by reporting “two kinds of seizures,” one of which is clearly epileptic and the other whose semiology is inconsistent with epileptic seizures.

Cognitive Symptoms

Recognizing cognitive symptoms in patients without established dementia is a crucial element of neuropsychiatric history-taking. Such symptoms may be outweighed by more dramatic behavior or mood change, but identification of cognitive impairment can reorient the diagnostic evaluation of late-life depression, for example. No doubt, the commonest complaint along cognitive lines is memory problems. In the setting of depression, the more intense the complaint of memory impairment, the less likely it is to have an organic basis and the more likely to testify to depressive ideation and attentional failure. The clinician should establish whether forgotten material (say, an acquaintance’s name or a task meant to be performed) comes to the patient later as a matter of absentmindedness rather than memory failure; recall when cued by a conversational partner likewise suggests memory impairment at the retrieval stage. Certain other complaints are highly characteristic of organic disease. These include a loss of the capacity for divided attention or for the automatic performance of familiar tasks. A patient might report, for example, no longer being able to read and listen to the radio at the same time. Getting lost or beginning to use aids for recall, such as a notebook, is suggestive of organic cognitive failure. A discrepancy between the examination and the patient’s everyday functioning (e.g., a patient who follows his favorite sports teams effectively but in the consulting room cannot count to 10) should be noted. Patients with memory or other cognitive deficits should be assessed for the safety of their living arrangements.

Appetitive Symptoms and Personality Change

Alterations of sleep, appetite, and energy are common in idiopathic psychiatric disorders as well as transiently in the healthy population and cannot be interpreted as implying brain disease. Certain patterns of altered sleeping and eating behavior and personality, however, are pointers to organic disease. Excessive daytime sleepiness or sleep attacks raise the question of sleep apnea or narcolepsy, or in a different temporal pattern, Kleine–Levin syndrome. Sleep apnea should be routinely screened for, with questions about daytime sleepiness, snoring, and morning headache, because it is a potential contributor to cognitive impairment and treatment resistance in depression. Abnormal behavior during sleep raises the question of parasomnia. Dream-enacting behavior during rapid eye movement (REM) sleep, accompanied by loss of the characteristic atonia of REM sleep, is termed REM-sleep behavior disorder. Typically the behavior is aggressive—flailing the arms, kicking, punching—and corresponds to aggressive dream content. This

Telegram: @medical_k

www.konkur.in

may be due to a pontine lesion or an autoimmune encephalopathy, but the absence of such disorders strongly points to an ingravescent synucleinopathy such as Lewy body disease. Much more rarely, nocturnal dream-enacting behavior, the so-called oneiric stupor, portrays with simple motor behaviors patient's daytime activities (such as, in one personal patient, arm movements like an orchestra conductor's, the patient, in fact, being an orchestra conductor). This usually discloses a prion disease, namely fatal familial insomnia. Loss of dreaming occurs with parietal or bifrontal damage; loss of visual imagery in dreams occurs with ventral occipitotemporal damage, part of the Charcot–Wilbrand syndrome (loss of visual imagery with brain damage).

In medial hypothalamic disease, eating behavior is marked by a lack of satiety and resultant obesity. In the Klüver–Bucy syndrome of bilateral anterior temporal damage (involving the amygdala), patients mouth nonfood items. With frontal damage, patients may stuff food into the mouth, a form of utilization behavior, sometimes with alarming or even fatal consequences. A change in food preferences with a new "sweet tooth" suggests frontotemporal dementia. A "gourmand" syndrome of excessive concern with fine eating has been associated with right anterior injury.

Changes in sexual behavior are common consequences of brain disease. Hyposexuality is common in epilepsy, possibly as a consequence of limbic discharges. A change in habitual sexual interests, quantitative or qualitative, developing in midlife suggests organic disease. It is possible, although understudied, that relevant organic disease, such as the sequelae of traumatic brain injury, is common in sexual offenders. Other changes in personality, such as the development of shallowness of affect, irritability, loss of sense of humor, reduced empathy for intimates, or a coarsening of sensibilities, may indicate ingravescent organic disease, for example, frontotemporal dementia.

Handedness

About 90% of people designate themselves as dextral, almost all the rest as sinistral, and a very few as ambidextrous. The true state of affairs is somewhat more complicated in that handedness may be considered dimensionally (i.e., as a matter of degree rather than categories). Patients may call themselves right-handed but use the left hand preferentially for certain tasks. Inquiring about a few specific tasks—writing, throwing, drawing, using scissors or toothbrushes—yields helpful information. A family history of sinistrality may also be relevant.

THE NEUROPSYCHIATRIC PHYSICAL EXAMINATION

In principle, any aspect of the general physical or neurologic examination may be relevant to neuropsychiatric diagnosis, if only in revealing an incidental clinical problem in a neuropsychiatric patient. Here, the focus is on elements of the physical examination with specific relevance to the detection and identification of organic

Telegram: @medical_k

www.konkur.in

disease in patients with mental presentations. The mental examination, including the cognitive examination, is discussed below in association with syndromes of behavioral disorder and insofar as it can elicit or elucidate these syndromes in the consultation room.

The General Physical Examination

General Appearance. Dysmorphic features include so-called minor physical anomalies, some of which are captured in the widely used Waldrop scale. These are associated with developmental disorders, including schizophrenia. These features center on the head, hands, and feet. No single minor anomaly is diagnostic of pathologic development, only the concurrence of multiple anomalies.

Many specific developmental disabilities syndromes can be diagnosed by the constellation of dysmorphic features presented. Cleft lip or palate may be associated with brain malformations and frontal cognitive impairment. Asymmetry of the extremities, often best seen in the thumbnails or of the cranial vault, points to a developmental abnormality. Occasionally, a patient even reports wearing shoes of different sizes on the two feet. The larger extremity and the smaller side of the head are ipsilateral to the abnormal cerebral hemisphere. Short stature is an important feature of many developmental syndromes, both common, such as fetal alcohol syndrome and Down syndrome, and uncommon, such as mitochondrial cytopathies. Abnormal habitus, such as the marfanoid habitus of homocystinuria, may be a clue to the diagnosis.

Vital Signs. Elevated temperature, blood pressure, or heart or respiratory rate should never be ignored, even in a patient whose agitation or anxiety might seem to explain the abnormality. Doing so risks missing infection, neuroleptic malignant syndrome, serotonin syndrome, connective tissue disease, or other important causes of morbidity. Abnormal respiratory patterns occur in hyperkinetic movement disorders, including tardive dyskinesia. Yawning is a feature of opiate withdrawal and serotonergic toxicity. Weight loss is an important clue to systemic diseases, such as neoplasia; it should not be dismissed even in a patient with depression, which may—but may not—account for the weight loss. Weight gain equally may point to the brain or systemic disease, especially an endocrinopathy, or may reflect the toxicity of psychotropic drugs.

Skin. Alopecia or rash may point to systemic connective tissue disease. Alopecia is also a feature of drug toxicity and hypothyroidism (where thinning of the lateral part of the eyebrow is characteristic). The malar rash of systemic lupus erythematosus is typically slightly raised and tender and extends to both cheeks in a “butterfly” pattern while sparing the nasolabial folds. Discoid rashes in lupus are characterized by hyperkeratosis, atrophy, and loss of pigment; the strong tendency to scarring means that the presence of a discoid rash does not necessarily indicate active disease. A pink periungual rash is also characteristic of lupus. A vasculitic

Telegram: @medical_k

www.konkur.in

rash is classically palpable purpura and may be seen in lupus or other connective tissue diseases. Livedo reticularis, a net-like violaceous pattern on the trunk and lower extremities, is not specific but raises the question of Sneddon syndrome when stroke or dementia is a clinical accompaniment. The neurocutaneous syndromes have typical skin manifestations: adenoma sebaceum (facial angiofibromas), ash-leaf macules, depigmented nevi, and shagreen patches (thickened, yellowish skin over the lumbosacral area) in tuberous sclerosis; a port-wine stain (typically involving both upper and lower eyelids) in Sturge–Weber syndrome; neurofibromas, café-au-lait spots, and axillary freckling in neurofibromatosis.

Head. Head circumference should be measured in patients with a question of developmental disorder. Most reference works give normal ranges for head circumference in developing children but not for adults. Fortunately, adequate data to establish normal ranges do exist. Although height and weight need to be taken into account along with sex, roughly the normal range for adult males is 54 to 60 cm (21.25 to 23.5 in); for females, 52 to 58 cm (20.5 to 22.75 in). An old skull fracture or intracranial surgery usually leaves palpable evidence.

Eyes. Exophthalmos usually indicates Graves disease; especially if unilateral, it may reveal a space-occupying lesion. Dry eyes, along with dry mouth, raise the question of Sjögren syndrome, although drug toxicity or the aging process are common confounds. Inflammation in the anterior portion of the eye, uveitis, can be appreciated at the bedside by the presence of pain, redness, and a constricted pupil; this is commonly associated with connective tissue disease. The Kayser–Fleischer ring is a brownish-green discoloration at the limbus of the cornea; it sensitively and specifically indicates Wilson disease. The examination of pupils, optic discs, visual fields, and eye movements is discussed below.

Mouth. Oral ulcers can be seen in lupus, Behçet disease, and other connective tissue diseases. Dry mouth is a part of the sicca syndrome, along with dry eyes discussed above. Vitamin B_{12} deficiency produces atrophic glossitis, a smooth, painful, red tongue.

Heart and Vessels. A carotid bruit indicates turbulent flow in the vessel but is a poor predictor of the degree or potential risk of the vascular lesion. A thickened, tender temporal artery points to giant cell arteritis; here, the physical examination is an excellent guide to clinical significance. Cardiac valvular disease, marked by cardiac murmurs, is important in assessing the cause of stroke and congestive heart failure may be relevant in delirium. In a schizophrenic patient, a murmur may imply the velo-cardio-facial syndrome (a deletion at 22q11, also called DiGeorge syndrome). Patients with developmental disabilities may have multiple anomalies, including structural heart disease.

Extremities

Telegram: @medical_k

www.konkur.in

Joint inflammation as a pointer to systemic rheumatic disease is distinguished from noninflammatory degenerative joint disease (osteoarthritis) by the presence of swelling, warmth, and erythema and is characteristically seen in wrists, ankles, and metacarpophalangeal joints, as opposed to the involvement of the base of the thumb, distal interphalangeal joints, and spine in degenerative joint disease. Raynaud phenomenon and sclerodactyly are signs of connective tissue disease. Joint laxity, such as is seen in the Ehlers–Danlos syndrome, is surprisingly associated with anxiety disorders.

The Neurologic Examination

Olfaction. Hyposmia is common in neurologic diseases but even more common in local disease of the nasal mucosa, which must be excluded before a defect is taken to be of neuropsychiatric significance. Assessment of olfaction is often ignored ("cranial nerves II through XII normal"), but it is easily performed and gives clues to the integrity of regions otherwise hard to assess, notably the orbitofrontal cortex. The olfactory nerve lies underneath the orbitofrontal cortex; projections go to the olfactory tubercle, entorhinal, and piriform cortex in the temporal lobes, amygdala, and orbitofrontal cortex. Testing of olfaction is best performed using a floral odorant, such as scented lip balms, which are inexpensive and simple to carry. Although a distinction can be made between the threshold for odor detection and that for identification of the stimulus, with differing anatomies, at the bedside without special equipment, the best one can achieve is recognition of a decrement in sensitivity (i.e., whether the patient smells anything, even without being able to identify it).

Eyes. Pupillary dilation may indicate anticholinergic toxicity; pupillary constriction is a characteristic feature of opiate toxicity. Argyll Robertson pupils are bilateral, small, irregular, and reactive to accommodation but not to light; the finding is characteristic of paretic neurosyphilis but also present in other conditions. Papilledema indicates elevated intracranial pressure; the earliest and most sensitive feature is the loss of venous pulsations at the optic disc. A homonymous upper quadrantic field defect is present when temporal lobe disease affects the loop of Meyer, the portion of the optic radiation that dips into the temporal lobe. A field defect in a delirious patient may point to an etiology in focal vascular disease (as discussed below). The normal spontaneous blink rate is 16 ± 8 per minute. Hypodopaminergia is associated with a reduction in blink rate. Impairment of voluntary eye-opening is seen in association with extrapyramidal signs, making the common appellation "apraxia" of eye-opening a misnomer. Impairment of voluntary eye closure is seen after frontal or basal ganglia damage.

Both saccadic and pursuit eye movements should be examined. The former is assessed by asking the patient to look to the left and the right, up and down, and at the examiner's finger on the left, right, up, and down. Pursuit eye movements are examined by asking the patient to follow a moving stimulus in both the horizontal

Telegram: @medical_k

www.konkur.in

and vertical planes. These maneuvers test supranuclear control of eye movements; the oculocephalic maneuver (doll's head eyes), that is, moving the patient's head tests the brainstem pathways and may be added to the assessment if saccades or pursuit is abnormal. Limitation of voluntary upgaze is common in the normal older adults. A limitation of voluntary downgaze, however, in a patient with extrapyramidal signs or frontal cognitive impairment may suggest progressive supranuclear palsy. Slowed saccades are characteristic of Huntington disease. Impairment of initiation of voluntary saccades, requiring a head thrust or head-turning, amounts to apraxia of gaze and is seen in developmental disorders as well as Huntington disease and parietal damage. Contrariwise, impairment of inhibition of saccades represents a visual grasp, with forced gaze at environmental stimuli. This can be usefully tested by placing stimuli (a finger and a fist) in the left and right visual fields of the patient and asking the patient to look at the fist when the finger moves and vice versa. The patient's inability to perform horizontal pursuit or saccadic movements without turning the head (head-eye synkinesia) may represent the same impairment of inhibition.

Facial Movement. Both spontaneous movements of emotional expression and movement to command should be tested. In pyramidal disorders, spontaneous movements may be relatively spared when the face is hemiparetic for voluntary movements. Contrariwise, in nonpyramidal motor disorders, voluntary movement may be possible despite a hemiparesis of spontaneous movement. The latter situation is seen *inter alia* in temporal lobe disease, including temporal lobe epilepsy, for which it has lateralizing value. Vertical furrows between the eyebrows are known as Veraguth folds and are associated with depression.

Speech. A number of speech abnormalities are listed in Table 2.1–1. A systematic examination of speech may include asking the patient to produce a sustained vowel ("ahhh"), the performance is assessed for voice quality, steadiness, and loudness; then strings of consonants ("puh-puh-puh") and alternating consonants ("puh-tuh-kuh-puh-tuh-kuh"), the performance is assessed for rate, rhythm, and clarity. Difficulty with the alternating sequence in the presence of normal production of individual consonants amounts to apraxia of speech.

Table 2.1–1.
Speech Syndromes

Telegram: @medical_k

www.konkur.in

Syndrome	Output	Characteristic Lesion Location or Associations
Aphemia	Initial mutism, recovery without agrammatism	Broca area (BA44), foot of left third frontal gyrus
Apraxia of speech	Inconsistent and slowed articulation, flattened volume, abnormal prosody	Left insula
Ataxic dysarthria	Slowed, equalization of or erratic stress (scanning), imprecise articulation	Cerebellum, especially superior-anterior vermis, left hemisphere to right
Pyramidal dysarthria	Slowed, strained, slurred	Anterior hemispheres, usually bilateral; may be accompanied by pseudobulbar palsy (dysphagia, drooling, pathologic laughing and crying)
Extrapyramidal dysarthria	Hypophonia, monotony of intonation, tailing off with longer phrases	Basal ganglia
Bulbar dysarthria	Nasality, breathiness, slurred articulation	Brainstem
Expressive aprosodia	Loss of emotional “melody of speech”	Right hemisphere
Foreign accent syndrome	Phonetic and prosodic alterations like those of dysarthria after cortical damage but giving listener feeling of foreign accent	Motor or premotor cortex or subjacent white matter of left hemisphere
Developmental stuttering	Repetition, prolongation, arrest of sounds; if overcome in childhood, may re-emerge after stroke, onset of Parkinson disease	Various hemisphere sites
Acquired stuttering	No dystonic facial movements as are seen in developmental stuttering	Various hemisphere sites
Cessation of stuttering	Not an abnormality but the reversal of an abnormality	Various hemisphere sites
Echolalia	Automatic repetition of interlocutor’s speech or words	Various anatomies, but seen in frontotemporal

Telegram: @medical_k

www.konkur.in

	heard in environment, sometimes with reversal of pronouns, correction of grammar, completion of well-known phrases	dementia, transcortical aphasias, other settings
Palilalia	Automatic repetition of own final word or phrase, with increasing rapidity and decreasing volume	Usually extrapyramidal system
“Blurting,” “echoing approval”	Automatic utterance of stereotyped or simple responses (e.g., “yes, yes”)	Frontal system

The mute patient poses a special problem in neuropsychiatric assessment. Mutism may occur at the onset of aphemia or transcortical aphasia due to vascular lesions, and it commonly develops late in the course of patients with frontotemporal dementia or primary progressive aphasia. The examiner should assess nonspeech movements of the relevant musculature, for example, tongue movements, swallowing, and coughing. Other means of communication should be attempted, such as gestures, writing, or pointing on a letter board or word board.

Abnormalities of Movement. The neuropsychiatric examiner should pay attention to weakness, abnormality of muscle tone, abnormal gait, and involuntary movements. Weakness due to muscle, peripheral nerve, or lower motor neuron disease is associated with atrophy, fasciculations, characteristic distributions, loss of reflexes, and tenderness in the case of muscle disease. Of greater relevance to cerebral mechanisms, pyramidal weakness, greatest in the distal musculature, is accompanied by increased muscle tone in a spastic pattern (flexors in the upper extremity, extensors in the lower extremity, with the sudden loss of increased tone during passive movement, the “clasp-knife” phenomenon), loss of control of fine movements, brisk tendon jerks, and the presence of abnormal reflexes such as the Babinski sign (discussed below). Less well recognized is the nonpyramidal motor syndrome, such as is seen in caudate or premotor cortical lesions: clumsiness, decreased spontaneous use of affected limbs, apparent weakness but production of full strength with coaxing. Mild degrees of impairment can be elicited with the pronator test by seeking pronation of the outstretched supinated arms; the forearm rolling test, by asking the patient to roll the forearms around each other first in one direction and then in the other, looking for one side that moves less thus appearing to be an axis that the other “orbits” around; rapid tapping of each hand and each foot; or fine finger movements, with the hands resting facing up on the thighs, the patient touching each finger to the thumb in turn and repeatedly.

Muscle tone can be increased not only in the pyramidal fashion just described but also as a manifestation of extrapyramidal or diffuse brain disease. In the latter case, paratonic rigidity, or Gegenhalten, is manifested by an erratic, “pseudoactive”

Telegram: @medical_k

www.konkur.in

increase in resistance to passive movement. The fluctuating quality of the resistance reflects the presence of both oppositional and facilitatory aspects of the patient's response to passive movement. The facilitatory aspect can be evoked by repeatedly flexing and extending the patient's arm at the elbow, then abruptly ceasing and letting go when the arm is extended; the abnormal response, facilitory paratonia, is for the patient to continue the sequence by flexion. In the case of extrapyramidal disease, the tone is increased in both extensors and flexors and throughout the range of movement, so-called lead-pipe rigidity. The "cogwheel" or ratchety feel to the rigidity is imparted by a coexisting tremor and is not intrinsic to the hypertonus; when paratonic rigidity co-occurs with a metabolic tremor, a delirious patient may mistakenly be thought to have Parkinson disease. Extrapyramidal rigidity can be amplified by activation techniques, such as movement of the limb contralateral to the one being examined (the Froment maneuver). However, this can occur bilaterally in healthy subjects, so it is most informative if unilateral.

Gait should always be tested, if only by focused attention to the patient's entering or leaving the room. Attention should be paid to the patient's station, postural reflexes, stride length and base, and turning. Postural reflexes can be assessed by asking the patient to stand in a comfortable fashion, then pushing gently on the chest or back, with care taken to avoid a fall. Gait should be stressed by asking the patient to walk in a tandem fashion and on the outer aspects of the feet. This may reveal not only mild ataxia (representing cerebellar vermis dysfunction) but also asymmetric posturing of the upper extremity (in nonpyramidal motor dysfunction). A short-stepped, "magnetic" gait in the context of unimpaired elementary movements of the legs (e.g., showing how to pedal a bicycle) is considered apraxia of gait.

Akinesia is manifested by delay in initiation, slowness of execution, and difficulty with complex or simultaneous movements. Mild akinesia may be observed in the patient's lack of spontaneous movements of the body while sitting or of the face or elicited by asking the patient to make repeated large-amplitude taps of the forefinger on the thumb (looking for decay of the amplitude). Akinesia is characteristically accompanied by rigidity. These plus rest tremor and postural instability represent the core features of the parkinsonian syndrome, seen not only in idiopathic Parkinson disease (IPD) but in several other degenerative, "Parkinson-plus" disorders such as progressive supranuclear palsy and multiple system atrophy as well as in vascular white-matter disease. Parkinsonian signs are not uncommon in frontotemporal dementia. Rest tremor is less common in these other disorders than in IPD.

Dystonia is sustained muscle contraction with consequent twisting movements or abnormal postures. Typically dystonia in the upper extremity is manifested as hyperpronation, in the lower extremity as an inversion of the foot with plantar flexion. Dystonia may occur only with certain actions, such as writer's cramp; focally, such as blepharospasm or oculogyric crisis; or in a generalized pattern, such as torsion dystonia associated with mutations in the DYT1 gene. The

Telegram: @medical_k

www.konkur.in

symptoms and signs often do not comport with a naïve idea of how things should be in organic disease; only expert knowledge will suffice for recognition. For example, a patient with early torsion dystonia may be able to run but not walk because the latter action elicits leg dystonia. Or a patient with intense neck muscle contraction may be able to bring the head to the midline by a light touch on the chin, a *geste antagoniste* diagnostic for dystonia.

A tremor is a regular oscillating movement around a joint. In rest tremor, the movement occurs in a relaxed, supported extremity, and is reduced by action. Often an upper extremity rest tremor is amplified by ambulation. The frequency is usually 4 to 8 Hz. This is the distinctive tremor of Parkinson disease. In postural tremor, sustained posture elicits tremor. It may be made more visible by placing a sheet of paper over the outstretched hand. Hereditary essential tremor presents as postural tremor, predominantly in upper extremities but also at times involving the head, jaw, and voice. A coarse, irregular, and rapid postural tremor is often seen in metabolic encephalopathy. In intention tremor, the active limb oscillates more prominently when approaching its target, such as touching with the index finger the examiner's finger. Maximizing the range of the movement increases the sensitivity of the test. Intention tremor is one form of kinetic tremor, which is a tremor elicited by movement; another sort of kinetic tremor is that elicited by a specific action, such as writing tremor or orthostatic tremor upon standing upright. The examiner can characterize tremor by observing the patient with arms supported and fully at rest, then with arms outstretched and pronated, then with arms abducted to 90 degrees at the shoulders and bent at the elbows while the hands are held palms down with the fingers pointing at each other in front of the chest. The patient should also be observed during ambulation. Anxiety exaggerates tremor; this normal phenomenon, for example, when the patient is conscious of being observed, should not be mistaken for a functional etiology. A good test for psychogenic tremor relies on the fact that although organic tremor may vary in amplitude, it varies little in frequency. A patient can be asked to tap a hand at a frequency different from the tremor frequency; if another tremulous body part entrains to the tapped frequency, a psychogenic tremor is likely.

Choreic movements are random and arrhythmic movements of small amplitude that dance over the patient's body. They may be more evident when the patient is engaged in an activity such as ambulation. When the movements are of large amplitude and forceful, the disorder is called ballism. Ballistic movements are usually unilateral.

Myoclonus is a sudden, jerky, shock-like movement. It is more discontinuous than chorea or tremor. The negative of myoclonus is asterixis, a sudden lapse of muscle contraction in the context of attempted maintenance of posture. Both phenomena, but more sensitively asterixis, are common in toxic-metabolic encephalopathy (not just hepatic encephalopathy). Asterixis should be carefully sought by observation of the patient's attempt to maintain extension of the hands with the arms outstretched ("like you are stopping traffic") because it is pathognomonic for organic disease and

Telegram: @medical_k

www.konkur.in

is never seen in acute idiopathic psychosis or other nonorganic disorders. Myoclonus is additionally an important feature of nonconvulsive generalized status epilepticus, serotonin syndrome, and Creutzfeldt–Jakob disease (CJD). Unilateral asterixis may be rarely seen in parietal, frontal, or (most often) thalamic structural disease.

Tics are sudden, jerky movements as well, but they may be more complex than myoclonic jerks and are subjectively characterized by an impulse to perform the act and a sense of relief for having done so (or mounting tension if restrained from doing so). Compulsions are not easy to differentiate from complex tics; the tiqueur may, like the patient with compulsions, report deliberately performing the act. Repetitive behavior superficially like compulsions may occur in organic disease but represent environment-driven behavior rather than having the same subjective structure as compulsive behavior. For example, a patient with frontal disease may repeatedly touch an alluring object without an elicitable subjective impulse and without anxiety if separated from the object. Organic obsessions and compulsions occur as well and have been associated with globus pallidus lesions, among others.

Akathisia is defined by both its subjective and its objective features. The patient exhibits motor restlessness, for example, by shifting weight from foot to foot while standing, and expresses an urge to move. At times psychotic or cognitively impaired patients cannot convey the subjective experience clearly, and the examiner must be alert for the objective signs in order to differentiate akathisia from agitation due to anxiety or psychosis. The complaints and the signs in akathisia are referable to the lower, not the upper, extremities; the anxious patient may wring the hands, and the akathisic patient shuffles the feet. Myoclonic jerks of the legs may be evident in the recumbent patient. The phenomenon occurs in IPD and with drug-induced dopamine blockade, but also rarely with extensive frontal or temporal structural lesions.

Ataxia is a disorder of coordinating the rate, range, and force of movement and is characteristic of diseases of the cerebellum and its connections. In the limbs, dysmetria represents a disordered determination of the distance to be moved so that the patient overshoots or undershoots the target; if the reaching limb oscillates in the process, the clinician observes an intention tremor. Asking patients to touch the examiner's finger, then their own nose tests this system. Accurately touching one's own nose with eyes closed requires both cerebellar and proprioceptive function. Eye movements also may be hypermetric or hypometric. The patient's difficulty in performing rapid alternating movements, such as supination/pronation of the hand or tapping of the foot, is called dysdiadochokinesia. The failure of coordination of movement is also demonstrated by loss of check, which should not be elicited by arranging for the patient to hit themselves when the examiner's hand is removed. In a normal situation, if the outstretched arms are tapped, only a slight waver is produced; the ataxic patient fails to dampen the movement. Gait may be affected by midline cerebellar (vermis) disease in the absence of limb ataxia, which is related to cerebellar hemisphere disease. Gait is unsteady, with irregular stride

Telegram: @medical_k

www.konkur.in

length and a widened base. (In the normal subject, the feet nearly touch at their nearest point; even a few inches of separation represent a widening of the base.) Gait and limb ataxia may be complemented by cerebellar dysarthria (described in Table 2.1–1) and by eye movement disorders, including nystagmus (usually gaze-paretic), slowed saccades, saccadic pursuit, and gaze apraxia.

The catatonic syndrome has been variously defined. The core of the syndrome is a mute, motionless state; variably added are abnormal movements, including grimacing, stereotypy, echopraxia, and catalepsy. The latter, also known as *flexibilitas cerea* (waxy flexibility), refers to posturing of a limb in the position in which it is placed by the examiner or in some other unnatural position. It is not seen in all or even most cases of catatonia, and it can be seen apart from the catatonic syndrome in patients with contralateral parietal lesions (as described below as the avoidance sign of parietal disease). Catatonic excitement refers to the sudden eruption into over-activity of a catatonic patient; this probably usually represents psychotic mania. The catatonic syndrome occurs in the course of schizophrenia or mood disorder as a manifestation of autoimmune encephalopathy due to antibodies to the NMDA receptor, in nonconvulsive generalized status epilepticus, in acute cerebral metabolic or structural derangements, or without other psychopathology as idiopathic catatonia. In the latter case, it is best thought of as a nonspecific reaction pattern, such as delirium, requiring a comprehensive clinical and laboratory evaluation to seek the cause of the behavioral disturbance. An important instance is catatonia as part of the neuroleptic malignant syndrome, the diagnosis of which requires exclusion of other metabolic encephalopathies, notably systemic infection. Catatonia is thus a medical emergency, requiring prompt attention to diagnostic evaluation as well as supportive care (fluids, nutrition, and measures to avoid complications of immobility, including venous thrombosis).

Motor sequencing tests assay the function of premotor cortical areas and striatum and are related to deficits in executive cognitive function seen with dysfunction of the dorsolateral prefrontal loop. The ring/fist test involves asking the patient to alternate between making a ring with his thumb and first finger and making a fist with the same hand (“ring, fist, ring, fist”). The abnormal response is perseveration of one or the other posture or disorganization of the sequence. At times, patients will be unable to perform the correct series even when repeating the verbal cues aloud. A more complex alternation is between striking the table gently with the fist, then the edge of the hand, then the palm (“fist, edge, palm, fist, edge, palm”). A different approach is to ask the patient to extend the arms, make a fist with one hand while keeping the other hand flat, and then switching hands. The abnormal response has the patient ending up with two fists or two palms outstretched.

A review of the material in this section on the motor system will reveal how much can be accomplished in the neurologic examination by asking the patient to stretch out their arms. With a few additional maneuvers (tapping the outstretched pronated hands, supinating them and asking the patient to close the eyes, then asking the patient to touch the nose with the eyes still closed, then asking the patient to

Telegram: @medical_k

www.konkur.in

perform the alternating fists test) all of the following can be assessed in a matter of a minute or so: postural and intention tremor, loss of check, asterixis and myoclonus, a pronator sign, dysmetria, and motor sequencing. Doing this, plus testing muscle tone, plus observing the patient's natural and stressed gait, and checking tendon jerks and abnormal reflexes, takes just a few minutes and does not elucidate disorders of muscle, nerve, and spinal cord but represents a rather extensive assessment of the central organization of the motor system.

Abnormalities of Sensation. Disorders of sensation are sometimes difficult to assess reliably in patients with cognitive and behavioral disorders. Nonetheless, several points should be familiar to the neuropsychiatrist. Distal loss of sensation, often accompanied by loss of ankle jerks, is characteristic of peripheral neuropathy. Often, all modalities of sensation are disturbed. If proprioception is sufficiently severely reduced, a Romberg sign will be present. The Romberg sign means that closing the eyes produces substantial impairment of balance; it is elicited by asking the patient to stand, allowing the patient to seek a comfortably balanced position, then asking the patient to close the eyes (ensuring against a fall).

Loss of sensation from sensory cortex injury is classically limited to complex discriminations, such as graphesthesia (recognizing numbers written on the palm), stereognosis (identifying unseen objects in hand), and two-point discrimination (telling whether the examiner is touching with one or two points, as these come closer together in space). However, patients with parietal stroke may have a pseudothalamic sensory syndrome (with impairments in elementary sensory modalities and subsequent dysesthesia) or other anomalous patterns of sensory loss. At times these patients will present with pseudomotor deficits: ataxia, fluctuating muscle tone and strength (dependent in part on visual cueing), "levitation," and awkward positioning of the arm contralateral (or at times ipsilateral) to the lesion. In the acute phase, the combination of deficits can amount to motor helplessness. These deficits result from the loss of sensory input to regions in which motor programs arise. The lessons here are that "cortical" sensory deficits should be sought if there is a question of cortical involvement and that more dramatic or unusual sensory abnormalities may also occur with cortical lesions.

Soft Signs. An extensive literature about the "soft signs" of neurologic dysfunction is difficult to comprehend because of the varied definitions and batteries used in the various studies. Most of the signs sought in these batteries are discussed in this section under their more specific headings, such as graphesthesia under abnormalities of sensation and the alternating fist (Oseretsky) test under motor sequencing. From the corpus of test batteries, a few simple maneuvers can be extracted that can contribute to the neurologic examination of the patient with a neuropsychiatric presentation.

While the patient is touching each finger to the thumb, as described above in the section on weakness, the examiner can watch the opposite hand for mirror movements. Obligatory bimanual synkinesia is seen specifically in disorders of the

Telegram: @medical_k

www.konkur.in

pyramidal pathways, such as the Klippel–Feil syndrome, and in agenesis of the corpus callosum, but also in putative neurodevelopmental disorders such as schizophrenia. Asking the patient, with eyes closed, to report whether the examiner is touching one or the other hand (with the patient's hands on the patient's lap), or one or the other sides of the face, or a combination, makes up the face–hand test. The examiner touches the left hand and right face simultaneously. If the patient reports only the touch on the face (i.e., extinguishing the peripheral stimulus), then the examiner can prompt (once), "Anywhere else?" Then the examiner touches the right hand and left cheek, left hand and left cheek, right hand and right cheek, both hands, and both cheeks. Extinction of the peripheral stimulus is the pathologic response and has been associated with schizophrenia and dementia.

Abnormal Reflexes. The Babinski sign is the shibboleth of the neurologic examination. It should be elicited by stroking the lateral aspect of the foot from back to front, with the leg extended at the knee, using a pointed object such as an orange stick or a key. The response of extension of the great toe with or without fanning of the other toes indicates corticospinal tract disease. Two confounding factors in the assessment of the Babinski sign are the striatal toe and the plantar grasp. The striatal toe is an extension of the hallux without fanning of the other toes or a flexion synergy in the other muscles of flexion of the leg. It may occur spontaneously or upon elicitation in patients with Parkinson disease in the absence of evidence of pyramidal dysfunction. The plantar grasp, the equivalent of the familiar palmar grasp, may mask an extensor response to lateral foot stimulation when stimulation in the midfoot brings about flexion of the toes.

Other important reflexes for the neuropsychiatrist are:

- Myerson sign, a failure to habituate to regular, one per second, taps on the glabella (with the tapping hand outside of the patient's visual field), present in parkinsonism and diffuse brain disease;
- Hoffmann sign, flexion of the thumb with snapping of the distal phalanx of the patient's middle finger, an upper extremity sign of pyramidal dysfunction though sometimes present bilaterally in normal subjects;
- Grasp, flexion of the fingers with stroking of the patient's palm toward the fingers during distraction, despite instructions to relax, associated with disease of the contralateral supplementary motor area;
- Avoidance, extension of the wrist and fingers to the same stimulus as the grasp, a less well-known sign that points to contralateral parietal cortex abnormality.

Several other "primitive reflexes" are less specific in that they are commonly present in the normal subject and are thus less useful for diagnostic purposes. These include the suck, snout, and palmomental reflexes.

FOCAL NEUROBEHAVIORAL SYNDROMES

Telegram: @medical_k

www.konkur.in

The idea that the brain is regionally specialized had a difficult gestation in the 19th century, and the key to its acceptance lies with the recognition of the effects of focal brain lesions. At the end of the 18th and early in the 19th centuries, phrenology drew adherents to the claim that personality traits could be inferred by inspection of the cranium. This claim was faulty, but phrenology had an underlying theory that was an important step forward for the brain sciences; in particular, the beliefs that the brain was the organ of the mind and that the mind could be fractionated into functions gave impetus to the development of neuroscience in a modern form. In the middle of that century, the gradual realization that aphasia occurred with damage to specific areas of the left hemisphere was another crucial step. The subsequent identification of numerous syndromes of localized damage—syndromes such as apraxia, agnosia, visuospatial impairment in its various forms, and so on—is a fascinating story of astute and painstaking clinicopathologic, and later clinicoradiologic, correlation.

Patients' introspective access to their deficits may be limited. Much of cognitive processing is unconscious, not in the sense of being excluded from awareness by motivated defense, but in the sense that it is not even in principle open to introspection. Jonathan Miller, in his television show *The Body in Question*, displayed this point by asking passersby, in a man-in-the-street interview, "Sir, where is your spleen?" No one can say from introspection where the spleen is. The same is true of much of cognitive processing. Explanations provided by patients may be confabulations that fill in such introspective gaps in a situation where the brain is functioning abnormally in a way not foreseen in its design. In neuropsychiatry, subjective experience and behavior are separate explicanda. The patient's appraisal of his or her own situation is always relevant to collaboration with treatment and its outcome and should be explored in every clinical encounter.

Dementia

The term dementia, like the term organic, has been officially replaced in the case of dementia by Major Neurocognitive Disorder. Psychologists and psychiatrists are more sensitive to this change than other clinicians, such as neurologists, so for the purposes of interdisciplinary communication, as with the term organic, this chapter uses the older term. Although commonly considered a syndrome of "global" cognitive impairment, implying global or diffuse brain dysfunction, in fact, each dementing disorder produces a distinct pattern of brain pathology and a corresponding pattern of cognitive dysfunction. For this reason, and against tradition, dementia will be discussed under the rubric of focal neurobehavioral syndromes. (Here, the science, not a committee, elicits the change.)

In Alzheimer disease, the earliest neuropathologic abnormality is a characteristically medial temporal accumulation of plaques and tangles, initially in the entorhinal cortex and subiculum (the input and output zones of the hippocampus). The disease progressively involves association cortices in temporoparietal and prefrontal regions. This burden of pathology determines the

Telegram: @medical_k

www.konkur.in

characteristic early memory impairment with ensuing anomia, failure of grasp, and coarsening of personality. On occasion, Alzheimer disease pathology is predominantly posterior, with a concomitant predominance of visuospatial impairment in the clinical course (the syndrome of posterior cortical atrophy), or predominantly in frontal networks, with executive dysfunction and characteristic behavioral alterations (the syndrome of frontal or executive variant Alzheimer disease). By contrast, in frontotemporal dementia, the earliest disease manifestations are pathologically in the frontal or temporal cortex, clinically presenting as primary progressive aphasia, semantic dementia, or a frontal apathy or disinhibition syndrome (bvFTD). In none of these situations is a view of dementia as a “global” impairment of brain function justified by the clinical or pathologic facts; rather, selective disruption of anatomic networks corresponds to symptomatic features.

Extensive subcortical white and gray matter damage due to small vessel disease is a common cause of dementia, and in this situation, the clinical picture is dominated by slowed mental processing, forgetfulness with relative preservation of recognition memory (as opposed to free recall), and executive cognitive dysfunction. “Strategically” located single infarctions can also produce dementia. These strokes can involve the left angular gyrus, genu of the internal capsule, and (perhaps most commonly) medial thalamus. The thalamic and internal capsule strokes may produce cognitive impairment by interfering with frontal networks.

Delirium

Classically a syndrome of “global” brain dysfunction due to toxic-metabolic or infectious encephalopathy, delirium may also point to focal brain disease. Delirium may be caused by infarction in the right posterior superior temporal gyrus due to occlusion of the inferior division of the right middle cerebral artery, or by infarction in the inferior temporo-occipital cortex, on the left or bilaterally due to posterior cerebral artery occlusion. In both instances, focal neurologic signs may be limited to a visual field cut or absent entirely. Finding bilateral asterixis or multifocal myoclonus strongly indicates a toxic-metabolic brain derangement, and the history and physical examination should provide pointers for the essential laboratory confirmation of the abnormality. Features of the mental state are of little use in determining the cause of the syndrome, except that agitation is far more common in certain disorders, such as substance withdrawal, hypoxia, and the syndromes of left posterior cerebral artery stroke or right-middle cerebral artery stroke with involvement of the temporal lobe. Agitation with prominent insomnia and sympathetic hyperactivity—together called *agrypnia excitata*—may raise the question of Morvan syndrome, associated with antibodies to CASPR-2 or, less commonly, LGI1.

Aphasia

Telegram: @medical_k

www.konkur.in

Acquired impairment of lexical or syntactic performance is termed aphasia. Lexicon and syntax do not exhaust the domain of language and attention is devoted below to prosody and discourse pragmatics. At the bedside, the clinician should be able to distinguish language impairment from other sources of abnormal discourse (such as psychosis), delineate the features of abnormality in the patient's linguistic function, and tentatively identify the locus of brain injury.

A simple distinction between "expressive" and "receptive" defects has some power to distinguish between anterior and posterior lesion sites, but it is not in current use in aphasiology because most aphasiogenic lesions produce some impairment in both production and comprehension of language, and these impairments are of multiple sorts.

A widely accepted approach to examination and classification of aphasia identifies six domains for elucidation: spontaneous speech, naming, comprehension, repetition, reading, and writing. Attention to spontaneous speech reveals dysfluency and word-finding difficulties. The dysfluent speaker produces shorter phrases and utterances without a natural flow. Substantives (nouns and verbs) may be preserved at the expense of function words (such as prepositions) and grammatical morphemes (such as tense endings), leading to agrammatical utterances that are nonetheless relatively information-rich. Lesions disrupting fluency are characteristically anterior in the left hemisphere or involve the putamen. Naming performance requires the adequate functioning of a network, including posterior temporal, temporoparietal, and inferior frontal sites. This is ordinarily tested by confrontation ("What do you call this?"), which can be conveniently done using body parts or common items at the bedside. Naming from description ("What do you call the vehicle that travels underwater?") is an alternative mode of testing, particularly useful for visually impaired or agnosic patients. Comprehension is tested best using probes with minimal demand on output, so "yes/no" questions ("Does a stone sink in water?") are better than motor commands, which may be impaired by concurrent apraxia. Impairment of comprehension results from posterior temporal lesions. Disordered repetition is disclosed by asking the patient to produce progressively longer utterances reiterating the examiner: "Airplane, he and she are here, the spy fled to Greece…." Repetition may be surprisingly spared (the so-called transcortical aphasias) or disproportionately impaired (conduction aphasia). The latter depends on lesions of the insula or external capsule. Reading comprehension (not reading aloud, a different skill) tests comprehension with a different input modality from aural comprehension and some patients will show significant dissociations. Similarly, writing tests output in a different modality from speech. Writing is a particularly sensitive probe for the anomia seen in early Alzheimer disease and the disorganization seen in delirium.

A classification of the aphasias using the data from an examination, as just outlined, is shown in Table 2.1–2. Clinicians recognize, however, that many patients will not fit well into the categories created by this scheme.

Telegram: @medical_k

www.konkur.in

Ideomotor apraxia commonly occurs together with aphasia. This is a disorder of performance of skilled movements to command in the absence of explanatory elementary sensory and motor disturbances. Oral apraxia is revealed by the patient's incapacity to show, for example, how to blow out a match or lick an envelope. Limb apraxia is shown by the patient's incapacity to show, for example, how to wave goodbye or use a hammer or screwdriver. Patients with these deficits may nonetheless be able to follow whole body commands: "Show me how a boxer stands," for example. Patients rarely complain of apraxic deficits, in part because they are artifacts of the examination, in the sense that they may not be present in the utilization of real-world items.

Attention

Several related phenomena cluster under the clinical description of attentional disorders. At the most fundamental level, alertness represents a continuum ranging from a coma to normal wakefulness. The clinician faced with a patient who is less than fully alert should quantify the disorder by assessing the patient's response to a graded series of probes: does the patient orient to the examiner's presence in the room, what does the patient do when his or her name is called or when touched or when shaken or when a (harmless) painful stimulus is applied, and so on. These responses should be recorded in detail rather than summarized by an ambiguous term such as "lethargic."

Alert patients may show deficits in sustained attention to external stimuli (vigilance) or internal stimuli (concentration). Attentional deficits of these sorts are characteristic of delirium. Vigilance can be assessed with a bedside adaptation of a continuous performance task, for example, by asking the patient to lift a hand each time the examiner says the letter "A" or (to raise the difficulty) each time the examiner says the letter "A" after the letter "D." The examiner then produces a series of random letters at a deliberate and steady rate over an extended period of time. Any error of omission or commission represents a failure. By asking the patient to count from 20 to 1 or give the days of the week or the months of the year in reverse, the examiner can appraise concentration. Digit span—asking the patient to repeat a list of numbers spoken at a slow, steady rate without separation into chunks—is a classic test of attention; the lower limit of normal digit span is five.

A "higher" level of attentional function is the capacity to manipulate information kept in consciousness over a short period of time: working memory. An excellent example is alphanumeric sequencing. The patient is asked to alternate between numbers and letters; the examiner provides "1-A-2-B-3-C" as a model, then allows 30 seconds for the patient to start at 1 and give as many alternations as possible. If only the number of correct alternations is counted (ignoring errors), the lower limit of normal is 15. A comparable, simple task is alphabetizing the letters of the word "world" (or any similar word). Working memory is known to require intact processing in the dorsolateral prefrontal cortex.

Telegram: @medical_k

www.konkur.in

Hemineglect is a focal disorder of attention, almost always of left hemispace in a patient with acute right hemisphere disease. Most characteristically, the lesion is parietal, but distinguishable patterns of hemineglect occur with frontal and cingulate lesions. Gross neglect can be recognized in the patient's ignoring, or even denying the ownership of, the left limbs or failing to attend to objects and people in the left hemispace. Subtler degrees of neglect can be elicited by presenting an array in which the patient must search into both hemifields to point to items, for example, all the yellow dots in a stimulus card with dots of varied colors to both left and right.

In the phenomenon of hypermetamorphosis, part of the Klüver–Bucy syndrome of bilateral anterior temporal damage, animals or patients exhibit an increased level of attention to individual items in the environment.

Amnesia

The term *memory* is used in several ways by clinicians and psychologists. The amnestic syndrome features impairment of learning of new material (anterograde amnesia) and a variable period of impaired recall prior to the onset of the syndrome (retrograde amnesia). It is due to damage to the hippocampus or to the anterior thalamus (including the mammillothalamic tract). Memory proper is distinguished from retention in the consciousness of material over the course of a few seconds, which may be called "working," "iconic," or "short-term" memory. This function is spared in the amnestic syndrome because it depends on frontoparietal mechanisms distinct from the hippocampal and thalamic pathways damaged in amnesia. Deficits due to hippocampal and thalamic lesions are dependent on the lateralization of the damage, left-sided damage producing predominantly verbal and right-sided damage figural memory impairments.

A distinction between free recall and recognition memory is of clinical significance and generally can be made adequately if imperfectly at the bedside. Hippocampal and thalamic patients show accelerated forgetting so that cues (such as providing the semantic category) are relatively ineffective in aiding recall. This is the characteristic pattern of Alzheimer disease. Recognition memory is always better than free recall on an absolute scale; exaggeration of the disparity (i.e., sparing of recognition memory) is characteristic of memory impairment due to dysfunction of frontal mechanisms of effortful search.

In addition, frontal patients show impairments of memory for the temporal context or source of information. This deficit is probably relevant to the occurrence of confabulation. Spontaneous confabulation occurs in only a minority of amnestic patients and depends on ventromedial frontal damage.

Memory is so commonly impaired in brain disorders that it should be tested in all patients undergoing neuropsychiatric evaluation. Recall of a test phrase (e.g., a name and address) or a word list over a several-minute distraction is a valid and simple screening test. However, a more detailed analysis of memory is necessary for patients with disorders likely to affect memory mechanisms, including (among many others) head injury, epilepsy, and dementing disorders. Testing should include

Telegram: @medical_k

www.konkur.in

both verbal and nonverbal material. For example, testing recall over several minutes' delay of three words and three shapes, or three words and three-pointed directions, or three object names and the locations in the room in which those objects were hidden is easily performed. Further, the examiner should be prepared with cues, including appropriate (incorrect) foils, to assess sparing of the capacity to make use of cues in frontal memory impairment. For example, if one of the words provided is "piano," the examiner could cue, "One was a musical instrument" and further provide "guitar, piano, violin" as multiple-choice options. Only rough inferences can be drawn from this bedside assessment as compared with neuropsychological evaluation.

Table 2.1–2.
Aphasia Syndromes

Aphasic Syndrome	Spontaneous Speech	Repetition	Naming	Aural Comprehension	Reading for Comprehension	Writing	Additional Features	Characteristic Lesion Location
Global	Impaired	Impaired	Impaired	Impaired	Impaired	Impaired	Right hemiplegia, hemisensory loss, hemianopia	Extensive anterior and posterior perisylvian cortex
Broca	Dysfluent, effortful, agrammatic	Impaired	Impaired	Spared	Spared	Impaired	Frustration, right hemiparesis, buccofacial and limb apraxia	Anterior perisylvian cortex and insula
Wernicke	Fluent, paraphasic, absence of substantive words	Impaired	Impaired	Impaired	Impaired (but not always to same degree as aural comprehension)	Impaired	Unawareness of illness, paranoia, visual field defect	Wernicke area (posterior superior temporal gyrus)
Conduction	Fluent, paraphasic with phonemic errors	Impaired	Impaired	Spared	Spared	Impaired		Supramarginal gyrus or primary auditory cortex
Transcortical motor	Dysfluent	Spared	Impaired	Spared	Spared	Impaired		Anterior/superior to Broca area or medial surface of hemisphere involving supplementary motor area
Transcortical sensory	Fluent, paraphasic	Spared	Impaired	Impaired	Impaired	Impaired		Temporoparietal or occipitotemporal cortex posterior and inferior to Wernicke area
Mixed transcortical	Dysfluent	Relatively spared	Impaired	Impaired	Impaired	Impaired	Echolalia	Isolation of perisylvian cortex by extensive watershed infarction
Anomic	Fluent, paraphasic	Spared	Impaired	Spared	Spared	Spared		Nonspecific within language areas

Apart from patients with persisting amnestic syndromes, the neuropsychiatrist may be presented with patients who suffered an amnestic state transiently or rarely may see one during a transient amnestic state. The syndromes of transient global amnesia and transient epileptic amnesia, and their differentiation, have been fully described and require thorough history taking, neuropsychological evaluation, and electroencephalogram (EEG) recordings. The neuropsychiatrist should also know that amnesia for criminal offenses is common; certainly, it is not confined to those who committed a crime while in a delirious, ictal, or postictal state, as is sometimes claimed for exculpatory reasons.

Visuospatial Dysfunction

The requirement to test visual as well as verbal memory has just been mentioned. Drawing and copying tasks can further the assessment of visuospatial function. Copying intersecting pentagons (as in the Mini-Mental State Examination) or the shapes used in the memory task begins the assessment. With more complex figures, failures with a slavish element-by-element strategy are characteristic of patients with right hemisphere damage, as is the neglect of the left side of the stimulus. Recognition of drawn objects presented in atypical ways, such as the Poppelreuter overlapping figures, tests visuospatial analysis without praxis.

Telegram: @medical_k

www.konkur.in

The variety of disorders of higher visual function has already been mentioned in describing the complex structure of visual association cortices. Prosopagnosia is a defect in the recognition of faces. Such a defect may be obvious from the history or may be a more subtle abnormality; it can be spotted at the bedside, albeit insensitively, with the use of a few pictures of famous people. Defects of topographic skill, although rarely presenting in an isolated form, also occur with right hemisphere dysfunction. The patient can be asked to describe a route between familiar places or a geographical question thought to be within premorbid capacities ("If you're going from New York to Los Angeles, is the Atlantic Ocean in front of you, behind you, to your left, to your right?").

The incapacity to grasp in attention multiple visual objects at once is known as simultanagnosia. The patient may fail in describing a complex visual scene by reporting only a single, perhaps peripheral, element. Together with psychic paralysis of gaze (inability to direct gaze voluntarily, or ocular apraxia) and optic ataxia (misreaching under visual guidance), it makes up Balint syndrome, the archetypal disorder of the dorsal visual pathway. The patient with impairment of reaching under visual guidance should be examined reaching without visual guidance (e.g., pointing to parts of their own body with eyes closed) to confirm the defect.

Executive Cognitive Dysfunction

This term refers to the initiation of cognition and action, their maintenance in the face of distraction, organized but flexible pursuit of goals, and self-monitoring with error correction. Executive processes are crucial for adaptive function, and performance in this realm is better correlated with real-world outcomes of brain-injured patients than are many other domains traditionally analyzed in neuropsychology or many psychosocial variables. Exploration of executive function is of central importance in the neuropsychiatric examination. Analysis of behavioral disturbance and neuropsychological deficits in patients with cerebral injury suggests that multiple dissociable processes compose executive cognitive function, and certainly, these processes are instantiated by anatomically distributed systems. However, many different tasks recruit a similar or identical set of regions in the mid-dorsolateral prefrontal cortex, the mid-ventrolateral prefrontal cortex, and the anterior cingulate. Nonetheless, the clinical examiner must know that no single probe can screen for all dysfunctions.

Many aspects of executive function are illuminated by attention to the patient's performance of elements of the history taking and examination. Disinhibition may be noted in abnormalities of comportment during social interaction. Motor impersistence, the failure to sustain actions that can be initiated properly, may be noted in the patient's peeking when asked to keep the eyes closed, repeatedly looking back at the examiner's face when lateral gaze (especially to the left) is attempted, or failing to keep the arms extended or the tongue protruded when instructed to do so. Perseveration is the continuation of elements of past actions into present activity. Perseverative responses may be noted when testing naming or

Telegram: @medical_k

www.konkur.in

attention. Echopraxia, for example, the patient's crossing the arms when the examiner (spontaneously) does so, even when some other behavior has been requested, can be observed during the interview and examination. Similarly, echolalia refers to the automatic repetition of an interlocutor's speech. Blurting, also called echoing approval or yes/no reversal, is the automatic response to a question, followed immediately by the patient's correction of the automatic response ("yes, yes") to the intended or correct response ("no"). Utilization behavior is an automatic tendency to make use of objects in the environment, for example, picking up a pen and starting to write, despite this behavior's being inappropriate to the setting.

More focused efforts to assess executive function are almost always indicated in the neuropsychiatric examination. Perseveration may be specifically sought in the motor sequencing tasks described above or with a sample of spontaneous writing. A tapping task with conflicting instructions may illuminate the inflexibility of goal-directed behavior that gives rise to perseverative responding. The patient is instructed to tap once if the examiner taps twice and twice if the examiner taps once. The examiner then taps on the table in a random series of one tap or two taps. This can be directly followed by a go/no-go tapping task, in which the patient is instructed to tap once if the examiner taps once, not at all if the examiner taps twice. Intrusions from the previous task's instructions represent perseverative responding; echopraxic responses (tapping just like the examiner) represent failures of inhibition. Inhibition of reflexive gaze can be tested during the examination of eye movements, as described above. Looking at the moving stimulus rather than in the opposite direction as instructed amounts to a visual grasp response and represents a failure of inhibition. Spontaneous word-list generation ("Tell me all the animals you can think of," or "Tell me all the words that start with 's'") depends on the capacity for an effortful search of semantic stores. A greater decrement in fluency to semantic cues ("animals") than to phonemic cues ("words with 's'") is seen in Alzheimer disease because of the degradation of semantic stores due to temporoparietal damage. Working memory can be assessed with the alphanumeric sequencing task described above.

Anatomic inferences from dissociations in performance on these tasks are limited. Go/no-go tasks depend on the integrity of the orbitofrontal cortex and other tasks on the dorsolateral prefrontal cortex and its circuit. Impersistence is associated with right hemisphere dysfunction. A further dissociation between executive cognitive impairments and personality change can be seen in frontal injury. Especially with orbitofrontal lesions, executive function can be spared even in the face of grave alterations in emotions and comportment. Nonetheless, it bears repeating that neuropsychiatric examiners always should consider executive cognitive function in their formulation of cases.

Dysnarration

The patient's narrative also gives clues to brain dysfunction. Clinicians are familiar with the information-poor accounts provided by patients with memory impairment,

Telegram: @medical_k

www.konkur.in

perhaps accompanied by glances at the companion seeking assistance. Patients with dorsolateral prefrontal lesions may be laconic, aspontaneous, and apathetic in ways that are evident in their accounts of symptoms. Patients with ventromedial prefrontal lesions may be impulsive, disorganized, and insightless in ways that are observable in the interview. Pragmatic disorders due to frontal and right hemisphere damage may impair narrative coherence through verbosity, vagueness, and disregard for the listener's informational needs. Thus, for example, pronoun use may be syntactically correct, but the referents of pronouns are obscure to the listener. Although language itself is normal, the way language is embedded in social interaction is not.

Disordered Mood and Emotion

Several syndromes of disordered emotion in organic disease can be delineated. Disturbances of recognition and expression of emotion with right hemisphere lesions have already been mentioned. Patients and their families are rarely aware of these deficits and do not complain about them; rather, the examiner must recognize the deficit and figure it into a formulation of the patient's social and functional decline. Impairment of prosodic expression should not be mistaken for depressed affect. Testing of affective prosody can be undertaken at the bedside without special equipment. The examiner can ask the patient to say emotionally loaded sentences in an emotional manner, expressing surprise, fear, pleasure, and anger. People vary considerably in their native acting talents, and the range of normal performance is wide. The examiner also can utter neutral sentences in various emotional tones: "I am going to the store," stated with surprise, and so on, with the examiner's face turned away from the patient to avoid providing a second input channel. Patients should be able to recognize the affect. Separately, if testing materials are available, the examiner can assess the patient's capacity to identify emotions in visual scenes and facial expressions. Lesions that involve both limbic and heteromodal cortices in the right hemisphere especially impair performance in recognizing emotional facial expressions.

Pathologic laughing and crying are stereotyped displays of affect incongruent with inner experience and elicited by inappropriate, nonemotional, or inadequate stimuli. The examiner may, in the extreme, be able to elicit full displays of affect by waving a hand in front of the patient's face. The patient is often embarrassed by the pathologic expression of affect. Features of pseudobulbar palsy are often present in these patients. In these cases, damage to a volitional control system has disinhibited a network subserving emotional display. This network includes the amygdala, hypothalamus, periaqueductal grey, and dorsal tegmentum. A broader form of affective dysregulation, which may be called emotionalism or emotional lability, is more commonly seen, usually in the direction of tearfulness. Patients report that they are more emotional than previously and that the tears are sudden, unexpected, and uncontrollable. However, they are generally congruent with the patient's subjective state. Such patients are often cognitively impaired. The rare

Telegram: @medical_k

www.konkur.in

phenomenon of *fou rire prodromique* (mad prodromal laughter) presages acute vascular lesions of the brainstem or thalamus.

Apathy is an emotional disturbance marked by a reduction of affect and motivation. Goal-directed behavior is reduced, and emotional responses are lacking. The distinction from depression is crucial: patients do not report negative emotional states or ideational content. Although they may meet the criteria for depression because of the loss of interest in activities, they are mentally empty rather than full of distress. Recognizing apathy rather than mistaking it for depression may imply treatment with different pharmacologic agents, for example, the use of dopamine agonists. Euphoria refers to a persistent and unrealistic sense of well-being without the increased mental or motor rate of mania. Although often mentioned in connection with multiple sclerosis (MS), it is unusual and almost always associated with extensive disease and substantial cognitive impairment.

The Klüver–Bucy syndrome, as described in the captive monkey, includes a reduction in aggression (tameness), excessive and indiscriminate sexual behavior, hypermetamorphosis (forced attention to environmental stimuli), and hyperorality (mouthing nonfood items). This mixture of emotional, perceptual, and motivational changes is dependent on bilateral damage to the amygdala. In human patients, pathologies including trauma, herpes simplex encephalitis, and frontotemporal dementia can produce the syndrome, usually in partial form.

Depression is common in patients with brain diseases including stroke, MS, traumatic brain injury, epilepsy, and Parkinson disease. Certainly, this is in part a reaction to altered circumstances and distressing disability. Nonetheless, the syndromal nature of the depressed state and its imperfect correlation with measures of disability have prompted extensive efforts to seek anatomic correlations. Converging evidence leads to a model of alterations in a distributed network involving neocortical and limbic elements. In particular, a dorsal compartment involving the dorsolateral prefrontal cortex, inferior parietal cortex, and the dorsal and posterior portions of the cingulate gyrus show underactivity in the depressed state; these regions are thought to mediate the cognitive alterations and impairments of depression. Inversely, a ventral compartment containing the anterior insula, subgenual cingulate, hippocampus, and hypothalamus are overactive; these elements are thought to mediate somatic ("vegetative") features of the depressed state. Interactions between the two compartments are mediated through the thalamus, basal ganglia, and especially rostral cingulate.

Mania is substantially less common than depression after brain injury. Mania is associated with right-sided lesions involving paralimbic cortices in orbitofrontal or basotemporal regions or subcortical sites in the caudate or thalamus. Some evidence suggests that subcortical lesions are more likely to produce a bipolar picture and cortical lesions unipolar mania. As with depression, the abnormal mood state does not necessarily appear in immediate temporal association with the injury, so determining whether the mood disorder is organic or idiopathic is not always straightforward. The absence of a personal history of mood disorder is an obvious

Telegram: @medical_k

www.konkur.in

criterion, but the presence of a family history of a mood disorder may mark a vulnerability factor not operative in the absence of the brain lesion. Age of onset is relevant, especially for mania: the onset of idiopathic mania after age 40 is rare.

A common issue in neuropsychiatric assessment is the patient with late-onset depression, in whom evaluation reveals executive cognitive dysfunction and subcortical white-matter disease. This state of vascular depression is marked by the presence of vascular risk factors, notably hypertension, a tendency to psychomotor retardation and anhedonia and not psychosis or guilty ideation, and poor outcome with usual treatments. Some but not all of these patients have apathy rather than depression.

Abnormalities in Agency

Ordinarily, the person performing an action has the sense of being the one performing it. The prototype abnormality of this normal subjective sense is the “alien hand” phenomenon. Patients with parietal lesions may report a sense of foreignness of the hand and the limb may exhibit levitation or avoidance reactions. More dramatically, with medial frontal or callosal lesions, the hand may engage in unwilled behavior (representing unilateral utilization behavior), or intermanual conflict may occur.

Abnormal Social Behavior

The multitude of behaviors exhibited in social interaction has multiple underpinnings. Several behavioral complexes, the neurobiology of which has come under scrutiny, can be observed in their abnormal form in patients and, at times, understood from an anatomic and physiologic point of view.

Failures of empathic understanding are common in patients with frontal injury. These impairments, in part, result both from cognitive inflexibility in assessing complex social situations, especially in patients with dorsolateral prefrontal lesions, and from emotional impoverishment, especially in patients with orbitofrontal lesions. The intensity of social interaction manifested by patients with temporal lobe epilepsy may be due to deficits in social cognition or to a limbic lesion that reinforces social cohesiveness.

The capacity of human beings to understand the mental states of others—and thus to recognize not just another’s goals or intentions but also the other’s deceptions or pretense—has been termed mentalization or “theory of mind.” Deficits in theory of mind are thought to be fundamental in autism spectrum disorders. Imaging and lesion data suggest that this capacity depends critically on the prefrontal cortex (particularly the right medial prefrontal cortex adjacent to the anterior cingulate gyrus), right temporoparietal cortices, and amygdala. Patients with isolated lesions of the amygdala are rare, but deficits in theory of mind are seen in patients with frontal disease and may contribute to their social failure. Patients with right hemisphere lesions have a range of deficits in social interaction that may be characterized as a disorder of pragmatics. Although they may grasp the

Telegram: @medical_k

www.konkur.in

propositional content of language correctly, they mistake aspects of communication that require an appraisal of the interlocutor's intent, for example, whether an utterance was intended as a joke.

Abnormal Beliefs and Experiences

Hallucinations are a common feature of diseases of the brain. Visual hallucinations in the absence of auditory hallucinations are suggestive of organic disease. Visual hallucinations may occur in a hemifield blind from cerebral disease, so-called release hallucinations. Visual hallucinations in the setting of visual impairment due to ocular disease, usually in the older adults, are known as the Charles Bonnet syndrome. The hallucinations are characteristically vivid images of living figures, and the patient is aware of their unreality. Other psychopathology is absent, and treatment aimed at the hallucinations is usually ineffective. Elaborate formed visual hallucinations may occur with lesions of the thalamus or upper brainstem, so-called peduncular hallucinosis. The symptoms are worse in the evening (crepuscular), and again the patient is aware of the unreality of the visual experiences. Prominent, early visual hallucinations in the context of progressive dementia suggest dementia with Lewy bodies (DLB).

Auditory hallucinations rarely occur with pontine lesions. More common are musical hallucinations in the setting of hearing impairment, akin to the Bonnet syndrome. Unilateral hallucinations are characteristically experienced as ipsilateral to the deaf ear. Olfactory hallucinations occur as a limbic aura in focal epilepsy, but they also occur in idiopathic psychiatric illness.

Palinopsia and palinacousis refer to persisting or recurrent perceptual experiences after the object is gone, in the visual and auditory domains, respectively. Lesions in the association cortex—parieto-occipital and temporal, respectively—are responsible, although (for the visual sphere more than the auditory) drug toxicity is often the explanation.

The content of delusions may yield clues to causative organic disease and its nature. Most notably, misidentification delusions have been associated with dysfunction of face processing and clearly linked—in some but not all cases—to right hemisphere dysfunction. Misidentification of place is regularly associated with visuospatial and executive cognitive dysfunction. Misidentification delusions have been of special interest in cognitive neuropsychiatry. Perceptual recognition without a sense of familiarity (as in the Capgras syndrome and perhaps the nihilistic delusions of the Cotard syndrome) may reflect a disruption of visual-limbic connections. In a sense, it is the reverse of déjà vu, which amounts to familiarity without perceptual recognition. However, many patients with misidentification delusions have no evidence of organic disease. Although such patients may have dysfunction of underlying mechanisms similar to patients with ascertainable organic disease, the similarity of clinical phenomena cannot be taken to prove an identity of mechanism.

Telegram: @medical_k

www.konkur.in

Particular delusional themes may mark delirious thinking, such as a focus on danger to or harm to others, as opposed to the more self-centered constructions in idiopathic psychotic disorders. However, most delusions in patients with brain disease are of a more banal nature, often with persecutory elements that bespeak cognitive failure (the reported theft of one's purse, e.g., deriving from a failure of memory as to its location). Complexity or elaborateness of delusional ideation is associated with the preservation of intellect, and delusions tend to become less complex with the progression of dementia.

Paraclinical Investigations

Specialized paraclinical investigations form a major part of the neuropsychiatrist's toolbox. Sometimes patients are referred for neuropsychiatric consultation when a routine investigation—such as a screening MRI or EEG—gives an unexpected abnormal result; the neuropsychiatrist is called on to assess the meaning of the finding in the psychiatric context. Atypical age of onset, atypical features or course (such as particularly rapid progression of symptoms), absence of relevant psychiatric family history or presence of a relevant general medical history, presence of cognitive impairment, and presence of abnormal physical signs should prompt increased scrutiny for organic disease in a patient presenting psychiatrically. Catatonia should also lead to exploration for organic disease: data from several centers suggest that one catatonic patient in five has an explanatory organic disease.

Neuroimaging

Structural neuroimaging with computed tomography (CT) and later with MRI revolutionized practice in the clinical neurosciences. No longer was the organ of interest invisible within the carapace of the skull. CT relies on the differential absorption of x-rays by brain tissues and on the power of computerized methods to integrate data from multiple perspectives. The strengths of CT are its speed and its sensitivity to blood and bone. Thus for neuropsychiatric purposes, situations in which a patient cannot tolerate a prolonged imaging procedure may mandate CT. This problem often arises with an agitated demented or psychotic patient. Bony abnormalities, parenchymal deposition of calcium, and intracranial hemorrhage are particularly well assessed by CT. Such questions arise in the acute aftermath of trauma in particular.

The advent of MRI was an advance over CT in several respects. The anatomic resolution is substantially better, and the discrimination of white matter abnormalities exceptionally so. The capacity to display data from a single acquisition in multiple views—sagittal, axial, and coronal—allows improved anatomic understanding. Gradient-echo and susceptibility-weighted images sensitively reveal the sequelae of hemorrhage and may be useful in assessing the damage from trauma. Infusion of gadolinium for contrast enhancement is not necessary for delineation of nonvascular anatomic structures, such as is the goal in

Telegram: @medical_k

www.konkur.in

the case of atrophy or old stroke or trauma but can identify areas of breakdown of the blood–brain barrier, such as in the meninges in meningitis or in parenchymal lesions of active multiple sclerosis, tumor, or acute stroke. Special imaging sequences should be used for the identification of cortical dysplasia or mesial temporal sclerosis. Volumetric MRI allows diagnosis by quantitative assessment of delineated brain structures, such as the hippocampus, in the case of temporal lobe epilepsy and potentially Alzheimer disease. MR angiography allows the delineation of medium and large vessels without the administration of contrast material, as is required for conventional angiography. Stenosis of these vessels, such as the vessels of the neck, or the presence of vascular malformations or aneurysms is reliably ascertained. However, the resolution is not sufficient to allow the assessment of small vessels; thus, some forms of vasculitis cannot be excluded with MR angiography and require contrast angiography.

Additional MRI sequences include diffusion-weighted imaging, which captures acute vascular injury; diffusion-tensor imaging, which discloses patterns of connectivity in white matter; and magnetization-transfer imaging, which promises even greater sensitivity to brain lesions than FLAIR imaging. Diffusion-weighted imaging is essential in the evaluation of stroke, and high intensities in the cortex (“ribboning”) are characteristic of CJD. Magnetic resonance spectroscopy (MRS) is a method for analyzing the regional chemical composition of the brain. The benefits of its ability to identify neuronal loss and glial proliferation are still under investigation, although in certain circumstances—such as distinguishing radiation necrosis from a recurrent brain tumor—it is of proven utility. Dopamine-transporter imaging (DAT-scan) sensitively and specifically shows loss of nigrostriatal neurons and aids in the differential diagnosis of DLB and drug-induced parkinsonism. However, loss of nigral cells occurs in frontotemporal lobar degeneration as well as in DLB, and DAT-scanning can be abnormal in frontotemporal dementia.

Functional Neuroimaging

Four methods of functional neuroimaging are available: single-photon emission computed tomography (SPECT), positron emission tomography (PET), functional MRI, and brain mapping by quantitative electroencephalography. All are exciting research avenues, but the established clinical role for functional imaging is limited. All the techniques have a place in the presurgical evaluation of epileptic patients. SPECT and PET in the patient with frontotemporal dementia or Alzheimer disease typically disclose the focal nature of the dysfunction. The demonstration of occipital hypoperfusion strongly supports a diagnosis of DLB. The evidence for other clinical uses of functional imaging is at present limited or anecdotal.

Electroencephalography

The expectation of the originators of EEG was that it would allow the tracking of mental processes. This hope has not been realized. EEG does have the advantage over other clinically available brain imaging tools in that it reflects function at high

Telegram: @medical_k

www.konkur.in

temporal resolution, a resolution corresponding to the time course of mental processing. Thus, at least from a research perspective, measurement of brain potentials in relation to stimuli—the technique of evoked potentials—has the capacity to identify anomalous modes of cerebral processing. Recordings from electrode placements in subdural or cortical sites provide irreplaceable information about the origin and spread of epileptic discharges, but this invasive technique is justified only under special circumstances. From today's practical point of view, scalp EEG can distinguish epileptic from nonepileptic spells and clarify the type of epilepsy. It can also distinguish acute encephalopathy from nonorganic psychosis.

Only 30% to 50% of patients with epilepsy show an epileptic abnormality on a single interictal waking EEG. With sleep deprivation, sleep during the recording, and repeated recordings, sensitivity improves to 70% to 80%. Anterior temporal electrodes add to the sensitivity and localizing power of the EEG, but nasopharyngeal electrodes, which are quite uncomfortable for the patient, do not provide additional sensitivity and are not recommended. A reasonable protocol would start with a routine EEG including anterior temporal leads; if this is negative, but suspicion remains high, a second EEG with sleep deprivation can be undertaken. A third and fourth EEG may be useful, but the rate of discovery of abnormalities declines after that. Even then, some epileptic patients will not have been shown to have interictal abnormalities. At times ambulatory EEG is of use to ascertain the epileptic nature of undiagnosed events, but the restricted montage of the ambulatory equipment limits its utility. Hospitalization for video EEG recording may be essential for clarifying the nature of puzzling spells.

Delirium is characterized by slowing of the EEG, a finding never seen in acute idiopathic psychosis. This differential point can be decisive in a confusing clinical setting. However, EEG is not indicated as routine in the screening of psychotic patients, except that the EEG is abnormal in almost all (>95%) patients with anti-NMDAR encephalopathy. Among the dementing disorders, frontotemporal dementia is distinctive in having a normal EEG even as the clinical state becomes moderately severe. In CJD, the EEG is always slow and may ultimately (not necessarily immediately) show the diagnostic feature of pseudoperiodic complexes.

Evoked potentials can identify abnormalities in neural transmission along myelinated pathways, such as the visual pathway or the sensory pathways of the spinal cord and brainstem. This can help in the diagnosis of disorders such as multiple sclerosis or B_{12} deficiency.

Polysomnography

Identifying sleep-related disorders by multimodal overnight recordings is helpful in identifying obstructive sleep apnea, which may produce cognitive or affective symptoms; REM sleep behavior disorder (RBD), which when idiopathic is a strong indicator of an alpha-synucleinopathy such as DLB; or narcolepsy, which produces a panoply of neuropsychiatric symptoms. Other sleep or circadian rhythm disorders may be of psychiatric relevance, for example, in explaining fatigue.

Laboratory Investigations

In general, empirical evidence for the utility of laboratory studies supports only a limited role for "routine" or screening investigations; for the most part, laboratory tests should be performed as guided by the history and examination. A full discussion of laboratory strategies for all neuropsychiatric situations is beyond the scope of this section. In regard to dementia, a complete blood count (CBC), chemistry panel, B_{12} assay, perhaps methylmalonic acid, and thyrotropin (TSH) assay are indicated as screening tests, in addition to a test for syphilis (the fluorescent treponemal antibody test [FTA] or other antitreponemal antibody tests) in those areas of the United States in which the prevalence of syphilis justifies the testing. (The region of high incidence is a broad belt across the South in addition to some urban areas in the North; 30 U.S. counties contribute more than half the national total of cases.) The reason the FTA is the test of choice is that reagin tests (the venereal disease research laboratory test [VDRL] or rapid plasma reagin [RPR]) may revert to normal after intercurrent antibiotic treatment or with the passage of time and thus are insufficiently sensitive to serve as screening tests for neurosyphilis.

Appropriate screening tests for mental presentations other than dementia, for example, first-episode psychosis (FEP), are less well established. Recent studies confirm one's clinical impression that organic cases are rare, probably fewer than 5%, of patients with FEP. The first step should be a neuropsychiatric history and examination. No laboratory approach substitutes for a psychiatrist's expert sense that the patient with FEP is atypical of idiopathic mental illness. The factors mentioned above (atypical age of onset, atypical features, the rapid evolution of symptoms, absence of relevant psychiatric family history or presence of a relevant general medical history, presence of cognitive impairment, and presence of abnormal physical signs) should prompt consideration of organic disease. However, these clinical "red flags" have not been shown to have adequate sensitivity and specificity to rule out autoimmune encephalopathy in particular. A reasonable laboratory screen might include CBC, chemistry panel, TSH, urinalysis, and urine toxicology. (A fasting lipid panel and, in women of reproductive potential, a pregnancy test are appropriate as well.) If it is considered justified to screen for rheumatic disease, an antinuclear antibody test (ANA) is adequate for this purpose, being abnormal in almost all cases of lupus, although not sufficient to confirm that diagnosis. (False positives from psychotropic drug-induced positive ANA assays will be an important confound.)

Of particular recent interest is the question of evaluating patients, especially patients with FEP, for autoimmune encephalopathy. Such an evaluation is mandated by the presence of catatonic features. EEG is a reasonable step given its very high sensitivity for anti-NMDAR antibody-mediated encephalopathy. CSF examination is necessary to make the diagnosis, so a serum antibody panel can be considered inadequate. This may create a difficult situation if the patient declines lumbar puncture. The literature suggests that most patients will agree to a spinal

Telegram: @medical_k

www.konkur.in

tap, and no doubt the clinician's manner and explanation will play a role in how the situation evolves. Nonetheless, in some situations, the data may be inadequate for a definite diagnosis, and how to proceed will be a matter of clinical judgment.

The clinician must remember that the utility of a test depends not just on its sensitivity and specificity but also on the prevalence of the disease tested for in the population tested (pretest probability). In a population with a very low frequency of disease, a positive test, even a highly specific one, is more likely to be a false positive than a true positive. Though the adverse consequences of missing an autoimmune encephalopathy are unquestioned, given the demonstrated infrequency of autoimmune encephalopathy in psychiatric populations, the clinician must realize that routine testing by means of an antibody panel in patients without organic features (such as cognitive impairment or motor abnormalities) can result in a cascade of positive but uninformative tests, frightening to the patient, misleading to the patient's family, and disruptive of good psychiatric care. In the patient without such organic features, the clinician can remember the advice given in what is now an old-fashioned textbook: "…[T]he second examination is the most helpful diagnostic test in a difficult neurological case."

Excessive laboratory testing is to be deplored; on the other hand, limiting laboratory testing to generally familiar diseases is inexpert. Many rare metabolic diseases can present in adolescence or young adulthood with purely psychiatric manifestations, with psychiatric manifestations on the background of developmental intellectual impairment, or with prominent psychiatric symptoms mixed with motor or systemic abnormalities. The family history, which may be of severe intellectual deficit or early mortality in a sibling, may be a pointer to the need for a more thorough investigation. Some of these disorders are listed in Table 2.1–3.

Genetic testing is relevant in certain neuropsychiatric situations, some of which are mentioned in Table 2.1–3. "Premutation"-range repeat expansions in the fragile X gene may at times provide an explanation for an anxiety disorder. Identifying a mutation in the prion protein gene or finding a mutation (such as in presenilin-1) or repeat expansion (such as in Huntington disease or a disorder due to C9orf72) can clinch an otherwise uncertain diagnosis of progressive cognitive impairment and put paid to otherwise plausible diagnostic avenues. Because of the implications of a positive test result, often genetic counseling is appropriate before testing.

A 28-year-old man was referred for cognitive impairment. He said, “I don’t have a big thought process right now.” At age 16, he was in a car crash, but his mother reported that he had not lost consciousness. A month later, he began to show myoclonic jerks at the breakfast table, and 3 months after the crash, he had a generalized seizure. After appropriate evaluation, including normal brain imaging, he was diagnosed with juvenile myoclonic epilepsy, which responded well to treatment. His mother had noticed a reduction in mental acuity about 5 years before evaluation. Two years before evaluation, he was unable to carry on working as a cashier, and by a year later was unable to operate a microwave. He displayed repetitive behaviors, such as switching a light on and off, which had been considered to be due to obsessive-compulsive disorder, but the behaviors were not driven by anxiety. By the time of evaluation, he required cues for personal activities of daily living.

His perinatal history was unremarkable, but his speech was delayed. He had been an average student and an average athlete. A college counselor raised the question of an autism spectrum disorder because of social awkwardness.

On examination, he had short 5th digits of both hands but no other dysmorphic features. Except for echolalia and a pronounced visual grasp, the neurologic examination was unrevealing. He was nearly unable to complete a coherent utterance of more than a few words. Detailed cognitive examination, insofar as it was feasible, disclosed a severe disorder of working memory, with other deficits seemingly consequent to that.

An extensive evaluation, undertaken before referral and after, was unrevealing. A panel of genetic tests disclosed a mutation in the serpin gene, and in retrospect, neuroserpinosis could have been suspected because of the history of juvenile myoclonic epilepsy. His mother proved to show mosaicism of the serpin gene.

		neuropathy, cataracts, xanthomas	
Urea cycle disorders, organic acidemias	Acute confusion/psychosis	Protein intolerance, headache, nausea, liver disease, pyramidal signs, seizures	Ammonia, urinary organic acids, plasma amino acids
Porphyria (acute intermittent or variegate)	Acute confusion/psychosis	Peripheral neuropathy, abdominal pain	Urine porphobilinogen, genetic testing
Wilson disease	Personality change, rarely psychosis	Extrapyramidal signs, Kayser–Fleischer ring, liver disease, basal ganglia hyperintensity on MRI	Ceruloplasmin, 24-hour urinary copper, liver biopsy, genetic testing

Examination of the Cerebrospinal Fluid

Examination of CSF obtained through lumbar puncture is sometimes a crucial element of the diagnostic process, in particular to diagnose infection or inflammation, more rarely in neuropsychiatric practice to seek evidence of neoplasia (such as meningeal carcinomatosis). Specific assays are available for the diagnosis of neuropsychiatrically relevant infectious agents. In rheumatic diseases involving the brain, the white cell count may not be elevated, but elevated protein and evidence of intrathecal elaboration of antibodies may give evidence of inflammatory activity. The latter is sought by the ratio of immunoglobulin-G (IgG) to albumin or, better, by the IgG index which requires measurement of serum IgG, and by the presence of oligoclonal bands specific to the CSF. As mentioned, for the autoimmune encephalopathies, the relevant antibodies may not be present in serum and CSF examination is required.

Measurement of the neuron-derived 14–3–3 protein in CSF was used to assist in the diagnosis of CJD, but the ratio of phosphorylated to total tau protein in spinal fluid is more sensitive and highly specific. RT-QUIC directly identifies prions in the CSF and gives even greater sensitivity and specificity for the diagnosis of CJD (though it is less sensitive for other presentations of prion disease). Increased CSF total and phosphorylated tau and reduced amyloid protein, in combination, show high sensitivity and high specificity for Alzheimer disease.

Telegram: @medical_k

www.konkur.in

Removal of CSF by lumbar puncture or external drainage is part of the evaluation of patients suspected of shunt-reversible normal-pressure hydrocephalus. Patients undergoing this procedure should have CSF assayed for amyloid and tau.

Neuropsychological Assessment

Neuropsychological evaluation has an important role to play in neuropsychiatric care, both for diagnosis and for management. Sound use of the clinical neuropsychologist as a consultant requires a first step formulation of a cogent consultative question. The more specific the consultant's question, the more able the neuropsychologist is to integrate the psychometric data with the rest of the clinical picture. Much of the early literature on neuropsychological assessment focused on identifying and localizing organic brain disease. With the advent of neuroimaging, neuropsychological testing is seldom the most powerful means of addressing this issue, although it certainly continues to play such a role, for example in lateralizing cognitive deficits as a preoperative tool in epileptic patients. Nor is the role of the neuropsychologist to make a disease diagnosis, although at times the psychometric picture is strongly suggestive of a particular diagnosis.

If substantial confounds make bedside evaluation difficult, neuropsychological data may be of considerable assistance. For example, identifying supervening cognitive impairment in an intellectually disabled or poorly educated patient or subtle impairment in a highly intelligent patient may be impossible for the clinician to do with confidence, while neuropsychological assessment may provide these diagnoses. Another example of utilizing neuropsychological assessment as a probe of brain function is disclosing a pattern of cognitive strengths and weaknesses amounting to right hemisphere learning disabilities in a patient with a clinical picture suggestive of autism spectrum disorder or a cluster A personality disorder. Obtaining neuropsychological data often allows for more precise targeting of behavioral interventions, more specific education of families, and a more confident assessment of decline or of benefit from pharmacologic treatments.

One common use of neuropsychological assessment requires a word of caution: identifying cognitive impairment in an older patient presenting with mood disorder or psychosis. No neuropsychological findings should deter the clinician from aggressive treatment of the psychiatric symptoms, and nonspecific state-dependent attentional and motivational factors may confound the neuropsychological results. Rather than devoting resources of time and energy to pinpointing a moving target in the acute phase, deferring the assessment until symptoms are reduced is often the wiser course. Similar caution applies to the situation of an acutely psychotic young person.

Another caution about neuropsychological assessment falls under the rubric of ecologic validity. This term refers to the extrapolation of results obtained in the neuropsychological laboratory by artificial paper-and-pencil methods to real-world performance. The concern arises in particular with orbitofrontal lesions, which may produce a paucity of cognitive findings but devastating personality change. Deriving

Telegram: @medical_k

www.konkur.in

clinical measures suitable to characterize such patients from the developing realm of affective neuroscience is a current challenge to neuropsychology.

Brain Biopsy

Biopsy of the brain has a limited role in neuropsychiatric evaluation. The morbidity and mortality of the procedure, as performed by an experienced neurosurgeon, are low, but the sensitivity of the procedure is lower than one might expect. For example, the sensitivity of biopsy for primary angiitis of the central nervous system (CNS) may be only 75%. In some circumstances, a biopsy of a peripheral tissue can substitute for a brain biopsy in a patient with primarily cerebral symptoms at lower risk. For example, lung or muscle biopsy may make a diagnosis of sarcoid, skin biopsy a diagnosis of vasculitis if a rash is present or of CADASIL, and temporal artery biopsy of giant cell arteritis. In neuropsychiatric situations, the major indication for biopsy of the brain is consideration of inflammatory disease, when the nature and aggressiveness of treatment depend on a tissue-proven diagnosis.

Although it cannot be considered a clinical diagnostic test, the neuropsychiatrist should not neglect the autopsy as a learning tool.

COMMON NEUROPSYCHIATRIC CONDITIONS

This section provides a survey of some issues commonly brought to the attention of neuropsychiatrists. The emphasis is on the priorities for clinical and laboratory assessment for a variety of presentations. The organization is by disease and syndrome as a complement to the anatomic and symptom-oriented discussion provided so far. This perspective is distinctive for neuropsychiatry within psychiatry; the disease processes underlying symptoms in the idiopathic disorders are unknown. For neuropsychiatric patients, one can hope and work to uncover the disease-causing the symptoms and, on fortunate occasions, to provide disease-specific treatment.

Dementia

Many diseases produce the clinical state of dementia. A shotgun laboratory approach to “ruling out treatable disease” is unwise, not only because finding reversibility is unusual but because, to a considerable degree, differential diagnosis among neurodegenerative diseases is possible and of clinical importance. Moreover, clinical clues to reversible disease are available in the history and examination: use of psychotoxic medicines, rapid course, mildness of cognitive impairment (even short of fully meeting criteria for dementia), subcortical features of the cognitive disorder, and presence of motor signs. Table 2.1–4 provides specific guidance to be gained from clinical clues. Progressive dementia supervening on developmental intellectual disability raises a particular differential diagnosis, including many of the diseases listed in Table 2.1–3.

Telegram: @medical_k

www.konkur.in

The clinician needs to gather data relevant to management issues other than reversibility, such as safety of living arrangements, driving safety, and preparation of a will and advance directives. Dementing patients often develop psychiatric symptoms, which respond to pharmacologic and behavioral treatment. All these considerations should prompt the clinician to cast a wide net in data gathering regarding the demented patient.

A 67-year-old woman presented with at least 1 year of progressive memory impairment, confusion, then irritability and suspiciousness. The mental state was typical of Alzheimer disease, and the physical examination disclosed only brisk tendon jerks. An EEG, done earlier because of a spell of uncertain nature, had shown left temporal spikes. The neuropsychological assessment had shown a pattern typical for Alzheimer disease, with memory impairment characterized by rapid forgetting, semantic more than phonemic verbal fluency deficits, and anomia. MRI, however, demonstrated extensive white-matter disease with bilateral confluent hyperintensities, which extended into the gyri and involved U-fibers. CSF examination was entirely normal. Skin biopsy for CADASIL and screening genetic assay for CADASIL were negative. Repeat EEG showed bilateral temporal spikes and carbamazepine (Tegretol) was begun. The clinical diagnosis was leukoencephalopathy due to cerebral amyloid angiopathy, possibly with Alzheimer disease. The patient's mother had died at age 86, having suffered from "the same thing" as the patient. Four of the mother's five siblings became demented in the eighth or ninth decade of life, none earlier, in most cases with a clinical diagnosis of Alzheimer disease. The patient herself was an only child. The patient's two daughters, both young adults, were very concerned that they might inherit the same disease as their mother, and they insisted the patient undergo the brain biopsy that a geriatrician had recommended. This disclosed pronounced amyloid angiopathy. Immunostaining for A-β confirmed showed neuropil plaques; immunostaining for tau did not reveal neuritic plaques. Nonetheless, Alzheimer disease could not be excluded. No inflammation was seen. Unfortunately, several days after the biopsy, she developed status epilepticus.

Among the dementias, bvFTD is of particular neuropsychiatric interest. In contrast to Alzheimer's disease (AD), the incidence of which increases with age, in FTD, the peak incidence is in the fifth and sixth decades of life. In contrast to AD, which characteristically has a cognitive presentation with memory failure most prominent, bvFTD presents with altered personality and behavior; typically, executive cognitive dysfunction can be detected. Other neuropsychiatric features may be present early in the course, including psychotic symptoms, especially in bvFTD due to repeat expansions in the C9orf72 gene.

Telegram: @medical_k

www.konkur.in

Epilepsy

Major concerns in patients with epilepsy include differential diagnosis, psychosis, personality change, depression, violence and other episodic behaviors, and PNES. The last will be dealt with below, along with other conversion disorders.

Patients with paroxysmal disorders can be misdiagnosed as having epilepsy when they do not have it or as having a different disorder when epilepsy is the correct diagnosis. Paroxysmal symptoms from panics, cardiovascular disease with syncope or near-syncope, endocrine disorders (pheochromocytoma, carcinoid, systemic mastocytosis), or conversion disorder can be mistakenly labeled epileptic; contrariwise, epilepsy can be missed when a diagnosis of panic disorder, in particular, is accepted.

A 59-year-old man was evaluated for 7 years of memory problems and spells refractory to treatment on a diagnosis of panic disorder. These spells characteristically lasted 5 to 10 seconds and recurred as often as hourly; he was sometimes amnestic for the spells afterward. During an attack, he had gooseflesh, and his speech became garbled; once at church, he was thought to be speaking in tongues. Extensive treatment trials with benzodiazepines and serotonergic drugs had given no consistent benefit. Apart from hyperlipidemia, he had no significant medical history. EEG had been negative on three occasions, MRI on two occasions, and Holter monitoring and SPECT on one occasion each. The neurologic and mental state examinations were normal. An episode was witnessed during the examination: He showed 10 seconds of facial flushing and stereotyped hand movements. The attacks were subsequently abolished by a trial of an antiseizure medicine.

A 52-year-old woman was referred for the evaluation of spells. In her 30s, she had been hospitalized for depression and was subsequently treated intermittently as an outpatient. The family history included several members with depression or bipolar disorder. Two years before evaluation, she presented with a headache and proved to have an unruptured aneurysm, which was clipped through a craniotomy. Several months later, she had a generalized convulsion. She went on to have spells at a rate of up to six a day. They were stereotyped and abrupt in onset and termination; she could not identify provocative factors or social contexts. During a spell, she would feel cold and have gooseflesh for about 3 minutes. Then she would become rigid and unable to speak or interact, although she was able to hear others' speech. This would last several minutes. Then she would begin to cry. The whole sequence would last some 6 to 10 minutes. She was on phenytoin (Dilantin) with a therapeutic serum level. Previous trials of divalproex (Depakote) and topiramate (Topamax) were not tolerated. EEGs had shown only right frontal slowing with no epileptic features on several tracings. The neurologic and cognitive examinations were normal, and she was not depressed at the time of evaluation. The clinical picture was inconclusive. In favor of epilepsy were the abrupt onset and termination, stereotyped nature of the spells, and background of craniotomy; against epilepsy were the weeping, length of the ictus (if all the phenomena were taken to be ictal), failure of response to treatment, relatively inactive EEG, and background of depression. Video EEG done after medication withdrawal recorded three focal seizures with impaired awareness with right anterior-inferior temporal onset with her typical semiology.

In exploring the psychiatric concomitants of epilepsy, the clinician needs to be aware of the nature of epilepsy. Most adult epilepsy is focal (localization-related epilepsy), with the ictal onset in the temporal lobe. However, other forms of epilepsy, including frontal epilepsy and primary generalized epilepsy, are common. These distinctions, and the laterality of the focus, can often be inferred from the semiology of the seizures as reported or as observed clinically. A history of febrile convulsions in childhood and the age of onset of epilepsy are relevant to the likelihood of mesial temporal sclerosis as the underlying pathology. Body asymmetry and dissociated facial paresis should be sought as indicators of laterality. The MRI and EEG provide crucial information on pathology and seizure type. Many of the findings relating psychiatric disorders to epilepsy are concerned with focal epilepsy of temporal onset; linking psychiatric symptoms to epileptic syndromes other than temporal lobe or limbic epilepsy may go beyond the evidence. Further, to what extent psychopathology is associated with seizures themselves and to what extent with the brain disease that gives rise to them remains controversial. Without question, cognitive impairments are related to the lateralization of the temporal focus.

Telegram: @medical_k

www.konkur.in

Psychotic states in epileptic patients are usually divided into those occurring during the epileptic ictus, often called epileptic twilight states; those occurring for a delimited period in the aftermath of a seizure or, more commonly, a flurry of seizures, called postictal psychosis; and those that are chronic, called interictal psychosis. Usually, this chronology can be ascertained by inquiry, but at times EEG monitoring is necessary to identify the occurrence of seizures in relation to psychopathological phenomena, especially because patients can be amnestic for focal seizures with impaired awareness. A further issue to be elucidated from the history is the relationship between seizure treatment and control and the level of psychopathology, especially psychosis. An inverse relationship is sometimes noted. Better seizure control is associated with the occurrence of psychosis, a phenomenon known as forced normalization. On the other hand, frequent seizures certainly can cause an increase in confusion and related failure in functional capacity.

A 35-year-old woman with lupus and intractable epilepsy was admitted several times with persecutory and nihilistic delusions ("I'm dead") and depressive symptoms. Investigations to identify active cerebral lupus were unrevealing, even when she had evidence of peripheral activity of the disease. In fact, MRI disclosed the findings of hippocampal sclerosis, suggesting that the epilepsy was idiopathic and not due to cerebral lupus. Without specific treatment, the psychotic symptoms diminished over the course of several days; this also was thought to make a diagnosis of cerebral lupus unlikely and a postictal psychosis likely. Between episodes, she showed no psychotic phenomena.

The interictal personality syndrome of temporal lobe epilepsy (the Gastaut–Geschwind syndrome) is characterized by hypergraphia, religiosity or deepened metaphysical interest, aggressiveness, and hyposexuality. Also described are altered social behavior depending on the intensity of interaction, an inability to end interactions, and circumstantiality of discourse (phenomena confusingly denominated "viscosity"). The syndrome remains controversial; what is of importance for neuropsychiatric assessment is that inquiry be directed to phenomena such as hypergraphia that are not included in the usual review of symptoms of idiopathic psychiatric disorder.

Episodic aggression is often suspected of being ictal but rarely is. Aggression occurring during seizures is almost always disorganized, not deliberately directed. A high threshold is justified in attributing a violent act to epilepsy in the absence of typical epileptic features. Amnesia for serious violence is common and not a strong pointer to an epileptic origin.

A special issue in the neuropsychiatric assessment of the epileptic patient is the presurgical evaluation. Surgical treatment, especially of temporal lobe epilepsy due to mesial temporal sclerosis, is underutilized; ideally, more and more patients with

Telegram: @medical_k

www.konkur.in

medically refractory epilepsy will be evaluated for their suitability for surgery. Along with an intensive electroencephalographic evaluation, volumetric MRI, functional neuroimaging, and neuropsychological assessment, the patient's psychiatric state should be systematically evaluated. The patient's ability to consent and issues such as the patient's capacity to cope with the stress of monitoring and surgery, as well as the expectations held for surgery, should be addressed. Neither depression nor psychosis is an absolute contraindication to surgery, although a chronic psychosis probably will not be alleviated by surgery. Indeed few if any psychiatric findings will contraindicate surgery, but psychiatric evaluation may well reveal deficits that need to be taken into account in developing a treatment plan.

Traumatic Brain Injury

Traumatic brain injury is epidemic in our society, with advances in emergency medical care leading to growth in the prevalence of survivors of severe injury. Issues commonly facing the neuropsychiatrist include aggression, depression and anxiety, and the delineation of deficits (sometimes for legal purposes) in patients with a mild traumatic injury. The features of the head injury should be ascertained, ideally with confirmation from medical records.

The altered behavior and personality common after traumatic brain injury are more burdensome for families than are the physical disabilities. Disinhibition and aggression are particularly uncomfortable and often hard to treat. A complicating factor is that preinjury impulsivity and substance abuse are common, as they predispose to head injury.

A 24-year-old woman was seen 19 months after a car crash in which she was an unrestrained passenger. She had been comatose for 3 months and underwent surgical evacuation of a left-sided intracranial hematoma. She had a few weeks of rehabilitation after regaining consciousness and returned home after spending most of a year in a nursing home. The family was at their wits' end over episodes of aggression, which appeared to be directed angry behavior elicited by frustration. She did not have depressive symptoms. On examination, she showed severe bilateral spasticity, including spastic dysarthria, drooling, and a brisk jaw jerk. She was able to recall dates and other details of her illness accurately, but she disclaimed behavioral or emotional alterations. Her language comprehension was adequate, but the output was telegraphic. Affect was labile. Behavior during the consultation was initially appropriate, with an obvious effort to cooperate with the evaluation, although she had greeted the examiner with, "I love you." At the end of the examination, however, she urgently requested the examiner's business card and rammed him with her wheelchair while cutting off his access to the door. Chronic phase CT showed atrophy and left temporal encephalomalacia.

Telegram: @medical_k

www.konkur.in

A 59-year-old man was referred by a court for an assessment of his ability to take part in proceedings related to his divorce. Three months prior to the evaluation, he was struck several times by an unknown assailant during an altercation regarding who was to get the use of a taxi. He suffered contusions of the left periorbital area but no other overt injury. He was able to recount the events in some detail, but he explained that this was because over time, by comparing notes with others, he had “put it all back together”; of his own recollection, he could remember the first punch that struck him but not the second or subsequent events of the altercation. Although he could not be certain of the duration of the gap in his recollection, it was clearly a matter of some seconds, possibly a minute or two, and at no time was he unconscious. In the aftermath, he was “confused” and had a headache. He found that he could not come up with names, dates, or numbers, although this information would generally come back to him later or with considerable unaccustomed effort. He also noticed that he “could not visualize” geographical scenes, so in planning to go to a familiar place, he was unable to picture it in his mind. Although he did not get lost, he found that when driving, he would turn the wrong way or miss a turn. He noted that his memory, previously highly trustworthy, could not be counted on: “I had to write everything down.” He found that he had to “take time to think” and “strain my brain to focus.” He distanced himself from business decisions and relied on trusted subordinates to counsel him. He acknowledged sensitivity to light, noting that he had begun to wear sunglasses even when the weather was cloudy and to turn off the room lights when he was watching television. To a lesser extent, he was bothered by noise. He noted that he was more readily irritated than was characteristic of him. He did not have depressive symptoms, intrusive recall of the altercation, or nightmares. The symptoms had gotten gradually less severe. His history included several head injuries in adolescence, with two of which he had a loss of consciousness for a few hours without recognized sequelae. The noncognitive mental state and neurologic examinations were normal. He scored 21 on the Mental Alternations Test, a normal performance on a task of mental speed and working memory. He scored 16 of 18 on the Frontal Assessment Battery, a collection of tasks assessing executive cognitive function. The two lost points were on the go/no-go task, on which he made perseverative errors. He was mildly disorganized in performing the ring/fist test of motor sequencing. MRI and EEG were normal. The picture was thought to be consistent with organic sequelae of traumatic brain injury. The case underlines the importance of prior traumatic brain injury in determining the effects of seemingly mild trauma and that loss of consciousness is not a prerequisite for significant sequelae.

Movement Disorders

Telegram: @medical_k

www.konkur.in

Cognitive impairment due to the involvement of subcortical structures is a common neuropsychiatric feature of movement disorders. This applies to cerebellar as well as basal ganglia diseases for the anatomic reasons described above. The anatomy of the close relationship between emotion and movement was also described above. Clinically, mood disorders are common in IPD and other movement disorders. Anxiety disorders, although less emphasized in the literature than depression, are also common. The evaluator should take into account that mood and anxiety can fluctuate according to the timing of doses of dopaminergic drugs. A mood disorder can occasionally present in advance of overt movement abnormalities, so IPD must be considered in the differential of late-onset mood disorders.

A 43-year-old woman with no personal or family history of psychiatric illness developed a psychotic depression. She had a severe extrapyramidal reaction to risperidone (Risperdal). Two years later, when euthymic and unmedicated, she developed progressive shuffling gait, upper extremity tremor, and micrographia. She then suffered another episode of depression. Three years later, she had severe anxiety, no cognitive impairment, and the motor features of IPD.

Psychotic reactions to dopaminergic drugs are an important feature of movement disorders. Sometimes this is the result of overuse of prescribed dopaminergic agents in an effort to increase time in the “on” state.

A 63-year-old man with long-standing IPD developed delusions while being treated with high-dose levodopa and carbidopa (Sinemet) on a five-times-a-day schedule, pramipexole (Mirapex), tolcapone (Tasmar), and amantadine (Symmetrel). Under inpatient observation for several days on the prescribed doses, he remained psychotic. He responded well to quetiapine (Seroquel).

Developmental Disabilities

Adult patients with developmental disabilities are underserved by the medical and social service communities and are frequently referred for neuropsychiatric attention. Some of these patients will have had an inadequate diagnostic evaluation for the cause of the disability. Beyond clinical assessment, with particular attention to dysmorphology, because features of the mental state and neurologic examination are generally nonspecific, the most useful diagnostic tests are MRI and genetic testing. Specific genetic probes can confirm tentative clinical recognition of syndromes of mental retardation. Patients with developmental disabilities are vulnerable—indeed especially vulnerable—to the mood, anxiety, and psychotic disorders that can afflict anyone and can be treated effectively for these; diagnostic overshadowing (attributing all psychological and behavioral disturbance to

Telegram: @medical_k

www.konkur.in

developmental disability *tout court*) is to be avoided. These syndromes may present atypically in the developmentally disabled population, and the clinician must be alert to indirect indicators of mood disturbance or psychotic experience. For example, while the patient may not report a depressed mood verbally, the caregivers may report the loss of interest in favorite activities and the other features of a depressive syndrome.

Of particular neuropsychiatric interest is the question of behavioral phenotypes and specific psychological correlates of developmental syndromes. Syndromes recognized to have behavioral phenotypes (and their correlates) include:

- Lesch–Nyhan syndrome (self-injury);
- Prader–Willi syndrome (excessive eating);
- Williams syndrome (anomalous cognitive profile, elevated sociability);
- Velo-cardio-facial (DiGeorge or 22q11 deletion) syndrome (schizophrenia).

Infectious and Inflammatory Diseases

Infectious and inflammatory diseases of the brain always need to be considered in acute or subacutely evolving mental disorders. Among the infectious diseases, HSV encephalitis has a particular claim on attention because delay in diagnosis, even by hours, can lead to substantially increased morbidity and mortality. Definitive diagnosis is possible without biopsy by assaying for HSV in the CSF with the PCR, but treatment may be indicated if suspicion is high in advance of a firm diagnosis. Chronic meningitis, for example, from infection with fungi, is a rare consideration in subacutely evolving dementia; the definitive diagnostic tests are CSF assays or serologic tests (e.g., for toxoplasmosis). In the acquired immunodeficiency syndrome (AIDS) era, infection with opportunistic agents and with the human immunodeficiency virus itself needs to be kept in mind. In more recent times, the question of long-lasting brain dysfunction due to SARS-CoV-2 (CoViD-19) has assumed great importance. Present evidence is insufficient to judge the pathophysiology in many of these patients.

Noninfectious inflammatory diseases include rheumatic diseases, of which the prototype is systemic lupus. A rheumatic disease review of systems is always of importance in exploring the differential diagnosis of a puzzling case, especially in a young woman. Although psychosis is often considered the psychiatric hallmark of lupus, in fact, psychotic states (other than delirium) are unusual and a variety of other psychiatric pictures need to be included in the clinician's consideration. Few clinical features of lupus are risk factors for cerebral disease, not even disease activity, which may be misleading in either a positive or a negative direction. One feature that is a risk factor for neuropsychiatric symptoms, including cognitive impairment, is the presence of antiphospholipid (aPL) antibodies; the primary aPL syndrome similarly carries mental risk.

Telegram: @medical_k

www.konkur.in

A 40-year-old woman presented with the typical features of psychotic depression. There was a family history of depression, and she had suffered two episodes of depression earlier in her adult life, both of which were brief, nonpsychotic, and responsive to treatment. For the previous year, however, her depression had been poorly responsive to pharmacologic treatment and electroconvulsive therapy (ECT). Examination disclosed no definite cognitive abnormality and brisker reflexes on the left. MRI showed striking areas of white matter abnormality in the right hemisphere. Extensive laboratory investigation, short of angiography and biopsy, revealed only high-titer IgA anti–β2-glycoprotein-1 antibodies. Neuropsychological assessment performed after partial remission of the depression showed deficits in attention and mental processing speed. The working diagnostic formulation was that an otherwise mild idiopathic depressive disorder had been rendered treatment-resistant and severe by a wave of cerebral injury due to the aPL syndrome.

Other rheumatic diseases, such as Sjögren syndrome and the vasculitides, are also of neuropsychiatric importance. Autoimmune encephalopathy in the absence of systemic autoimmune disease often but not always presents as limbic encephalitis comprising memory impairment, anxiety, and seizures. Some but not all of these patients have neoplasms, the frequency depending on the particular autoantibody present. An expanding list of antigenic targets for the autoimmune process allows for specific diagnosis. No one believes that the list is complete; antibodies of yet-unknown specificity may in the future be found to explain neuropsychiatric illnesses.

A 56-year-old man without prior psychiatric history presented because of “a few months of memory problems.” Beginning 5 months prior to the neuropsychiatric evaluation, he seemed confused and forgetful to his family. For example, he repeatedly called his daughter at college and could not recall what she was studying. He declined over the ensuing months, with anxiety, depression, reduced energy, and difficulty in maintaining sleep but without anhedonia or diurnal variation of mood. A psychiatrist treated him with quetiapine and lithium on a diagnosis of an affective mixed state but without benefit. The neurologic examination was normal. On cognitive examination, he showed mild memory impairment but no disturbance of naming or executive function. MRI was unremarkable. The neuropsychological assessment showed impaired memory with both rapid forgetting and reduced encoding. A panel of autoimmune serologies showed antibodies to the voltage-gated potassium channel, and he responded to immunomodulatory treatment.

When and how to screen for autoimmune encephalopathy in psychiatric patients, for example, those with FEP has been controversial, as discussed above.

www.konkur.in

Conversion Disorder (Functional Neurologic Symptom Disorder)

Neuropsychiatrists often see patients whose symptoms appear to arise from brain disease but do not. These patients' condition has been described under various names: hysteria, functional disorder, psychogenic disorder, conversion disorder, or medically unexplained symptoms. None of the designations is entirely satisfactory. Whatever the designation, such patients are not uncommon. Complicating matters is the not uncommon coexistence of organic disease and conversion symptoms. For example, a sizable minority of patients with PNES have epilepsy as well. Brain disease may have produced, in some patients with conversion disorder, organic personality change with a reduction in the maturity of defenses and the too-easy resort to somatization.

Various techniques have been advocated for the identification of nonorganic diseases by means of physical examination. These have several shortcomings. First, they easily lend themselves to a counter-therapeutic alliance in which the examiner is trying to trick the patient—not a good start for the treatment, whatever the findings. Second, they fail to distinguish deliberate falsification on the patient's part (i.e., malingering) from conversion disorder. Third, most such findings are commonly present in patients with an organic disease who are trying to help the examiner make the diagnosis. That is, they may show a patient to be histrionic or suggestible but fail to rule out organic disease. Thus, for example, reporting a difference in vibratory sensation between the two sides of the sternum is by no means confined to patients with conversion disorder but may arise from the demand characteristics of the examination setting. Exceptions to this caution occur in cases where the nonphysiologic finding is precisely the phenomenon of the complaint.

Even then, however, the phenomena of brain disease are sometimes sufficiently odd that the examiner should maintain an attitude of humility about achieving diagnostic certainty by recognizing the nonphysiologic at a glance. Of the described "signs of hysteria," perhaps the best is the Hoover sign. The examiner places a hand underneath the heel of the affected leg of a supine patient who complains of leg weakness. Asked to press down with the heel, the patient fails to generate power with the leg. Asked to raise the opposing leg, however, the patient produces an automatic synergistic downward movement of the affected leg.

Recent systematic findings of progressively greater methodologic sophistication confirm the belief that experiences of neglect and abuse in childhood, and other childhood adversities are common in the background of patients with conversion disorder. This may indirectly account for another progressively more solidly substantiated finding, namely that the prognosis of conversion disorder is sometimes poor. Although a given symptom may wax and wane or disappear, patients commonly have a chronic course of disability, interpersonal difficulties, emotional symptoms, and fruitless seeking of medical help. Although hysterical symptoms have often been taken to represent a psychological conflict symbolically, the fundamental difficulty is that patients who make prominent use of somatization have a disorder of the symbolic function itself. The goal of the psychiatric examiner

Telegram: @medical_k

www.konkur.in

should be not to expose the patient but to establish an alliance that allows exploration of areas of the patient's life outside the presenting symptoms and the construction of a plan to reduce distress and manage emotions (including focused treatment of commonly coexisting depressive disorder) and to develop alternative ways of seeking attention and assistance for distress.

THE NEUROPSYCHIATRIC PERSPECTIVE

This section has surveyed a neuropsychiatric approach to the patient. The neuropsychiatrist thinks anatomically about mental state disorders, even as cognitive neuroscientists attempt to construct a sufficiently sophisticated model of large-scale brain function to do justice to the complex mental states of neuropsychiatric interest. The neuropsychiatrist relies on rich data gathered at the bedside and on laboratory methods of investigating brain structure and function and diagnosing disease. The effort is to identify not just behavioral syndromes as found in DSM or ICD, but the pathologic processes underlying them in two senses. First, neuropsychiatry seeks medical diagnoses of systemic or brain diseases that account for the patient's illness. Second, neuropsychiatry seeks to understand clinical phenomena in terms of the disruption of elementary mental processes, the nature of which is beginning to be elucidated by the cognitive neurosciences. The result is a highly differentiated diagnostic enterprise. With continual refreshment from a multidisciplinary base—ranging from cognitive neuroscience to general medicine—the neuropsychiatric approach to the patient is certain to remain exciting.

2.2 Neuropsychiatric Aspects of Cerebrovascular Disorders

STANLEY LYNDON, M.D., AND JUAN CARLOS URIZAR, M.D.

Definition

Cerebrovascular disorders consist of a large number of disorders that interrupt the blood supply to the brain. These disorders are divided into two groups based on etiology, ischemic (i.e., absence of blood flow) and hemorrhagic (i.e., bleeding in or around the coverings of the brain). They may also be classified according to the size of the affected blood vessel. Large artery disease produces large lesions of the brain, while small artery (arteriolar) disease results in small lacunar lesions. Vascular lesions may occur in any region of the brain.

Clinicians have recognized the association between neuropsychiatric disorders and cerebrovascular disease for over a century. However, this subject has only been the focus of systematic scientific scrutiny over the last 40 years. This chapter will focus on the neuropsychiatric correlates of stroke.

A stroke is defined as the sudden loss of blood supply to the brain leading to permanent tissue damage. Nearly 90% of strokes are due to ischemia, while the remaining 10% are caused by hemorrhagic events. While less common, hemorrhagic strokes tend to be more severe and are associated with greater mortality than ischemic strokes.

As the most common serious neurologic disorder in the world, stroke represents a global public health burden. The World Health Organization estimates that 15 million people are diagnosed with a stroke each year worldwide. The age-specific incidence of stroke varies dramatically over the lifespan. According to the 2021 Update of Heart Disease and Stroke Statistics published by the American Heart Association, the overall incidence of perinatal stroke in children in the United States is 29 per 100,000 live births. Stroke incidence increases considerably with age, and the incidence of first stroke is greatest in those 85 years or older.

Telegram: @medical_k

www.konkur.in

However, approximately 10% of all strokes occur in individuals 18 to 50 years of age. In adults ages 55 to 64, the annual incidence of first-ever stroke is 2.2 to 5.3 per 1,000 persons, while the incidence is 8.9 to 13.8 per 1,000 persons in those 75 to 84 years old. Patients with stroke >85 years of age make up 17% of all patients with stroke. In the United States alone, 795,000 strokes and approximately 130,000 stroke-related deaths occur annually. Stroke is the fourth-leading cause of death in the United States and the second-leading cause of death globally. Over the period 2010 to 2050, the number of incident strokes is expected to be more than double, with the majority of the increase among older adults (≥75 years of age) and minority groups. Very older adult patients have a higher risk–adjusted mortality, have greater disability, have longer hospitalizations, receive less evidence-based care, and are less likely to be discharged to their original place of residence.

History

Early reports of depression after brain damage (usually caused by cerebrovascular disease) were made by neurologists and psychiatrists in case descriptions. Adolf Meyer warned that new discoveries of cerebral localization, such as language function in the early 1900s, led to an overly hasty identification of centers and functions of the brain. He identified that several clinical syndromes such as delirium, dementia, and aphasia were the direct result of brain injury. However, in keeping with his view of biopsychosocial causes for most mental “reactions,” he saw manic-depressive illness and paranoiac conditions as arising from a combination of brain injury (specifically citing left frontal lobe and cortical convexities), family history of psychiatric disorder, and premorbid personal psychiatric disorders. Eugen Bleuler described “melancholic moods lasting for months and sometimes longer appear frequently” in patients after strokes. Emil Kraepelin recognized an association between manic-depressive insanity and cerebrovascular disease. He stated, “the diagnosis of states of depression may offer difficulties, especially when arteriosclerosis is involved.” Kraepelin concluded that cerebrovascular disorder may be an accompanying phenomenon of manic-depressive disease or may itself produce depressive disorder.

Pseudobulbar affect (PBA) is another emotional disorder that has been associated with brain injuries, including cerebral infarction, and represents one of the differential diagnoses for depression in stroke patients. In 1956,

Telegram: @medical_k

www.konkur.in

Redvers Ironside described the clinical manifestations of this condition, noting that patients' emotional displays were characteristically unrelated to their reported inner emotional state. Laughing and/or crying may occur spontaneously or after some seemingly minor provocation. The emotion expressed is exaggerated relative to both the stimulus and the experienced emotional state and sometimes completely incongruent with the experienced emotional state. The expression of emotion here is involuntary and uncontrollable. This phenomenon has been given various names, including pathologic laughter and crying (PLAC), emotional incontinence, emotional lability, pathologic emotionalism, and involuntary emotional expression disorder. For the purpose of uniformity, this chapter will use the more widely used term in clinical settings, PBA.

Another emotional abnormality, also thought to be characteristic of brain injury, is the indifference reaction described by Derek Denny-Brown in 1952. Associated with right-hemispheric lesions, this reaction was described as indifference toward failures, lack of interest in family and friends, enjoyment of foolish jokes, and minimization of physical difficulties. In the late 19th century, Leonore Welt first described euphoria and loquaciousness associated with orbital frontal injury. Hermann Oppenheim used the term "witzelsucht" to refer to the inappropriate humor in these patients, while Karl Kleist stated that the orbital frontal cortex was the center of emotional life and the dorsal lateral frontal cortex was the source of psychomotor and intellectual activity.

Kurt Goldstein described another neuropsychiatric disorder historically associated with brain injury such as stroke, and he called it the catastrophic reaction. He characterized this reaction as an emotional outburst involving various degrees of anger, frustration, depression, tearfulness, refusal, shouting, swearing, and sometimes aggressive behavior. Goldstein ascribed this reaction to the inability of the organism to cope when faced with a serious defect in its physical or cognitive functions.

Joseph Jules François Félix Babinski introduced the term anosognosia to indicate a patient's lack of awareness of their hemiplegia. Babinski described this condition as "a mental disorder which I had the opportunity to observe in cerebral hemiplegia, consisting in the fact that the patients ignore or seem to ignore the paralysis which affects them." This term has been extended to unawareness of other deficits after strokes, such as cortical blindness, hemianopia, and amnesia.

Telegram: @medical_k

www.konkur.in

Comparative Nosology. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) defines poststroke psychotic, mood, and anxiety disorders as disorders due to another medical condition (stroke). Relevant specifiers are applied to the diagnosis to provide additional details about the patient's clinical presentation. For example, as per DSM-5, a poststroke depressive syndrome meeting full criteria for a major depressive episode would be called depressive disorder due to stroke, with major depressive-like episode. Poststroke subsyndromal depression, also known as minor depression, provides another instructive case example. Common following stroke, subsyndromal depressive symptoms are characterized by more than two but less than five of the required symptoms for a major depressive episode and persist for at least 2 weeks. According to DSM-5 nomenclature, such a clinical scenario is classified as a depressive disorder due to stroke with depressive features.

The diagnosis of poststroke anxiety based on DSM-5 criteria is termed "anxiety disorder due to stroke" regardless of the phenomenologic features of the anxiety disorder. For example, one patient may have anxiety symptoms suggestive of panic disorder and another patient may have symptoms more consistent with generalized anxiety disorder (GAD). Both of these patients would receive diagnoses of "anxiety disorder due to stroke" according to DSM-5.

The only DSM-5 disorders that are specific to cerebrovascular disease are the major or minor vascular neurocognitive disorders. DSM-5 identifies two forms of cognitive impairment due to vascular disease: major and minor vascular neurocognitive disorders. The term major neurocognitive disorder due to vascular disease replaces the term vascular dementia, which was used in the fourth edition of the DSM (DSM-IV). Minor vascular neurocognitive disorder is now used in lieu of mild cognitive impairment. The other aforementioned neuropsychiatric disorders which are specific to brain injuries, such as PBA or catastrophic reactions, do not have defined diagnostic criteria in DSM-5.

Investigators of depression that co-occurs with physical illness have also debated the most appropriate method for the diagnosis of these disorders when some symptoms (e.g., sleep or appetite disturbances) could result directly from the physical illness. The following four approaches have been used to assess depression in this complicated scenario:

Telegram: @medical_k

www.konkur.in

1. *The inclusive approach:* depressive diagnostic symptoms are counted regardless of whether they may be related to physical illness.
2. *The etiologic approach:* a depressive symptom is counted only if the diagnostician feels that it is not caused by the physical illness. Of note, this is the method to be used when making DSM-5 diagnoses.
3. *The substitutive approach:* other psychological symptoms of depression replace the neurovegetative symptoms.
4. *The exclusive approach:* symptoms are removed from the diagnostic criteria if they are not found to be more frequent in depressed than nondepressed patients.

In 1997, Sergio Paradiso and colleagues examined the utility of these methods in the diagnosis of depression during the first 2 years following stroke. Among 205 patients with acute stroke, 142 patients were followed up for examination at 3, 6, 12, or 24 months following stroke. Of the 142 patients with follow-up, 60 (42%) reported the presence of a depressed mood (depressed group) while they were in the hospital, and the remaining 82 patients were nondepressed. Depressive symptoms were divided into vegetative (e.g., autonomic anxiety or subjective anergia) and psychological (e.g., worrying or hopelessness) subtypes. The only vegetative symptoms that were not significantly more frequent in the depressed compared to the nondepressed patients at the different follow-up intervals were as follows: at the initial evaluation, weight loss and early morning awakening; at 6 months, weight loss and early morning awakening; at 1 year, weight loss, early morning awakening, anxious foreboding, and loss of libido; and at 2 years, weight loss and loss of libido. Among the psychological symptoms, the depressed patients had a higher frequency of most of the psychological symptoms throughout the 2-year follow-up. The only psychological symptoms that were not significantly more frequent in the depressed than in the nondepressed group were as follows: at 3 months, suicidal plans, simple ideas of reference, and pathologic guilt; at 6 months, pathologic guilt; at 1 year, pathologic guilt, suicidal plans, guilty ideas of reference, and irritability; and at 2 years, pathologic guilt and self-depreciation.

These findings are supported by a more recent study by Cumming and colleagues from 2010. This study included 149 stroke patients at 18 months poststroke and 745 age- and sex-matched controls from the general population. A major depressive episode was diagnosed in 25 of 149 (17%) stroke patients and 61 of 745 (8%) of controls. When symptom

Telegram: @medical_k

www.konkur.in

profiles were compared across these two depressed groups; the controls reported a greater “inability to feel” in comparison to the stroke group. Otherwise, there were no statistically significant differences between symptom profiles in the groups. Moreover, a factor analysis of 10 psychological and somatic symptoms of depression showed no difference between the stroke and control groups, regardless of depression diagnosis.

In sum, these two studies suggest that the phenomenology of poststroke depression (PSD) is similar to depression in the general population. In other words, the use of the same diagnostic criteria for depression in these two populations appears to be valid. Thus, DSM-5 defines depressive disorder due to stroke according to the same symptoms as major depression occurring in patients without stroke.

EPIDEMIOLOGY

Vascular Major Neurocognitive Disorder

As discussed in the nosology section, DSM-5 now categorizes vascular dementia as an etiologic subtype of either major or mild neurocognitive disorder. Dementia and vascular dementia continue to be the popular terminologies used in published research, so we will use the terms “dementia” and “major neurocognitive disorder” (and “vascular dementia” and “vascular major neurocognitive disorder”) interchangeably in the following sections reviewing published work. In 2000, Antonio Lobo and colleagues performed a review of the prevalence of dementia in Europe based on population-based studies. Based on a total of 2,346 cases of mild to severe dementia, the age-standardized prevalence was 6.4% for all-cause dementia, 4.4% for dementia due to Alzheimer disease (dAD), and 1.6% for vascular dementia. The authors found a consistent increase in the lifetime prevalence of vascular dementia with advancing age. The pooled prevalences for those aged 65 to 69 years were 0.5% in men and 0.1% in women, while the rates were 3.6% in men and 5.8% in women 90 years and older. In 2007, the Aging, Demographics, and Memory Study estimated the prevalence of dementia in the United States. Composed of approximately 850 elders aged 71 and older, the prevalence of dementia overall was 13.9%, equating to 3.4 million people. The prevalence of vascular dementia was 2.43%. In Asia, vascular dementia was more common than dAD until the last two decades. In a review of the

Telegram: @medical_k

www.konkur.in

epidemiology of dementias in developing countries, Raj Kalaria and coauthors concluded that the prevalence of vascular dementia appears to be low except for some Latin American and Asian countries. Overall, they estimate the prevalence of vascular dementia in developing countries to be 0.6% to 2.1%. Finally, a 2021 meta-analysis by Una Clancy et al. that included 81 studies found associations between worse white matter hyperintensity (WMH) severity and apathy. Worse WMH severity was also associated with delirium and fatigue.

Hypertension has been shown to be the most common modifiable risk factor for stroke worldwide, and it may potentially have a mediating effect on the strong association between vascular-related cognitive impairment and Alzheimer disease. A longitudinal study of 173 patients with vascular dementia examined the frequency of risk factors for stroke and cerebral atherosclerosis. Although hypertension was the most common risk factor for cerebral atherosclerosis and stroke, hypotension was the most common risk factor for vascular dementia in this sample. Heart disease of the atherosclerotic type, with or without cardiac arrhythmia, was also present in the majority of cases of vascular dementia. Cardiac disease may provide a source of cerebral emboli leading to vascular dementia. Cigarette smoking of one or more packs per day was a risk factor in 21%. Hyperlipidemia type 4, that is, hypertriglyceridemia, was present in 29% of cases. Diabetes mellitus of sufficient clinical severity to require medical treatment was found in 20% of the cases, while symptomatic peripheral vascular disease with ischemic symptoms referable to the lower extremities was present in 6%. Vascular dementia was also associated with limited education suggesting that prevention efforts that are related to education may be effective in slowing or preventing the disease. Alternatively, the association with limited education may suggest some social or neurobiologic benefits of learning that may inhibit the development of this disease.

Depression

Several reviews have examined the prevalence of depression following stroke. In the most recent, Luis Ayerbe and colleagues evaluated data from 43 studies, including 20,293 patients. They found the pooled prevalence of depression observed at any time point was 29%. The prevalence rates did not differ significantly over time or in studies in different settings. The cumulative incidence of PSD was 39% to 52%

Telegram: @medical_k

www.konkur.in

within 5 years of stroke. In another large review of 51 cohorts and 25,207 patients, Maree L. Hackett's group estimated that 33% of stroke patients experience depression. Both reviews emphasize that the estimation of the prevalence of PSD is confounded by heterogeneity in important clinical variables, such as the type of depression (e.g., syndromic vs. subsyndromic depression) or population type (e.g., hospital-based vs. outpatient sample). To address these limitations, Bob Robinson and coinvestigators conducted a systematic review of these factors in 2006. Among the 2,108 patients in community-based settings, the prevalence rate of major depression was 14.1%, while the rate of minor depression was 9.1%. A total of 2,769 patients were treated in acute or rehabilitation hospitals. Of these patients, 21.6% met the criteria for major depression, and an additional 20.0% had minor depression. Among studies of outpatients, the prevalence rates of major and minor depression were 24.0% and 23.9%, respectively. Suicidal thoughts may develop shortly after the onset of acute stroke, especially in patients with a lower educational level, a previous mood disorder, and those who developed depressive symptoms in the acute phase of stroke. In a 2015 review, Maurizio Pompili and colleagues concluded that PSD, pre-existing mood disorder, prior history of stroke, and cognitive impairment were found to be the most important risk factors for poststroke suicide.

Mania

Compared to PSD, mania after stroke is a rare neuropsychiatric occurrence, and the literature consists primarily of case reports or small case series. Catarina Santosa and colleagues performed a systematic review of poststroke mania in 2011 to better understand its demographic and clinical features. Their literature search covered approximately 50 years and yielded a total of 74 cases of mania in adult stroke patients. The authors observed the typical patient was male without a personal or family history of psychiatric illness, with at least one vascular risk factor, without subcortical atrophy, and with a right cerebral infarct. Overall, this study demonstrates the rarity of mania after stroke.

Anxiety

In their 2018 review and meta-analysis, Lena Rafsten and colleagues estimated the pooled prevalence of anxiety disorders at 29.3% during the first year poststroke. The risk was highest immediately after stroke,

Telegram: @medical_k

www.konkur.in

reducing over the year, with frequency estimation of 36.7% 0 to 2 weeks poststroke, 24.1% 2 weeks to 3 months poststroke, and 23.8% 3 to 12 months poststroke.

A meta-analysis from 2013 of 44 reports and 5,760 stroke patients found the pooled estimate of poststroke anxiety disorders, as determined by clinical interview, was 18%. When anxiety symptoms were assessed by a rating scale, the prevalence of anxiety was 25%. Three of the included studies examined the relative frequency of the different anxiety disorders and found that phobic disorders and GAD were the most common. In addition, the prevalence of anxiety tended to increase with time. The prevalence was 20% in the month following stroke, 23% between 1 and 5 months, and 24% had anxiety symptoms at 6 months or more. These results suggest that anxiety symptoms are common after stroke and tend to persist. The review also found similar prevalence estimates regardless of study setting (population-based vs. hospital vs. rehabilitation vs. community-based).

A significant number of patients with a poststroke anxiety disorder also have depression. A review of 1,445 patients within 3 months following stroke found that 49% met the criteria for GAD without comorbid depression, while 14% had comorbid GAD and major depression. Among community samples, the rate of GAD alone was 2%, and GAD with depression was 8%. Hospital and outpatient samples found that GAD alone occurred in 5.5% of cases, while GAD with depression occurred in 15.2%. Thus, anxiety disorders following stroke are frequently comorbid with a depressive disorder, although a significant number of patients have anxiety alone.

While numerous case reports exist, a paucity of data is available from systematic studies of the frequency of different types of anxiety disorders (e.g., phobia or panic disorder) after stroke. However, a growing literature now pertains to the occurrence of PTSD after stroke. For instance, Goldfinger and coinvestigators evaluated 535 patients who had a stroke or transient ischemic attack (TIA) and found that 18% likely had PTSD. In general, those with likely PTSD had worse physical and mental health. Predictors of poststroke PTSD included low income, a history of recurrent stroke or TIA, more disability, and greater medical comorbidity. Older age, the presence of a romantic partner, and having emotional support were protective against developing PTSD. While this literature is still in its

Telegram: @medical_k

www.konkur.in

infancy, such studies are a valuable contribution to studies of PTSD after a variety of acute medical events.

Psychosis

Although rare, case reports and empirical studies have documented that psychosis, primarily identified by the presence of delusions or hallucinations, may occur after a stroke. Two hospital registry studies initially evaluated the epidemiologic characteristics of poststroke psychosis. The reported frequency of psychotic disorders was 0.4% and 3.1% of stroke patients with an incidence of 1.1 per 1,000 person-years and a median time to onset of 6.1 months following stroke. Psychosis following stroke was also evaluated in a recent systematic review by Helle Stangeland et al. They included 76 studies. The average age for poststroke psychosis was 66.6 years, and delayed onset was common. The neurologic presentation was typical for stroke, but a significant minority had otherwise “silent strokes.” The most common psychosis was delusional disorder, followed by schizophrenia-like psychosis and mood disorder with psychotic features. Estimated delusion prevalence was 4.67% and hallucinations 5.05%. Twelve-year incidence was 6.7%. Lesions were typically in the right hemisphere, particularly frontal, temporal; and parietal regions, and the right caudate nucleus. In general, poststroke psychosis was associated with poor functional outcomes and high mortality. Psychosis considerably adds to the illness burden of stroke.

Apathy

Although DSM-5 does not include diagnostic criteria for this condition, apathy is typified by the absence or lack of feeling, emotion, interest, concern, or motivation and has been reported frequently among patients with brain injury, including stroke. Over the last 5 years, apathy has become one of the most intensely studied stroke-related disorders. Table 2.2–1, a summary of several recent studies, shows the reported prevalence of apathy in poststroke patients.

van Dalen JW, Moll van Charante EP, Nederkoorn PJ van Gool WA, Richard E. Poststroke apathy. *Stroke*. 2013;44:851–860.

A 2013 meta-analysis of 2,221 stroke patients found that apathy was associated with older age, depression, and cognitive impairment. The frequency of apathy did not differ when the following factors were considered: gender, stroke type (i.e., ischemic vs. hemorrhagic), and lesion location (i.e., left- vs. right-hemispheric lesions). Interestingly, the presence of apathy did not appear to affect the clinical outcome when measures of activities of daily living (ADLs) were examined. In a study of 80 acute stroke patients, 18 (22.5%) had apathy compared to 62 stroke patients without apathy. Nine (11.3%) had comorbid apathy and depression. The apathetic patients, with or without depression, were significantly older than the nonapathetic patients. Also, the apathetic patients showed significantly more severe deficits in ADLs. The nine cases who met the criteria for both apathy and depression were significantly more impaired in their ADLs than patients with apathy or depression alone. Seiji Hama and colleagues further examined the differential impact of depression and apathy on functional recovery. Based on a sample size of 237 patients with hemorrhagic or ischemic stroke, the authors found that apathy was a stronger predictor of poor functional recovery than depression. Douven et al.'s meta-analysis of studies of imaging markers also concluded that lesion type rather than lesion laterality or location might be an important factor in determining who is at risk of developing PSA in the acute as well as postacute phase.

A recent meta-analysis of 2,706 patients from 24 cohorts found a mean prevalence of apathy of 34.6% at a median of 120 days following stroke. Depression occurred in 40.1% of patients with apathy which suggests that apathy often occurs distinctly from depression. The estimated relative risk of depression among apathetic patients was 1.8. A very recent

Telegram: @medical_k

www.konkur.in

longitudinal, 1-year study found that 41.1% of patients met diagnostic criteria for apathy during the first year after stroke. Further, the mean months to onset was 3.8 ± 3.3 months, and the mean duration of meeting diagnostic criteria for apathy was 5.6 ± 2.3 months, as seen in Figure 2.2–1. In a linear mixed model, the authors controlled for age, initial severity of impairment, and major depression and found that patients in the apathy group had significantly less recovery in cognition and ADLs during the first year after stroke compared with nonapathetic patients.

FIGURE 2.2–1. Incident apathy after stroke. **Left:** The number of patients who met diagnostic criteria as proposed by Robert et al. for apathy for the duration indicated by the right edge of the column (e.g., 5 patients had 3 months' duration, whereas in the next column 10 patients had 4.5 months' duration). **Right:** The approximate time from initial evaluation to onset of apathy. The column on the **left** shows nine patients had onset at the initial evaluation, whereas the next column shows seven patients had onset at 1.5 months (i.e., no apathy at initial evaluation but present at 3 months). Thus, except in a few cases, apathy occurred within the first 5 months after stroke and lasted almost 6 months. (Reprinted with permission from Mikami KI, Jorge RE, Moser DJ, Jang M, Robinson RG. Incident apathy during the first year after stroke and its effect on physical and cognitive recovery. *Am J Geriatr Psychiatry.* 2013;21(9):848. doi:10.1016/j.jagp.2013.03.012.)

Catastrophic Reaction

Telegram: @medical_k

www.konkur.in

First described by Goldstein, catastrophic reactions are characterized by anxiety, tears, aggressive behavior, swearing, displacement, refusal, renouncement, and/or, sometimes, compensatory boasting. In an early study, the Catastrophic Reaction Scale (CRS), which was developed to assess the existence and severity of catastrophic reactions, was introduced. Based on a survey of 62 consecutive patients, 12 (19%) with acute stroke lesions were found to have catastrophic reactions. Of these 12, 9 (75%) met the criteria for major depression, and an additional 2 had minor depression. Further, the 12 patients with catastrophic reactions showed elevated scores on a measure of anxiety, the Hamilton Anxiety Scale. In a larger prospective study, 202 consecutive patients received the CRS within 4 days of stroke. Anger was seen in 71 (35%) patients, and 26 of these were severely angry. In a third study, the 10-item Spielberger Trait Anger Scale was used, and 47 of 145 (32%) of outpatients had evidence of the inability to control anger or aggression 3 to 12 months poststroke.

Pseudobulbar Affect

In a cohort study of 508 consecutive patients with ischemic stroke, 9.4% of patients had evidence of pathologic emotions during their admission for the care of acute stroke. Three months later, the frequency increased to 11.7%. Yet, in a separate study of 516 patients 3 months after stroke, the estimate of PBA was 7.6%. In a third study, 127 stroke patients who initially received care at a university-affiliated regional hospital were evaluated for PBA 3 months poststroke. When caregivers were involved in the assessment, the prevalence of PBA was 17.9%. In contrast, the estimate fell to 6.3% when only patients were evaluated. Such studies illustrate how relevant clinical factors (e.g., timing of study; involvement of informant) can significantly influence prevalence rates.

Anosognosia

Estimates of the prevalence of anosognosia vary considerably in the literature. Several factors contribute to this heterogeneity. For instance, the inclusion of patients with aphasia or dementia tends to conflate estimates due to significant language and cognitive limitations, respectively. Further, anosognosia is uncommon beyond 3 months poststroke. Therefore, the timing of the study assessment is another important factor in this literature. In the only meta-analysis to date,

Telegram: @medical_k

www.konkur.in

Lorenzo Pia and colleagues identified 52 studies from 1938 to 2001 for study inclusion. They found the frequency of anosognosia for hemiplegia to range from 20% to 44%, depending on when the study was conducted relative to stroke occurrence. Further, in patients with complete contralateral motor impairment, the prevalence of anosognosia was 32.3%.

ETIOLOGY

Depression

Several hypotheses about the etiology of PSD have been postulated. Numerous studies have found abnormalities in biomarkers linked to mood dysregulation, such as the serotonin transporter gene and certain inflammatory cytokines, particularly interleukins 6 and 18. Elevated levels of glucocorticoids, which affect glutamate transmission, and stroke location, which results in the interruption of biogenic amine transmission, are additional findings. Of these factors, lesion location has been a topic of considerable interest.

A systematic review and meta-analysis of studies on imaging markers for PSD by Douven et al. suggested that lesion location rather than lesion laterality or type may be an important risk factor for PSD in the postacute stroke phase. In studies performed 3 to 12 months after stroke, the prevalence of PSD is similar in those with left- and right-hemispheric lesions. However, in the first few months after stroke, lesion location does appear to increase the risk of PSD. This relationship has been the subject of a meta-analysis conducted by Robinson and colleagues who evaluated the frequency of depression within 2 months following stroke. Of the 128 patients with left anterior and left posterior strokes, the presence of a left anterior stroke increased the odds for PSD by 2.3 in comparison to the posterior lesion. In a comparison of right anterior and left anterior strokes, having a left anterior lesion increased the odds of PSD by 2.18. In a separate meta-analysis of 8 studies conducted within 6 months of stroke, the proximity of the anterior border of the stroke lesion to the left or right frontal pole and severity of PSD was evaluated. The authors found a significant inverse relationship between severity of depression and distance of the stroke from the left frontal pole, but not the right frontal pole. A third meta-analysis paints a different picture. Performed by Na Wei and colleagues, the meta-analysis consisted of 43 studies and

Telegram: @medical_k

www.konkur.in

approximately 5,500 patients. The overall analysis failed to show a relationship between lesion location and PSD. However, the impact of time since stroke was evaluated in subsequent subgroup analyses, and a modest, albeit statistically significant relationship (odds ratio of 0.79), was found between right-hemispheric stroke and PSD risk within the subacute (i.e., 1 to 6 months poststroke) group. The fourth and most recent meta-analysis performed by Douven et al., however, included 74 studies with PSD and showed a clear risk of PSD with frontal and basal ganglia lesions.

In sum, while patients appear to be at elevated risk for PSD within the first few months after stroke, meta-analyses have reported somewhat conflicting results regarding the association between PSD and lesion location. Such conflicting results exemplify a fundamental concept seen across neuropsychiatry: specific clinical symptoms are unlikely to be the product of an isolated lesion but instead due to dysfunction of key neurocircuitry. Further, a major problem with these meta-analyses, as indicated earlier, is that combining findings across studies frequently overlooks potential modifying variables. For example, specific types (i.e., major vs. minor depression), specific symptoms of depression (i.e., neurovegetative vs. psychological), and type of brain injury (e.g., ischemic vs. hemorrhagic) may be other crucial variables that are overlooked by meta-analytic techniques.

Several studies have evaluated the clinical correlates of PSD. The most consistent finding has been increased severity of impairment in ADLs in those with PSD. In 2005, Hackett and colleagues performed a systematic review of observational studies. In 9 of 11 studies evaluating this factor, disability after stroke showed a positive and significant association with PSD. In a separate review by Robinson's group, 15 out of 18 studies (83%) found a statistically significant relationship between the severity or existence of PSD and the severity of impairment in ADLs. However, the temporal relationship between these factors (i.e., whether the depression preceded or followed the severe functional impairment) was not examined in most of these studies.

In addition, numerous studies have demonstrated that a personal history or a family history of psychiatric disorders is an important risk factor for PSD. This combination of biologic, clinical, and psychological correlations has led many investigators to hypothesize a biopsychosocial

Telegram: @medical_k

www.konkur.in

etiology for PSD. This may be a helpful clinical construct for the explanation of PSD as a whole, but it remains to be tested systematically.

Mania

Like other neuropsychiatric disorders, the etiology of mania remains unknown. The relatively rare occurrence of mania following stroke suggests that a combination of variables may be needed to produce this syndrome. For example, a study of 17 patients with stroke and mania (i.e., DSM-IV diagnosis of mood disorder due to stroke, with manic features) found that 12 had unilateral right-hemispheric lesions. The frequency of right-hemispheric lesions was significantly higher compared to 28 patients with major depression who tended to have left frontal or basal ganglia lesions, or patients with no mood disorder following stroke. Lesions associated with mania were either cortical (basotemporal or orbitofrontal cortices) or subcortical (frontal white matter, basal ganglia, or thalamus). A PET study using (^{18}F)fluorodeoxyglucose (FDG) showed focal hypometabolic deficiency in the right basotemporal cortex in three manic patients with right subcortical lesions, but this hypometabolism was not seen in seven, age-comparable, normal controls. Another systematic review of single or small series of cases of mania by Santos et al. found, among 49 patients, associations with male sex, vascular risk factors, and right-hemispheric infarcts.

Thus, mania appears to be provoked by injury to specific right-hemispheric structures that have connections to the limbic system. The right basotemporal cortex may be particularly important because direct lesions as well as distant hypometabolic effects of this cortical region, which is suggestive of diaschisis, were associated with secondary mania. The basotemporal cortex has strong efferent connections to the orbitofrontal cortex, suggesting that the lateral orbitofrontal circuitry in the right hemisphere may play a role in the etiology of mania. A combination of biogenic amine system dysfunction and release of tonic inhibitory input to the orbitofrontal–thalamic circuit may lead to the production of mania.

Another study by Starkstein et al. compared patients with secondary mania to patients with no mood disturbances. Participants were matched for size, location, and etiology of brain lesions. Patients with secondary mania had a significantly greater degree of subcortical atrophy as measured by the ratio of bifrontal and third ventricular volume to brain volume. Moreover, of the patients who developed secondary mania, those

Telegram: @medical_k

www.konkur.in

with a positive family history of psychiatric disorders had significantly less atrophy than those without such a family history. This implies that genetic predisposition to affective disorders and brain atrophy may be independent risk factors for poststroke mania. On the other hand, the systematic review of 49 cases by Santos et al. reported no associations with subcortical atrophy or family history of psychiatric disorder, and many of the studies included in this review did not examine those two factors. Therefore it may have been inadequately powered to explore those associations.

Psychosis

Information about the mechanism of poststroke psychosis is derived from anecdotal reports or small case series. One study of five patients with psychosis following stroke found that all patients had right-hemispheric lesions, primarily involving frontoparietal regions. When compared with five patients matched for age, education, lesion size, and location but no psychosis, patients with secondary psychosis had significantly greater subcortical atrophy. This atrophy was manifested by larger areas of both the frontal horn of the lateral ventricle and the body of the lateral ventricle on the side contralateral to the brain lesion. However, the majority of patients with right hemisphere stroke do not develop delusions. Neuroimaging analyses reveal that lesions of the right lateral prefrontal cortex and lesions that affect connectivity to this area correlate with the development of delusional beliefs. Several investigators have also reported a high frequency of seizures among patients with secondary psychosis. These seizures usually started after the brain lesion but before the onset of psychosis. The aforementioned study of patients with poststroke psychosis compared with lesion-matched controls found a seizure disorder among three of five patients with poststroke psychosis, as compared to zero of five stroke patients without psychosis. Overall, a right-hemispheric lesion, especially the right lateral prefrontal cortex or lesions that affect connectivity to this area, seizures, and subcortical brain atrophy appear to be important factors in the pathogenesis of poststroke psychosis.

Apathy

The mechanism of poststroke apathy has been the focus of many studies. For example, in a sample of 55 chronic stroke patients, patients who

Telegram: @medical_k

www.konkur.in

showed little behavioral response to positive reinforcement in the laboratory reported higher levels of apathy. These patients were also found to have lesions of the ventral putamen and globus pallidus, as well as the dorsal thalamus and prefrontal cortex. Another study of 106 acute stroke patients found that apathy at the time of acute stroke predicted apathy at 1-year follow-up. A meta-analysis reported that apathy among 2,221 patients was associated with PSD and greater cognitive impairment. Imaging studies have found that apathy is significantly associated with lesions of the pons, frontal cortex, basal ganglia, dorsal thalamus, posterior limb of the internal capsule, and temporal cortex (Table 2.2–2).

Overall, lesions along the anterior cingulate subcortical circuit (including cingulate gyrus, frontal cortex, ventral striatum, ventral pallidum, and magnocellular dorsomedial thalamus) have been frequently associated with the occurrence of apathy and may constitute an anatomical substrate for poststroke apathy.

Catastrophic Reaction

In a study of 62 patients with acute stroke, those demonstrating catastrophic reactions had a significantly higher frequency of lesions involving the basal ganglia compared to acute stroke controls. When 10 depressed patients with a catastrophic reaction were compared to 10 depressed patients without a catastrophic reaction, the catastrophic reaction group had significantly more anterior lesions, which were located primarily in subcortical regions (i.e., eight of nine depressed patients with

Telegram: @medical_k

www.konkur.in

catastrophic reaction had subcortical lesions; three of nine depressed patients without catastrophic reaction had subcortical lesions).

In another study, catastrophic reactions occurred in 12 of 62 patients (19%) admitted to the hospital with acute stroke. Patients with catastrophic reactions were found to have a significantly higher frequency of familial and personal history of psychiatric disorders, mostly depression, than patients without catastrophic reactions. Catastrophic reactions, however, were not significantly more frequent among aphasic compared with nonaphasic patients. This finding did not support the contention that catastrophic reactions represent an understandable psychological response of “frustrated” aphasic patients. Furthermore, 9 of 12 (75%) patients with catastrophic reactions also had PSD, 2 (17%) had minor depression, and only 1 was not depressed. Thus, the catastrophic reaction was closely linked with PSD.

Based on these findings, catastrophic reactions may result from neurophysiologic dysfunction rather than the realization of intellectual impairment. Catastrophic reactions occurred predominantly in patients with major depression associated with anterior subcortical lesions. Subcortical damage has also been hypothesized to underlie the “release” of an emotional display by removing inhibitory input to limbic areas of the cortex.

Pseudobulbar Affect

Pathologic emotions have traditionally been explained as secondary to the bilateral interruption of descending neocortical upper motor neuron innervation of bulbar motor nuclei. Some patients with pathologic emotions have such bilateral lesions, but this is not a uniform finding. For instance, one study found that patients with frontal or temporal lesions in either hemisphere had a significantly increased frequency of pathologic emotions. Examination of lesion size and location in 12 patients with pathologic crying found that patients with the most frequent crying episodes had relatively large bilateral pontine lesions. The intermediate group had large bilateral lesions. The least affected patients had relatively large unilateral subcortical lesions. Such evidence has led to the hypothesis that pathologic emotions may arise from the partial destruction of raphe serotonergic neurons or their projections. There is also increasing evidence of cerebellar involvement, and investigators at the

Telegram: @medical_k

www.konkur.in

University of Iowa have suggested that the critical lesions eliciting PBA are located along fronto-ponto-cerebellar pathways.

DIAGNOSIS AND CLINICAL FEATURES

Mild and Major Vascular Neurocognitive Disorders

The DSM-5 classification of vascular cognitive impairment (VCI) includes both patients with dementia (i.e., major vascular neurocognitive disorder) and its precursor (i.e., mild neurocognitive disorder). The following three conditions must be met to reach diagnostic criteria for major vascular neurocognitive disorder:

1. Criteria are met for major neurocognitive disorder (i.e., the presence of acquired impairment in one or more cognitive domains and significant impairment in ADLs not better explained by another medical condition);
2. The clinical features are consistent with a vascular etiology as suggested by either (a) cognitive deficits that are temporally related to one or more cerebrovascular events or (b) presence of prominent executive dysfunction (e.g., inattentiveness or slow processing speed);
3. The patient's history, physical examination, and/or neuroimaging findings are consistent with cerebrovascular disease of sufficient severity to account for patient's cognitive impairment.

Patients with mild vascular neurocognitive disorder have impairment in one or more cognitive domains, but daily functioning remains relatively intact. However, affected individuals may take longer than usual or engage in compensatory techniques to overcome their cognitive disturbances. Cognitive impairment due to vascular disease is expected to occur in the presence of multifocal motor and/or sensory deficits on the physical examination. A single vascular lesion could result in a clinical picture consistent with major vascular neurocognitive disorder.

Depression

The assessment for depression in patients with stroke or other physical illness has been a topic of considerable debate. According to DSM-5, two types of poststroke depressive disorders are recognized: depressive disorder due to stroke with major depression-like episode and depressive

Telegram: @medical_k

www.konkur.in

disorder due to stroke with depressive symptoms (i.e., subsyndromal depression). The diagnostic criteria, however, require the clinician to determine whether they believe that the mood disorder is the direct physiologic consequence of the stroke. If this judgment is made, then the patient is diagnosed with “depression due to stroke.”

The problem with this diagnostic schema is that even the most experienced clinician cannot be certain if the depression is due to the direct physiologic consequences of the stroke. Even if the patient has a history of depression prior to the stroke, the physiologic response to brain injury may or may not provoke a new depressive episode. Furthermore, the clinical manifestations of depression appear to be the same regardless of whether the depression followed a stroke. That is, empiric evidence has shown that all the symptoms of major depression with poststroke onset have been shown to be significantly more frequent in depressed compared with nondepressed stroke patients. Thus, the symptoms of depressed mood, anhedonia, weight loss, insomnia, psychomotor agitation or retardation, loss of energy, worthlessness, poor concentration, and suicidal thoughts characterize patients with PSD just as well as depressed patients without structural brain injury. Thus, a better diagnostic system may be to make stroke a specifier akin to *postpartum onset.* Namely, the diagnosis of “major” or “minor” depression would be qualified with *poststroke onset.* Empirical data appears to support such nomenclature more so than the current diagnostic classification.

To promote the early detection of PSD in patients hospitalized for acute stroke, Janneke de Man-van Ginkel and colleagues developed the Post-Stroke Depression Prediction Scale. The authors validated this scale in a study of 410 stroke patients. Within the first week after stroke, participants were assessed for various PSD predictive factors and then reassessed 6 to 8 weeks after stroke. Based on a multivariate model, a medical history of depression or other psychiatric disorder was the most important predictor (odds ratio 7.2) of PSD. Other predictive factors included a medical history of hypertension, angina pectoris, and impaired ability to dress oneself based on the dressing item of the Barthel Index of ADLs. Further, the lowest risk category (<10 sum score) at 1-week poststroke was associated with a 2% risk of depression at 6 to 8 weeks follow-up, while 82% of the highest-risk category (>21 sum score) developed depression at 6 to 8 weeks.

Telegram: @medical_k

www.konkur.in

Mania

The symptoms of mania were examined in a series of 25 consecutive patients who met DSM-IV criteria for a mood disorder due to brain injury with manic features. These patients, who developed mania after a stroke, traumatic brain injury, or tumors, were compared to 25 patients with primary mania (i.e., no known neuropathology). Both groups of patients showed similar frequencies of elation, pressured speech, flight of ideas, grandiose thoughts, insomnia, hallucinations, and paranoid delusions. Thus, the symptoms of mania that occurred after stroke (now diagnosed by DSM-5 as bipolar disorder due to stroke with manic-like episode if full criteria for mania are met, or bipolar disorder due to stroke with manic features if full criteria for mania are not met) appear to be the same as those found in idiopathic cases of mania (i.e., bipolar disorder). As with depression, a better diagnostic classification might be mania with *poststroke onset.*

Anxiety

A 2013 study including 374 patients found that 23% had anxiety defined by a score of eight or more on the Anxiety Section of the Hospital Anxiety Depression Scale. Patients with poststroke anxiety had a poor stroke-related quality of life in general and in several areas, including energy, mood, personality, thinking, and work. Another 2013 study looked at long-term outcomes of poststroke anxiety in 220 patients followed longitudinally. At 5 years poststroke, 64 (29%) of patients were deemed anxious, and 73 (33%) were depressed, with anxiety and depression comorbidity in 43 (20%). Higher anxiety scores at 6 months following stroke were associated with anxiety at 5 years poststroke but not ADLs scores at 6 months. Finally, an imaging study of 693 patients with acute stroke reported that the anxious patients, as defined by a score of eight or more on the Hospital Anxiety Depression Scale, had a significantly increased frequency of right-frontal infarcts even after controlling for other relevant variables. In sum, anxiety is common after a stroke and its prevalence remains elevated even several years out from the stroke. Since anxiety (along with depression) is associated with poor recovery, regular assessments for anxiety (and PSD) are warranted.

The following case illustrates a typical clinical course of poststroke anxiety and its frequent comorbidity with depression:

Telegram: @medical_k

www.konkur.in

A 71-year-old farmer suffered a thrombosis of the basilar artery. He developed blurring of his vision, gait impairment, and paresthesias of his face. Within 2 months of the stroke, the patient developed panic attacks and GAD. His GAD was characterized by almost constant anxiety about minor issues, insomnia, restlessness, and poor concentration. The panic attacks were typified by the rapid onset of anxiety with tachycardia, shortness of breath, sweating, and fearfulness that he would pass out or die from another stroke or a heart attack. The panic attacks occurred first when he was away from home and later while he was at home. The panic attacks were controlled by alprazolam, but in spite of taking this medication four times per day, he continued to have significant anxiety marked by worrying, restlessness, muscle tension, poor concentration, and insomnia. About 2 months later, the patient also developed depression with symptoms of low mood, loss of interest, poor concentration, self-blame, hopelessness, and psychomotor slowing. He responded to electroconvulsive therapy but relapsed quickly. He was then treated with nortriptyline, which led to remission of both his depressive and anxiety disorders.

Apathy

The clinical manifestations of apathy were utilized by Marin and Starkstein in the 1990s to develop an apathy rating scale and to propose diagnostic criteria. The essential symptom of apathy is the loss of motivation or drive which is the required symptom for the diagnosis of apathy. Lack of motivation may be manifested emotionally, cognitively, or behaviorally as reflected in the recently proposed diagnostic criteria for apathy by Roberts and colleagues, as reflected in Table 2.2–3.

The following vignette illustrates a case of poststroke apathy and some of its differences from other conditions:

Telegram: @medical_k

www.konkur.in

A 55-year-old office manager was recovering from a right-prefrontal ischemic stroke, believed to be a consequence of poorly controlled hypertension and obesity. A week after his admission, a psychiatric consultation was requested to evaluate him for depression. His wife and physical therapist reported that he was not engaging in rehabilitation as expected and that he seemed “disconnected.” He avoided therapy by saying, “I don’t have energy now,” even when he maintained a cooperative and polite attitude. He denied feeling sad but reported “feeling disinterested and flat.” He was otherwise hopeful about his recovery. Visits from his family did not seem to cheer him up as they did previously, and his daughter commented that he seemed “as if he had lost his sparkle.” The patient denied feeling like crying and his family concurred that he didn’t display crying spells or abnormal laughing. While he did not have a history of psychiatric or neurologic conditions, the staff was concerned about poststroke depression. His routine blood work-up was unremarkable and imaging studies did not yield any new findings. His most recent neurologic examination revealed improved mild-left hemiparesis, stronger muscle strength, and steadier ambulation. The confusional state that was documented at the time of his admission seemed to have resolved and he was completely oriented to himself, the date, his surroundings, and the circumstances of his hospitalization. He recognized all his family members and clinicians and was not suspicious. He was attentive during conversations but seemed easily tired. There were no fluctuations in his mental state throughout the day, and at night, his sleep was reported as sound. His appetite was reduced but was gradually improving. It was thought that recovering from delirium could have been the most likely cause of the patient’s symptoms, and therefore observation and monitoring as an outpatient were recommended. Unfortunately, in his first ambulatory medical follow-up 3 weeks later, his family reported that his lack of energy and motivation had worsened and that he would get angry and refused to engage in his recovery meaningfully. The wife was concerned about cancelation of rehabilitation services by the medical insurance. Once again, the screening for depression was negative. A diagnosis of poststroke apathy was made, and he was initiated a low dose of methylphenidate. Within a couple of weeks of this intervention, the

Telegram: @medical_k

www.konkur.in

patient started to participate in regular sessions of physical therapy and perform the prescribed exercises at home in between them.

Table 2.2–3.
Questions from the Apathy Scale Used to Determine the Existence of Lack of Emotion, Slowed Activity, and Impaired Cognitive Activity Seen in Apathy

Lack of Emotion	Slowed Motor Activity	Impaired Cognitive Activity
Are you concerned about your condition?	Does someone have to tell you what to do each day?	Are you interested in learning new things?
Are you indifferent to things?	Do you put much effort into things?	Do you have anything that interests you?

The proposed criteria for the diagnosis of apathy is lack of motivation (e.g., "Do you have motivation?") plus two of the three symptoms above (i.e., lack of emotion, slowed motor activity, and/or impaired cognitive activity) present most of the time for at least 4 weeks based.

Data from Mikami K, Jorge RE, Moser DJ, et al. Prevention of poststroke apathy using escitalopram or problem-solving therapy. *Am J Geriatr Psychiatry*. 2013;21(9):855–862.

Catastrophic Reactions

Currently, no diagnostic criteria are available for catastrophic reactions. As described earlier in the chapter, patients typically present with sudden outbursts of refusal, swearing, tears, and sometimes aggressive behavior. This intense emotional reaction is usually provoked by stressful situations such as cognitive testing and typically subsides within a few minutes.

Pseudobulbar Affect

There are no established diagnostic criteria for PBA. This condition is characterized by the sudden onset of crying, or more rarely, laughing, which is out of proportion to the conversation or situation in which the emotional reaction occurred. The emotion may last from a few seconds to a few minutes with no residual feelings of sadness or happiness.

At least five studies have examined the clinical features of pathologic emotions. The hallmark features of PBA are as follows: an inability to

Telegram: @medical_k

www.konkur.in

control crying or laughter; an increased frequency of such emotional display; and recognition by the patient that the emotional display is inconsistent or excessive to their underlying emotional feelings. Several rating scales are available for PBA, but only the PLACS scale was specifically developed for poststroke pathologic emotions. As seen in Figure 2.2–2, this scale assesses the existence and severity of pathologic emotion among patients with stroke.

PATHOLOGY AND LABORATORY EXAMINATION

Mild and Major Vascular Neurocognitive Disorders

The clinical identification of vascular neurocognitive disorders requires a medical history, neurologic examination, psychiatric interview, and neuropsychological assessment. Diagnostic testing also plays an important role and is informed by blood chemistries (chiefly B_{12}, folate, and thyroid function), head CT and/or brain MRI, and, in certain cases, cerebral angiography. These laboratory and imaging data are used to evaluate for potentially treatable forms of dementias caused by tumor, vascular malformation, cerebral hematoma, normal pressure hydrocephalus, infections, endocrine abnormalities, or vitamin deficiencies. Structural imaging studies (i.e., head CT or brain MRI) should document the existence of one or, more likely, several cerebrovascular lesions and, when present, the distribution of the cerebral volume loss associated with those lesions. Cerebral angiography may identify vascular lesions (e.g., aneurysms or cerebral artery stenosis) that may be reversible through interventional radiology or neurosurgical procedures. Additional tests that may be helpful include CSF analysis to rule out infectious causes as well as other causes of dementia like Alzheimer disease and paraneoplastic syndromes, electroencephalogram (EEG) to help with prognostication after acute ischemic stroke, differentiate delirium from dementia, and also differentiate vascular dementia from Alzheimer disease, and EEG with evoked responses to evaluate for functional limitations after stroke (visual-evoked potential evaluates the visual pathway, brainstem evoked potential evaluates stroke that occurs in brain structures supplied by the vertebrobasilar system, and somatosensory and motor evoked potentials represent a useful early prognostic marker of functional recovery in ischemic stroke).

Pathological Laughing and Crying Scale

Part 1: Patient Interview

1. Have you recently experienced sudden episodes of laughter?
2. Have you recently experienced sudden episodes of crying?

If you have experienced sudden episodes of laughter, please answer the following (questions 3-10), otherwise skip to question 11.

3. Have these episodes occurred without any cause in your surroundings?
4. Have these episodes lasted for a long period of time?
5. Have these episodes been uncontrollable by you?
6. Have these episodes occurred as a result of feelings of happiness?
7. Have these episodes occurred in excess of feelings of happiness?
8. Have these episodes of laughter occurred with feelings of sadness?
9. Have these episodes occurred with any emotions other than happiness, or sadness, such as nervousness, anger, fear , etc.?
10. Have these episodes caused you any distress or social embarrassment?

If you have experienced sudden episodes of crying, please answer the following (questions 11-18).

11. Have these episodes occurred without any cause in your surroundings?
12. Have these episodes lasted for a long period of time?
13. Have these episodes been uncontrollable by you?
14. Have these episodes occurred as a result of feelings of sadness?
15. Have these episodes occurred in excess of feelings of sadness?
16. Have these episodes of crying occurred with feelings of happiness?
17. Have these episodes occurred with any emotions other than happiness, or sadness, such as nervousness, anger, fear , etc.?
18. Have these episodes caused you any distress or social embarrassment?

Poststroke Depression

Currently, no laboratory or neuroimaging studies are routinely used to inform the clinical diagnosis of PSD (except for B_{12}, folate, hemoglobin, and thyroid function, which are routinely done to rule out other causes of depression symptoms). This topic, nevertheless, is an area of considerable interest for the scientific community. Studies to date have largely focused on endocrine markers linked to major depression. For instance, the dexamethasone suppression test (DST) has been investigated as a possible biologic marker. A total of nine studies involving 327 patients demonstrated a statistical association between PSD and a failure to suppress serum cortisol in response to the administration of dexamethasone. The mean pooled data specificity of the test was 87%, while the sensitivity was 47%. These values are insufficient to be diagnostically useful. The inadequacy of the DST as a diagnostic tool was

Telegram: @medical_k

www.konkur.in

also seen in a study of 65 patients whose acute strokes had occurred within the preceding year. Of these cases, 67% with major depression failed to suppress serum cortisol compared to 25% of patients with minor depression and 32% of nondepressed patients. The sensitivity of the DST for major depression was 67%, with a positive-predictive value of 50%. The specificity was only 70%, with a negative-predictive value of 80%. False-positive tests, found in 33% of patients, were related to large lesion volumes.

In a different line of work, a study of growth-hormone response to desipramine found that growth-hormone responses were significantly blunted in patients with PSD. These results suggest that diminished α_2-adrenergic receptor function may be an important marker for PSD. The sensitivity of the test was 100%, and the specificity was 75%. Future studies of endocrine responses as markers of PSD may prove to have diagnostic validity. Alternatively, such markers may help define more homogeneous subtypes of PSD for research purposes.

Another prominent line of inquiry revolves around identifying various biomarkers that predict the risk of PSD. The majority of this research has focused on the numerous inflammatory biomarkers that are deranged in patients with PSD compared to patients with stroke who do not develop depression, including decreased serum BDNF concentrations, increased early markers of inflammation like C-reactive protein and ferritin, serum proinflammatory cytokines (TNF-α, IFN-γ), as well as proinflammatory/anti-inflammatory ratios, lowered complement expression, decreased serum vitamin D levels, hypercortisolemia and blunted cortisol-awakening response.

Neuroimaging markers have also been identified. Lesions affecting the frontal-subcortical circuitry of mood regulation (prefrontal cortex, basal nuclei, and thalamus) predominantly in the left hemisphere appear to predict PSD 1 year after stroke. Additional pontine and lobar cerebral microbleeds in acute stroke patients, as well as severe microvascular lesions of the brain, increase the likelihood of PSD.

Other Disorders

The utility of laboratory examinations in the diagnosis or prognosis of poststroke mania, anxiety disorders, psychosis, apathy, catastrophic reactions, and anosognosia has not been established except as discussed under etiology.

Telegram: @medical_k

www.konkur.in

COURSE AND PROGNOSIS

Mild and Major Vascular Neurocognitive Disorders

The course of major vascular neurocognitive disorder is characterized by a close temporal relationship between stroke occurrence and deterioration of cognitive function. The probability of recurrent stroke is approximately 7% per year. The course and prognosis of poststroke cognitive impairment, however, can be influenced by preventative measures.

The Framingham Heart Study was the first to prospectively examine the effect of new-onset stroke on cognition, as reported in 2014. In this study, 132 new-onset, dementia-free stroke patients were prospectively followed and received serial cognitive testing. At 6 months after stroke, significantly greater impairment in the following cognitive domains was seen: immediate recall of logical and visual memory, verbal learning, naming, executive function, visuospatial, and motor skills. These deficits were independent of prestroke cognitive function and vascular risk factors.

A 2014 update on subcortical vascular neurocognitive disorder noted that subcortical vascular dementia is driven by severe stenosis of the small vasculature of white matter and small vessel disease. In turn, these processes lead to white matter ischemia, slow progression of symptoms, and cholinergic neuronal damage that makes it difficult to differentiate cognitive impairment due to subcortical vascular disease from dAD.

In their prospective study on survivors of incident stroke, Levine and colleagues found an association between acute decline in cognitive function and accelerated and persistent cognitive decline over 6 years.

Depression

The longitudinal course of PSD has been examined in a number of studies. At the time of the initial acute or rehabilitation hospital evaluation (e.g., 1-week poststroke), 21.6% of patients had a symptom cluster consistent with major depression, and 20% had a symptom cluster of minor depression (i.e., subsyndromal depression). Although both major and minor depressive disorders appear to continue for months, the observed course has varied from one study to the next. Philip Morris and colleagues calculated a mean duration of major depression of 39.0 ± 31.8 weeks and a mean duration of minor depression of 12.2 ± 18.2 weeks. Another report by Robinson and colleagues of 142 patients over 2 years

Telegram: @medical_k

www.konkur.in

following acute stroke found a mean duration of 31.2 weeks for major depression but 11.9 months for minor depression. A mean of 26% of patients continued to have major depression 1 year after initial diagnosis. A study of 1,233 stroke patients followed over 15 years found that 50% of patients with PSD at 3 months had recovered by 1 year. A 2013 meta-analysis of 4,022 patients from 50 studies found that among patients depressed a few months following a stroke, recovery at 1 year ranged from 15% to 57%. In sum, these findings indicate that a significant number of patients who develop either major or minor depression following stroke may experience persistent depression for 2 or more years after stroke.

FIGURE 2.2–3. Cognitive impairment related to depression and lesion site. Mini-mental state examination scores following acute stroke in three studies among patients with major or no mood disturbance grouped according to the hemisphere of ischemia. In all three studies, there was a significant difference between patients with major depression following left-hemispheric stroke and nondepressed patients with similar lesions (P = .001). Major depression following right-hemispheric lesions did not lead to the same phenomenon. (Reprinted with permission from Robinson RG. *The Clinical Neuropsychiatry of Stroke: Cognitive, Behavioral and Emotional Disorders following Vascular Brain Injury*. 2nd ed. Cambridge University Press; 2006:155.)

Nearly all the studies that have examined the relationship between depression and physical/functional recovery from stroke (as measured by ADLs) have found that the more severe the depression, the more impaired patients were in ADLs. Furthermore, a subset of these studies has demonstrated that depression severity after acute stroke is an independent predictor of the severity of ADLs impairment 1 or more years

Telegram: @medical_k

www.konkur.in

after stroke. Thus, the prognosis for recovery in ADLs is significantly worse if a patient has depression following their acute stroke. Interestingly, Cevdet Bilge and colleagues found that patients with PSD who responded to treatment with citalopram showed significantly better improvement in ADLs than patients who were never depressed.

Similarly, the prognosis for cognitive functioning is also dependent, in part, upon the existence of PSD. Three separate studies have shown that major depression following acute stroke is associated with more severe cognitive impairment if the stroke occurred in the left hemisphere (Fig. 2.2–3). This effect of right- versus left-hemispheric stroke is not seen among nondepressed patients with similar lesions.

Longitudinal studies have also shown that patients with major depression following left-hemispheric stroke have greater severity of cognitive impairment in the 12 months following a stroke in comparison to patients with comparable stroke but no major depression. Between 12 and 24 months following a stroke, however, cognitive function among these patients tends to improve. By 24 months of follow-up, no difference exists in the severity of cognitive impairment among patients regardless of lesion location (i.e., right- vs. left-hemispheric strokes) or depression status (i.e., depressed or nondepressed patients) following the acute stroke.

Importantly, PSD has a dramatic association with increased mortality. The first study to report this phenomenon using standardized interviews and diagnosis was performed in 1993 on a sample of 103 acute stroke patients. At 10 years poststroke, patients with major or minor depression had a 3.4-fold increase in the odds of mortality in comparison to those with no depression. Another study of 976 patients with stroke found that patients with depression, assessed at 3 weeks poststroke using the Wakefield Self-Assessment Depression Inventory, had 50% higher mortality at 1 year compared to nondepressed patients. A 2013 meta-analysis of 50 studies found that patients with depression within 3 months of stroke had poor clinical outcomes defined by lower quality of life, increased disability, and increased mortality at follow-up compared with nondepressed stroke patients.

Perhaps the most provocative finding, however, is the relationship between mortality following PSD and treatment with antidepressant therapy. A 9-year follow-up of patients who had been treated for PSD found that active treatment with nortriptyline or fluoxetine (n = 53) versus placebo (n = 28) over 12 weeks resulted in an increased probability of

Telegram: @medical_k

www.konkur.in

survival (i.e., 59.2% for treated vs. 36.4% for placebo patients) at 6 years follow-up (Fig. 2.2–4). A logistic regression that examined the effects of age, diabetes, relapsing depression, and antidepressant use found that antidepressant use and the existence of diabetes mellitus independently and significantly predicted survival.

A series of recent findings demonstrated that the use of fluoxetine (20 mg/day) or nortriptyline (100 mg/day) was associated with improved recovery from a stroke at 3 or 12 months, respectively, after 3 months of treatment. Interestingly, this effect was independent of PSD.

The course of poststroke mood disorders is exemplified by the following case history:

FIGURE 2.2–4. Poststroke mortality after 3 months of treatment. Survival rates over 9-year follow-up for stroke patients who received a 12-week course of antidepressants or placebo during the first 6 months following stroke. Probability of survival was significantly greater in the patients receiving antidepressants ($\chi 2$ = 8.2, df = 1, P =.004, Kaplan–Meier survival analysis, log-rank test). (Reprinted with permission from Jorge RE, Robinson RG, Arndt S, Starkstein S. Mortality and poststroke depression: a placebo-controlled trial of antidepressants. *Am J Psychiat.* 2003;160(10):1827. Telegram: @medical_k

www.konkur.in

Ms. A. was a 35-year-old woman who had been the regional director of marketing for a national company. Deadlines, frequent travel, and sales quotas were all part of her high-pressure work. She developed hypertension during her first pregnancy, but in spite of this, she kept up her hectic work schedule. While on a business trip during her subsequent pregnancy, however, she suffered a stroke that caused mild weakness on her right side as well as aphasia characterized by difficulty producing speech but not comprehension (i.e., nonfluent, expressive aphasia). These motor and language impairments were relatively mild and cleared up within several months of the stroke.

When she was approximately 6 months poststroke, she was convinced that there was still something wrong with her as a result of the stroke. Several physicians told her that there was nothing physically wrong with her and all she needed to do was to get back to work. She had never experienced prolonged depressive symptoms prior to the stroke and her affect did not appear depressed at the time of the assessment. She was talkative, and her thoughts and speech were not slowed, as often occurs in depression. She was not tearful or suicidal. She did, however, feel depressed and had a loss of interest, concentration, and motivation. She had returned to work for a couple of hours a day but was unable to concentrate well enough to accomplish even simple tasks. She had lost interest and pleasure in virtually all of her work and social activities. She no longer had the ambition to climb the corporate hierarchy. She also had sleep disturbance with early morning awakening, loss of appetite and weight, decreased sexual interest, and decreased energy. A diagnosis of PSD was made, and antidepressant therapy with nortriptyline was started. Her response to antidepressant treatment was dramatic. Between 4 and 6 weeks after beginning nortriptyline, her mood greatly improved and she returned to work. She found that she was able to concentrate and experience interest and pleasure in her work. Over a period of 2 to 3 months, she reverted from somebody who was virtually immobilized by depression vocationally and socially to an effective, energetic woman. She also had a return of some of her previous ambition, though she still lacked her prior drive to reach the top of the corporate hierarchy.

After 9 months of taking nortriptyline, she wanted to discontinue this medication. Her rationale was that she felt she had fully recovered and

Telegram: @medical_k

www.konkur.in

did not want to continue taking medication that produced a dry mouth and constipation. The medication was tapered over a period of about 6 weeks and then stopped. She remained well for approximately 1 year but then had a recurrence of the same symptoms that were initially observed. Namely, she was uninterested in work, had no feeling of pleasure in any of her usual activities, and was unable to attend to the demands of work or home. She also had difficulty sleeping, lost her appetite, and felt depressed. These symptoms subsided after restarting her antidepressant medication, which she continued to take for another year. After that year, she again insisted on stopping her antidepressant medication. Over the next 2 years of follow-up, she remained free of depressive symptoms, but she was counseled that her previous history placed her at increased risk for another recurrence of depression. She was advised to remain vigilant for any signs or symptoms of her depression and to report them immediately so resumption of treatment could be discussed in a timely fashion.

Mania

The course of mania following stroke has not been systematically examined. Anecdotal cases have been reported indicating that recurrent episodes of mania or depression may occur in these patients (Fig. 2.2–5).

Anxiety

The prevalence of GAD and major depression based on standardized interviews and diagnostic criteria was documented in two separate studies (Fig. 2.2–6). Note that the rates of GAD with and without comorbid depression are stable at about 20% over 3 years poststroke. A 5-year longitudinal study of 220 patients found that at 5 years poststroke, the prevalence of anxiety was 29%, and those with anxiety at 6 months were significantly more likely than nonanxious patients to have anxiety at 5 years. Another 10-year study reported that anxiety ranged from 17% to 24%, with a cumulative incidence of 57% over 5 years. Further, comorbid anxiety and depression each year ranged from 57% to 73%.

Lesions mainly involved the orbitofrontal cortex and the right basitemporal cortex. (Reprinted with permission from Robinson

Telegram: @medical_k

www.konkur.in

RG. *The Clinical Neuropsychiatry of Stroke: Cognitive, Behavioral and Emotional Disorders following Vascular Brain Injury*. 2nd ed. Cambridge University Press; 2006:302.)

Another study of 142 patients over 2 years found that early-onset (i.e., within 3 months after stroke) anxiety disorder without depression had a mean duration of 1.5 months while delayed onset (i.e., more than 6 months after stroke) GAD without depression had a mean duration of 3 months. In addition, the existence of anxiety also influenced the duration of depression. Patients with GAD and major depression had a mean duration of depression that was significantly longer than the duration of depression without a comorbid anxiety disorder.

The longitudinal study of poststroke anxiety by Luis Ayerbe and colleagues in 2014 reported that anxiety at 3 months poststroke was associated with lower quality of life at 10-year follow-up. In 2014, Maya Lambiase and coauthors found among 6,019 patients with stroke that higher scores of baseline anxiety were associated with an increased risk of incident stroke within the 16-year follow-up period (Fig. 2.2–7).

Apathy

A prospective cohort study found an association between baseline VCI and increasing apathy levels from baseline to the chronic stroke phase. Interestingly, no association was found between baseline VCI and the course of depressive symptoms.

FIGURE 2.2–6. Longitudinal association of major depression with anxiety disorder after stroke. The frequency of generalized anxiety disorder (GAD) with and without major depression over the 3 years following acute stroke. Results obtained from Schultz et al. (1997) using the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) criteria were compared to the results of Astrom (1996) using the third revised edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) criteria. Results indicate a slightly lower frequency of GAD using the DSM-IV criteria and emphasize the prominence of major depression in this population of patients with poststroke anxiety disorder. (Reprinted with permission from Robinson RG. *The Clinical Neuropsychiatry of Stroke: Cognitive, Behavioral and Emotional Disorders following Vascular Brain Injury*. 2nd ed. Cambridge University Press; 2006:336.)

Other Disorders

The course and prognosis of patients with psychosis, apathy, catastrophic reaction, PBA, and anosognosia have not been systematically studied.

TREATMENT

Mild and Major Vascular Neurocognitive Disorders

Telegram: @medical_k

www.konkur.in

Some of the risk factors for stroke can be effectively treated, thus giving hope that cognitive impairment due to vascular disease may someday be a preventable condition. In the past decade, treatment with antiplatelet aggregate drugs has reduced the number of repeated ischemic vascular episodes in patients with TIAs. Acetylsalicylic acid (ASA) and other antiplatelet drugs have been shown to be effective in the secondary prevention of stroke. The United Kingdom-TIA Aspirin Trial, with 2,435 patients using two different dosages of ASA (300 mg daily and 1,200 mg daily), found that there were 21.7% and 25.1% reductions, based on dosage, in the risk of nonfatal strokes, myocardial infarction, or death compared with placebo treatment.

FIGURE 2.2–7. Estimated survival function based on the relationship between anxiety symptoms and incident stroke after adjustment for age and gender. Higher anxiety symptoms levels were associated with higher risk of stroke. (Reprinted with permission from Lambiase MJ, Kubzansky LD, Thurston RC. Prospective study of anxiety and incident stroke. *Stroke*. 2014;45(2):438. doi:10.1161/ STROKEAHA.113.003741)

Given that hypertension is the biggest risk factor for stroke, its impact on the incidence of vascular dementia has been an area of great interest. A 2011 meta-analysis by Sally Sharp and coscientists of 768 cases of vascular dementia and nearly 10,000 control cases found a significant association between hypertension and risk of vascular dementia with an

Telegram: @medical_k

www.konkur.in

odds ratio of 1.6 and 4.8, respectively, based on longitudinal studies and cross-sectional studies. A separate meta-analysis from 2011 based on 14 studies demonstrated that individuals prescribed antihypertensive medications had a reduced risk of vascular dementia (pooled relative risk of 0.67). A 2018 Cochrane systematic review that evaluated 38,742 participants found a pooled risk ratio of 0.88 for dementia among people taking a blood pressure-lowering agent compared with people taking a placebo. To date, it is unclear if this benefit is attributable to a certain class(es) of antihypertensives and/or from the treatment of hypertension alone.

For patients who are at particular risk for stroke-related cognitive impairment but are yet to show signs of dementia (i.e., those with a history of TIAs, stroke, or silent cerebral infarctions), carotid endarterectomy, when carotid stenosis ranges from 70% to 99%, may be indicated to minimize the risk of future strokes. After a cardioembolic stroke, anticoagulation is an effective treatment to reduce the risk of stroke recurrence. Stroke of cardioembolic origin is responsible for about 15% of all ischemic strokes, and this percentage is even higher among younger patients.

In patients with vascular dementia, ongoing treatment of vascular risk factors is generally recommended unless the risks clearly outweigh the benefits. For example, generally, antihypertensive treatment is recommended to minimize the risk of further stroke and thus further stroke-related cognitive decline. However, if antihypertensive treatment is leading to orthostatic hypotension, the risk of falls may outweigh the benefit of such treatment. Therapeutic measures aimed at reducing vascular risk factors include antihypertensives (e.g., β-blockers or calcium channel blockers), lipid-lowering agents such as statins, smoking cessation, and prevention or careful management of diabetes mellitus. Finally, treatment may also include cholinergic agonists (e.g., donepezil and galantamine) for cognition, antidepressant agents, antiplatelet aggregation agents, and statins for other comorbidities.

Depression

As reported in 1984, the first randomized, blinded, placebo-controlled study in PSD found that 14 patients treated with nortriptyline (50 to 100 mg/day) had a significantly greater reduction in Hamilton Depression Scores over 6 weeks than 20 patients given a placebo. The first double-

Telegram: @medical_k

www.konkur.in

blind, placebo-controlled trial to examine the efficacy of selective serotonin inhibitors (SSRIs) was reported by Grethe Anderson and colleagues in 1993. Among 33 poststroke patients given citalopram (20 mg/day under age 65; 10 mg/day over age 65), a significantly greater reduction in Hamilton Depression Scores over 6 weeks was observed in comparison to 33 similar patients given a placebo. Consisting of 16 trials and 1,655 subjects, a Cochrane Review from 2008 by Hackett and colleagues found an odds ratio of 0.47, favoring pharmacologic treatment over control for the treatment of PSD. Most recently, a 2020 meta-analysis that included 5,370 patients showed an RR of 0.78 for patients taking SSRIs. Thus, the efficacy of antidepressant treatment for PSD, particularly severe depression, has been established. However, a 2019 Cochrane review showed that SSRIs do not appear to aid functional recovery of neurologic impairment after stroke.

Cognitive-behavioral therapy (CBT) appears to have some positive effects on depression, but there is not enough evidence for it to be used as a monotherapy in PSD.

Perhaps the most promising recent advance in the treatment of PSD has been the study of preventative treatments (Fig. 2.2–8). To date, at least four randomized studies have been designed to evaluate the prevention of PSD using SSRI antidepressants. The results of these studies are shown in Figure 2.2–8. Although three of the four studies failed to show a significant effect on prevention, the similarities in the rate of prevention suggest that lack of power may have been the cause of the lack of an effect. The fourth study, conducted by Robinson and colleagues, involved 58 nondepressed acute stroke patients who were treated with escitalopram (5 mg/day over age 65; 10 mg/day under age 65) over 1 year. The incidence of PSD was 8.5% compared with 11.9% among 57 patients receiving problem-solving therapy (PST) and 22.4% among 58 patients receiving placebo (escitalopram vs. placebo, $P \leq .001$; PST vs. placebo, $P \leq .001$).

Telegram: @medical_k

www.konkur.in

FIGURE 2.2–8. A summary of four randomized trials for the prevention of poststroke depression. For each study, the percent of patients who developed depression during the duration of the prevention trial is shown. The Robinson and Rasmussen studies showed remarkably similar findings. The difference between antidepressant and placebo were statistically significant for the Robinson and the Tsai studies. (The data were extracted from Robinson RG, Jorge RE, Moser DJ, et al. Escitalopram and problem-solving therapy for prevention of poststroke depression: a randomized controlled trial. *JAMA*. 2008;299(20):2391–2400; Rasmussen A, Lunde M, Poulsen DL, Sorensen K, Qvitzau S, Bech P. A double-blind, placebo-controlled study of sertraline in the prevention of depression in stroke patients. *Psychosomatics*. 2003;44(3):216–221; Almeida OP, Waterreus A, Hankey GJ. Preventing depression after stroke: results from a randomized placebo-controlled trial. *J Clin Psychiatry*. 2006;67(7):1104–1109; and Tsai CS, Wu CL, Chou SY, et al. Prevention of poststroke depression with milnacipran in patients with acute ischemic stroke: a double-blind randomized placebo-controlled trial. *Int Clin Psychopharmacol*. 2011;26 (5):263–267.)

Another promising recent advance includes the use of noninvasive brain stimulation like repetitive transcranial magnetic stimulation (rTMS) and transcranial direct current stimulation (tDCS) for the treatment of PSD. Data from rTMS trials are especially promising. However, larger randomized controlled studies need to be conducted once protocols are standardized before they can be considered viable treatment options.

Mania

Telegram: @medical_k

www.konkur.in

Data on individual patients with single or recurrent episodes of mania suggest that they respond to lithium, although some fail to respond to either lithium or carbamazepine. No randomized controlled studies of the treatment of poststroke mania have been conducted, but one longitudinal study of 23 patients showed that most patients' manic episodes remit within a few months.

Anxiety Disorders

Data from three randomized, double-blind treatment studies were merged to evaluate nortriptyline (n = 13) versus placebo (n = 14) in the treatment of patients with comorbid GAD and depression following stroke. The severity of anxiety was measured using the Hamilton Rating Scale for Anxiety, and the severity of depression was measured using the Hamilton Rating Scale for Depression. Although there were no significant differences between the nortriptyline and placebo groups in demographic characteristics, stroke type, and neurologic findings, patients receiving nortriptyline treatment showed significantly more rapid improvement on the Hamilton anxiety scores compared with the Hamilton depression scores, suggesting that anxiety may respond more quickly to treatment than depression. Furthermore, the anxiety symptoms showed greater improvement in response to nortriptyline treatment compared with placebo. Katsunaka Mikami and colleagues performed a secondary analysis of patients in the previously described prevention trial of PSD conducted by Robinson's group. Of 52 patients without poststroke GAD treated for 1 year with escitalopram, only three cases developed GAD compared with 3 of 53 treated with PST and 9 of 49 patients given placebo (P = .0005). A 2017 Cochrane Review of treatment of poststroke anxiety without placebo control concluded that there is overall insufficient evidence to guide the treatment of anxiety after stroke.

Psychosis

There are no controlled treatment trials among patients with delusions or hallucinations following stroke. Anecdotal reports have suggested two basic approaches to treatment: utilization of antiseizure medication or antipsychotic medication. The use of antiseizure medications has its rationale in the frequent coexistence of seizures with psychotic disorders following stroke. Antipsychotic medications would need to be used with

Telegram: @medical_k

www.konkur.in

caution given their propensity to lower the seizure threshold and patients with strokes having a higher risk of seizures.

Apathy

Apathy following stroke has been treated with nortriptyline, bromocriptine, methylphenidate, amantadine, selegiline, and tacrine with some success. Nefiracetam is a novel GABA-A agonist, and in a double-blind trial for the treatment of comorbid apathy and depression by Robinson and colleagues, nefiracetam (900 mg/day) was significantly better than placebo in reducing scores on the apathy rating scale. Of note, nefiracetam has not been approved by the U.S. Food and Drug Administration (FDA) for any indications. Since apathy is a relatively common consequence of stroke and can have devastating effects on poststroke recovery, treatment trials are urgently needed.

Mikami and colleagues performed a secondary analysis of the previously mentioned depression trial to evaluate the prevention of apathy after stroke. Among 51 nonapathetic patients treated for a year with escitalopram (10 mg/day for those less than age 65; 5 mg/day for those greater than age 65), 2 developed apathy compared with 3 of 56 treated with PST and 7 of 47 given placebo (P = .0031). Thus, treatment trials with a primary outcome of apathy prevention are needed to determine if the administration of antidepressant medication such as escitalopram may prove helpful for the prevention of poststroke apathy.

Pseudobulbar Affect

A Cochrane Review of treatment trials of pathological affect in 2019 included seven trials totaling 239 people with stroke. Antidepressant treatment, including both tricyclic, SSRI and selective serotonin-norepinephrine reuptake inhibitors (SNRIs), significantly reduces the frequency and severity of PBA. For example, a double-blind, placebo-controlled cross-over study of 16 patients reported a greater than 50% reduction in the number of crying episodes while receiving citalopram. Eight patients responded to treatment within 24 hours of taking citalopram (20 mg/day); three patients responded within 3 days, and four patients took more than a week to respond. Further, an FDA-approved combination drug consisting of dextromethorphan and quinidine (Nuedexta) is now available with a specific indication for the treatment of

Telegram: @medical_k

www.konkur.in

PBA. Thus, treatments that have shown to be effective in treating PBA are available for clinical use.

The clinical manifestations of PBA can be appreciated in this case history:

A 64-year-old right-handed, retired, married woman with no prior history of a stroke suffered a thrombotic right-hemispheric stroke with hemiparesis but no sensory deficit. Beginning within a few days of the stroke, the patient had uncontrollable crying episodes that occurred 5 to 10 times per day, and each lasted about 1 to 2 minutes. In addition to the crying episodes, the patient had major depression with a Hamilton Depression Scale score of 19. She stated that she felt sad, but the crying was greatly in excess of her sadness at the time of her episodes and she had no sense of being able to control the crying. The pathological emotional expression was more troublesome to her than the depressed mood. Although she and her husband previously had an active social life, she stopped seeing friends and leaving the house for fear of being embarrassed socially by these crying episodes. Her PLACS score was 24, which was in the severe range. She improved greatly after a course of nortriptyline.

Other Disorders

Effective treatments have not been established for catastrophic reactions or anosognosia.

2.3 The Neuropsychiatry of Brain Tumors

ALASDAIR G. ROONEY, MB.CHB., M.D., PH.D.

Neuropsychiatric disorders are common in brain tumor patients and can present particular diagnostic and treatment challenges. Identifying an affective psychosis in someone on high-dose corticosteroids may be straightforward, but deciding when natural grief crosses the line into pathologic depression may not; neurocognitive impairment can be easily missed unless directly examined and personality change may only come to light via collateral history. Meanwhile, the treatment of common psychiatric disorders mostly lacks a brain tumor-specific evidence base, and management of more specialized disorders such as neurocognitive impairment and personality or behavioral change can be difficult. There is a tremendous clinical need for psychiatric input to neuro-oncology teams. In this chapter, we will discuss some clinical aspects and themes on the neuropsychiatry of brain tumors.

PSYCHIATRIC CLASSIFICATION

Telegram: @medical_k

www.konkur.in

The diagnostic validity of psychiatric classification remains unclear when applied to brain tumor patients. In these patients—as with many other neurologic disorders—the balance and causes of neuropsychiatric symptoms can differ in certain ways from psychiatric patients who are otherwise physically well. When the DSM system was developed in the 1970s, there was (and to a large extent still is) an absence of careful studies of the phenomenology of psychiatric syndromes as they present in brain tumor patients. The absence of disease-specific studies permits a range of opinions about the nature of psychiatric symptoms in these patients. Two arguments will be made briefly here to illustrate this point, hopefully without over-emphasizing its importance.

In the DSM and the ICD (WHO) classification systems, the core symptoms of listed psychiatric syndromes relate to emotions or inner psychic realities (fear, sadness, anger, pleasure, paranoia, delusions, hallucinations, and so on). We infer that psychopathology must arise in some way from the brain. In that context, the presence of a metabolically active tumor invading, altering, distorting, and destroying brain tissue presents a unique theoretical challenge. At the least, it must be unclear whether the pathophysiologic causes of psychiatric symptoms are similar in those with a brain tumor compared to those without. If they are not, then the founding assumption of an operationalized classification system—that covarying symptoms reflect a common underlying pathophysiology—is challenged. First, therefore, one should keep at least an open mind about the validity and reliability of psychiatric syndromes in brain tumor patients. These patients have—confoundingly—a tumor growing in the seat of the psyche.

Second, much of the context of symptomatology is now stripped away. The jettisoning in DSM-5 of the “bereavement exclusion” criterion for major depressive disorder (MDD) is one example of this strategy. Minimizing context has several advantages, including better reproducibility and, in some ways, less theoretical speculation. The problem, however—as any clinician familiar with brain tumor patients will agree—is that it is quite difficult to think of a neurologic patient group for whom context is more relevant. It is hard to think of a good reason to ignore the context of a catastrophic existential threat arising out of the blue, where toxic treatments have side effects identical to key psychiatric symptoms, which cause multiple and progressive losses in multiple domains of personhood and life and is associated with cognitive impairment, epilepsy, personality

Telegram: @medical_k

www.konkur.in

change, and in many cases, death. This is a challenging test for the philosophy of minimizing or abandoning context. Few other psychiatric patient groups face quite the same sudden, severe, persisting, and progressive mix of stressors.

Do these theoretical objections matter? The only way to find out is to conduct prospective studies of the reliability and validity of psychiatric diagnoses in large cohorts of brain tumor patients of all ages and at all stages of disease. As a community, unfortunately, we are nowhere near this ideal. Brain tumor-specific studies of psychiatric symptom validity and reliability remain rare. Brain tumor-specific randomized controlled trials (RCTs) of psychiatric interventions are similarly scarce.

In general, the day-to-day psychiatric management of brain tumor patients is therefore pragmatic more than it is dogmatic. It is an open field with great unmet need and an even greater challenge to psychiatrists: to systematically study the abnormal emotional, behavioral, and neurocognitive consequences of brain tumors.

BRAIN TUMORS

Epidemiology

Primary brain and central nervous system (CNS) tumors are reportable diseases in many countries, including the United States. The word “primary” in this context refers to a tumor that arises de novo in the brain and is not the result of a “secondary” spread from a site outside the CNS. The Central Brain Tumor Registry of the United States (CBTRUS) is a nonprofit organization that collaborates with state registries to provide an annual statistical analysis. It is an authoritative resource for epidemiologic statistics on new primary brain tumor diagnoses, although limited in scope to the United States.

The most recent publicly available CBTRUS data show that the average annual incidence of all adult primary brain and other CNS tumors is 23.8/100,000. In the United States alone, this translates to nearly 84,000 new adult cases of brain and other CNS tumors expected to be diagnosed in 2020, with over 16,000 deaths per year. The median age at diagnosis for all primary brain and CNS tumors is 59 years. In young adults (aged 18 to 40), the incidence is most similar to that of testicular or thyroid cancer, and in older adults (aged 40+) to that of bladder cancer or melanoma. In children and adolescents, meanwhile, primary brain and

Telegram: @medical_k

www.konkur.in

CNS tumors are the single most common cancer and the most common cause of cancer death. Primary brain tumors overall are slightly more common in females, and incidence rates for certain tumors vary according to ethnicity (see CBTRUS annual reports).

Brain tumors are a heterogeneous group of diseases with a wide range of etiologies, ages of onset, anatomical locations, clinical courses, responses to treatment, and prognosis. The simplest division is into nonmalignant and malignant tumors. Most nonmalignant brain tumors arise in the meninges, pituitary gland, or cranial nerve sheaths. Psychiatrists in routine practice are more likely to encounter nonmalignant tumors in the course of their work because they are more common. Many such tumors picked up on routine brain scans will be incidental findings such as a small calcified meningioma. Most malignant brain tumors, meanwhile, are gliomas—primary cancer arising from neuroepithelial tissue. Malignant tumors may be seen more often by psychiatrists linked to general hospitals or neuro-oncology services because, unlike the typical nonmalignant tumor, which is cured by surgical excision and does not require long-term follow-up; glioma is generally invasive and incurable. Patients with glioma often become markedly physically and cognitively impaired and require ongoing clinical follow-up.

The gliomas are categorized by the World Health Organization (WHO) according to the predominant tissue histologic profile (astrocytic, oligodendrocytic, etc.) and by malignancy. Malignancy is judged according to histologic features known to confer a poorer prognosis, such as the extent of proliferating cancer cells in a biopsy or the presence of neovascularization and tumor necrosis indicative of very rapid growth. The WHO grades glioma on a level from I to IV, where IV is the most malignant type, also known as glioblastoma multiforme (GBM). GBM, which has the worst prognosis, is sadly also the most common malignant primary brain tumor. By convention, WHO grades I and II are called “low-grade” while WHO grades III and IV are “high-grade.” Most low-grade tumors eventually progress and transform into a higher grade; they are therefore not truly “benign.” In adults, most gliomas are supratentorial and situated in the frontal, temporal, or parietal lobes. In children, by contrast, glioma is usually infratentorial (Fig. 2.3–1).

The incidence of most histologic classes of primary brain tumors rises continuously with advancing age. The main exceptions are pilocytic astrocytoma, germ cell tumors, and embryonal tumors such as

Telegram: @medical_k

www.konkur.in

medulloblastoma, which are more common in younger children and rare in adults. The most common tumor histologic cell of origin across different ages is shown in Table 2.3–1.

In contrast to primary brain tumors, the epidemiology of metastatic brain tumors is less well understood. There is no requirement on national cancer registries to document their incidence. There is a general assumption that metastatic or “secondary” tumors outnumber primary tumors. Metastatic brain tumors occur in a sizeable minority of cancer patients, are usually multiple, and are especially more likely to occur when the primary site is lung, breast, skin, kidney, or colon. Because their presentation and management are therefore scattered across multiple clinical pathways, and because the prognosis of metastatic brain tumors is particularly poor, studies of their psychiatric effects are difficult. Here, we will focus only on primary brain tumors and mainly on glioma.

Management of Brain Tumors

In many countries, treatment decisions are made by a multidisciplinary neuro-oncology team. In the United Kingdom, the minimum core personnel requirement for this team is stated in NHS clinical guidance and includes a team coordinator, neurosurgeon, neuroradiologist, neuropathologist, neurologist, oncologist, clinical nurse specialist, palliative care specialist, and neuropsychologist. Psychiatry or neuropsychiatry input is optional. One consequence of this arrangement is that, at least in the United Kingdom, psychiatric involvement is sporadic and often restricted to tertiary neuro-oncology centers with well-developed links to liaison or neuropsychiatry services. U.K. neuro-oncology teams have said clearly, however, that more input from psychiatry would be desirable.

www.konkur.in

A postal questionnaire survey of U.K. neuro-oncology multidisciplinary teams (MDTs) was conducted to determine: the reported proportion of new patients referred for psychiatric assessment in the previous year, whether neuropsychiatry services were available locally, and whether the team perceived an unmet need for neuropsychiatry. Of 39 neuro-oncology MDTs, 29 (74%) responded, treating a total estimated 3,500 new patients/year. A median of 1% (mean 4%, range 0% to 25%) of these new patients were reported as having been referred to psychiatry in the previous year. Eight MDTs had made no psychiatric referrals. Most often, significant emotional difficulties were either first identified by the clinical nurse specialist or brought to clinical attention by the patient's relatives. A minority of MDTs had access to neuropsychiatry (12/29; 41%), and 24/29 (82%) perceived an unmet need for neuropsychiatry. In summary, therefore, nurse specialists were central to referral procedures in most U.K. centers. Most neuro-oncology MDTs had no regular access to neuropsychiatry assessment. There was a clear national and clinical demand for more neuropsychiatry input to neuro-oncology services. *Data collected by Cliodhna Carroll (University of Cambridge, UK) and the author, with supervision from Dr. Howard Ring (Consultant neuropsychiatrist, University of Cambridge, UK) and Dr. Robin Grant (Consultant neurologist, NHS Lothian, UK).*

FIGURE 2.3–2. The neuro-oncology multidisciplinary team (MDT) is key to planning the care and treatment of brain tumor patients.

Allowing for some differences in international healthcare models, the main treatment decisions are shown diagrammatically in Figure 2.3–2. Newly diagnosed patients can be treated with varying combinations of established treatments: surgery, radiotherapy, chemotherapy, watchful waiting, or supportive (palliative) care. The search for curative treatments continues and the range of “experimental” additional therapies is wide. Currently, the most common active treatment for GBM—the most malignant form of glioma—is a combination of maximal surgical resection, radiotherapy, and chemotherapy. High-dose corticosteroids may be started with the intention of reducing cerebral edema and alleviating symptoms caused by mass effect and raised intracerebral pressure. Antiseizure medications are often also prescribed, though if the patient has not presented with seizures, their value in prophylaxis is unclear and the subject of ongoing research. Childhood brain tumors are often managed with treatments focused on the posterior fossa or brainstem, again comprising surgery, radiotherapy, and/or chemotherapy.

Telegram: @medical_k

www.konkur.in

Patients with a simple meningioma may be cured by surgery and discharged from follow-up. Patients with glioma, meanwhile, will receive follow-up during which they are regularly reviewed by the treating neuro-oncology team. Many patients report that the transition from active treatment to follow-up is an unexpectedly difficult period. The energy of the primary treatment phase is over, and they must readjust to a life that may now be very different. Physical disability, epilepsy, cognitive impairment, emotional difficulties, and behavioral changes are so common as to be normal. Many patients—having had brain surgery and possibly epilepsy—will be forbidden to drive by national authorities and unable to work, placing sudden and continuing strain on previously stable family routines. Although some patients—especially younger patients with low-grade tumors and well-controlled epilepsy—can regain much of their independence, the reality for many is partial dependence on carers and an uncertain future.

Prognosis

The prognosis of a brain tumor depends on the type. Nonmalignant tumors such as meningioma and some pituitary tumors can be cured surgically with relatively little in the way of long-term deficit. Malignant tumors such as glioma present an impossible challenge to surgical cure because, by the time of clinical presentation, tumor cells are microscopically dispersed throughout much of the brain (not just in the macroscopic area seen on an MRI or CT scan).

Low-grade gliomas (WHO grades I–II) typically follow an indolent course before eventually transforming into a higher grade after a highly variable period ranging from a few years to many years. Higher grade tumors (WHO grades III–IV) are more rapidly progressive and fatal. The median survival of patients with GBM in the field-leading RCT was around 14 months: around one-quarter of these patients survived to 2 years postdiagnosis and only 10% were alive after 5 years. These numbers apply at the population level: it is impossible to give a precise duration of survival for an individual patient at the point of diagnosis, although younger patients and those with better preserved physical and cognitive functioning tend to survive longer.

It is clear that tumor molecular characteristics play an additional prognostic role, with some mutations conferring a better prognosis than others. A seminal example of this feature was the discovery that tumors in

Telegram: @medical_k

www.konkur.in

which the O^6-methylguanine-DNA methyltransferase (MGMT) promoter region is methylated (meaning their DNA-repair mechanisms are switched off) are more sensitive to the DNA-disrupting, tumor cell-killing effects of radiation and chemotherapy. MGMT testing is now routine for new glioma diagnoses. Unsurprisingly, molecular characterization in neuro-oncology is extremely complex and well beyond the scope of this chapter; interested readers are, however, directed to further reading (see Further Readings).

Thus, the tempo of the clinical course of a malignant primary brain tumor is characterized by sudden presentation, a flurry of multidisciplinary management amid a period of intensive assessment and primary treatment lasting for several months, and then a variable period of follow-up in which patients must attempt to rediscover a normality of life. The profile of disability in the patient is initially moderate and often relieved for a while by primary treatment, before a progressive but unpredictable series of impairments that sadly but typically end in the death of the patient after months or a modest number of years. It is in this context that we will consider the neuropsychiatry of brain tumors.

BRAIN TUMORS IN PSYCHIATRIC PATIENTS

Does your psychiatric patient have a brain tumor? The idea that psychiatric symptoms are in some way indicative of an underlying brain tumor is certainly reinforced by popular culture. In the movie “Phenomenon,” the main character experiences unusual psychic changes, which are ultimately attributed to a developing astrocytoma. The movies “The Green Mile” and “Saw” feature characters whose motivations and actions are violently twisted by brain tumors. A character in the TV series “Grey’s Anatomy” experiences visual hallucinations secondary to brain metastasis. Real-life examples, meanwhile, include George Gershwin, the musical composer and pianist, whose olfactory hallucinations and erratic behavior were initially attributed to hysteria before he collapsed and died from a brain tumor aged 37. Speculative associations between a brain tumor and some form of psychopathology are drawn by hundreds of single case studies in the academic literature.

Indeed, large population-based epidemiologic datasets do suggest that among all occult developing cancers, the risk for psychiatric hospitalization in the period before a cancer diagnosis is highest for brain tumors. The effect is not marked compared to other cancers, but it does

Telegram: @medical_k

www.konkur.in

seem that some patients will experience symptoms and end up in a psychiatric hospital because, in fact, they have a brain tumor. Many such patients (and their doctors) may initially attribute psychiatric symptoms to various environmental or situational stresses. The problem for the general psychiatrist is that these “secret tumor” patients are a vanishing minority: almost certainly under 1% of their caseload over an entire professional career. How should psychiatrists attempt to identify the small number of patients whose symptoms are due to a brain tumor? Can investigations be targeted, or is indiscriminate screening required?

The importance of targeted investigation is illustrated by autopsy data from chronic–psychiatric patients dying in mental hospitals from other causes. These data show unsuspected and undiagnosed brain tumors in roughly 3% of patients examined. More recent studies converge on a similar conclusion: the frequency of clinically unsuspected space-occupying lesions on brain CT or MRI scanning of inpatient psychiatric populations is in the order of 3% to 4%. Similarly, the frequency of incidental abnormalities observed on brain scans in the general nonpsychiatric population is approximately 3%. The likely conclusion is that many abnormalities encountered in routine scanning of psychiatric patients will be incidental (functionally silent). Because at least some, if not most, of these tumors will never progress to cause any kind of clinical problem, they do not require treatment, and indiscriminate scanning may increase the risk of unnecessary intervention. So how should investigations be targeted?

Telegram: @medical_k

www.konkur.in

We identified adult psychiatric inpatients referred consecutively over a 4-year period for a head CT on suspicion of organic pathology. Patients were excluded if they were diagnosed with a brain tumor before the psychiatric admission. The primary aim was to determine the prevalence of brain tumors. A secondary aim was to describe presenting psychiatric symptoms and neurologic signs. Consultant radiologist CT reports were obtained from computerized records and reviewed. Psychiatric notes were traced for patients noted to have suspected or possible primary brain tumor on CT report. To simplify the analysis, presenting psychiatric symptoms were grouped heuristically into the following broad categories: *low mood* (anxiety, depression, or psychomotor retardation); *cognitive dysfunction* (confusion or cognitive impairment); *personality/behavior change*; and *psychosis* (delusions, mania, or paranoia).

A total of 328 psychiatric inpatients (mean age 65; range 37 to 86; 43.3% male) were identified as referred for a head CT. Space occupying lesions were identified from the CT report in 19 cases, of which 12/328 (3.7%) were newly discovered tumors. The most common radiologic diagnosis was meningioma (5/12). Eight tumors involved the cerebral hemispheres (five right-sided and three left-sided). The rest were located in the midline or involved the ventricular system.

Most patients with newly discovered tumors had symptoms from more than one psychiatric category. The most common were *low mood* and *cognitive dysfunction*, each seen in 9/12 patients. *Personality/behavior change* was reported in 6/12 and *psychosis* in 5/12. In five patients, no neurologic signs were documented in the psychiatric notes. In the remainder, brisk reflexes (five patients) and speech deficits (four patients) were the most common signs. Papilledema was seen in one patient and was associated with a ventricular tumor. In summary, therefore, few (in this study, roughly 1 in 27) head CTs for suspected brain pathology in adult psychiatric inpatients revealed a new case of brain tumor. *Data were collected by Anita Vas-Falcao (year 4 medical student, University of Edinburgh) with supervision from the author and Dr. Robin Grant, Consultant Neurologist.*

www.konkur.in

“Red flag” Symptoms and Signs

Brain tumors can present with nonspecific psychiatric and behavioral changes. It is wise to maintain a low threshold for investigating the possibility of a brain tumor in any patient with new-onset or newly different psychiatric symptoms. A high index of suspicion is particularly warranted in certain situations: if the patient is a child; if the patient has a negative past or/and family history of psychiatric illness; if the psychiatric symptoms have atypical features; if they are associated with additional unexplained symptoms; or if there is evidence on examination of neurologic or neurocognitive dysfunction. The psychiatrist should take a careful history from the patient and, ideally, an informant, asking for physical symptoms associated with brain tumors and do a neurologic examination. As a trainee, the author clinically predicted a right-sided parietal lobe tumor in a middle-aged lady who was brought to the hospital wandering and confused, wearing a jumper back-to-front, with dysgraphesthesia of the left palm.

Look particularly for a history of recent mental state change in association with *unexplained*:

1. Headache. The classical headache of raised intracranial pressure (ICP) is worse on wakening secondary to cerebral vasodilatation during sleep. It may transiently worsen with coughing, straining or sneezing. Not all brain tumor-associated headaches fit this pattern (nor do all tumors cause headaches). As in the general population, too, the vast majority of headaches in psychiatric patients will not be caused by a brain tumor. Other common explanations may include opiate medication overuse, migraine, somatization, tension headache, and selective serotonin reuptake inhibitor (SSRI) discontinuation syndrome. Nevertheless, headache with new-onset psychiatric symptoms comprise the neurologic combination of “headache +” (“headache plus…” unusual symptoms), which is a useful rule of thumb to trigger suspicion of an organic cause.
2. Nausea or vomiting. Presumed secondary to raised ICP compressing vagal centers in the medulla, nausea or vomiting is a classic “red flag” which is, however absent in many brain tumor patients.
3. Cognitive impairment. Some degree of cognitive impairment is detectable in most brain tumor patients. Impairment may range in severity from subtle to profound. The more subtle deficits may only be picked up on detailed neuropsychological testing or a careful history.

Telegram: @medical_k

www.konkur.in

Slower processing speed is very common. Patients may appear sluggish and vague. Since poor concentration and executive function —features of many psychiatric conditions—may mimic and overlap with slower processing speed, cognitively impaired psychiatric patients need a full neurologic history and examination.

4. Epilepsy. Most brain tumor patients will have seizures at some point in the disease trajectory, but epilepsy is more commonly a presenting symptom for patients with low-grade (WHO grades I–II) glioma. Common alternative explanations for seizures in psychiatric patients may include alcohol or benzodiazepine withdrawal, a lower seizure threshold secondary to antipsychotic use, hyponatremia, or functional nonepileptic attacks.
5. Weakness or clumsiness. Motor weakness or clumsiness due to a brain tumor is often subacute (onset of duration over a few weeks) and gradually progressive. Again a careful history is valuable. Weakness may be described as seemingly mild difficulties in dressing, handling the TV remote control, or taking lids off jars. A history of unexplained falls should prompt examination for foot drop or ataxia. Apraxia (such as difficulty dressing correctly or manipulating gadgets) may indicate a parietal lobe lesion, although it is not specific for this location.
6. Visual or sensory disturbance. The patient may not be fully aware of any deficit. Hemisensory or visual neglect may manifest in the history as the patient bumping into doorways on the same side or walking out into traffic, or in the examination by the patient ignoring people on one side of the bed (sometimes a very subtle sign), asymmetry of personal grooming, altered visual fields, or visual or sensory inattention.
7. Unusual (“noncanonical”) psychiatric symptoms. Case reports provide anecdotal evidence only, but many odd symptoms that “don’t quite fit” with the classical psychiatric syndromes have been reported in association with an occult brain tumor. These symptoms have included visual or musical hallucinations, palinacousis, palinopsia or similar “simple” perceptual phenomena, with a scattering of rare and exotic symptoms (e.g., polyopic heautoscopy). The unexplained development of personality abnormalities in adulthood is another indication to order neuroimaging.
8. Objective neurologic deficit. A comprehensive neurologic examination can be difficult to perform in patients who are acutely psychiatrically unwell, but is obviously a key part of the full assessment. Readers are directed to further reading on a full neurologic examination. More

Telegram: @medical_k

www.konkur.in

obvious abnormalities may be picked up in a short 1- to 2-minute screening examination by: testing for visual and sensory inattention; examining eye movements (the cranial nerves supplying the eye have long intracranial courses and may be particularly affected by raised ICP); looking for pronator drift (a sensitive test for pyramidal weakness in the upper limbs); assessing muscle tone and reflexes; assessing gait including a heel-toe test; and screening for dysmetria with the finger-nose test. These examination components are a basic skim: a full examination (including fundoscopy) should be done if the patient allows. In isolation, neurologic “soft signs” such as sensory abnormalities or the subtle persistence of developmental reflexes may lack specificity. If there is doubt a neurologist or neuropsychiatrist can give a second opinion.

9. Papilledema. A difficult neurologic sign to elicit in acutely psychiatrically ill patients, papilledema indicates raised ICP. The presence of papilledema should always trigger further assessment.
10. Endocrine abnormality. Pituitary tumors can cause a variety of endocrine disturbances. Systemic physical or blood biochemical signs of acromegaly, Cushing disease, abnormal lactation, or altered menstruation would raise suspicion. The textbook neurologic deficit of pituitary tumor is a bitemporal hemianopia secondary to midline compression of the optic chasm. These patients may, also, walk out into traffic.

This list is not exhaustive and neurologic examination may be normal in the presence of a brain tumor. A normal examination may especially occur with slow-growing tumors involving a relatively neurologically silent brain region such as the corpus callosum, nondominant temporal and parietal lobes, and the frontal pole.

Investigations

Brain CT or MRI scanning is indicated in psychiatric patients with focal neurologic findings and/or symptoms such as those listed above. When brain tumor is suspected, lumbar puncture should be avoided until imaging confirms that there is no obstruction to the free flow of cerebrospinal fluid (CSF). There is a risk of causing fatal coning by lumbar puncture if CSF cannot circulate freely out of the ventricles in the context of raised intracerebral pressure. Lumbar puncture may however be helpful

Telegram: @medical_k

www.konkur.in

when cytology studies are required in the assessment of established tumors such as leukemias, lymphomas, and meningeal metastasis.

CT scanning will pick up about 90% of cerebral tumors and is enhanced further by the use of intravenous (IV) contrast. CT scan may be especially useful in the evaluation of tumors which are calcified, eroding bony intracranial structures, or causing shifts in middle cerebral structures. CT scans can detect abnormalities involving the ventricular system such as obstructive hydrocephalus, and gauge the extent of cerebral edema. Certain types of tumors remain difficult to identify with CT scans. These include: lesions smaller than 0.5 cm in diameter; tumors occurring next to bony structures (such as acoustic neuromas, pituitary tumors, some meningiomas, and tumors deep in the posterior fossa); low-grade astrocytomas; and meningeal carcinomatosis. CT scanning also involves a degree of radiation exposure.

MRI outperforms CT scanning in those latter respects. Owing to greater image resolution MRI is also better at identifying the architecture of brain tumors (whether they are solid or cystic, or both), and in more precisely defining the relationship of a tumor to nearby vascular structures. However MRI scanning can be claustrophobia-inducing and takes longer: some psychiatric patients may better tolerate CT, and a CT scan costs less.

Newer quantitative diagnostic techniques can provide further information. These techniques include single photon emission computed tomography (SPECT), positron emission tomography (PET), magnetoencephalography (MEG), and diffusion tensor imaging (DTI) tractography. Although—at least in the United Kingdom—these techniques are not yet in routine clinical use, they may be useful in certain situations. SPECT and PET can enhance the ability to differentiate tumor recurrence from radiation necrosis in patients who have received prior radiotherapy and in whom structural imaging suggests progression. They may also help discriminate between CNS lymphoma and opportunistic infections such as toxoplasmic encephalitis in patients with acquired immunodeficiency syndrome. MEG and DTI tractography may be helpful in more precisely characterizing cerebral “disconnection” syndromes which may occur. MEG, along with functional MRI, is used in the preoperative localization of specialized cortical function such as motor, speech, and vision. These modalities aid neurosurgeons in planning stereotactic surgery that removes as much tumor as possible while

Telegram: @medical_k

www.konkur.in

minimizing the risk of critical cortical damage. Increasingly such location-critical operations are performed as “awake craniotomies” under sedation but with consciousness maintained. With the patient awake, surgeons can stimulate an area of brain before its removal and check whether it is functionally vital.

PSYCHIATRIC SYMPTOMS IN BRAIN TUMOR PATIENTS

Switching focus to the neuro-oncology team, we will consider the neuropsychiatric symptoms that may arise in someone who has a primary brain tumor.

Predisposing Factors

Tumor Location. The notion that brain tumors in particular lobes of the brain cause specific psychiatric symptoms is attractive but simplistic. Although there can be a relationship of sorts, anatomical tumor location is only one factor to consider in the assessment. A classically “frontal lobe” dysexecutive syndrome can arise in the context of a brainstem tumor. Symptoms may arise from structures seemingly far removed from the tumor due to the functional vascular phenomenon of diaschisis, or from structural white matter disconnection syndromes secondary to tumor-associated damage.

Older textbooks might hold that tumors in the left hemisphere cause depression whereas right-hemisphere tumors cause euphoria. Right-sided lesions of the temporal skull base have indeed been associated with a disinhibition syndrome in one small but interesting prospective cohort study conducted after CT scanning became widespread. Overall, however, the association between laterality and psychopathology is mostly inconsistent. Most large studies of this question predate the more recent psychiatric classification systems, many the advent of widespread CT scanning, and a few even the introduction of modern research standards of methodology and reporting. Most recent studies are limited to case studies or small series. It remains difficult to interpret the literature on how tumor laterality affects psychopathology.

It is likely that unpicking the causal relationships between tumor location and psychopathology will require more sophisticated functional

Telegram: @medical_k

www.konkur.in

neuroimaging techniques than CT or MRI. To date, few studies have utilized the likes of DTI tractography or SPECT to address this issue, however (see Jutten et al. for an interesting introduction to this topic).

Tumor Grade. Does tumor grade influence the development of neuropsychiatric symptoms? Like tumor location, various authors have proposed a causal relationship between WHO grade and psychopathology. In some ways, this is a plausible hypothesis. Advocates could postulate high/low-grade differences between: edema, ICP, and mass effect; metabolic profiles in the cellular microenvironment; or impairment of neuronal functioning by contact from invading cancer cells. Again, however, the evidence suggests a more complex picture. There is a lack of robust supporting evidence from prospective studies that directly compare high- and low-grade glioma patients. A few studies do make this comparison but lack power because low-grade glioma is rarer than high-grade glioma, and it is usually difficult to accrue large sample sizes. As it stands, therefore, evidence supporting a role for tumor grade is inconsistent. There is about as much supporting evidence for greater generalized distress in *low-grade* tumors, an association that could be rationalized a posteriori by the younger median age of low-grade brain tumor patients and the greater prevalence of epilepsy.

This slightly deflating appraisal of the roles of location and malignancy is perhaps a caution against making sweeping statements about how anatomo-clinical tumor characteristics affect psychiatric outcomes. Such statements risk: (1) ignoring the role of sociodemographic variables; (2) conflating cognitive with psychiatric psychopathology; (3) glossing over methodologic limitations in the literature; and (4) sounding so plausible that the first three things are overlooked. One of the most consistent findings is the absence of evidence correlating tumor- and treatment-related variables with neurotic psychopathology, but even this statement is based mostly on underpowered studies. Properly powered studies are required to identify brain tumor patients at high risk of future psychiatric complications.

The evidence that tumor and treatment characteristics can influence neurocognitive functioning is stronger but it remains difficult to compare clinical studies against each other. There is little doubt that brain surgery, radiotherapy, and chemotherapy can impair cognitive function, however. A recent retrospective study proposed a relationship between a certain

Telegram: @medical_k

www.konkur.in

molecular subtype of faster growing tumors and greater cognitive impairment. If confirmed by prospective research, insights like these may offer useful perspectives on mechanisms of neurocognitive impairment in other clinical populations and identify groups to target with early interventions.

Premorbid and Psychosocial Factors. In contrast to most tumor-related variables, the patient's premorbid psychiatric and psychosocial histories may well influence their risk of postoperative psychiatric complications including anxiety, depression, and distress. In some ways, this makes intuitive sense. Even after adjusting to the diagnosis there will be many sources of ongoing stress: neurocognitive and physical disability, side effects of surgery, radiotherapy, or chemotherapy, the threat of clinical progression, and many changes to lifestyle. One can expect that the patient's premorbid vulnerabilities, cognitive abilities, behavioral coping mechanisms, and psychosocial support systems would play important roles in determining the impact and degree of neuropsychiatric symptoms.

Contributory factors that determine psychiatric and behavioral symptoms co-occurring with brain tumors are therefore multiple and complex. To varying degrees and depending on the symptom of interest they may include tumor type, the rate and extent of tumor growth, anatomical location, the presence or absence of increased ICP, the type of treatment used and the severity of treatment complications, premorbid patient characteristics, psychiatric history, the adequacy of coping skills, and the quality of psychosocial and family support systems. In adults, on balance and with a risk of over-generalizing one might be particularly alert for neuropsychiatric and/or neurocognitive dysfunction in patients with any of the following: frontotemporolimbic, bifrontal, or deep midline tumors; large (>5 cm) or multifocal tumors; aggressively growing malignant tumors; raised ICP or obstructive hydrocephalus; significant tumor-related physical functional impairment; a history of any psychiatric disorder; prior brain injury; a family history of psychiatric illness; lower premorbid intellectual capabilities; poorer adaptive coping skills; or lower psychosocial support.

General Treatment

Telegram: @medical_k

www.konkur.in

General Approach. When a psychiatric disturbance is directly caused by a brain tumor, its surgical removal may associate with remission of the psychiatric symptoms. Such improvements are however reported by only a few handfuls of single case studies and comprise a tiny minority of brain tumor-associated neuropsychiatry. Most psychiatric morbidity in brain tumor patients occurs after surgery during primary chemo- or radiotherapy and the subsequent follow-up. Depending on the problem, psychiatric input is most likely to be requested when a patient's behavior or neurocognitive symptoms start, worsen, or persist during primary treatment or follow-up. Dealing with the issue may reduce symptomatic distress, improve functional ability, and enhance overall well-being and quality of life in the time remaining to the patient. Accordingly, referrals should never be dismissed or evaded as "understandable/normal/futile because they have a brain tumor." There is nearly always something that can be done. Treatment typically involves nonpharmacologic support, pharmacotherapy when necessary, psychoeducation and support of the family, and clear communication about treatment between the psychiatrist and the neuro-oncology team.

The lifetime prevalence of psychiatric disorders is as high among people who will eventually develop brain tumors as it is in the general population. Patients with a history of previous depressive or anxiety disorders are at high risk of relapse due to the fear and ongoing stress of being diagnosed with a brain tumor, among other causes. Neurocognitive impairment is the exception to this general rule: this very common problem can often be attributed directly to the tumor or from side effects or complications related to its treatment. It is also one of the most challenging problems to treat.

In planning a therapeutic approach, the psychiatrist may find it useful to attempt to characterize the patient's psychiatric and behavioral symptoms as (1) a relapse or a continuation of pre-existing psychiatric disorder, or (2) arising de novo in response to either the psychological and/or biologic stress of having a brain tumor. This broad framework can be clinically helpful in communicating with patients and their families, and in planning optimal drug and nondrug interventions.

Pre-Existing Psychiatric Medication. The management of a relapse or a continuation of pre-existing psychiatric disorders is grounded in common sense and best practice. The balance of risks and benefits of

Telegram: @medical_k

www.konkur.in

treatment should be fully discussed with the patient. Drug treatment follows the same general principles as in the general psychiatric population. The prescriber should adjust doses (and occasionally drugs) as necessary to accommodate for the increased risk of CNS side effects. Common side effects include delirium and the increased potential for an epileptic seizure. Prescribers should anticipate cytochrome P450 (CYP450) system pharmacokinetic interactions between psychiatric drugs and the array of medication these patients may be on.

Many older psychopharmacological agents are potentially deliriogenic. Examples include the tricyclic antidepressants (TCAs), typical antipsychotics, anticholinergic antiparkinsonian drugs, the benzodiazepines as a group, and lithium carbonate. As a rule of thumb, these older agents are first-line only when they have previously been effective and well tolerated by the patient. The drug may be reintroduced at a low dose and titrated to efficacy. In many patients newer drugs may be better as first-line treatment. These include the SSRIs, other relatively nonanticholinergic antidepressants, atypical antipsychotics, nonbenzodiazepine anxiolytics, and anticonvulsant mood stabilizers. Caution is especially needed for older adults and those with multiple medical conditions who may be on many other medications.

It is common to hear patients and doctors voice concern about the risk of causing epilepsy. Many psychotropic drugs have the potential to lower seizure threshold, particularly in overdose. The risk of inducing seizures in brain tumor patients with different psychotropic medications at routine prescription doses is unknown. There is little brain tumor-specific evidence to inform practice. There is a lot of clinical anecdote suggesting that drugs are usually safe, but such general and uncontrolled views are difficult to extrapolate to individual cases.

Newer atypical antipsychotics may have less epileptogenic potential at comparable doses than older typicals. If high-potency older antipsychotics are required, haloperidol may be less likely to lower seizure threshold than others in its class. For antidepressants, licensing data from RCTs in patients without a brain tumor suggest that most antidepressants do not affect seizure threshold in therapeutic doses, apart from bupropion and maprotiline which have a relatively higher risk of inducing seizures. These particular drugs may therefore be best avoided where possible in brain tumor patients. A reasonable first choice when considering treatment of

Telegram: @medical_k

www.konkur.in

depression would be an SSRI with few effects on the CYP450 system, started at half-dose and monitored if there are particular concerns.

Pharmacokinetic interactions may occur through the CYP450 system; for example, some antidepressants are CYP450 system inhibitors. If antiseizure medication is metabolized by the same enzyme, administration of a directly competing SSRI could predispose to an interaction. In this particular example, the main theoretical risk would be of antiseizure medication toxicity (rather than increased metabolism and inefficacy leading to seizures). In the reverse direction, coprescription of an enzyme-inducing antiseizure medication might necessitate higher therapeutic levels of an antidepressant. This example is extremely general: prescribers should consider interactions on a case-by-case basis, consulting a pharmacist for specialist advice when in any doubt. If interactions cannot be avoided clinicians may wish to monitor antiseizure medication levels. Others may choose to closely monitor the patient.

In brain tumor patients with a history of schizophrenia or other psychotic disorders, atypical antipsychotics should be used where possible. In some circumstances it may still be necessary to use high-potency agents with a long history of successful use in medical disorders (such as haloperidol), or other individual drugs known to be well-suited to a particular patient. With appropriate dosage adjustments these may well be tolerated.

Patients with longstanding type I bipolar disorder have the same risk of developing a brain tumor as everyone else. As is also the case with schizophrenia, the combination of these two devastating illnesses is rare. A complicating factor in this population is that lithium carbonate can, at toxic or high blood concentrations, cause seizures and delirium and for this reason may be better avoided if possible. There may be cases where lithium has been used for many years and where the relative risks and benefits can only be weighed on an individual basis. Mostly though, in acute type I bipolar mania a mood-stabilizing agent with documented efficacy in acute mania such as valproic acid would be a reasonable first choice. An anticonvulsant mood stabilizer may have obvious additional advantages in patients with epilepsy. An atypical antipsychotic may be added if required. In type I bipolar depression there is a well-known risk of precipitating secondary mania or rapid cycling when traditional antidepressants are used. The anticonvulsant lamotrigine may be effective here and appears to have the advantage of not precipitating secondary mania or causing rapid cycling, although it also has the

Telegram: @medical_k

www.konkur.in

potential for causing rare but serious and potentially life-threatening dermatologic side effects.

Specific Neuropsychiatric Syndromes

Neuropsychiatric problems often arise after the diagnosis of a primary brain tumor. Here the most frequent ones are discussed for adults with a primary brain tumor (except delirium, which is also a common problem and is discussed in Section 10.2).

Depressive Disorder Due to Another Medical Condition (DSM-5 293.83)

CLASSIFICATION. When assessing a brain tumor patient for depression you will have to make a series of judgments that broadly fall into two groups. One relates to whether somatic symptoms (weight, sleep, and psychomotor changes, and fatigue) should count toward a diagnosis of depression given the considerable risk of confounding from biologic effects of the tumor and its treatment. The other group of judgments relates to whether psychological symptoms (depressed mood, anhedonia, guilt, poor concentration, and suicidal ideation) are abnormally severe in the context of multiple personal losses and a profound existential threat. Because these judgments are difficult, they can cause variability in clinical practice. This variability might threaten the intended reliability of the DSM system: indeed, that is probably what happens.

When assessing patients with a brain tumor for depression, doctors have to decide whether to attribute symptoms to a likely mood disorder, or else to the direct consequences of the tumor and its treatment. Different doctors may interpret the same diagnostic information in different ways, causing unreliability which may go on to influence their downstream treatment decisions. To test this, a written vignette was constructed for a hypothetical brain tumor patient meeting criteria for major depressive episode (DSM-IV-TR 296.2). The vignette was sent to NHS Consultants in five neuro-oncology-related specialties in Scotland. The aims of the study were to determine how many doctors diagnosed depression; whether their diagnosis influence their preferred treatment; and among doctors who diagnosed depression, whether concern over a history of epilepsy influenced their readiness to recommend an antidepressant.

Telegram: @medical_k

www.konkur.in

The vignette contained eight of the nine symptoms of DSM-IV-TR MDD. However, each symptom also had a realistic alternative explanation directly related to the tumor or its treatment. All NHS consultant neurologists, clinical oncologists with neuro-oncology interest, neurosurgeons, and liaison psychiatrists working in Scotland, as well as the general practitioners (GPs) of all local glioma patients were invited to participate. Respondents were asked to state the diagnosis ("major depression" or "an understandable reaction"); specify treatment; and state to what extent the history of epilepsy had influenced their treatment decision ("not at all," "a little," "moderately," or "markedly"). The vignette read as follows:

Telegram: @medical_k

www.konkur.in

You are seeing Mrs. Smith, a previously fit and well 54-year-old language teacher, in your clinic. Four months ago she presented with focal seizures with impaired awareness, followed by a prolonged generalized tonic–clonic seizure which required admission to ITU. CT head revealed a left temporal lobe tumor which was debulked and found to be a high-grade glioma. She completed a course of radical radiotherapy last month and continues on chemotherapy. There is no other past medical history and no past psychiatric history.

About a month ago Mrs. Smith found a website on the internet saying chemotherapy gives her a 20% chance of being alive in 2 years. She has thus been thinking a lot about her death and how it would affect her family, and has been tearful and feeling sad since then. Her hair fell out toward the end of the radiotherapy, which she found distressing. She used to enjoy sports, and meeting friends, but says that both the self-consciousness and a marked increase in tiredness have left her totally disinterested in her old activities for some weeks. She feels bad about this, worries that she is letting her friends down, and struggles with thoughts that she has become a “weak” person instead of being her usual strong self. She has put on 5 kg in weight since she stopped going out.

Mrs. Smith is currently unable to return to her teaching job due to persisting word-finding difficulties. She has begun to lie awake at night worrying about her finances. Since the radiotherapy finished, she has also been much more forgetful and finds it hard to read the newspaper. She smokes 10 cigarettes per day, does not drink and has a supportive relationship with her husband and two adult daughters. One has just become pregnant and Mrs. Smith finds the thought of not seeing her first grandchild particularly painful. She would consider going to Switzerland for euthanasia if she deteriorated and was no longer able to walk, but otherwise hopes to live to see the child.

Steroids were stopped soon after the operation. She was initially started on phenytoin but switched to a low dose of lamotrigine after the operation. It was increased slightly to control focal seizures a few weeks later. She remains on the same dose and has had no seizures since. She is on no other medicines and has no allergies.

Today’s brain MRI shows postoperative scarring with a small amount of residual tumor. At interview, Mrs. Smith sits with little spontaneous movement, and cries when talking about her family. She

Telegram: @medical_k

www.konkur.in

is not psychotic. Her speech is quiet and halting at times. Her concentration occasionally wanders but she is orientated to time and place. Mrs. Smith asks you if this is a normal reaction to her situation and treatment. She has no strong feelings about how you manage her.

Of 228 questionnaires distributed, 105 were returned complete (46% response rate). There was a clear split in opinion. Sixty-four doctors (61%) diagnosed major depression and forty-one (39%) diagnosed an "understandable reaction". There were no significant interspeciality differences. Choice of diagnosis strongly influenced treatment. Antidepressants were more likely to be suggested when the doctor had preferred the diagnosis of depression (38/64 vs. 2/41; $P < .00001$). For an "understandable reaction," meanwhile, counseling (23/41 vs. 15/64; $P < .001$) or watchful waiting (13/41 vs. 0/64; $P < .00001$) were more likely to be suggested as the first-line management. Eleven distinct types of counseling were identified with no consensus on the best sort. Just over half of the doctors diagnosing depression stated that the history of epilepsy had "moderately" or "markedly" influenced their choice of treatment (34/64). There was a trend for concern about epilepsy to be associated with avoidance of antidepressant prescription. GPs and psychiatrists appeared to be more concerned about epilepsy than neurologists. In summary, therefore, a sample of over 100 consultants presented with exactly the same clinical information showed marked disagreement in whether to diagnose MDD in a brain tumor patient. Preferred diagnosis strongly influenced preferred management. Psychiatrists were significantly more concerned about a history of epilepsy than neurologists. *Data collected by the author with supervision from Dr. Robin Grant and Dr. Alan Carson (Consultant neuropsychiatrist, NHS Lothian).*

Attempting to mitigate these problems by setting diagnostic "rules" for individual symptoms often raises further questions. One could, for example, decide to exclude all reports of insomnia if the patient is also on high-dose corticosteroids. But insomnia is a common symptom of depression and the relationship between steroids and sleep is not straightforward. In a local series of over 150 glioma patients, most of those taking dexamethasone shortly after primary surgery reported either no sleep changes at all or *hyper*somnia at clinical interview (author's non–

Telegram: @medical_k

www.konkur.in

peer-reviewed data). It may be impossible to confidently attribute causality to individual depressive symptoms.

What can be done? The “general comments” section above considered whether the patient’s depressive disorder arose (1) as a recurrence of prior depressive disorder, or (2) de novo in response to either the psychological or biologic stress of having a brain tumor. This provides a clinical framework by which to communicate the meaning of a diagnosis to patients. It may also suggest particular therapeutic strategies. However as can be seen above, the DSM entities of MDE or MDD do not make it easy to secure the diagnosis in the first place.

DSM-5 instructs users to discount depressive symptoms if the symptoms are clearly due to another medical condition. Yet, as shown in the vignette above, almost every depressive symptom can often quite plausibly be attributed to the brain tumor or its treatment. It may therefore be simpler instead to assess potentially depressed brain tumor patients for the simpler syndrome of “**Depressive Disorder Due To Another Medical Condition**” **(DSM-5 293.83**). This syndrome is more agnostic about the cause of symptoms. The criteria are discussed below: they are different from MDD in that they do not rest on theoretical judgments about the causes of symptoms. The presence or absence of a prior history of MDD/E can be labeled as secondary if desired.

A blanket approach like this could raise objections, including: (1) depressive disorder arising in patients with a prior history of depression may be a simple relapse rather than caused de novo by the tumor; (2) the lower diagnostic threshold could lead to overdiagnosis; and (3) individual symptoms still have to be weighed when assigning specifiers. But the strategy: (1) is testable by comparing the clinical course of brain tumor patients with, and without, a prior history of depression; (2) minimizes inter-clinician variability in practice, helping to standardize diagnosis; and (3) side-steps the questions of whether to count somatic and psychological symptoms toward the main diagnostic label. It is also easily communicable.

Apart from the upcoming section on “Diagnosis and clinical features” which for consistency also focuses on the suggested pragmatic diagnosis of **Depressive Disorder Due To Another Medical Condition**, the rest of this section is based on the historic literature. The authors of this literature, including the present author, used either traditional DSM

Telegram: @medical_k

www.konkur.in

diagnoses of MDD or questionnaires which were validated against DSM-IV MDD (or its equivalent at the time).

EPIDEMIOLOGY. MDD is more common in glioma patients than in the healthy general population. Retrospective clinical data from the U.S. Nationwide Readmissions Database (NRD) suggest that among people receiving craniotomy for glioma, the frequency of MDD is 11.4%; comparable to lung or breast cancer patients and greater than patients with head and neck, colorectal, and prostate cancers (see Rumalla et al.). The biggest individual study to use prospective "clinical interview" diagnostic methodology in these patients found that the 6-month prevalence following diagnosis of glioma was 20%; while reviews of studies using clinical interview methodology return a median frequency of 15%. If depressive symptoms are measured by rating scale, frequency estimates vary depending on the scale that is used. For example, the Beck Depression Inventory (BDI) returns a median frequency of 39%, whereas the Hospital Anxiety and Depression Scale (HADS) suggests a median of 16%.

Original data and reviews suggest that MDD is most consistently associated with impaired physical and cognitive functioning, longer-term corticosteroid use, a prior history of depression, and reduced quality of life. Unlike in the general population, female sex is not a clear risk factor. A concurrent clinical diagnosis of MDD has been associated with worse perioperative outcomes and greater depressive symptoms may predict increased mortality from the tumor, but further studies are needed on this issue. Longitudinal studies of depression in glioma are rare: based on very limited samples, a clinical diagnosis of depression can persist in about half of patients, for at least 3 months. The extent to which biologic symptoms of tumor or its treatment contribute to artificially inflate these estimates is not known.

ETIOLOGY. The etiology of MDD in brain tumor patients is likely to be multifactorial. As is the case in other forms of cancer, a prior history of depression is likely to confer increased risk of depression after diagnosis of a brain tumor such as glioma ("brain cancer"). In some cases therefore the cause is likely to be a relapse of a pre-existing tendency to depressive disorder. Genetic influences could be inferred when there is a family history of depression. Post-tumor diagnosis, a new case of depression

Telegram: @medical_k

www.konkur.in

could have a number of speculated possible causes, including tumor- or edema-associated disruption of critical tracts; a functional diaschisis; critical metabolic alterations of the neuronal microenvironment; the putative depressogenic effect of long-term corticosteroids; or the long-term effects of radiotherapy or chemotherapy on hippocampal neurogenesis or white matter tracts. A good case can often be made for emphasizing a psychological reaction to the devastating losses that accompany the onset, treatment, and natural course of many brain tumors. Various neuroendocrine abnormalities may be etiologically implicated in pituitary tumors including hypercortisolemia and hypothyroidism. It is, of course, usually very difficult to know which of these theories may be correct.

A subset of brain tumor patients meets criteria for a depressive disorder by having marked anhedonia but no depressed mood. This clinical picture is recognized in both pituitary tumor and glioma, and implies causal mechanisms distinct from the classical depressive picture of pervasively sad mood. The biologic basis of any such difference remains to be studied.

DIAGNOSIS AND CLINICAL FEATURES. **Depressive Disorder Due To Another Medical Condition** (Table 2.3–2) requires clinical interview evidence of a prominent, persistent, and socially disruptive change of mood. The change is depressive, apathetic, or both, and occurs in the context of a radiologically or histologically diagnosed brain tumor. Adjustment disorder with depressed mood should be excluded along with delirium. It can be further specified with respect to the full criteria for MDD/E: w*ith major depressive-like episode* if they are met, and *with depressive features* if not.

The traditionally required minimum duration of symptoms is 2 weeks. Some psychiatrists may prefer to allow at least 1 month to pass from the point of brain tumor diagnosis before considering whether a mood disorder is present, unless extremely severe symptoms manifest before then. Waves of grief are normal postdiagnosis. Social disruption can be difficult to assess: many brain tumor patients are unable to drive. They are often more socially isolated than previously and are unlikely, at least initially, to be able to work. Questions about social interaction should focus on what the patient *is* able do. The psychiatrist can assess their daily interaction with carers, family and friends, and whether this has changed

Telegram: @medical_k

www.konkur.in

along with mood. If anhedonia is the main clinical feature a similar problem arises: questions about “enjoying things they normally enjoy” will often be met with the reply that they “can’t do those things now” because they have a brain tumor. A useful question may be whether they still feel the same pleasure from spending time with grandchildren or other close family. Symptoms should be new and not attributable to the patient’s long-standing personality. Excluding adjustment disorder is a matter of assessing severity and persistence of the cardinal depressive symptoms. Excluding hypoactive delirium may be difficult if the patient is already cognitively impaired but in the history, the absence of fluctuating agitation or disorientation in time should be noted. Proxy report (e.g., from the patient’s main carer) is important and is likely to add to diagnostic reliability.

Telegram: @medical_k

www.konkur.in

Table 2.3–2.
DSM-5 Criteria for Mood Disorder Due to Another Medical Condition (293.83)

A prominent and persistent disturbance in mood predominates in the clinical picture and is characterized by either (or both) of the following:

(1) Depressed mood or markedly diminished interest or pleasure in all, or almost all, activities or

(2) elevated, expansive, or irritable mood

There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiologic consequence of having a brain tumor

The disturbance is not better accounted for by another mental disorder (e.g., adjustment disorder With depressed mood in response to the stress of having a brain tumor)

The disturbance does not occur exclusively during the course of a delirium.

The following specifiers can be used to characterize the disorder:

- *With Depressive Features* if the predominant mood is depressed but the full criteria are not met for a Major Depressive Episode; *With Major Depressive-Like Episode* if the full criteria are met for a Major Depressive Episode; *With Manic Features* if the predominant mood is elevated, euphoric, or irritable; *With Mixed Features* if the symptoms of both mania and depression are present but neither predominates

This is a suggested diagnosis with some advantages in these patients (see text); psychiatrists may alternatively diagnose Major Depressive Episode/Disorder according to standard criteria.

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:206.

LABORATORY INVESTIGATIONS. Investigations are as those required to exclude delirium and a physical cause for MDD. An endocrine screen is indicated in patients with a remote history of radiotherapy to the brain, if the radiation field included the pituitary gland.

Telegram: @medical_k

www.konkur.in

DIFFERENTIAL DIAGNOSIS. The main competing psychiatric diagnoses are delirium, neurocognitive disorder due to a brain tumor, and (probably most commonly) adjustment disorder with depressed mood. The medical differential is as broad as that for MDD in patients without a brain tumor. In brain tumor patients specifically, potential medical causes include: postepileptic personality change; neuroendocrine abnormalities (including systemic diseases such as secondary hypothyroidism); and steroid-induced depressive symptoms.

COURSE AND PROGNOSIS. Longitudinal studies of depression in brain tumor patients are rare. This is partly because few have asked the question, but also partly because depression is more likely in functionally impaired patients with a poorer prognosis who are difficult to retain in long-term studies. Available evidence suggests that among patients who can be followed up, clinically significant depressive disorders can persist for at least three months. This duration is roughly in keeping with the median duration of depression in the non–brain tumor population. It lends some support to the argument that depressive symptoms cause significant clinical burden in these patients.

MDD and moderate–severe depressive symptoms have been shown to correlate with shorter survival times in meta-analyses of studies of cancer. They also correlate with functional impairment, which is a strong negative prognostic factor for brain tumor patients. An open question is therefore whether depression is independently predictive of mortality in brain tumor patients after controlling for functional impairment. Again only a few studies have asked and results are mixed. One difficulty in demonstrating such an impact is that median survival time for the most often-studied tumor (high-grade glioma) is measured only in months. A large sample would likely be required to show even a modest impact of depression on mortality. An individual patient data meta-analysis may be one way to clarify this issue, or more obliquely examining survival times in cohorts of people who receive antidepressants versus those who do not. Studies examining this issue must take care to untangle the prognostic effect of depression from that of poorer physical function (which correlates with depression and poorer survival and is therefore a prominent confound).

Clinical depression is associated with an increased risk of epileptic seizures in the general population. It is possible that left untreated, it may predispose these vulnerable patients further to epilepsy. Suicidal ideation

Telegram: @medical_k

www.konkur.in

is also a complication of uncontrolled MDD. Brain tumor patients have been reported to have one of the highest-risk ratios for completed suicide in the year following diagnosis of tumor. Reported suicidal ideation was however rare in other cohorts which examined the clinically busy first 6 months after brain tumor diagnosis. Overall the frequency of suicidal ideation is also unclear and deserves further study.

TREATMENT. No phase III RCT has examined the effectiveness of antidepressants for MDD in brain tumor patients. Although the same can be said for nearly every psychiatric condition in this patient group, the absence is felt more acutely here. Depression is a common condition which many psychiatrists will feel relatively comfortable recognizing and prescribing antidepressants for, yet in brain tumor patients, one moves a little closer to clinical equipoise between their effectiveness and risk. The equipoise is on the one hand whether these drugs are more effective than placebo in the grossly abnormal cerebral environment of a primary tumor (glioma especially). On the other hand, the likelihoods that they cause AED or chemotherapeutic toxicities by CYP450 interaction, worsen fatigue as per the main recognized side-effect profiles of all antidepressants, contribute via anticholinergic mechanisms to cognitive impairment, worsen seizure control in this highly susceptible population, or even by contrast improve seizure control by treating depression, are in each case also unknown. These factors (professional confidence, and for lack of a better term academic ignorance) might combine to create a “blind optimism” in favor of automatic prescribing for MDD. Conversely, doctors might fear unquantified consequences such as epilepsy, and hesitate to prescribe when treatment may actually be effective. The solution will be to conduct RCTs in depressed brain tumor patients who meet treatment thresholds at enrolment. In the meantime, treatment is based on commonly accepted principles and empirical best practice. Patients should be fully informed about the possible risks and benefits, treated cautiously, and reviewed regularly.

In some patients, antidepressants do appear clinically to be helpful in treating new depressive symptoms. The author routinely offers them to depressed brain tumor patients (subject to caveats and safeguards above), and they do often seem to help. Given that depression plays a major role in decreasing the overall quality of life that these patients experience, its early recognition and rapid treatment is potentially of great

Telegram: @medical_k

www.konkur.in

benefit if life is shortened by the tumor. An SSRI with a relatively clean CYP450 side-effect profile such as sertraline may be a reasonable first-line treatment. The SSRIs are increasingly clinically familiar, generally well-tolerated, and may be less likely to cause delirium than older antidepressants. A particular clinical drawback with these agents can be sexual side effects and brain tumor patients are already at high risk of sexual difficulties. Experience with newer drugs like SNRIs (e.g., venlafaxine) or Noradrenergic and specific serotonergic antidepressants (NaSSAs) (e.g., mirtazapine) in this patient group—in the research literature at least—is limited to sparse case reports. As in the case of prescribing any antidepressant, care should be taken to minimize the risk of a gastrointestinal bleed, a risk which may be higher in the older adults and in patients who have been prescribed corticosteroids to reduce brain edema. An ECG should be checked before prescribing to confirm that the QTc interval has not been prolonged by chemotherapy.

TCAs have a side-effect profile which includes sedation, anticholinergic effects, and orthostatic hypotension. For this reason, they are often considered second line unless previously effective for the patient. If TCAs are considered for refractory depression, some clinicians report that nortriptyline may be well tolerated. In some circumstances, such as severe refractory depression or where there is a long history of previous effective treatment, monoamine oxidase inhibitors (MAOIs) may be appropriate. Caution is required however as procarbazine—another drug of the MAOI class—may form part of certain chemotherapy regimens used to treat glioma. Before using these older agents, the psychiatrist should therefore discuss with the treating clinical team to confirm the choice of cancer treatment and hospital pharmacy to explore potential interactions.

Rarely and in severely depressed brain tumor patients refractory to drug treatment, ECT may be considered. ECT was once thought to be absolutely contraindicated in the presence of brain tumor. A recent review, however, examined published and indexed case reports of 75 patients who underwent ECT in the presence of a brain tumor over the last 80 years. The most common type of tumor was a meningioma or arachnoid cyst, indicating that the case report literature is strongest for patients with benign, small, or clinically insignificant tumors. In this context, unilateral brief pulse ECT has been reported to be safe, effective, and mostly well tolerated. Precautions have included close attention to the patient's

Telegram: @medical_k

www.konkur.in

capacity to consent to treatment, careful dose titration, and the need to monitor the patient carefully for post-ECT delirium. Dexamethasone was used pre-emptively in a substantial number of patients to reduce the risk that increased blood flow and edema around the tumor would lead to neurologic signs. Phenytoin was administered to one patient to prevent a prolonged seizure. Since the presence of a brain tumor may not be known when patients start ECT, the authors of the review suggest ordering neuroimaging in any patient displaying new neurologic symptoms manifesting after ECT, such as a significant lateralization of the seizure, secondary or prolonged seizures, Todd paresis, aphasia, or eye-movement disorders.

Psychostimulants can be effective in treating cancer-related fatigue and have been proposed as a treatment for depression in patients with brain tumor. Systematic trial evidence is currently limited. Modafinil is effective for cancer-related fatigue in general, but trials in brain tumor patients specifically are negative or absent. At present, there is no good evidence that modafinil is effective for depression in these patients. Methylphenidate may reduce subthreshold depressive symptoms, but studies to date measured these only as secondary outcomes and conclusions are inconsistent. Whether these drugs are more effective than placebo in treating clinical MDD is not known. Anecdotally, some clinicians find them helpful in some patients, but studies suggest a considerable placebo effect. If a trial of treatment is considered, methylphenidate has the advantages of a lower effect on seizure threshold and no major sedating or deliriant properties. Adverse effects are however estimated to be three times more likely than with placebo. In a recent meta-analysis, vertigo, anxiety, anorexia, and nausea were significantly more frequent in the treatment arm.

For all patients with MDD, psychological treatments should be considered and offered wherever possible alongside antidepressants. Once more it is unclear whether these treatments work (and if so which ones, and in what circumstances) in patients with progressive cognitive and communication deficits of varying severity. Decisions about their suitability for individual patients should be made empirically. Patients with a lower severity of subthreshold depressive symptoms and distress, meanwhile, may benefit from supportive or group therapy or referral to external services such as a brain tumor charity (nonprofit or patient

Telegram: @medical_k

www.konkur.in

advocacy support group, such as in the United States, the American Brain Tumor Association or the National Brain Tumor Society).

Anxiety Disorders

EPIDEMIOLOGY. As with depression, screening for anxiety disorders may capture elements of “normal” distress as well as the more severe and specific symptoms that present to adult psychiatry. In the brain tumor literature, anxiety has generally been measured using general self-report questionnaires. Frequency estimates usually range between 30% and 50%: how much would be regarded as clinically pathologic in structured interviews is not well characterized. These numbers probably reflect, in part, reaction to the natural fear, agitation, uncertainty and stress of having a brain tumor. Anxious reaction may be more likely in low-grade glioma, in younger adult patients, in women, and in those with lower premorbid IQ.

ETIOLOGY. Rarely, anxiety can be caused directly by the brain tumor. One example would be a coarsening of pre-existing anxious personality traits as the tumor disrupts higher inhibitory circuits. Another direct tumor cause would be stereotyped panic-like attacks occurring in the context of focal seizures with impaired awareness. Isolated case reports record the association of new-onset obsessive or compulsive symptoms with a brain tumor or its treatment in the brainstem, right parietal lobe, and left frontotemporal lobe (a tumor site that has also been associated with greater obsessional thinking in a small cohort study). A large part of anxiety and distress however usually arises as a psychological reaction to the stress of having a brain tumor. Anxiety presenting during outpatient follow-up may be related to occupational or social stress, especially in well-functioning patients with a low-grade glioma. For example, a hairdresser who has returned to work may have subtle cognitive deficits that cause difficulty in such a high-pressure environment. Or a patient may be under pressure from bullying work colleagues and find it harder to contain the anxiety this situation naturally creates. Both are real-life examples from the author’s caseload.

DIAGNOSIS AND CLINICAL FEATURES. Generalized anxiety disorder (GAD, 300.02) requires symptoms of anxiety to be present for at least 6 months. Additionally and as with MDD, several further symptoms (e.g., being

Telegram: @medical_k

www.konkur.in

easily fatigued, or difficulty concentrating) can also be caused by the physiologic effects of the tumor or its treatment. This combination of features means GAD is unlikely often to be the preferred diagnosis. A more commonly diagnosable anxiety disorder in brain tumor patients, and perhaps the most common psychiatric disorder of all, will be **Adjustment Disorder (309.xx)**. The diagnosis (Table 2.3–3) requires emotional or behavioral symptoms occurring in response to the stress of having a brain tumor. The specific stressor may be the diagnosis itself or one or more physical or social complications that can arise during treatment and follow-up. Symptoms should arise within 3 months of the stressor. Criteria of “disproportionate” distress and occupational impact may be difficult to assess in the circumstances. Impairment in social functioning can be partly explored by asking about the impact of symptoms on contacts with friends. Additional specifiers code for prevailing mood and behavioral state. Differentiating an adjustment disorder (plus or minus specifiers for depressed mood and anxiety) from a depressive disorder is a clinical judgment that may turn on the severity or persistence of cardinal depressive symptoms such as low mood and anhedonia.

Telegram: @medical_k

www.konkur.in

Table 2.3–3.
DSM-5 Criteria for Adjustment Disorder (309.xx)

Emotional or behavioral symptoms develop in response to an identifiable stressor or stressors within 3 months of the onset of the stressor(s) plus:

Marked distress that is out of proportion to the severity or intensity of the stressor, even when external context and cultural factors that might influence symptom severity and presentation are taken into account, AND/OR significant impairment in social, occupational, or other areas of functioning;

The stress-related disturbance does not meet criteria for another mental disorder and is not merely an exacerbation of a pre-existing mental disorder;

The symptoms do not represent normal bereavement;

After the termination of the stressor (or its consequences), the symptoms persist for no longer than an additional 6 months

The following six specifiers are used to identify subtypes of adjustment disorder:

- With depressed mood
- With anxious mood
- With mixed anxiety and depressed mood
- With disturbance of conduct
- With mixed disturbance of emotions and conduct
- Unspecified

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:319, 320.

Diagnostic features of panic disorder (300.xx) are discussed in later chapters. In the general population, classical panic attacks have a characteristically sudden onset, stereotyped (repeating) pattern of features, and relatively short duration. In brain tumor patients, similar things can be said about some types of epileptic seizure. Although it is not a very common occurrence it may be difficult, purely on the basis of history, to distinguish between these two causes of paroxysmal panic symptoms. One symptom which may point toward focal epilepsy is the

Telegram: @medical_k

www.konkur.in

presence of an unusual prodromal aura (such as deja vu, rising gastric sensations, a strange smell, or visual disturbance). Another is the presence of orofacial movements during the attack. For this reason, a corroborative eyewitness account is recommended when assessing panic in a brain tumor patient. With the patient's consent carers may be asked to video-record an attack on their mobile phone for the psychiatrist's review.

DIFFERENTIAL DIAGNOSIS. Psychosis and depressive disorder should be excluded. Alongside the medical differential for anxiety disorders, it may be helpful to consider in particular focal epileptic seizures, pituitary-related endocrinologic abnormalities (hypopituitarism being a late consequence of certain radiotherapy regimes), and PE/DVT presenting as difficulty breathing or hyperventilation.

LABORATORY INVESTIGATION. Most anxiety will be—for lack of a better term—psychological in origin. It is still valuable to exclude potential reversible physical causes. Brain tumor-specific investigations may include EEG, endocrine blood screen, and a chest x-ray as per the medical differential.

COURSE AND PROGNOSIS. In cancer generally, distress characteristically peaks at the times of diagnosis, end of primary treatment, relapse, and the terminal phase. Distress occurring at these points can at first be observed supportively unless it is very severe. Patients can be reassured that it is normal and may pass. For example, much of the generalized distress and grief at diagnosis resolves (as one might expect) within the first few months. Brain tumor patients often face the added and recurring stressor of routine interval scanning: repeat neuroimaging at intervals usually ranging from every 3 months to every year and tracking progress of the tumor. These times can be highly distressing for those affected. They are temporary and supportive care is again indicated.

Symptoms may persist preferentially in the minority of patients with other risk factors for psychiatric disorders, a pre-morbid anxious predisposition, or a direct tumor-related cause of symptoms. In these patients, or in those with severe levels of distress or anxiety at the points noted above, more systematic treatment may be indicated.

TREATMENT. Currently, no phase III RCTs have studied interventions for anxiety in brain tumor patients. General management principles from adult

Telegram: @medical_k

www.konkur.in

psychiatry should be applied. In a demonstration of their power, anxiety management and relaxation techniques—including listening to music, good communication, aromatherapy, slow breathing, distraction, visualization, and prayer—have been used intraoperatively to facilitate awake craniotomy without sedation and only minimal analgesia. A biopsychosocial formulation may be a useful starting point for treatment decisions. Full and detailed explanations of all diagnostic procedures and proposed treatments may help. There is observational evidence that information-giving lowers anxiety, for example, in the perioperative phase. The patient and family should have the opportunity to ask questions. Patients can also be referred to a local brain tumor charity, patient advocacy support group, or non-profit organization.

In patients whose anxiety persists or is moderately severe, talking therapies may be indicated. Not all patients may be suitable candidates, however. Severe cognitive, functional, or practical concerns may hamper their delivery. Where possible, adjustments may need to be made to allow the patient to participate. Questions to consider include: (1) Does the patient have cognitive dysfunction that is too severe for them to engage with treatment, remember, and internalize therapeutic strategies? (2) Do they have any physical impairment that may limit their participation such as dysphasia or uncontrolled epilepsy? (3) If the patient is unable to drive, how will they get to regular sessions? and (4) If there *is* a cognitive, physical, or practical difficulty, is it possible to adapt therapy to compensate? Questions of this sort should ideally be considered by the psychiatrist or psychologist together in liaison with the neuro-oncology team.

Anxiolytic drug treatment in brain tumor patients may include SSRI antidepressants, low-dose regular trazodone, or buspirone, in conjunction with supportive or structured psychotherapy. Alternative medications such as pregabalin (Lyrica) and propranolol (if tolerated and safe to prescribe) may be helpful. Where essential for short-term control of severe anxiety, low-dose, long-acting benzodiazepines may have a role. Antipsychotics should probably be avoided as treatments for anxiety unless specific psychotic symptoms are associated with the patient's anxiety and agitation, or they have been first-line for that patient before.

The general principle for patients with a pre-existing, longstanding anxiety disorder who subsequently develop a brain tumor is to continue previously effective treatment where possible. In line with the general

Telegram: @medical_k

www.konkur.in

comments above attention should be paid to the possibility of interactions with other prescribed medicines. One or more of the selective serotonin reuptake inhibitors, buspirone, propranolol, or clonazepam may be effective and well tolerated in treating acute symptomatic exacerbations. Patients with fear or panic disorder symptoms occurring as a part of a temporal lobe tumor-induced focal seizure may respond to treatment with ASMs. If such symptoms occur during the interictal period, anxiolytic agents discussed previously may be helpful. Close collaboration with the neuro-oncology team is essential.

Steroid-Induced Psychotic Disorder (292.9)

EPIDEMIOLOGY. Corticosteroids are prescribed to brain tumor patients to reduce brain edema, lower ICP and thereby improve physical and cognitive functioning. The typically high doses (in the United Kingdom, the standard initial dose is 8-mg dexamethasone orally, twice per day) and often urgent necessity mean that newly diagnosed brain tumor patients are at risk of developing a steroid-induced psychotic disorder (hereafter "steroid-induced psychosis"). This sounds worrying but most brain tumor patients do not become psychotic from any cause, including steroids. The frequency of steroid-induced psychosis is estimated at under 5% from review of case and clinical study literature. Much of this literature is focused on rheumatology patients receiving prednisolone. It suggests that women may be more at risk, but the most consistently identified risk factor is higher steroid dose.

ETIOLOGY. The relationship between dose and emergence of psychotic symptoms is incompletely understood: while probably not linear, psychotic symptoms are clearly more likely in patients on very high doses. The molecular pathologic mechanism is unknown and may be due to a primary effect of the corticosteroid on brain function or a secondary effect (e.g., severe sleep disruption), coupled with particular—and currently unknown—biologic predisposition(s).

DIAGNOSIS AND CLINICAL FEATURES. The diagnosis of steroid-induced psychosis (Table 2.3–4) rests upon psychotic symptoms (delusions and/or hallucinations, together with other symptoms consistent with psychosis) occurring in association with the use of corticosteroids. The risk is highest soon after starting treatment and most patients destined to develop

Telegram: @medical_k

www.konkur.in

psychosis are thought to do so in the first fortnight from steroid onset. On stopping the offending drug, most cases of psychosis could be expected to settle within a week. Associated affective symptoms may take longer to resolve. High dose (e.g., >40-mg prednisolone equivalent/day) makes the syndrome more likely but is not essential: the reaction appears to be idiosyncratic. The psychiatrist should exclude a prior history of primary psychosis and, if possible, delirium. The latter may not be straightforward as the clinical picture may fluctuate from both psychosis and delirium, and white cell count is likely to be raised secondary to the corticosteroid. To help exclude delirium clues to infection may be sought in the physical examination. These might include fever, tachycardia, and a raised respiratory rate, as well as various focal signs of infection. Investigations can help include metabolic and infective causes (electrolyte or liver function abnormalities, urinalysis, chest x-ray if possible). The drug prescription sheet should be reviewed for any potentially deliriogenic medicines. The tempo of onset in relation to steroid prescription should be considered.

Anecdotally, steroid-induced psychosis often has a prominent affective rather than schizophreniform flavor. There is however, no sole characteristic phenotype other than the presence of delusions or hallucinations. Anecdotally oncologists treating brain tumor patients comment that many of their patients are often subtly elated for the first few weeks of corticosteroid treatment, without ever becoming frankly manic or psychotic.

Table 2.3–4.
DSM-5 Criteria for Steroid-Induced Psychotic Disorder (292.9)

Evidence of symptom(s) of psychosis:
- Abnormal psychomotor behavior
- Negative symptoms
- Impaired cognition
- Depression
- Mania
- Disorganized speech

PLUS at least one of the following:
- Delusions
- Hallucinations

The symptom(s) developed during or soon after substance use or withdrawal, AND the involved substance is capable of producing the symptom(s);

The disturbance in not better explained by a psychotic disorder that is not substance-induced;

The disturbance does not occur exclusively during the course of a delirium;

The disturbance causes clinically significant distress or impairment in important areas of functioning

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of steroid-induced psychosis in brain tumor patients includes delirium, psychosis secondary to focal epilepsy, MDD with psychotic features, and a stress-induced relapse of a pre-existing primary/affective psychosis. There is no clear evidence that either paranoid schizophrenia or type I bipolar disorder are associated with brain tumor whether in cause or effect. In the fast-moving environment after presentation to hospital however, on occasion the clerking medical history may be incomplete, especially for historical psychiatric episodes.

LABORATORY INVESTIGATION. Treat the patient as per any severe psychotic episode, with the addition of trying to reduce or stop the offending steroid.

Telegram: @medical_k

www.konkur.in

Physical investigations to consider as the clinical situation allows are those relevant to delirium and the major primary psychotic syndromes. If obtainable, an EEG may be clinically useful. Epileptogenic foci in deep frontal lobe structures can occasionally present with a bizarre behavioral syndrome that looks quite unlike either a classical generalized or focal seizure with impaired awareness.

COURSE AND PROGNOSIS. Psychotic symptoms should abate with the combination of antipsychotic and a lowering or reduction of steroid dose. If there is no evidence of improvement, perhaps particularly in patients with schizophreniform features, consider the possibility of an emergent or previously undiagnosed psychotic illness such as schizophrenia or bipolar I disorder. In this situation, a detailed family history may be of additional value. Coemergence of the catastrophic events of brain tumor and a primary psychosis is rare but does occasionally happen in younger patients. The literature on this topic consists almost entirely of single case reports and there is currently no robust evidence that it is anything other than a coincidence of timing.

The literature is similarly sparse on prognostic guidance. What evidence there is suggests that prior steroid-induced psychosis may not accurately predict the likelihood of future episodes. Unlike, say, puerperal psychosis where a previous episode greatly increases the future risk, florid psychic reactions to corticosteroids appear to be largely idiosyncratic both between individuals, and within the same individual over time.

TREATMENT. If possible, the corticosteroid should be reduced or stopped. This may well have consequences such as the re-emergence of cognitive or neurologic symptoms and the decision rests on a balance of risks specific to each individual case. Check with the treating medical or surgical team before changing the steroid dose. Sometimes the risk of changing it may be deemed too high, for example, in the case of a brainstem tumor threatening to compress respiratory centers.

Standard nonpharmacologic methods to reduce patient agitation, anxiety, and disorientation can be applied. These methods are identical to those used widely for delirium and dementia and include nursing by familiar faces, adequate ambient lighting, regular reassurance and reorientation, and de-escalation and gentle distraction when necessary. Antipsychotic medication is also indicated. Brain tumor

Telegram: @medical_k

www.konkur.in

patients are likely to be antipsychotic naive; they are also at high risk of epilepsy. Neither efficacy nor the risks of causing a dystonic reaction or epileptic seizure by prescribing any antipsychotic to brain tumor patients are conclusively known. Case studies in varying clinical populations have reported successful treatment with haloperidol, quetiapine, risperidone, olanzapine, or aripiprazole. If the patient is manic, a mood stabilizing agent may also be required (e.g., sodium valproate, or lithium). If the patient is depressed, TCAs are best reserved for second line: there is some evidence from older studies that these drugs may worsen symptoms. The successful use of ECT for steroid-induced psychotic depression has been reported.

The acutely disturbed brain tumor patient who presents an immediate danger to themselves or others should be managed according to local rapid tranquillization protocols. Such extreme situations are rare. If an intramuscular injection is necessary to rapidly sedate the patient, close nursing observation is essential afterwards. Always consider risk and communicate and document decisions on risk mitigation, as for any psychiatric patient. The patient should be reviewed regularly by the psychiatrist, since the neuro-oncology team may wish to restart steroids. It is probably sensible to seek to minimize the future doses of both corticosteroid and any ongoing antipsychotic as a starting point. Clinicians should also check that the patient's carers know how to contact services in the event of any future emergency.

Personality, Cognitive, and Behavioral Change. Personality, cognitive, and behavioral changes are among the most distressing symptoms for families and carers. Evidence specific to brain tumor patients on how best to manage these problems has however been lacking. Defining "personality change" is not entirely straightforward and studies make variable use of questionnaires about changes in attitudes, objective behavior, and/or cognitive function. It can be especially challenging to untangle the influence upon personality of cognitive function, which may be markedly affected by a brain tumor. In some cases it may be simpler to focus on the identification, formulation, and management of observable behavior.

EPIDEMIOLOGY. Personality changes are very frequent and reported across tumor subtypes, ages, and stages of disease. Studies conducted

Telegram: @medical_k

www.konkur.in

in various primary brain tumor populations report a point prevalence ranging from between 16% in patients with low-grade oligodendroglioma during follow-up to over 70% in patients with primary CNS lymphoma. In general terms, only a minority of patients will present with clear behavioral symptoms from the outset and they probably become more common as the disease progresses. Behavioral symptoms are highly prevalent in the palliative stage of glioma. There is no evidence in adult patients that men and women are affected differently.

In practice, cognitive symptoms are meanwhile very common following radiotherapy. A heuristic working model is that radiotherapy can particularly affect elements of executive function and information processing. The academic literature on postradiation neurocognitive impairment, however and perhaps surprisingly for an anecdotally prevalent issue, is contradictory and difficult to concisely summarize. Discrepancy between study outcomes may arise from the many confounding variables including: often retrospective study designs; tumor type, location and extent of response to radiotherapy; level of patient fatigue, depression, or effort; and differences in cognitive outcome measures. Higher radiation doses, broader radiation fields, and radiation delivered to children or the older adults may confer higher risk of cognitive impairment. Interested readers are directed to the recent review by Koutsarnakis et al. as an introduction to the difficulties of accurately studying this topic.

ETIOLOGY. Patients with brain tumors report significantly more post-operative subjective emotional changes compared to non–brain tumor postsurgical controls. Irritability and mental inflexibility may be particularly common in the early period postsurgery. In the longer term, it is not uncommon to see a “coarsening” of pre-existing personality traits, or childlike dispositions.

Unlike in neurology—where destruction of a critical circuit or nucleus may cause predictable “hard” neurologic signs—in neuropsychiatry the relationship is often less clear. One does see references linking tumor lobe location (e.g., “the frontal lobe”) with specific psychopathology, but these are usually general statements repeated from venerable older textbooks or historical small case series. More recently, it has been recognized that the brain is organized primarily in circuits and small-world networks, not siloed lobes.

Telegram: @medical_k

www.konkur.in

It is possible that behavioral correlates of frontotemporal–subcortical circuits may include apathy (ventromedial prefrontal cortex), lability or disinhibition (orbitofrontal cortex), or aggression and paranoia (medial temporal lobes). However, unpicking the role of tumor upon the functionality of a specific brain circuit is difficult and consequently, the question of whether a tumor is “causing” personality or behavior change is often unresolved. There is a lack of high-quality evidence to underpin simplistic or blanket assertions. Recent studies have used sophisticated neuroimaging to link tumor location with behavioral phenotype, but consist mainly of case reports. It is plausible that critically located tumors may have specific neuropsychiatric consequences (see case study below), but in practice the etiology of personality change is messier, difficult to prove, and potentially encompassing biologic, psychological, social, and iatrogenic causes. Depressive and anxiety symptoms, too, are associated with poorer attention and processing speed in primary brain tumor patients receiving radiotherapy.

Table 2.3–5.
Major Neurocognitive Disorder Due to Another Medical Condition (294.11)

Evidence of significant cognitive decline from a previous level of performance in one or more cognitive domains—such as complex attention, executive function, learning, memory, language, perceptual-motor, or social cognition

This evidence should consist of:

- Concern of the individual, a knowledgeable informant (such as a friend or family member), or the clinician that there's been a significant decline in cognitive function; and
- A substantial impairment in cognitive performance, preferably documented by standardized neuropsychological testing. If neuropsychological testing is not available, another type of qualified assessment is accepted

The cognitive deficits interfere with independence in everyday activities (e.g., requiring assistance with complex instrumental activities of daily living, such as paying bills or managing medications)

The cognitive deficits do not occur exclusively in context of a delirium, and are not better explained by another mental disorder

This diagnosis should be used to code for brain tumor-associated personality and behavioral change which is felt to be driven primarily by cognitive impairment.

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:729, 730.

DIAGNOSIS AND CLINICAL FEATURES. For some patients the appropriate DSM-5 diagnosis will be **Personality Change Due To Another Medical Condition** (310.1). Where the dominant feature underlying the behavioral syndrome is judged to be neurocognitive dysfunction, a more appropriate diagnosis may be **Major (or Mild) Neurocognitive Disorder Due To Another Medical Condition** (294.11 or 331.83, Table 2.3–5). To illustrate, a case study of one of the author's patients is briefly presented in the box below and Figure 2.3–3.

Telegram: @medical_k

www.konkur.in

A 54-year-old female professional manager, who had been previously well, presented abruptly with a cluster of generalized tonic–clonic seizures. Brain MRI revealed a nonenhancing diffuse cortical lesion in the medial aspect of the left temporal lobe. The left hippocampus was abnormal and swollen. A glial series tumor was suspected, but acute changes related to seizures could not be excluded. A short period of follow-up with repeat scanning was recommended. Repeat MRI subsequently showed an increase in size and enhancement of the mass. Following surgical biopsy, neuropathologic testing was unable to fully characterize the tumor. Further surgery was considered too risky due to lesion location. A grade III (anaplastic) glioma was presumed from key molecular characteristics although lymphoma could not be excluded.

Initially, the only psychiatric symptoms displayed by the patient were anxiety attributed to the uncertainty regarding diagnosis, and perhaps some mild forgetfulness which was regarded as very subtle by her husband and clinically negligible by her treating team. She remained well with no physical complaints or clinical evidence of disease. She received treatment of the presumed anaplastic glioma with radiotherapy and chemotherapy.

A few months after initially presenting she was referred to neuropsychiatry. She had symptoms of normal grief—denial, waves of sadness, anger, and bargaining—but also some new depressive symptoms which were unusual for most people in her situation: anhedonia, early morning wakening, deriving no pleasure from food, and worsening anxiety. She commenced mirtazapine for a presumed depressive disorder. This led to improvements in sleep, appetite, and partially mood, though grief at the loss of future time with her family remained prominent. She was referred to neuropsychology but declined cognitive assessment. Six months after her initial presentation, she had returned to work—from home and part-time—successfully doing remote administrative tasks. She felt back to around 80% of her old cognitive functioning. She continued to participate in psychiatric follow-up with no evidence of significant cognitive impairment in general conversation. MRI scans from this time revealed reduced tumor volume in the left temporal region and minimal residual enhancing disease elsewhere (Fig 2.3–3A).

Telegram: @medical_k

www.konkur.in

Her personality markedly changed over the next 4 months. Gradually, anxiety increased further with the onset in particular of repetitive questioning. She could not be satisfied with answers, asking her husband questions again only minutes after they had been answered. She became very agitated at times and was admitted to hospital in high distress on two separate occasions. On closer questioning her husband reported the gradual but progressive onset of memory difficulties. Further psychiatric review was arranged. On assessment, there was a new dense anterograde and partial retrograde amnesia. She was aware of having a brain tumor but was now unable to remember previous psychiatric appointments or discussions. Her ability to register and learn new material was intact, but she was completely unable to recall or even recognize it after a few minutes. Strikingly when shown a clock face she had drawn minutes before, she looked bewildered and said, “When did I draw that?”

Repeat MRI and neuroradiologic review confirmed tumor recurrence in the left temporal lobe, notably with extensive, progressive tumor now also in the midline, at the anterior columns of the fornices and foramina of Munro (Fig 2.3–3B). The clinical finding of new-onset anterograde amnesia—a form of nonalcoholic Korsakoff syndrome—was most likely attributable to the forniceal location of progressive tumor.

This lady’s case is an unusual example of tumor in an anatomically critical location causing a discrete and identifiable neuropsychiatric syndrome. Her personality changes of intractable anxiety, repetitive questioning, and severe agitation were secondary to a near-complete anterograde amnestic deficit. It is more commonly the case that tumor location and psychiatric phenotype are not so clearly linked. *The author is extremely grateful to the patient and her husband who both consented to this anonymized summary being presented for teaching purposes.*

Assessment of behavioral change should be person-centered, encompassing behavioral analysis, cognitive functioning, and assessment of the patient’s emotional state. Assessment by both neuropsychiatry and neuropsychology is recommended. Reversible causes should be excluded or addressed including depression, anxiety, delirium, epilepsy, hypoxia,

Telegram: @medical_k

www.konkur.in

hypoglycemia, pain, confusion, or frustration at physical or communication deficits. Brain tumor medication may contribute to unwanted behavioral symptoms, including a disinhibition syndrome secondary to corticosteroids or ASMs. The ASM levetiracetam has been reported to have association with increased irritability in some patients. However, these medications may also be essential for control of brain edema or epilepsy, and full discussion with the treating team is vital.

One should aim to identify and characterize the main behavioral syndrome. A collateral history from a carer who knows the patient well is essential. The problems most likely to be reported are anger, apathy, emotional lability, or disinhibited behavior. Establish the patient's premorbid personality and behavioral characteristics and confirm that the emergence of the troublesome behavior aligns with the timeline for presentation or treatment of the brain tumor. The new behavior may be context-specific but should persist over time. An assessment of exacerbating and alleviating factors may suggest strategies for treatment.

DIFFERENTIAL DIAGNOSIS. The psychiatric differential includes delirium, chronic pain, substance dependence, MDD, and GAD. The psychiatrist should consider reversible causes and the possible role of any medication.

LABORATORY INVESTIGATION. Physical investigations should be targeted at reversible medical causes. They may include as appropriate: standard hematologic and biochemical screens for causes of delirium; pulse oximeter reading to exclude hypoxia (DVT/PE is very common in these patients); blood-glucose measurement to exclude steroid-associated diabetes and consequent hypoglycemic episodes; chest x-ray to exclude chest infection or DVT/PE; and a repeat head CT or MRI to exclude tumor progression or intratumoral bleed.

COURSE AND PROGNOSIS. There is limited observational evidence of the longitudinal evolution of personality changes in adult brain tumor patients. Anecdotally once established these symptoms tend to persist and are difficult to treat. The patient's family can learn effective behavioral management strategies to mitigate the causes and consequences of the patient's symptoms. Psychiatry and psychology services may helpfully contribute by teaching and reinforcing these strategies, prescribing

Telegram: @medical_k

www.konkur.in

medication if necessary to manage any unacceptable risks to the patient or carers, and signposting carers to trusted support services.

TREATMENT. Few RCTs have studied interventions for behavioral syndromes in brain tumor patients. A single-center randomized control trial showed some benefit from a home-based psychosocial intervention combining neuropsychological assessment, psychological therapy, and a person-centered approach to treatment (see Ownsworth et al.). In general however, there is a lack of specific therapy resources tailored to problematic behaviors in brain tumor patients. Clinical management is mostly based on discussion with the patient and family and a tailored behavioral approach with carer education and support. Many situations can be managed acceptably by treating reversible causes, educating the patient and carer, and using behavioral strategies. A range of nonpharmacologic management strategies, which are not specific to brain tumor but likely to be generalizable across patient groups, are provided in the narrative review by Leppla et al. (see Further Readings).

In terms of medication, there is currently little high-quality brain tumor-specific evidence to guide practice. As always, one would weigh the risks and benefits of treatment and consider empirical therapeutic trials. Depression and anxiety symptoms should be sought and treated where possible. Where the main problem is cognitive impairment, a trial of a psychostimulant such as methylphenidate or modafinil should be weighed against the risk of causing seizures in these vulnerable patients. In settings of severe uncontrolled disinhibition, options may include treatment with a mood stabilizer such as lithium, carbamazepine, or valproic acid. Explosive anger characteristic of acquired brain injury might respond to β-blocker such as propranolol, if the patient is physically able to tolerate it. Low-dose risperidone has been reported as of some benefit in a case study set in palliative care. Other single-case studies have reported improvement in psychomotor retardation, abulia, and apathy after experimental treatment with dopamine agonists such as bromocriptine. Behavioral agitation associated with the terminal stages of disease can be complex to manage, and palliative care / hospice services should be involved.

A small number of RCTs have examined cognitive rehabilitation strategies for tumor- and treatment-associated cognitive dysfunction (e.g., Gehring et al.). These trials were not aimed specifically at the problem of

Telegram: @medical_k

www.konkur.in

personality change, but cognitive changes may often affect behavior. Cognitive rehabilitation techniques might therefore be of use in treating personality or behavior change in these patients. They can be delivered successfully both in the early postoperative and the later outpatient phases of tumor treatment. In general, studies show that while these treatments can lead to significant improvements, they are usually limited to narrow psychometric parameters (e.g., attention and visual memory). It is unclear whether cognitive retraining is effective for more complex social behaviors underpinned by executive function and impulse control, and "real-world" outcomes like return to work are largely unstudied.

Some studies have also tested the efficacy of medications for the treatment or prevention of cognitive changes in brain tumor patients. Methylphenidate, modafinil, and donepezil have shown some efficacy in small phase II RCTs. These studies recruited general samples of brain tumor patients rather than targeting those with frank behavioral disturbances. They showed modest improvements in relatively narrow neuropsychological parameters, again mostly attention and some aspects of memory. The clinical utility of these treatments has not been studied in large phase III studies. Psychiatrists may consider therapeutic trials as appropriate in individual patients.

Childhood Brain Tumor Survivors. Brain tumors are the leading cause of mortality from childhood cancer. Childhood brain tumors however show major differences from adult tumors in molecular characterization, histology, intracerebral location, and prognosis. Epidemiologic datasets report 5-year survival rates of pediatric brain tumor in the region of 80%. Increasing life expectancies have potential to increase the personal and societal impact of neuropsychiatric morbidity on quality of life and cognitive function. Survivors of childhood brain tumors can display complex symptoms and disabilities, at the crux of which are the long-term cognitive effects of surgery, radiotherapy, and chemotherapy on the young developing brain.

EPIDEMIOLOGY. Keng et al. reported a recent systematic review of the neuropsychiatric consequences of pediatric brain tumor (see References). They discussed acute and longer-term cognitive deficits, and a range of emotional and behavioral disorders including depression, anxiety, somatization, distress, and ADHD.

Telegram: @medical_k

www.konkur.in

Acute Cognitive Deficits. Cerebellar mutism (posterior fossa syndrome) is a common early complication of childhood brain tumor resection, arising in the first few days postoperatively, and characterized by postoperative mutism and reduced speech. Reported risk factors include medulloblastoma histopathology, brainstem involvement, midline location, larger tumors, periventricular ischemia, higher mean body temperature in the first few days after surgery, and lower socioeconomic status. Cerebellar mutism usually recovers within months but has the potential for ongoing deficits in IQ, memory, and learning.

Longer-Term Cognitive Deficits. Late (>1 year) cognitive outcomes have received the most attention. Although some recovery can be expected, childhood deficits have long-term impacts on psychosocial development. IQ is hard hit with scores approximately 1 to 2 *standard deviations* lower than population norms. Other studies report deficits across cognitive domains with impaired attention, visuospatial function, memory, learning, processing speed, and/or executive function/planning. Some clinical variables have been associated with poorer cognitive outcomes including younger age of treatment, medulloblastoma histopathology, supratentorial location, receiving chemotherapy, and a history of uncontrolled epilepsy. However at an individual level it is difficult to predict which children will face the greater impairments later in life.

Emotional and Behavioral Disorders. A recent meta-analysis indicates that survivors of pediatric brain tumors have relatively higher levels of depressive symptoms, anxious symptoms, and general distress than healthy comparison groups. Other reviews report that behavioral and social problems may be common at school, and that survivors tend to report lower amounts of physical activity than peers. Estimates of ADHD prevalence in childhood brain tumor survivors range from 9% to 23.8% in association particularly with a history of adjuvant cranial radiation, intrathecal chemotherapy, and corticosteroid use.

Among adult survivors, frequency estimates for affective symptoms range from 9% to 18% with potentially a high prevalence of suicidal ideation. Survivors with depression, anxiety, or somatization report lower quality of life and greater psychoactive medication use. Evidence is currently scarce to draw firm conclusions about PTSD, eating disorders, mania, psychosis, or catatonia.

Telegram: @medical_k

www.konkur.in

ETIOLOGY. In acute pediatric neuro-oncology, posterior fossa syndrome has been associated with abnormal functional neuroimaging in mute postoperative patients, with observation of global supratentorial cortical hypoperfusion akin to a cerebello–cerebral diaschisis. These abnormalities affect multiple supratentorial sites during the acute episode and appear to resolve as the mutism resolves.

Several cellular mechanisms may explain persisting neurocognitive impairment in childhood survivors. Radiotherapy to the brain adversely affects neural stem cell proliferation and neurogenesis in the rodent hippocampal subgranular zone. The precise functional contribution of postnatal neurogenesis to human cognition is not yet clear, but it is likely that the impact of radiotherapy is functionally relevant in humans too, given key hippocampal roles in modulating learning, memory, and emotion. A second vulnerable cell population may be oligodendrocyte precursor cells (OPCs). These cells generate oligodendrocytes which ensheath neurons in myelin. They support the biologic integration and normal functioning of white matter tracts which may be critical to cognition. Animal and human studies suggest that OPCs are vulnerable to the effects of chemotherapy.

Genetic studies provide some preliminary evidence that children with a history of cranial radiotherapy and COMT gene heterozygosity (Val/Met) may have better working memory than patients with COMT gene homozygosity (Met/Met or Val/Val). Structural candidates include supratentorial white matter tract changes with loss of volume and atrophy of cortical and subcortical structures correlating to poorer functioning. Meanwhile functional magnetoencephalography (MEG) data suggest that loss of high-frequency resting-state and task-oriented gamma oscillations may be associated with greater cognitive impairment and slower processing speeds in children undergoing radiotherapy. The clinical utility of these and other recent discoveries remains to be shown.

DIAGNOSIS AND CLINICAL FEATURES. Posterior fossa syndrome consists of cognitive, emotional, and behavioral disturbances characteristically presenting in the days following cerebellar surgery. Mutism can be present to varying degrees (milder cases may be dysarthric) but is often complete. Patients may have shown similar, if less marked, symptomatology preoperatively. Whether such preoperative abnormalities might indicate a higher risk of developing the post-surgical syndrome is currently unknown.

Telegram: @medical_k

www.konkur.in

The PFS typically moves from complete mutism, through a period of cerebellar dysarthria, to resolution. The few case studies or small series charting its recovery suggest that this period can often be measured in weeks, rather than days or months. Even after 1 year however, many children who have recovered from PFS may remain cognitively impaired in multiple domains. Whether the PFS is a risk factor for even greater cognitive impairment than normal for adult survivors is currently unclear.

In brain tumor survivors, psychiatrists should carefully consider the contribution of subtle cognitive impairments which can persist for many years. These impairments are often dysexecutive, with working memory, attention, and processing speed commonly lower than normal levels for the patient's age and developmental stage. Deficits may become more apparent with age.

DIFFERENTIAL DIAGNOSIS. Children presenting acutely with an apparent PFS should receive an MRI brain scan to rule out post-operative bleeding or cerebral edema. In the longer term the psychiatric differential will depend on the particular syndrome presented by the individual patient. Considering a general syndrome of subtle cognitive dysfunction in young adult, treatable conditions to be excluded may include MDD, anxiety, and alcohol or drug use or dependence. Medical causes to exclude will depend on the specific presentation, but the general health of these patients is often poor. In particular, hypertension, diabetes, and endocrine abnormalities secondary to radiation-induced pituitary dysfunction should be excluded. Some forms of chemotherapy can cause deafness which may contribute to psychosocial or emotional difficulties. It may help to quantify cognitive deficits through formal neuropsychological assessment.

COURSE AND PROGNOSIS. The literature on the neuropsychiatric sequelae of childhood brain tumor is richer than it is for adults, both in the number of longitudinal studies and in the broader emphasis on psychosocial outcomes. It is clear that many childhood brain tumor survivors have considerable impairments of cognitive and emotional functioning. Attention, working memory, and processing speed may all remain affected. These impairments may manifest as social, educational, and vocational disability. Reading, spelling, and arithmetic may all be affected. Impaired emotional functioning with increased anxiety is seen in some children with some evidence of defective cognitive processing of

Telegram: @medical_k

www.konkur.in

emotions. Behavioral problems may manifest at school including aggression and possibly a higher level of somatization. Peer relationships suffer accordingly and adaptive and developmentally important behaviors such as communication and socialization are often adversely affected. Patients may report cognitive and behavioral difficulties that do not fully meet diagnostic thresholds, suggesting a large hidden morbidity.

In late adolescence and adulthood, the general picture is similar. Medulloblastoma survivors are highly likely to need some form of accommodation for acquired impairments in learning skills. The physical health of this group can be very poor. Hearing impairment, secondary cancers, diabetes, hypertension, and endocrinopathies may be common. Many patients are likely to remain dependent on parental income into their fourth decade. One-third of adult survivors of posterior fossa tumors display clinically significant levels of apathy. Themes of impaired identity formation, social isolation, difficulty securing financial independence, and limited career options are common in young adult survivors generally. Completion of higher education is relatively rare. Unemployment is often the norm, although by no means universal and if there is a glimmer of silver lining it is that despite an often-formidable array of psychosocial disadvantages, most adult patients will be functionally independent in daily life.

TREATMENT. Treatment of Posterior Fossa Syndrome is mostly supportive. In cases that do not recover as expected, a trial of the hypnotic Zolpidem may be of value. Families should be informed of the often gradual process of recovery, and where needed should be supported in making arrangements for their child returning to school. The condition can have a considerable impact on cognitive skills at a critical period for educational and social development, so detailed neuropsychological testing is valuable.

Treating chronic, biologically mediated, multimodal impairments that present in the longer term is difficult. A person-centered, problem-focused, and realistic approach is recommended. In adult survivors, neuropsychological assessment will help inform treatment plans ideally developed in a collaboration of psychology, psychiatry, the patient, and carers. Other professions including occupational therapy, physiotherapy, and dietetics may be involved. If the neuro-oncology team is still following the patient up they should be consulted; they will know the patient better

Telegram: @medical_k

www.konkur.in

than nearly any other professional service. Recommendations and adaptations should be feasible to implement.

Specifically, cognitive rehabilitation—structured exercises to boost cognitive skills—has some evidence for efficacy in childhood survivors. Improved executive and memory skills are seen particularly in the domains of attention, processing speed, cognitive flexibility, and declarative memory. As with adults, the “real-life” impact of these interventions is largely unknown: the literature consists mainly of small pilot studies that did not examined impact on broader educational and social attainment.

Empirical medication trials can be considered for neurocognitive impairment in survivors. There is some evidence that the psychostimulant methylphenidate may improve attention and behavior, in the short term, in childhood survivors of brain tumor. Boys, those of older age, and a higher baseline IQ may respond better. It has not been consistently shown to improve educational performance. The acetylcholinesterase inhibitor donepezil has limited evidence of efficacy for executive and memory impairments. It is important to stress that evidence underpinning drug treatment is, again, limited in this situation. A therapeutic trial may form part of a holistic treatment package, but given the empirical nature it should be time-limited, reviewed regularly, and discontinued if unsuccessful. Primary psychiatric syndromes arising in adult survivors should be treated as outlined above.

As well as treating established dysfunction, researchers are exploring strategies that may help minimize neurologic damage at the time of primary treatment. In particular, hippocampal-sparing radiotherapy schedules have recently been associated in both pediatric and adult brain tumor patients with better preservation of cognitive functioning. A full understanding of the clinical scope and limitations of hippocampal-sparing radiotherapy will require further study, but they hold promise for the future.

FUTURE DIRECTIONS

Clinical

There is increasing awareness of the potential for benefit of multidisciplinary neurorehabilitation for adult and pediatric brain tumor patients. Among the wide range of patients with differing types of primary brain tumor, those with persisting disability but a medium- to long-term life

Telegram: @medical_k

www.konkur.in

expectancy may derive considerable benefit. The evidence in support of multidisciplinary interventions is largely observational and therefore at a high risk of bias. Available studies tentatively suggest that multidisciplinary rehabilitation for brain tumors can be effective, particularly for improving some functional outcomes, vocational skills, and quality of life. It is difficult to design and successfully conduct trials that provide integrated care to such a complex population. A recent U.K. study has however shown the feasibility of delivering multimodal lifestyle coaching interventions to highly fatigued brain tumor patients. This study is, notably, the first to selectively target highly impaired patients in an attempt to modify aspects of quality of life—an important nettle to grasp when one seeks evidence of how to treat highly impaired patients in clinic.

A strong case can be made that psychiatrists have a critical role to play in growing this evidence base. Psychiatrists, especially consultation-liaison and neuropsychiatrists, have sophisticated transferable professional skills that are relevant to both neuro-oncology and rehabilitation. These skills include experience working in a multidisciplinary environment; the mindset, technical abilities, and time required to conduct comprehensive and holistic person-centered assessments; and knowledge of how to manage chronic and complex illnesses affecting vulnerable individuals. They also have direct expertise in the assessment and management of the many cognitive and psychiatric problems which very commonly affect these patients. They may have experience of developing and delivering behavioral treatment plans.

Despite the strong case for involving psychiatry in neuro-oncology, the current clinical reality in most centers is that neuro-oncology, neurorehabilitation, and neuropsychiatric services remain separate. There are exceptions but mostly these systemic divisions are a natural consequence of separate service evolution. They create practical barriers to clinical integration. Resistance to the idea that brain cancer patients can be meaningfully rehabilitated is common, if almost certainly wrong. One consequence is that psychiatric diagnoses may be missed in surviving patients. Skilled and caring clinicians nonetheless may think something like “I’d be depressed if I had a brain tumor”; patients themselves may be reluctant to “bother the doctor” with emotional symptoms; and the pressure of time in a busy neuro-oncology clinic may well mitigate against a thorough exploration of psychiatric symptoms. One solution to these problems would be for psychiatrists themselves to

Telegram: @medical_k

www.konkur.in

recognize and make the case for their skills in managing brain tumor patients. There is a clear need for psychiatry, both in established acute neuro-oncology, and in emerging rehabilitation neuro-oncology teams.

Research

The presence of a brain tumor distorting and destroying critical cerebral pathways poses questions for traditional diagnoses of some kinds of mental disorder. Part of the challenge therefore lies in testing and where necessary refining diagnostic criteria. Large, longitudinal studies will inform better prognostication. The relative rarity of brain tumors should promote multicenter collaborations. Research is also needed into mechanisms that contribute to the risk, onset, maintenance, and resolution of brain tumor-associated neuropsychiatric disorders. The unique clinical context means these mechanisms should be studied in brain tumor patients specifically. A third high-value area will be in finding effective treatments for neuropsychiatric disorders, by RCTs conducted in brain tumor patients specifically. These are by no means easy to conduct in such an impaired population, but will be essential to be sure that treatments work in the context of the many difficulties of having a brain tumor.

ACKNOWLEDGEMENTS

With thanks to Dr. Robin Grant, Prof. Alan Carson, and the Edinburgh Centre for Neuro-Oncology for many years of support.

2.4 Neuropsychiatric Aspects of Epilepsy and Psychogenic Nonepileptic Seizures

MARIO F. MENDEZ, M.D., PH.D., LEILA PARAND, M.D., AND GASTON BASLET, M.D.

NEUROPSYCHIATRIC ASPECTS OF EPILEPSY

Clinicians have reported associations between epilepsy and psychiatric disorders since antiquity. In modern times, however, many clinicians are unfamiliar with these associations and the unique challenges involved in their management. The development of new antiepileptic and psychiatric therapies and novel neuroimaging techniques makes understanding the association between epileptic seizures and psychopathology increasingly important. Psychiatrists and neurologists are increasingly investigating the neuropsychiatric aspects of epilepsy, as exemplified by the amount of new research and publications in this field.

Epidemiologic data support an increased risk for psychiatric comorbidity among epilepsy patients as compared to nonepileptic patients. The most established association is between epilepsy and depression or dysthymia, but a range of psychopathology occurs in one-fourth or more epilepsy patients. For example, epilepsy is associated with anxiety disorders, somatic symptom disorder, personality changes, hyposexuality, and, perhaps most dramatically, several forms of psychosis. These behaviors and others have different potential relationships to the ictus or seizure itself. Psychiatric manifestations may result directly from ictal discharges (e.g., psychic auras), as peri-ictal phenomena (e.g., postictal confusion), interictally or between seizures (e.g., interictal psychosis), or with a variable and less-established relationship to the seizure discharges (e.g., most mood disorders).

Psychiatric comorbidity has a serious impact on the quality of life and well-being of patients with epilepsy. Psychiatrists and neurologists need to

Telegram: @medical_k

www.konkur.in

maximize positive (e.g., mood-stabilizing) and minimize negative psychotropic effects of antiepileptic drugs (AEDs), consider the seizure threshold lowering effects of some psychotropic medications, and monitor the potential interaction of antiepileptic and psychotropic drugs. Before committing patients to antiepileptic treatment, psychiatrists and neurologists must also be able to distinguish epileptic seizures from other spells, particularly psychogenic nonepileptic seizures.

Definition

Seizures are sudden, involuntary behavioral events associated with excessive or hypersynchronous electrical discharges in the brain. The seizure itself is known as the *ictus.* The *interictal period* refers to the period between the postictal abnormalities and the next ictus, and the *peri-ictal period* refers to the period just before or after the ictus and is applied when there is insufficient information to know when the ictus ends or begins. Seizures can be symptomatic of a transient or physiologic disturbance. They may also have a genetic basis or can be caused by an acquired insult such as trauma, stroke, inflammation, or neoplasm. Symptomatic seizures are not equivalent to epilepsy. *Epilepsy* is a disease of the brain most commonly characterized as having at least two unprovoked or reflex seizures occurring greater than 24 hours apart. *Status epilepticus* is prolonged (>5 minutes) or two or more seizures in a 30-minute period without an intervening recovery.

In epilepsy, abnormal electrical discharges are due to hyperexcitable neurons with sustained postsynaptic depolarization. Proposed mechanisms for this sustained depolarization include changes in ionic conductance, decreased gamma-aminobutyric acid (GABA) inhibition of cortical excitability, and increased glutamate-mediated cortical excitation. In animals, alumina-induced membrane changes alter the ratio of intracellular to extracellular ionic concentrations and result in abnormal neuronal firing. AEDs, such as phenytoin (Dilantin), carbamazepine, and valproate, reduce this repetitive firing through effects on sodium channels. Ethosuximide (Zarontin) works through the blockage of calcium currents. Penicillin-induced cortical injury causes seizures through decreased GABA inhibition. Barbiturates and benzodiazepines may reduce seizures by enhancing GABA receptor current, and valproate may also block GABA catabolism. Kainic acid, a glutamate agonist, induces seizures through increased synaptic action at its *N*-methyl-D-aspartate (NMDA)

Telegram: @medical_k

www.konkur.in

receptors. Work is underway on potential AEDs that may work through inhibition of this excitatory receptor mechanism.

FIGURE 2.4–1. Electroencephalogram demonstrating the focal onset of seizure discharges from the left frontotemporal region that are consistent with the onset of focal seizures with impaired awareness.

The electroencephalogram (EEG) is a surface recording of brain wave activity used in the evaluation of seizures. Basic waves include normal waking alpha waves (8 to 13 Hz), which are most prominent over the occipital region, high-frequency beta waves (greater than 13 Hz), theta waves (4.0 to 7.5 Hz), and delta slowing (3.5 Hz or less). Seizures are manifest as multiple spikes or spike-and-wave discharges on the EEG (Fig. 2.4–1). A spike is a sharp transient with a duration of 20 to 70 milliseconds. Interictally, single spikes and other markers of abnormal electrical activity may be seen, often emanating from a temporal lobe.

History

In his book on epilepsy, *On the Sacred Disease,* Hippocrates (460 to 377 BC) attacked the prevailing belief that those afflicted with epilepsy were possessed by gods or goddesses. He proposed that epilepsy was a brain disease caused by the blockage by phlegm of air-carrying vessels to the brain. Despite this initial view, throughout most of human history, epilepsy constituted demonic possession or the accumulation of bad humors, and attempts at exorcism involved trephination, cautery of the back of the skull, diuretics, emetics, bloodletting, purging, sweating, and even intercourse to release sperm. In the 18th century, the first so-called scientific treatise on epilepsy since ancient times attributed seizures to masturbation. By happenstance, bromides, which were introduced to

Telegram: @medical_k

www.konkur.in

diminish libido and masturbation, proved to be the first successful antiepileptic medication. With the development of effective AEDs and the introduction of EEG, physicians have come full circle to Hippocrates' belief that epilepsy is rooted in organic brain disease.

The purported association of epilepsy with behavioral disorders also dates to antiquity. The brain was the seat of "the falling sickness" and of "madness," and both were related to phlegm. With demonic possession as a form of punishment, unusual or abnormal behaviors became associated with seizure patients, even during their seizure-free periods. At the turn of the 20th century, the psychiatric writings of Emil Kraepelin emphasized that epilepsy patients possessed personality changes and a predisposition to psychosis. With a greater understanding of the physical basis of epilepsy, many clinicians sought to protect epilepsy patients from the demonic stigma of their disease; in their view, psychiatric problems resulted from the psychosocial difficulties associated with having seizures rather than any unique relationship of epilepsy with psychiatric illness. The current age was initiated by the definition of temporal lobe epilepsy and the concept of a physiologic disturbance in the limbic or emotional brain.

Nosology

The classification and terminology of seizures were revised by the International League Against Epilepsy in 2017 to reflect updated advances in the understanding of epilepsy (Table 2.4–1). Seizures are classified based on the mode of etiology and mode of onset. Etiology can be grouped into genetic, structural–metabolic, and unknown. The mode of onset can be *generalized* or *focal.* Generalized onset seizures are those with an initial widespread bihemispheric involvement, and focal onset seizures are those that emanate from a focus limited to part of one hemisphere. In adults, most generalized seizures are *tonic–clonic* seizures (grand mal seizures or convulsions) and are characterized by an abrupt loss of consciousness with tonic rigidity followed by a synchronous, clonic release. Focal seizures (previously partial or localized seizures) can occur with or without impairment of consciousness or awareness. Simple partial seizure is an old term for focal onset without impairment of consciousness, whereas complex partial or dyscognitive seizure is an old term used for seizures with focal onset with impaired awareness. Focal seizures produce isolated motor, sensory, autonomic, psychic, or mixed symptoms in a clear sensorium. "*Auras*" refer to focal seizures without

Telegram: @medical_k

www.konkur.in

impaired awareness that involve subjective sensory or psychic phenomena without observed motor or autonomic changes. Focal seizures with impaired awareness usually manifest as motionless staring combined with simple automatisms or automatic motor activity and last approximately 1 minute. Focal seizures with impaired awareness can evolve to become a tonic, clonic, or tonic–clonic seizure. Finally, there is a form of generalized onset seizures, *absence* (petit mal) seizures, which occur less commonly in adults and manifest as brief lapses of consciousness. Absence seizures differ from focal seizures with impaired awareness in that they are generalized in the mode of onset. They also differ in that they are short (10 seconds in length) and repetitive; lack auras, postictal confusion, or complex automatisms; and have characteristic generalized two to four counts per second spike-and-wave discharges on EEG.

Adapted with permission of John Wiley & Sons from Fisher RS, Cross JH, French JA, Higurashi N, et al. Operational classification of seizure types by the International League Against Epilepsy: Position paper of the ILAE Commission for Classification and Terminology. *Epilepsia*. 2017;58(4):522–530. doi: 10.1111/epi.13670.

Most adults with epilepsy, regardless of seizure type, have an epileptic focus in the temporal lobe, and many generalized tonic–clonic seizures are secondarily generalized from a temporal lobe focus without a preceding focal seizure with impaired awareness.

Epidemiology

Seizure disorders are common and usually have an early onset. Epilepsy affects over 45 million people worldwide and has a prevalence of at least 0.62% and an annual incidence of approximately 0.06%. The overall incidence is high in the first year, drops to a minimum in the third and fourth decades of life, then peaks again after age 75 years. More than 75% of patients have their first seizure before 18 years of age, and 12% to 20% have a familial incidence of seizures. Among adults, the most common seizures are focal with impaired awareness and generalized tonic–clonic seizures. Focal onset is most frequent in the temporal lobes. The most common cause of new-onset seizures in adults is cerebrovascular disease.

Etiology

Diagnosing the specific cause can have important implications for management. Previous descriptions of idiopathic epilepsy are increasingly found to have evidence of specific genetic defects. Other frequent secondary causes include trauma in the third and fourth decades of life, neoplasms in the fifth and sixth decades of life, and cerebrovascular disease in the elderly. Although some focal seizures with impaired awareness originate from the frontal or temporal neocortex and other areas, at least two-thirds of these focal seizures and generalized tonic–clonic seizures originate from the mediobasal temporal limbic structures (hippocampus, amygdala, and parahippocampal gyrus).

Psychopathology. Epidemiologic studies from communities, psychiatric hospitals, and epilepsy clinics report a 20% to 60% prevalence

Telegram: @medical_k

www.konkur.in

of psychiatric problems among epilepsy patients. Psychiatric disorders often occur at rates two- to threefold or higher than in the general population without epilepsy. Epilepsy patients are prone to psychosis, mood disorders, especially depression, anxiety disorders, somatic symptom disorders, personality disorders, hyposexuality, and dissociative symptoms. These problems are approximately equally divided between those that occur actually or peri-ictally and those that occur interictally or are variably related to the ictus. The percentage of epilepsy patients in psychiatric hospitals is also higher than the general prevalence of epilepsy and ranges from 4.7% of all inpatients in a British psychiatric hospital to 9.7% in a U.S. Veterans Affairs psychiatric facility. Among patients attending epilepsy clinics, approximately 30% have a prior psychiatric hospitalization, and 10% to 20% are on at least one psychotropic drug. Furthermore, epidemiologic studies indicate increased interictal psychopathology among head-injured patients with epilepsy compared to head-injured patients without epilepsy. There exists a bidirectional relationship between psychiatric disorders and epilepsy, such that patients with epilepsy are more likely to develop depression than the general population, and patients with depression, anxiety, and psychosis are more likely to develop epilepsy. Despite criticisms of selection bias, these studies constitute a broad spectrum of sources that indicate greater overall psychopathology among epilepsy patients.

Do epilepsy patients have greater psychopathology than other similarly impaired patients? If this were so, then it would suggest that the psychopathology is of biologic origin rather than a less specific reaction to chronic disease. Although disputed by some investigators, several studies report more psychopathology among epilepsy patients than among patients with chronic diseases that do not directly affect the brain. Furthermore, the pattern of behavioral changes in seizure patients appears specific to epilepsy. For example, on the Minnesota Multiphasic Personality Inventory (MMPI) 2, patients with epilepsy score higher on the schizophrenia scale and paranoia scale than patients with other neurologic disabilities. In addition to a potential genetic overlap between epilepsy and psychiatric conditions, the neural networks for epilepsy and for psychoses appear to overlap considerably, potentially explaining some of the comorbidity.

Many studies found a special relationship to psychopathology in patients whose seizures emanate from mediobasal temporal lesions.

Telegram: @medical_k

www.konkur.in

Psychiatric disturbances, primarily psychosis and personality disorders, are two to three times more common in patients with focal seizures with impaired awareness, most of temporal lobe origin, compared to those with generalized tonic–clonic seizures. Other studies have failed to find a difference in psychopathology based on focal or generalized seizure onset. Major depression, dissociative symptoms, obsession, and compulsion were also seen more frequently in temporal lobe epilepsy compared to generalized epilepsy. Psychic auras from the temporal lobe, particularly if associated with negative feelings (e.g., *jamais vu* and fear), predispose to psychosis or personality disorders.

Psychosis. Psychosis is a specific psychiatric disorder associated with epilepsy. The lifelong prevalence of all psychotic disorders among epilepsy patients ranges as high as 12%. In a follow-up of 100 children with focal seizures with impaired awareness for as long as 30 years, of the 87 patients who survived to adulthood and who did not have intellectual impairment, 9 (10%) experienced a psychotic illness. In temporal lobectomy studies, in which there is the surgical removal of an epileptic focus in the temporal lobe, psychosis occurred in 7% to 8% of patients, even long after the seizures were arrested. The data from a meta-analysis also indicate that the prevalence of psychosis in temporal lobe epilepsy was 7%. That percentage is higher than in the other types of epilepsy (5.6%) and represents approximately a five- to eightfold greater risk of psychosis for epilepsy patients than for the general population.

In some patients, autoantibodies may play a role in psychotic symptoms in epilepsy. Data from studies found that specific autoantibodies, for example, anti-NMDA, anti–voltage-gated potassium channel (VGKC), and anti–GABA-B receptor ($GABA_B$), can be identified in up to 10% of patients with epilepsy and psychosis. Moreover, those patients who have autoimmune encephalitides usually develop convulsive seizures during the course of the illness.

Regarding lateralization and neuropathology, results from many studies suggest an association of a left-sided focus and hippocampal sclerosis with psychosis. Although conclusions derived from surface EEG recording are open to criticism, depth recordings of presurgical patients show that twice as many patients with left temporal lesions have psychosis. Data from studies using voxel-based morphometry analysis of magnetic resonance imaging (MRI) also show that patients with temporal lobe

Telegram: @medical_k

www.konkur.in

epilepsy and psychosis have more severe gray matter loss in the entire temporal lobe as well as in the left hippocampus, insulae, anterior cingulum, and left inferior parietal lobule. The results from white matter data further demonstrate white matter reduction in widespread brain regions. Finally, positron emission tomography (PET) scans and single-photon emission computed tomography (SPECT) scans may show predominant left temporal hypometabolism among epilepsy patients with psychosis.

Depression. The prevalence of depression in different studies varies from 7.5% to 34% of patients with epilepsy. This discrepancy is attributed to various diagnostic measurements and different definitions of depressive disorders across studies. Major depressive episodes can be found in up to 20% of the patients. Those with focal seizures with impaired awareness originating from the mesial temporal lobe and those with poor seizure control are more likely to have mood disorders. Psychological studies also suggest a greater incidence of self-criticism and depression among epilepsy patients with a left hemisphere focus. Patients with focal seizures of temporolimbic origin also have a higher incidence of depression than patients with other types of seizure disorders. Specific instruments are available for assessing depression among epilepsy patients, such as the Neurological Disorders Depression Inventory for Epilepsy (NDDI-E).

www.konkur.in

Table 2.4–2.
Psychic Auras

Type	Symptoms	Probable Source
Dysphasic[a]	Nonfluent	Left perisylvian language areas
	Impaired comprehension	
Dysmnesic	*Déjà vu, déjà vécu, déjà pensé, déjà entendu, jamais vu,* etc., prescience, illusion of memory	Mesobasal temporal,[b] especially on right
Cognitive	Dreamy state, altered time sense, derealization, depersonalization	Mesobasal temporal and temporal neocortex
	Forced thinking, forced actions, and altered or obscure thoughts	Frontal association cortex
Affective	Fear, anxiety, apprehension, depression, pleasure, displeasure	Mesobasal temporal and temporal neocortex
Illusions[c]	Macropsia, micropsia, teleopsia, movement, metamorphopsia, increased color intensity, increased stereopsis intensity	Lateral superior temporal neocortex, especially on right for visual illusions
Hallucinations[c]	Structured, hallucinatory remembrances, autoscopy	Mesobasal temporal and temporal neocortex

[a]Does not include speech arrest or simple vocalizations.

[b]Includes hippocampus, amygdala, and the parahippocampal gyrus.

[c]Includes interpretive (size, motion, shape, and stereopsis) or experiential (elements of past experience or involvement).

Other Behaviors. The prevalence of other specific behavioral disorders among patients with epilepsy is less well established. However, there is evidence to suggest that personality disorders, suicidal behavior, anxiety disorder, and hyposexuality are more prevalent among epilepsy patients than among those without seizure disorders.

Telegram: @medical_k

www.konkur.in

Pathophysiology. The relationship between seizures, psychiatric syndromes, and the mediobasal temporal lobes implies that many behavioral changes are more than psychological reactions to the psychosocial stressors of epilepsy. Stimulation and ablation studies in humans and animals link temporal limbic structures to emotion and behavior.

For example, temporal limbic stimulation in a person evokes psychic auras (Table 2.4–2) and automatisms, and amygdala stimulation and ablation in animals result in aggression or placidity. Moreover, psychotic behavior in cats occurs when their limbic structures undergo kindling (i.e., the repeated application of epileptogenic agents to induce lasting behavioral changes).

There are several potential causes of psychiatric disturbances in epilepsy (Table 2.4–3). First, the pathology itself could be the source of seizures and behavioral changes. Left hemisphere and temporal lobe lesions may be associated with interictal psychosis, and psychosis in epilepsy may be particularly frequent if there is specific underlying pathology, such as ventricular enlargement. Psychotic disorders may be more common with temporal dysplasia or neurodevelopmental abnormalities and depression with mesial temporal sclerosis. Second, ictal or subictal epileptiform activity may promote behavioral changes by facilitating distributed neuronal connections, increasing limbic–sensory associations, or changing the overall balance between excitation and inhibition. This may occur not only with temporal lobe seizures but also with those that originate in the frontal lobes. Third, the absence or hyperactivity of function, such as the interictal hypometabolism observed on PET scans (Fig. 2.4–2), may lead to depression or other interictal behavioral changes. For example, a reduction in cerebral blood flow in the left medial temporal region from SPECT may be associated with interictal psychosis. In contrast, auditory hallucination during a focal onset seizure without impairment of consciousness may demonstrate a cerebral hyperperfusion in the primary auditory cortex. Fourth, seizures may result in neuroendocrine or neurotransmitter changes, such as increased dopaminergic or inhibitory transmitters, decreased prolactin, increased testosterone, or increased endogenous opioids, all of which can affect behavior. Furthermore, neurobiologic factors may be potentiated by psychodynamic factors, such as feelings of helplessness, learned helplessness, dependency, low self-esteem, and the disruption of reality

Telegram: @medical_k

www.konkur.in

testing. In summary, the psychiatric manifestations of epilepsy are heterogeneous disorders with potentially different causes.

Table 2.4–3.
Proposed Relationships of Psychiatric Disturbances to Epilepsy

Common neuropathology, genetics, or developmental disturbance
Ictal or subictal discharges potentiate abnormal behavior
Kindling or facilitation of a distributed neuronal matrix
Changes in spike frequency or inhibitory–excitatory balance
Altered receptor sensitivity, e.g., dopamine receptors
Secondary epileptogenesis
Absence of function at the seizure focus
Inhibition and hypometabolism surrounding the focus
Release or abnormal activity of remaining neurons
Dysfunction or downregulation of associated areas
Neurochemical
Dopamine and other neurotransmitters
Endorphins
Gonadotropins and other endocrine hormones
Psychodynamic and psychosocial effects of living with epilepsy
Dependence, learned helplessness, low self-esteem, weak defense mechanisms
Disruption of reality testing
Neurobiologic and psychodynamic factors potentiate each other
Sleep disturbance
Antiepileptic drug related

Diagnosis

The Diagnostic and Statistical Manual of Mental Disorders, 5th edition, text revision (DSM-5-TR) does not have an exclusive diagnostic entity for epilepsy-related psychiatric disorders. Each psychiatric syndrome must be judged by a physician whether it is a direct consequence of epilepsy or not. If the syndrome is clearly associated with epilepsy, it will fall under the “mental disorder due to another medical condition” diagnosis; if not, the diagnosis should be listed as a primary psychiatric disorder. Nevertheless, since the DSM removed the multiaxial system, all the psychiatric

Telegram: @medical_k

www.konkur.in

diagnoses have to be recorded alongside a diagnosis of epilepsy. The DSM-5 also encourages clinicians to perform a dimensional assessment, measuring the severity of specific psychiatric symptoms and recording the disability of patients.

The other way to categorize psychiatric behaviors associated with epilepsy is their relationship to the ictus or seizure discharges. These behaviors may occur as part of the ictus, peri-ictally, or during the interictal period (Table 2.4–4). A range of other behaviors appear to have some relation to the ictus but do not clearly fall into one of the former three categories.

FIGURE 2.4–2. Neuroimaging from a 30-year-old man with focal seizures with impaired awareness of temporal lobe origin and ictal activity on invasive EEG. **A:** Coronal T2-weighted MR does not disclose abnormalities. **B:** Ictal single photon emission tomography image shows left temporal hyperperfusion. **C:** Fluorodeoxyglucose positron emission tomography confirms left temporal hypometabolism. The patient had a left temporal lobectomy and hippocampal sclerosis. (Reprinted with permission from Won HJ, Chang KH, Cheon JE, et al. Comparison of MR imaging with PET and ictal SPECT in 118 patients with intractable epilepsy. *AJNR Am J Neuroradiol.* 1999;20(4):593–599. Copyright © American Society of Neuroradiology.)

Ictal Features. Seizure discharges can produce semipurposeful automatisms and psychic auras, such as mood changes, derealization and depersonalization, and forced thinking. Ictal fear, which ranges from a vague apprehension to abject fright, has occurred without any other seizure manifestation, and ictal depression has extended days or longer after the seizure has passed. Some patients have pleasurable auras. Fyodor Dostoyevsky had “ecstatic auras” in which he felt in perfect harmony with the entire universe and “would give 10 years of this life,

Telegram: @medical_k

www.konkur.in

perhaps all of it, for a few seconds of such bliss." The experience of epileptic derealization or depersonalization could impair reality testing. Another psychic aura is "forced thinking," characterized by recurrent intrusive thoughts, ideas, or crowding of thoughts. Forced thinking must be distinguished from obsessional thoughts and compulsive urges. Some patients may experience vivid auditory and visual hallucinations during an epileptic discharge. Epilepsy patients with forced thinking experience their thoughts as stereotypical, out of context, brief, and irrational, but not necessarily as ego-dystonic.

Table 2.4–4.
Behavioral Disorders in Epilepsy

Ictal
- Ictal psychic symptoms (aura)
- Nonconvulsive status: focal onset seizures without impaired awareness, focal onset seizures with impaired awareness, and periodic lateralizing epileptiform discharges
- Catatonia

Peri-ictal (includes prodromal, postictal, and mixed ictal)
- Prodromal symptoms: irritability, depression, headache, etc.
- Postictal confusion
- Peri-ictal psychoses
- Concomitant with increased seizure frequency
- Concomitant with decreased seizure frequency
- Postictal psychoses

Interictal
- Interictal psychosis and personality disturbances
- Interictal psychosis (schizophreniform psychosis)

Other behavioral disorders associated with epilepsy
- Personality disorders
- Gastaut–Geschwind syndrome
- Behavioral disturbances variably related to ictus
- Mood disorders (depression and mania)
- Anxiety disorders including panic and posttraumatic stress disorder
- Aggression and violence
- Hyposexuality
- Suicide

Telegram: @medical_k

www.konkur.in

A 36-year-old right-handed man presented with frontal headaches and 5 years of focal seizures with impaired awareness. His seizures began with 15 seconds of a sense of “impending doom,” speech arrest, and orobuccal movements followed by 30 seconds of altered consciousness. At seizure onset, the patient felt forced to think the phrase “tell me yes.” The phrase was repeated several times without his being able to control it. Concomitantly, his mouth would open, and he would attempt to say the phrase but could utter only unintelligible sounds. The patient interpreted this phrase as a call for help. On examination, he had a mild memory deficit, normal language testing, a right facial droop, and brisk right-sided reflexes with a right Babinski sign. Neuroimaging revealed a left frontal mass lesion. EEGs showed amplitude attenuation and polymorphic delta in the left frontal area, and intraoperative electrocorticography disclosed polyspike and spike–wave discharges associated with impaired language from just below the lesion. The patient underwent subtotal resection of a 4.3- × 3- × 3-cm oligodendroglioma. Postoperatively, his forced thinking and seizures resolved, but he had nonfluent aphasia.

Cognitive disorders follow status epilepticus with focal or absence seizures. Recurrent or prolonged focal seizures may not result in alteration of consciousness or invariable abnormalities on EEG, and, if manifested by psychic auras, focal seizures may be difficult to distinguish from primary psychiatric disturbances. Status epilepticus from focal seizures with impaired awareness and absence of seizures results in prolonged alterations of responsiveness. With the addition of various ictal auras, focal status epilepticus (epilepsia partialis continua) can appear psychotic. Nonconvulsive status epilepticus can also present with immobility, waxy flexibility, and behavioral negativism resembling catatonia. Occasionally, EEGs and a therapeutic trial of antiepileptic medications may be the only way to distinguish behavioral disturbances due to nonconvulsive status epilepticus. Finally, recurrent interictal EEG complexes, known as *periodic lateralizing epileptiform discharges,* may also be associated with prolonged confusional behavior and focal cognitive changes.

www.konkur.in

A 68-year-old man had a left temporal–parietal hemorrhagic stroke. Initial fluent aphasia and right hemiparesis completely resolved, but he developed poststroke epilepsy. His seizures began with speech arrest and were followed by secondary generalization to tonic–clonic seizures. The postictal periods lasted days due to continued left-hemisphere periodic lateralizing epileptiform discharges. During these prolonged postictal periods, he was confused and placid and had a return of his aphasia. One year later, after achieving seizure control, the patient developed mania for the first time in his life. His mania was in a clear sensorium without a change in his neurologic examination or epileptiform activity on EEG. He did not sleep, had a flight of ideas, and had grandiose ideation, including beliefs that he was a three-star general, had killed Adolf Hitler, and was now a millionaire. He exposed himself to everyone, including his daughter, and inserted pencils up his penis because he believed that he needed catheterization. His psychosis lasted for 3 months until he had two generalized tonic–clonic seizures. Postictally, for 10 days, he remained placid, confused, and aphasic, with right beating nystagmus and periodic lateralizing epileptiform discharges maximal in the left temporal region (Fig. 2.4–3). With new antiepileptic medication, he returned to normal with a total resolution of his mania.

FIGURE 2.4–3. Periodic lateralizing epileptiform discharges. Left-sided electrodes per the International 10/20 System.

Peri-Ictal Features. Psychiatric disturbances can occur before seizures (prodromal), after seizures (postictal), or during intermittent seizure activity. Some patients experience prodromal symptoms that begin at least 30 minutes before seizure onset, last 10 minutes to 3 days, and are continuous with irritability, depression, headache, confusion, and other symptoms. The postictal period is characterized by a confusional state lasting minutes to hours or, occasionally, days. Prolonged, postictal confusion may particularly follow right temporal focal seizures. Some "twilight states" result from a protracted period of intermixed ictal and postictal changes.

Peri-ictal psychotic symptoms often worsen with increasing seizure activity. Rarely psychotic symptoms alternate with seizure activity. In this *alternating psychosis,* when patients are having seizures, they are free of psychotic symptoms, but when they are seizure free, and their EEG has *forced* or *paradoxical normalization,* they manifest psychotic symptoms. The mechanism for this phenomenon is unclear, although dopamine may play a major factor. This alternating pattern is much less common than the increased emergence of psychotic behavior with increasing seizure activity.

An important peri-ictal psychiatric disorder consists of brief psychotic episodes that follow clusters of generalized tonic–clonic seizures (i.e.,

Telegram: @medical_k

www.konkur.in

postictal psychosis). These psychotic episodes occur in patients who have focal seizures with impaired awareness, frequent secondary generalization to tonic–clonic seizures, bilateral interictal discharges, and frequent discharges involving the left amygdala. The postictal psychosis of epilepsy emerges after a lucid interval of 2 to 72 hours (with a mean of 1 day), during which the immediate postictal confusion resolves, and the patient appears to return to normal. The postictal psychotic episodes last 16 to 432 hours (with a mean of 3.5 days) and often include grandiose or religious delusions, elevated moods or sudden mood swings, agitation, paranoia, and impulsive behaviors, usually without perceptual delusions or voices. The postictal psychoses remit spontaneously or with the use of low-dose psychotropic medication.

A 33-year-old man with a 15-year history of generalized tonic–clonic seizures and a 4-year history of peri-ictal psychotic episodes had several hospitalizations for recurrent postictal psychosis. The initial flurry of generalized tonic–clonic seizures was followed by a 24- to 48-hour latency period and, subsequently, 2 to 7 days of delusions, hallucinations, and disordered thought processes. He believed that people could transmit messages and could read his thoughts, and voices commanded him to love his neighbor. The patient claimed to read the future and to communicate with a dead grandfather who voiced dissatisfaction with things on Earth. During these episodes, the patient had loose associations, euphoria, agitation, and occasional spike and waves on EEGs. Between psychotic episodes, he was psychiatrically and neurologically normal, and his EEGs showed left temporal interictal spikes. After the postictal psychosis, the patient returned to baseline without residual changes in behavior.

Interictal Features

INTERICTAL PSYCHOSIS (SCHIZOPHRENIFORM/SCHIZOPHRENIA LIKE PSYCHOSIS). Most psychotic episodes that occur in epilepsy patients are interictal psychosis which usually has no known direct relationship to seizure events or ictal discharge. The duration of psychotic episodes varies greatly from days to years but usually lasts longer than 1 month in the vast majority of cases. However, many of these patients develop

Telegram: @medical_k

www.konkur.in

worsening psychotic symptoms that are concomitant with an increase in seizure frequency or with AED withdrawal, and a few others have worsening psychotic symptoms on control of the seizures (alternating psychosis). The terms *alternating psychosis* and *forced* or *paradoxical normalization* refer to this demonstrable antagonism between the psychosis and the seizures or EEG discharges. Although a spontaneous resolution of interictal psychosis is not common, it may occur in patients with a shorter duration of epilepsy history and later onset of epilepsy. Patients with chronic interictal psychosis often have an early age of onset of seizures and a decade or more of poorly controlled focal seizures with impaired awareness with secondary generalized tonic–clonic seizures. Interictal psychosis may evolve from prior recurrent postictal psychotic episodes. Seizure control with AEDs or removal of the seizure focus does not prevent the development of interictal psychosis, which occasionally emerges for the first time after successful seizure treatment. This disorder sometimes resembles schizophreniform psychosis and schizoaffective psychosis with intermixed affective symptoms. In addition, there are prominent paranoid delusions, relatively preserved affect, normal premorbid personality, and no family history of schizophrenia. Other reported differences with idiopathic schizophrenia are outlined in Table 2.4–5.

www.konkur.in

Table 2.4–5.
Proposed Predisposing Factors for the Interictal Psychosis of Epilepsy

Epilepsy characteristics
Focal onset seizures with impaired awareness and with secondary generalized tonic–clonic seizures
More auras and automatisms than nonpsychotic epilepsy patients
Epilepsy present for 11–15 years before psychosis
Long interval of poorly controlled seizures
Recently diminished seizure frequency, especially generalized tonic–clonic seizures
Left temporal focus
Mediobasal temporal lesions, especially tumors
Psychosis characteristics
Atypical paranoid psychosis–paranoia with sudden onset
Psychosis alternating with seizures
Preserved affective warmth
Failure of personality deterioration
Less social withdrawal than schizophrenia
Less systematized delusions than schizophrenia
More hallucinations and affective symptoms than schizophrenia
More religiosity than schizophrenia
More positive, as opposed to negative, symptoms
Few schneiderian first-rank symptoms

Telegram: @medical_k

www.konkur.in

A 23-year-old man developed paranoid delusions after his daily seizures were controlled for the first time. His focal seizures with impaired awareness dated from 8 years of age and consisted of a rising epigastric sensation and facial flushing followed by a motionless stare and automatisms, often culminating in secondary generalized tonic–clonic seizures. Before initiating antiepileptic therapy, there was no history of paranoid or psychotic behavior. Afterward, he believed that people were sending energy to him through small concealed batteries. He believed that he was able to work this energy off with his fluorescent watch dial and a one-armed plastic crucifix in his boot. The patient also felt that people were observing him, trying to manipulate him, and threatening him through telephone lines and telephone poles. His examination was remarkable for the degree of emotion when relating his bizarre ideas. He had a lesion in the left anterior temporal area, probably consistent with an old calcified cyst, and left temporal spikes on EEG. His paranoid delusions subsequently abated with antipsychotic therapy.

PERSONALITY DISORDERS. Among epilepsy patients, there is a high prevalence of personality disorders, including borderline, atypical or mixed, histrionic, and dependent disorders. Although many seizure patients show dependent and avoidant personality traits, the most common personality disorder in epilepsy is a borderline personality. Not surprisingly, epilepsy patients frequently lack a stable character structure and can be immature and impulsive. This personality constellation partially explains the increased incidence of irritability, suicide attempts, and intermittent explosive disorder. Those with epilepsy are stigmatized, feared, and subject to difficulties in obtaining a job, driving an automobile, and maintaining a marriage. Their experience, stigmatization, and psychosocial difficulties, along with any associated mental retardation, contribute to the dependency, low self-esteem, and overall borderline personality traits present in many such patients. In addition, the experience of epileptic auras may contribute to the development of personality disorders.

Another way to understand personality changes in patients with epilepsy is from the evidence of impaired social cognition in this population. Recent studies consistently showed that patients with

Telegram: @medical_k

www.konkur.in

temporal lobe epilepsy usually have an impairment in the ability to understand others' feelings, thoughts, and perspectives. Such ability is known as the "theory of mind (ToM)." It is also common for patients with temporal lobe epilepsy to have deficits in other aspects of social cognition, including affective and cognitive empathy, processing of implied meaning, and semantic social concept. These components may eventually lead to decreased personal warmth and inappropriate social behaviors.

GASTAUT–GESCHWIND SYNDROME. Although there is no general epileptic personality, a group of traits termed the *Gastaut–Geschwind syndrome* occurs in a subset of patients with focal seizures with impaired awareness. Some epilepsy patients with a temporal limbic focus develop a sense of the heightened significance of things. These patients are serious, humorless, and overinclusive and have an intense interest in philosophical, moral, or religious issues. Occasionally, epilepsy patients experience multiple religious conversions or experiences. In interpersonal encounters, they demonstrate *viscosity,* the tendency to talk repetitively and circumstantially about a restricted range of topics. They can spend a long time getting to the point, give detailed background information with multiple quotations, or write copiously about their thoughts and feelings (hypergraphia). Viscosity may particularly occur in patients with left-sided or bilateral temporal foci.

Telegram: @medical_k

www.konkur.in

A 39-year-old man developed seizures after a contusion of the left temporal region. His seizures began with stereotypical voices and generalized to tonic–clonic seizures. He was extremely circumstantial and tangential, stressed every detail, and had difficulty getting to the point. Ironic and minor philosophical insights were fascinating to him. He wrote 30-page rambling letters to his physician, and his writings were full of metaphors and quotes. An example of his writing was as follows: “I became overwhelmed by the sentiment of a letter composed in my head before reaching paper. The sentiment of this letter continued to expand in all dimensions until it seemed no longer connected to any specific ideal but more to an all-pervasive color, yellow, and a smell, like burning leaves. I felt deliriously happy, but I felt in danger as well. Afterward, I got an acute attack of aphasia and could do nothing but shrug. My prior prophet voices, which went away with the Dilantin, were saying something profound that I needed to get down on paper. It seems as though I am a prophet, and I will never have another problem for the rest of my life.”

Conclusive proof that epilepsy patients with temporal lobe foci are disproportionately prone to the Gastaut–Geschwind syndrome has remained elusive. Most of the early studies used the MMPI, a test that proved insensitive to most of the specific traits attributed to epilepsy. Studies with the Bear–Fedio Inventory, an MMPI-like instrument developed to assess these “epileptic traits,” found that epilepsy patients with temporal lobe foci were sober and humorless, dependent and circumstantial, and had strong philosophical interests. In addition, those with a left-sided focus had a more reflective ideational style and maximized their problems, whereas those with a right-sided focus had emotional tendencies and minimized their problems. Further investigations with the Bear-Fedio Inventory described these seizure patients as having a viscosity in interactions, prominent religious interests, a pronounced sense of personal destiny, and deepened affect. However, other applications of this inventory found the same characteristics in nonepileptic patients with psychiatric disorders or with comparable physical disabilities. Although these personality characteristics do occur in some epilepsy patients, they may not be specific to patients with seizure disorders.

Telegram: @medical_k

www.konkur.in

Behavioral Disturbances Variably Related to Ictus

MOOD DISORDERS. Depressive disorder is the most prevalent neuropsychiatric disorder in epilepsy; it is also the main diagnosis among epilepsy patients in psychiatric hospitals. Depression is twice as common in epilepsy patients as in comparably disabled populations, suggesting that much of the depression in epilepsy patients is more than just a psychological reaction to a disability.

Depression can manifest in several forms; MDD, persistent depressive disorder (formerly dysthymic disorder), adjustment disorder, and depressive episodes of bipolar disorder. Most patients with mood disorders and epilepsy have dysthymia; some investigators refer to this condition as chronic interictal depression (*interictal dysphoric disorder of epilepsy*) and emphasize its association with paroxysmal irritability and agitation along with a good therapeutic response to antidepressant medications. These patients may have accompanying paranoia and hallucinations, emphasizing the continuum with psychotic disorders. Patients with interictal dysphoria tend to have frequent focal seizures with impaired awareness, possibly with greater left-sided temporal foci, although this lateralization is not well established. The experience of certain psychic auras, especially those with cognitive content, may predispose to interictal depression. Several investigators also report increased seizure control or a decrease in seizures before the onset of interictal depressive symptoms. Patients with this “alternating depression” experience relief with a seizure or Electroconvulsive therapy (ECT).

There are other associations between depression with epilepsy. The rare occurrence of ictal depression may not only outlast the actual ictus but also may lead to suicide. Depression also occurs peri-ictally. Episodic mood disturbances, often with agitation, suicidal behavior, and psychotic symptoms, may occur with increased seizure activity. Finally, postictal depression is common, and a prolonged depressive state occasionally follows focal seizures with impaired awareness, even when ictal experiences do not include depression.

Mood disorder due to epilepsy with manic features or with mixed features is much rarer than mood disorder due to epilepsy with depressive features or with major depressive-like features. Rarely, manic symptoms may emerge with an increase in seizure frequency or after seizure control.

Telegram: @medical_k

www.konkur.in

Although a right temporal focus is a possible source of mania in epilepsy, this laterality is not well established.

ANXIETY DISORDERS. Anxiety disorders, including generalized anxiety disorder (GAD), panic disorder, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), phobia, and social anxiety disorder, are the second most common psychiatric comorbidities in patients with epilepsy after depressive disorders. GAD appears to be the most common anxiety disorder among patients with epilepsy. The prevalence of anxiety disorders in epilepsy patients may be as high as 30%. Anxiety disorders that occur during the interictal phase must be distinguished from focal seizures without impaired awareness manifesting as anxiety or panic attacks. Anxiety may be present with depression or other psychopathology, as part of Cluster C personality disorders or independently as a GAD. Some patients with epilepsy clearly have PTSD from the psychological trauma of their recurrent seizures. Finally, among women with epilepsy, the risk of both anxiety and depression is higher during pregnancy and after childbirth compared to the general population.

AGGRESSION. Lay people have attributed aggressive and violent acts to epilepsy and have even used this epilepsy defense in criminal proceedings. This belief peaked in the 19th century when the criminologist Cesare Lombroso promoted the association of epilepsy with aggressive, sociopathic tendencies. Investigators have bolstered this association with studies showing aggressive verbalizations with stimulation of the amygdala and interictal defensive rage in cats with epileptic hippocampal lesions. A minority of violent epilepsy patients have left-sided amygdala atrophy, probably from prior encephalitis. Among patients in a maximum-security psychiatric hospital, the violent patients had focal temporal slowing or sharp waves on EEG and dilated temporal horns or small temporal lobes on CT scans. Moreover, on neuropsychological tests, patients with left temporal lobe seizure foci have higher scores on hostile feelings than other patients with epilepsy. These results suggest that aggression is associated with abnormal temporal structure and electrical discharges.

Telegram: @medical_k

www.konkur.in

A 37-year-old left-handed man with epilepsy presented with aggressive episodes. The seizures consisted of an olfactory aura followed by “spacing out” or alteration of consciousness for approximately 1 minute. In addition to these focal seizures with impaired awareness, the patient had occasional secondary generalized tonic–clonic seizures with urinary incontinence and tongue biting. During the postictal period, as he began to recover consciousness, he experienced an overwhelming sense of threat or of having been harmed. These feelings became focused on any individual who was in his immediate environment. That person was believed to have beaten or otherwise hurt him and was going to harm him further. The patient felt compelled to attack these individuals, often inflicting significant physical injury. Although his postictal confusion would clear in approximately 1 hour, his sense of being harmed or threatened slowly diminished over approximately 24 hours after a seizure. After the resolution of these feelings, he felt great remorse over the harm that he had done. Nevertheless, on several occasions, he was charged with aggravated assault. Sleep-deprived EEGs confirmed the presence of left anterior temporal epileptiform activity. The patient’s aggressive postictal episodes abated with control of his focal seizures with carbamazepine.

Although aggression can occur in relation to an ictus, as exemplified by this patient’s subacute postictal aggression, most aggression among epilepsy patients is not related to epileptiform activity. Aggression in epilepsy is usually associated with psychosis or with intermittent explosive disorder and correlates with subnormal intelligence, lower socioeconomic status (SES), childhood behavior problems, prior head injuries, and possible orbital frontal damage. Moreover, although the prevalence of epilepsy among prison inmates has been two to four times that among the general population, studies from the United Kingdom and the United States have not found more violent crimes among prisoners with epilepsy than among prisoners without epilepsy. Antiepileptic medication may also trigger aggression and mood lability in some patients, especially levetiracetam.

Can violence itself be a seizure? After the 1976 case of a New York City policeman who had never had seizures and successfully claimed the

Telegram: @medical_k

www.konkur.in

epilepsy defense, criteria for ictal violence were proposed that included video-EEG (VEEG) telemetry (Table 2.4–6). Since then, epilepsy has rarely, if ever, been proved to directly result in well-organized, premeditated, purposeful violence. Such acts require a series of coordinated steps that rarely occur as manifestations of seizures. Simple violent automatisms, such as spitting, verbal profanities, or flailing the arms, can occur at the onset of focal seizures with impaired awareness, and secondary violent automatisms can occur as a response to an unpleasant or emotional aura or peri-ictal sensation (Table 2.4–7). More commonly, nondirected violent movements, aimless destructive behavior, or angry verbal outbursts occur during postictal delirium when patients misinterpret attempts to protect or restrain them (resistive violence) or as a manifestation of postictal psychosis and subacute postictal aggression.

Table 2.4–6.
Criteria for the Assessment of Ictal Violence in Epilepsy

The diagnosis of epilepsy is established by at least one specialist in epilepsy.
The presence of epileptic automatisms is documented by history and by closed circuit television EEG telemetry.
The presence of violence during epileptic automatisms is verified in a videotape-recorded seizure in which ictal epileptiform patterns are also recorded on the EEG.
The aggressive act is characteristic of the patient's habitual seizures, as elicited by history.
A clinical judgment is made by the epilepsy specialist attesting to the possibility that the aggressive act was part of a seizure.

EEG, electroencephalogram.

SEXUALITY. Patients with epilepsy tend to be hyposexual. Men and women experience disturbances of sexual arousal and a lower sexual drive. Some patients have a disinterest in "all the usual libidinous aspects of life," including loss of erotic fantasies or dreams, and may experience impotence or frigidity. In general, sexual dysfunction is most likely to occur among patients with uncontrolled and frequent seizures, longer duration of epilepsy, focal seizures with impaired awareness, and those receiving enzyme-inducing and multiple AEDs.

Telegram: @medical_k

www.konkur.in

Although comorbid depression and anxiety may affect sexual behavior, men with epilepsy have a two- to threefold increased risk of erectile dysfunction, suggesting a neurophysiologic component, and studies of sex hormones suggest the possibility of subclinical hypogonadotropic hypogonadism. Moreover, there can be undesirable effects on the sexual performance of antiepileptic medication, including erectile dysfunction, decreased sexual desire, retrograde ejaculation, and altered semen quality. AEDs such as oxcarbazepine, lamotrigine, and levetiracetam may be associated with significant sexual dysfunction. Hormone replacement therapy may normalize sexual drive and sexual performance in some patients. Substantial improvement to the point of public hypersexuality can occur after seizures are brought under control. Before temporal lobectomy, most epilepsy patients were hyposexual, but nearly one-third of them had an increase in libido after the operation, providing that their seizures were controlled.

Table 2.4–7.
Mechanisms of Aggression among Epilepsy Patients

Period	Cause
Interictal	Impulse control disorder
	Intellectual disability or cognitive impairments
	Personality disorders
	Schizophreniform/schizophrenia-like psychosis
	Medication related
Prodrome	Mounting tension, irritability
Ictal	Direct manifestation of the seizure
	Violent automatism
	Reaction to a negative aura
	Subtle seizure equivalents
Postictal	Resistive
	Postictal psychosis
	Subacute postictal aggression
	Poriomania and somnambulism

Telegram: @medical_k

www.konkur.in

Other sexuality changes are rare. Individual cases of homosexuality, transvestism, fetishism, and gender dysphoria are not frequent enough to exclude a coincident association. True ictal sexual manifestations are also unusual; however, libidinous feelings, erotic sensations, sexual remembrances, and even orgasm rarely occur, primarily in women and probably from seizure discharges in the amygdala. In addition, ictal masturbation has occurred with absence status. A woman with nymphomania proved to have incidental sexuality from sensory focal seizures caused by a tumor in the sensory cortex representing her genital region.

SUICIDE AND SELF-HARM. Patients with epilepsy are at risk of higher rates of self-harm, suicidal ideation, and complete suicide. The risk of completed suicide in epilepsy patients is 4 to 5 times greater than that among the nonepileptic population, and those with focal seizures of temporal lobe origin have a particularly high risk, as much as 25 times greater. Death by suicide occurs in 3% to 7% of epilepsy patients. A comparison of suicide attempts among patients with epilepsy and comparably handicapped nonepileptic controls has reported that 30% of those with epilepsy had attempted suicide as compared to 7% of the controls. This increased risk of suicide continues even long after temporal lobectomy and successful control of seizures. Although many studies showed that the severity of depressive symptoms and psychosocial status influence suicidal ideation in patients with epilepsy, most suicidal behavior among epilepsy patients is not directly due to reactions to the psychosocial stressors of having a seizure disorder. Rather, these patients are likely to attempt suicide in conjunction with borderline personality behaviors and are likely to complete suicide during postictal psychosis. In addition, some evidence suggests that antiepileptic medications may also increase suicidality. This conclusion is still controversial. Contributors to successful suicides include paranoid hallucinations, agitated compunction to kill themselves, and occasional ictal command hallucinations to commit suicide. In sum, the cause of self-injurious behavior in patients with epilepsy is often multifactorial, and clinicians should consider any potential cause for an early intervention to prevent self-harm and suicide.

Telegram: @medical_k

www.konkur.in

A 26-year-old woman had her initial seizure during her first pregnancy at 18 years of age. Her seizures included echoing sounds “like walking in a cave,” a motionless stare with stereotypical automatisms, postictal confusion, and occasional secondary generalized tonic–clonic seizures. Because of variable AED response, she underwent EEG and closed-circuit television video-EEG (CCTV-EEG) telemetry that documented focal seizures from a right temporal focus and nonepileptic seizures. The patient, who had six children by six different individuals, had prominent feelings of inadequacy and isolation and was considering cutting her wrists “just to see if anyone cared.” Her multiple suicide attempts and threats resulted in five psychiatric hospitalizations. During one period of time, she complained of decreased menses, weight gain, stretch marks, increased appetite and sleep, and exhaustion. She insisted that she was pregnant despite six negative pregnancy tests and multiple evaluations.

OTHER BEHAVIORAL CHANGES. Other psychiatric disorders may be associated with epilepsy or epileptiform EEG activity. A specific association of epilepsy with dissociative identity disorder, depersonalization disorders, possession states, fugue states, and psychogenic amnesia is intriguing but unresolved. In one intracarotid amobarbital (Amytal) study of dissociative identity disorder in two seizure patients, the different personalities were precipitated without seizure activity. Persistent alterations in the experience of self and feelings of being taken over by others may occur in patients with auras of derealization and depersonalization. In epilepsy, prolonged periods of compulsive wandering with amnesia have resulted from an admixture of ictal and postictal changes and have been termed *poriomania.* Finally, patients with epilepsy are subject to other behavioral difficulties stemming from their epilepsy, such as adjustment disorders, subtle cognitive effects of seizures, and the potential behavioral effects of antiepileptic medications.

Pathology and Laboratory Examination

Neurodiagnostic Tests. Seizure and epilepsy are clinical diagnoses. Additional tests can help identify provocative factors and diagnose seizure

Telegram: @medical_k

www.konkur.in

syndromes. In addition to the routine laboratory data and toxicology screens used to exclude reactive seizures, several neurodiagnostic tests are useful in the assessment of epilepsy. Scalp EEG is the most common confirmatory test for seizures; however, sensitivity ranges from 29% to 55%. This is because the source area of epileptic discharge has to be large enough in order to be detected by scalp EEG. Only 10% of cortical spikes having a source area of less than 10 cm^2 produced scalp potentials; the source area, which is less than 6 cm^2 of gyral cortex, is rarely captured by scalp EEG. Single routine EEGs are frequently normal and must be repeated, particularly with provocative maneuvers, such as photic stimulation, hyperventilation, and sleep deprivation. Occasionally, VEEG telemetry for an extended period of time is necessary to characterize spells of unknown etiology, for localization of seizure focus, and to the classification of seizures in a patient with known epilepsy. Inpatient epilepsy monitoring units are very helpful in distinguishing epilepsy from Psychogenic nonepileptic seizures (PNES). Neuroimaging procedures, such as CT scans and MRI, can more precisely visualize a seizure focus or even mesial temporal sclerosis (Fig. 2.4–4). If the patient is a candidate for epilepsy surgery due to medication-resistant epilepsy, other tests that occasionally aid in localizing the seizure focus include invasive EEG, SPECT scans, and PET scans. PET scans may show interictal hypometabolism around the temporal seizure focus and are also useful in the presurgical assessment of medically intractable seizure patients. Neuropsychological examinations, particularly during a Wada test, further help in localizing and lateralizing memory and language before surgery.

Telegram: @medical_k

www.konkur.in

FIGURE 2.4–4. Coronal T2-weighted (**left**) and FLAIR (**right**) MR images showing prominent right-sided mesial temporal sclerosis. The high signal indicates gliosis. There is associated atrophy with enlargement of the right temporal horn of the lateral ventricle. (From Robin Smithius, MD. http://www.radiologyassistant.nl/)

Neuropathology. The most common pathologic findings in epilepsy are mediobasal temporal lobe lesions. Approximately two-thirds of epileptic adults have a temporal lobe focus, and two-thirds of these have mesial temporal sclerosis with pyramidal cell loss in the hippocampus. Theories about the cause of mesial temporal sclerosis include perinatal insults, dysgenesis, and kindling from reactive seizures. Another 20% to 25% of those with temporal lobe lesions have tumors, such as hamartomas and gangliogliomas. The rest have scars from trauma and other causes or lack a distinct histologic lesion.

Course and Prognosis

Most epileptic patients have a good prognosis. The majority of seizures can be controlled sufficiently with antiepileptic medications so that the patient can live a productive life. Some seizures, such as absence seizures, tend to disappear by adulthood. For epilepsy patients who are medically intractable, epilepsy surgery offers a good alternative (e.g., temporal lobectomy), provided that the focus can be localized. In addition, most epileptic patients do not have psychiatric disorders, and others have psychiatric difficulties only if they endure many years of poorly controlled

Telegram: @medical_k

www.konkur.in

seizures. For those with behavioral problems, AEDs or epilepsy surgery may relieve some symptoms, such as aggression and impulsivity, but may not affect the emergence of others, such as psychosis and suicidal behavior. Existing cognitive-behavioral therapy (CBT) and mindfulness-based interventions appear to have some benefit for psychiatric symptoms in epilepsy. Psychological interventions targeting the enhancement of health-related quality of life (HRQOL) and adherence and a decrease in comorbidity symptoms (anxiety, depression) need to be incorporated as part of a comprehensive epilepsy care program. Clinicians can also address and minimize the “stress profile” of patients with epilepsy, which may not only protect against psychiatric comorbidities but also reduce seizure frequency.

Treatment

Antiepileptic Medications. In the treatment of psychiatrically disturbed epilepsy patients, the first consideration is the behavioral effects of antiepileptic medications. Carbamazepine and valproate have significant antimanic and modest antidepressant properties. They have efficacy in the long-term prophylaxis of manic episodes and may also ameliorate some dyscontrolled, aggressive behavior in brain-injured patients. Lamotrigine has well-established efficacy in preventing the recurrence of depressive episodes in bipolar disorder, and lacosamide may additionally exert a beneficial effect on mood. Clonazepam, in addition to its anxiolytic properties, can serve as a supplement to other antimanic therapies. Gabapentin and pregabalin also decrease anxiety and improve general well-being in some epilepsy patients. Carbamazepine and ethosuximide may have value for borderline personality disorder in reducing mood swings and behavioral disinhibition.

Encephalopathic changes occur at toxic levels of all AEDs. Even at therapeutic levels, barbiturates may need discontinuation because of drug-induced depression, suicidal ideation, sedation, psychomotor slowing, and paradoxical hyperactivity in the very young and the very old. The exact incidence of aggressive behavior as an adverse effect of AEDs is difficult to estimate, with some reports of up to 16%. Treatment with levetiracetam, perampanel, and topiramate, which have diverse mechanisms of action, can result in aggressive behavior. Psychiatric and behavioral side effects occur in up to 8% of patients with drug-resistant epilepsy with treatment-emergent psychiatric adverse events regardless

Telegram: @medical_k

www.konkur.in

of the AED, although most frequent with levetiracetam and zonisamide. Levetiracetam is a well-known cause of irritability and aggression and may need to be avoided in emotionally unstable patients. Gabapentin may induce aggressive behavior or hypomania, and vigabatrin (Sabril) may precipitate depression. In addition, clinicians need to be aware of the potential emergence of psychopathology on withdrawal of antiepileptic medications. Anxiety and depression are the most common emergent symptoms of withdrawal, but psychosis and other behaviors may also occur (Table 2.4–8).

Zonisamide	Agitation, depression, psychosis, somnolence, impaired cognition, rare psychosis	

Psychotropic Medications

ANTIPSYCHOTICS. A small number (up to 15%) of the interictal psychosis resolves without any treatment, but a majority of patients require antipsychotics. There are no distinct differences in efficacies between second- antipsychotics and first-generation antipsychotics. Therefore, a second consideration is the seizure threshold lowering effect of psychotropic medications (Table 2.4–9). This is usually not a problem but can occasionally reach clinical significance in poorly controlled epilepsy. Haloperidol, risperidone, paliperidone, and aripiprazole may be the least seizure threshold lowering agents in contrast to clozapine, olanzapine, quetiapine, chlorpromazine, thioridazine, and perphenazine. Quetiapine has clinically significant interaction with enzyme-inducing drugs, even for dosages below 700 mg/day. These psychotropic drugs are most convulsive with the rapid introduction of the drug and in high doses. Clozapine, for example, had induced seizures in 1% to 4.4% of patients, particularly when the dose was rapidly increased. In general, mild-to-moderate psychotic episode patients usually require 300 to 1,000 mg/day of chlorpromazine equivalent (CE) dose (Table 2.4–10). Although patients with a severe psychotic episode, for example, unshakable delusion with severe aggression and suicidal ideation, may require dosages higher than 1,000 mg/day of CE, it is still the best to initiate with a low dose and titrate up slowly while monitoring antiepileptic levels and EEGs.

ANTIDEPRESSANTS. Prescribing antidepressants can alleviate both anxiety and mood symptoms at the same time. Given that the overall efficacies of

Telegram: @medical_k

www.konkur.in

antidepressants in treating depressive symptoms are the same, the principle of choosing antidepressants will be based on adverse effects and tolerability of the patients. The most concerning issue for antidepressants in epilepsy is the seizure threshold lowering property. Although therapeutic doses do not usually promote seizures, overdose and intoxication of tricyclic (TCA) and tetracyclic antidepressants (TeCA), selective serotonin reuptake inhibitors (SSRIs), and serotonin–norepinephrine reuptake inhibitors (SNRIs) are potential causes of seizures. Other antidepressants known to lower the seizure threshold usually avoided among patients with epilepsy are amoxapine, bupropion, clomipramine, and maprotiline. Paradoxically, some studies demonstrated that antidepressants might help in reducing the frequency of seizures in some patients.

(Risperdal)	reuptake inhibitors
Paliperidone (Invega)	
Aripiprazole (Abilify)	
Pimavanserin (Nuplazid)	
Lumateperone (Caplyta)	
Asenapine (Saphris, Secuado)	
Cariprazine (Vraylar)	
Lurasidone (Latuda)	

According to their better tolerability profile, most SSRIs and SNRIs can be given as first-line antidepressants in patients with epilepsy (Table 2.4–11). SSRIs may be more suitable in patients with a depressive disorder associated with comorbid anxiety disorder, while SNRIs may be more beneficial in patients with depressive disorder with psychomotor retardation, fatigue, anhedonia, and cognitive slowness. These medications should not be discontinued abruptly because of withdrawal symptoms.

ANTIANXIETY. Although anxiety disorders are common comorbidities in epilepsy, there is a lack of evidence from good quality randomized controlled trials (RCTs) with epilepsy patients. Therefore, regimens of psychotropic prescription largely come from evidence in general psychiatric populations. Benzodiazepines may be particularly helpful in the rapid relief of symptoms of anxiety, but a recent study demonstrated that chronic use of benzodiazepines in epilepsy patients with GAD did not decrease anxiety severity. If patients have comorbid panic disorder, GAD, OCD, or PTSD, SSRIs are probably the best choice for treatment. Pregabalin recently showed an antianxiety effect in a small open-label trial

Telegram: @medical_k

www.konkur.in

in patients with epilepsy and GAD. Therefore, it can be an alternative choice if the patient does not respond to an SSRI.

Drug Interactions. A third treatment consideration is a potential for interaction of antiepileptic and psychotropic medications. Most commonly, AEDs can increase the metabolism of a psychotropic drug with a consequent decrease in its therapeutic efficiency. Conversely, withdrawal of an AED can precipitate rebound elevations in psychotropic drug levels. Moreover, the initiation of a psychotropic drug may result in competitive inhibition of AED metabolism with elevations of AED levels to toxicity. These interactions should be considered carefully, especially in older antiepileptic medications. However, the newer antiepileptic medications have fewer potential interactions with psychotropic medications. Lacosamide (Vimpat), levetiracetam (Keppra), zonisamide (Zonegran), gabapentin (Neurontin), clobazam (Onfi), perampanel (Fycompa), ethosuximide (Zarontin), vigabatrin (Sabril), and tiagabine (Gabitril) are relatively free of enzyme-inducing or -inhibiting properties. Lamotrigine (Lamictal) and topiramate (Topamax) have interactions as described in Table 2.4–12.

Surgery. Up to a third of epilepsy patients may have seizures that are not fully controlled with medications. For these patients, resection of epileptogenic brain regions may offer a far better chance of seizure control than medication alone. The most commonly performed operation is a temporal lobectomy, involving resection or removal of 4 to 6 cm of the anterior temporal lobe. More than 80% of temporal lobectomy patients experience some reduction in their seizure frequency, and more than 60% of patients are entirely seizure free. Less common epilepsy surgeries include resection of cortical dysplasia, tumors, vascular malformations, areas of old stroke, removal of the epileptogenic hemisphere, and ligation of the corpus callosum. Neocortical resections result in about 50% of seizure freedom.

Neuropsychiatric manifestations of peri-surgery are beginning to be characterized, and data is most robust in temporal lobectomies. Similar to medically managed patients, surgical patients suffer from depression and anxiety. Most depression occurs during the first 3 months following epilepsy surgery, with the majority manifesting depressive symptoms during the 3- to 12-month postoperative period. Depressive symptoms may correlate with dysfunction in temporolimbic structures contralateral to

Telegram: @medical_k

www.konkur.in

the epileptogenic zone. Studies have shown that independent of postoperative seizure outcome, the severity of depression and anxiety independently predict the quality of life. These psychiatric symptoms gradually improve after surgery; only a minority of patients will suffer from refractory depression and anxiety.

Table 2.4–10.
Chlorpromazine Equivalent (CE) Dosages of Antipsychotics

First Generation Antipsychotics	Chlorpromazine Equivalents (mg)
Chlorpromazine	100
Fluphenazine	2
Haloperidol	2
Loxapine	10
Perphenazine	8
Pimozide	2
Prochlorperazine	15
Trifluoperazine	2–5
Thioridazine	100
Thiothixene	4
Second Generation Antipsychotics	
Aripiprazole	7.5
Asenapine	4
Brexpiprazole	N/A
Cariprazine	N/A
Clozapine	100
Iloperidone	3–4
Lurasidone	16
Olanzapine	5
Paliperidone	2
Quetiapine	75
Risperidone	1
Ziprasidone	60

CE: 1 mg of each antipsychotic can be converted into a certain dose of chlorpromazine, e.g., 1 mg of haloperidol is about 50 mg of chlorpromazine.

Removal of the amygdala and most of the hippocampus may have postoperative behavioral effects. Some patients develop anomia or a verbal memory deficit after resection of the dominant hemisphere, and patients occasionally develop a transient postoperative affective disorder. Others experience a reduction in postictal psychosis, depression, and hyposexuality, but epilepsy patients may continue to develop interictal psychosis, personality changes, and suicidal behavior even long after the temporal lobectomy. Patients with preoperative psychotic symptoms are at higher risk for poor surgical outcomes and postoperative psychosis. Corpus callosotomy, which aims to prevent the interhemispheric spread of seizures, results in a unique, transient disconnection syndrome of mutism, apathy, agnosia, apraxia of the nondominant limbs, difficulty naming, and difficulty writing with the nondominant hand.

Table 2.4–11.
Suggested Antidepressants for Patients with Epilepsy

Suggested Level	Drug Name and Classification	Dose Range
First-line	SSRI	
	Fluoxetine	20–60
	Sertraline	50–150
	Escitalopram	10–20
	SNRI	
	Venlafaxine	75–300
	Duloxetine	30–90
Second-line	TCA	
	Amitriptyline	150–300
	Nortriptyline	50–150
	Imipramine	75–150
	Clomipramine	75–150
	TeCA	
	Maprotiline	75–150
	Mirtazapine	7.5–30

SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressants; TeCA, tetracyclic antidepressants.

Seizure Management. In treating the neuropsychiatric disorders of epilepsy, a final consideration is altering the seizure management itself. In addition to the occasional behavior alleviated by strict seizure control, neuromodulation techniques may offer promise. ECT, vagus nerve stimulation (VNS), and repetitive transcranial magnetic stimulation (rTMS) may relieve some cases of peri-ictal psychosis, depression, or other behaviors. Studies also suggest that VNS ameliorates depressive symptoms in drug-resistant epilepsy patients and that the VNS effect on depression is not correlated to seizure response. On the horizon, promising new treatments for epilepsy include the use of stem cells to treat both the biologic and psychiatric components. All patients with epilepsy should have optimal care by addressing seizure effects on their

Telegram: @medical_k

www.konkur.in

quality of life, such as emotional health, physical health, social health, and independent lifestyle. Ultimately, the optimal management of the neuropsychiatric comorbidities of epilepsy involves an interdisciplinary team that may include neurologists, psychiatrists, psychologists, social workers, and, when indicated, neurosurgeons.

PSYCHOGENIC NONEPILEPTIC SEIZURES

PNES are sudden involuntary episodes of any combination of altered movement, sensation, or awareness that bear a resemblance to epileptic seizures but are not explained by epileptiform electrical activity and are instead presumed to be associated with a psychological origin. PNES are classified as a subtype of functional neurologic symptom disorder (FNSD, also known as conversion disorder) in DSM-5, and they are also called dissociative seizures or functional seizures. Some clinicians refer to PNES episodes as “events” or “spells” instead of “seizures” to create less confusion for patients who associate the word “seizure” with epilepsy.

PNES are frequently misdiagnosed as epilepsy. The mean latency from initial manifestation to proper diagnosis is 5 to 7 years. PNES can represent up to 30% of admissions to epilepsy monitoring units. PNES are associated with significant medical resource utilization, disability, and low quality of life. They affect women during their reproductive years at a 3:1 ratio compared to men. While more frequently identified in young adult patients, PNES can occur across the lifespan.

Diagnosis

Telegram: @medical_k

www.konkur.in

Diagnosis is established by capturing semiology characteristics of PNES without accompanying electrographic changes during VEEG monitoring. Semiologic signs suggestive of PNES include preserved awareness during bilateral movements, eye fluttering or forced eye closure, responsiveness to bystander intervention during the episode, prolonged duration (>2 minutes), waxing and waning course during the episode, and rapid full recovery immediately following the episode. Frontal lobe seizures may present a particular diagnostic challenge as clinical manifestations may be reminiscent of PNES and show minimal or no changes in EEG at the time of the episode. Semiologic features typical of frontal lobe seizures that distinguish them from PNES include short duration (<30 seconds), occurrence from EEG-verified sleep, open eyes, tonic posturing, and ictal grasping. Table 2.4–13 lists semiologic signs that can help distinguish epileptic seizures from PNES. Induction techniques using conventional activation procedures (hyperventilation and photic stimulation) can accelerate the capture of a typical episode during VEEG and offer a diagnostic admission of a shorter duration. Interictal abnormalities and even epileptiform discharges can be seen in patients with sole PNES and should not lead to overinterpretation. EEG results should be contextualized with history and semiology.

Table 2.4–14.
Physiologic Paroxysms that Need to be Differentiated from Epileptic Seizures and PNES

Telegram: @medical_k

www.konkur.in

Physiologic Paroxysm	How to Identify and Diagnose?
Syncope	Very short (seconds) loss of consciousness, prodromal signs (lightheadedness, pallor, diaphoresis, nausea/vomiting, tunnel vision), can be accompanied by myoclonic jerks, no postepisode confusion, can be triggered by changes in position or specific situations (micturition, blood sight). *Recommended tests to support diagnosis: electrocardiogram (ECG), holter ECG, tilt table test.*
Parasomnias	Complex behaviors during sleep (eating, walking, etc.), behaviors are not stereotyped, usually last minutes, little or no recollection, onset typically in childhood. *Recommended tests to support diagnosis: polysomnography or video polysomnography.*
Narcolepsy	Excessive daytime sleepiness, sleep attacks, sleep paralysis, hypnogogic hallucinations, cataplexy (sudden transient episodes of loss of tone with preserved consciousness, triggered by strong emotions), onset in childhood or young adulthood. *Recommended tests to support diagnosis: polysomnography, multiple sleep latency test.*
Transient ischemic attack	Usually presents with negative symptoms (weakness, aphasia, sensory loss), preserved consciousness, can last minutes to hours, cardiovascular risk factors present. *Recommended tests to support diagnosis: brain imaging, carotid ultrasound, ECG, echocardiogram, other tests depending on suspected etiology.*
Migraines	Auras include visual, sensory, motor, and speech symptoms, headache is often unilateral, throbbing, worsens with exercise, associated with nausea/vomiting, phono/photophobia, fully reversible weakness in hemiplegic migraines. *Recommended tests to support diagnosis: clinical diagnosis, imaging as clinically indicated.*

Telegram: @medical_k

www.konkur.in

Transient global amnesia	Repetitive questions demonstrating poor recent memory, can last hours, can carry out complex tasks. *Recommended tests to support diagnosis: imaging as clinically indicated.*
Paroxysmal movement disorder	Movements can include dyskinesias, dystonia, myoclonus, ballismus, tics, tremors; there is preserved consciousness, movements improve during sleep, some may be triggered by exercise. *Recommended tests to support diagnosis: imaging as clinically indicated.*
Vestibular disorder	Severe vertigo, tinnitus, preserved awareness. *Recommended tests to support diagnosis: vestibular examination.*
Breath holding spells	Occurs in young children (1–3 years old), brief loss of consciousness, no postevent confusion, pallor and cyanosis may be present. *Recommended tests to support diagnosis: clinical diagnosis.*

Other physiologic paroxysms can resemble epileptic seizures and should be considered in the differential diagnosis of PNES and epileptic seizures. Some may call these paroxysms "physiologic nonepileptic seizures," substituting the "psychogenic" prefix with the word "physiologic." Table 2.4–14 lists common physiologic paroxysms and how to clinically distinguish and diagnose them.

Psychiatric comorbidities are common in PNES. Mood disorders, for instance, are frequent in PNES but not significantly more frequent than in epilepsy. Prior exposure to traumatic experiences, PTSD, and personality disorders are usually more frequent in PNES than in epilepsy. Comorbid epilepsy (electrographically and clinically confirmed) is variably reported in 10% to 20% of adult patients with PNES, and the comorbidity rate is higher in pediatric patients. Conversely, PNES is reported in approximately 10% to 20% of adult epilepsy patients. Mild traumatic brain injury, multiple allergies, and somatic symptom disorder, including chronic pain syndromes, are commonly reported in PNES. While important to formulate a diagnosis and treatment plan, clinicians should not assume a

Telegram: @medical_k

www.konkur.in

PNES diagnosis solely based on the presence of comorbid psychiatric diagnoses such as PTSD or personality disorders.

Pathophysiology

The underlying pathophysiology of FNSD, of which PNES is a subtype, involves alterations in the activity and functional connectivity in brain regions involved in body awareness, emotion processing, self-monitoring, cognitive control, agency and motor intention, initiation, and inhibition. These findings are restricted to a few studies with phenotypically heterogeneous subjects but provide insight into a nascent neurobiologic explanation for PNES. Conversion and dissociative hypotheses have predominantly explained the phenomenon psychologically. A more modern and integrative cognitive hypothesis describes PNES as the result of automatic, reflex-like execution of a learned mental representation of seizures, typically in the context of dysfunction of inhibitory processes due to chronic stress, arousal, and other factors that compromise high-level cognitive processes.

Treatment

Once the diagnosis of PNES is confirmed, it has to be clearly communicated to patients, family members, and involved clinicians. Communication of the diagnosis can lead to improvement in symptom frequency or severity and medical utilization for a small subset of patients, at least temporarily. Elements to be covered during the diagnosis explanation include (1) reassurance that symptoms are genuine and not considered fabricated; (2) explanation of how the diagnosis was arrived at and names for the condition; (3) discussion of hypothetical mechanisms for the disease (including a neurobiologic model) and potential role of identified risk factors if any; and (4) review of effective treatments. Multidisciplinary collaboration is essential for a successful outcome. The diagnosing neurologist can help manage comorbid neurologic conditions (such as headaches or epileptic seizures), manage or taper unnecessary medications (such as antiseizure medications), and provide recommendations related to work and driving restrictions. Mental health clinicians are best suited to deliver treatment.

Evidence-based treatment for PNES favors the use of psychotherapy. Multicenter RCTs have shown the efficacy of CBT in a number of functioning and symptom severity measures. Other psychotherapeutic

Telegram: @medical_k

www.konkur.in

interventions studied in PNES in either small RCTs or uncontrolled trials with promising results include paradoxical intention (using imagery exposure to induce PNES), operant conditioning (positive reinforcement and punishment through withdrawal of privileges), long-term interpersonal psychodynamic psychotherapy, group psychotherapy, mindfulness-based psychotherapy, CBT-based inpatient programs, and prolonged exposure for PNES with comorbid PTSD.

There is no convincing evidence that pharmacologic treatment can reduce PNES frequency and/or severity. Psychopharmacologic interventions should be limited to the treatment of comorbid psychiatric conditions. Noninvasive stimulation therapies lack sufficient evidence for the treatment of PNES at this point, with case reports highlighting the need for further exploration.

Outcomes

Most currently available data on long-term outcomes do not consider participation in evidence-based treatment. Participation in psychotherapy is, however, associated with improved PNES frequency 1 to 2 years after diagnosis. Disability rates do not decrease years after the diagnosis. Poor outcomes are correlated with comorbid epilepsy and psychiatric diagnoses, dramatic seizure semiology, and younger age of onset, while better outcomes are correlated with higher education, shorter duration of illness, employment, acceptance of the diagnosis, and social support.

2.5 Neuropsychiatric Consequences of Traumatic Brain Injury

Melissa B. Jones, M.D., Amy R. Corcoran, M.D., Joanne A. Byars, M.D., and Ricardo E. Jorge, M.D.

Traumatic brain injury (TBI) is defined as an acute disruption of brain function and/or structure induced by an external force to the head. In the United States, an estimated 1.7 million TBIs occur annually and contribute to 30.5% of injury-related deaths. For survivors of TBI, the cognitive and neuropsychiatric sequelae of TBI contribute to postinjury disability, poorer functional recovery, and increased health care utilization.

This chapter summarizes the emotional, cognitive, and behavioral sequelae associated with TBI most pertinent to psychiatric practice. The chapter begins with brief descriptions of the epidemiology and pathophysiology of TBI, followed by an overview of neuroimaging, biomarker, electrophysiology, and neuroendocrine-based assessments of its neurobehavioral outcomes. We then introduce TBI severity grading as a precursor to understanding the range and patterns of cognitive sequelae

Telegram: @medical_k

www.konkur.in

following TBI of different severities. Finally, the chapter concludes with a section on the clinical features and management of individual neuropsychiatric disorders post TBI.

EPIDEMIOLOGY OF TBI

In 2014, approximately 2.87 million TBI-related emergency department visits, hospitalizations, and deaths occurred in the United States. Direct and indirect costs of TBI exceed $76 billion per year (expressed in 2010 U.S. dollars).

Most TBIs occur among infants, adolescents/young adults, and elderly individuals. Males are 40% more likely to suffer brain injury than females. African Americans and individuals of low socioeconomic status also experience higher rates of TBI than other groups. In the United States, falls represent the most common cause of TBI, both overall and in the specific populations of children and older adults. Among young adults, motor vehicle accidents and assaults produce the most TBIs.

TBI may be categorized as closed or penetrating, depending on the integrity of the meningeal coverings. The most common cause of penetrating injuries is gunshot wounds. However, closed head injuries constitute the vast majority of TBIs. TBI may also be categorized by severity (see “Categorization of TBI Severity” below). Approximately 80% of patients with TBI have mild head injury, 10% have moderate head injury, and the remaining 10% severe.

Patients with TBI have a greater risk of recurrent TBI than noninjured controls; about 10% will sustain a second TBI within the year following the initial event. The single greatest risk factor, however, is alcohol/drug abuse. One epidemiologic study reported that close to one-third of brain injury patients had an identifiable alcohol problem before the trauma, and more than 50% were intoxicated at the time of injury.

In general, military service members experience higher rates of TBI compared to civilian populations. TBI was coined the “signature wound” of Operation Iraqi Freedom (OIF), Operation Enduring Freedom (OEF), and Operation New Dawn (OND) conflicts involving U.S. troops in Iraq and Afghanistan. Approximately 10% of veterans of these conflicts seeking care at Veterans Affairs (VA) medical facilities experienced a TBI while deployed. While military-related TBI can occur from training activities, sports, and motor vehicle accidents, blast exposure represents the most

Telegram: @medical_k

www.konkur.in

common cause of deployment-related TBI in veterans of recent eras. For instance, improvised explosive devices (IEDs) or mines produced the majority of injuries (97%) observed among a Marine unit in Iraq. In addition, an estimated 59% of soldiers with blast injuries sustain a TBI.

MECHANISMS OF TBI

The definition of TBI requires damage inflicted by an external force to the head. Such external forces may include rapid acceleration/deceleration, being struck in the head by an object, penetration of a foreign object into the brain, or blast-related forces. Trauma-induced neuroimaging and neuropathologic abnormalities may also be categorized as primary or secondary injuries. Primary injuries refer to the damage occurring immediately at the time of injury. Secondary brain damage refers to physiologic processes initiated by the injury but spanning a variable period following the traumatic episode (such as edema, seizures, and hydrocephalus).

Closed injuries produce regional patterns of injury due to variations in brain tissue densities, elasticities, and proximity to bony and fibrous restrictions of the skull and dura, respectively. On the other hand, penetrating injuries destroy, displace, and/or deposit bone fragments or other infectious materials into bone or brain tissue. Regional vulnerabilities to penetrating injuries depend on such features as the object's location of entry, trajectory, and size. While this section provides an overview of closed injuries, it is worth noting that patients may experience a combination of closed and penetrating-type injuries. For example, a blast exposure from an IED may induce combinations of closed and penetrating TBIs (see the section on blasts below).

When linear and/or rotational forces are applied to the head, inertia causes the brain's movement to lag relative to that of the skull. The bony protuberances of the skull and rigid, tough fibers of the falx and tentorium cerebri may deform and damage brain parenchyma. Furthermore, the brain's elaborate and complex neurovascular and axonal structures are particularly susceptible to rotational and shearing–tensile forces.

This deformation, shearing, and/or stretching of blood vessels may lead to intracranial and intracerebral hemorrhages that can expand over an interval of hours to days after the injury. Contusions may occur at the crest

Telegram: @medical_k

www.konkur.in

of cerebral gyri, with a predilection for the frontal and temporal lobes (housed within the anterior and middle fossae, respectively).

Vascular shearing injury may also produce intraparenchymal hemorrhages visualized with computed tomography (CT) or magnetic resonance imaging (MRI); their presence indicates that enough force was applied to the brain to induce underlying traumatic axonal injury (see Fig. 2.5–1). Other vascular injuries include intracranial–extracerebral hemorrhages in the epidural (i.e., between the skull and the dura), subdural (i.e., between the dura and the arachnoid), or subarachnoid spaces. Finally, ischemia may occur from other traumatic vascular lesions (e.g., carotid arterial dissection), intracranial hypertension, or vasospasm following subarachnoid hemorrhage.

Traumatic axonal injury, also known as “diffuse axonal injury,” refers to multifocal regions of white matter damage caused by traumatic rotational and tensile-shearing forces. Injured regions commonly include upper brainstem and diencephalic structures, gray–white matter junctions, the parasagittal white matter of the cerebrum, and the corpus callosum. The latter white matter tract is particularly sensitive to TBI due to its location near the falx. Although a traumatic axonal injury is usually associated with immediate and persistent coma, lesser degrees of axonal disruption may also be seen in patients who suffered mild brain injuries (Fig. 2.5–1).

The injuries produced at the time of impact may continue to expand via several mechanisms. For instance, increasing edema may augment tissue deformation, raise intracranial pressure, reduce cerebral perfusion pressure, and ultimately cause ischemia and/or herniation. Another example of progressive injury may include hydrocephalus resulting from an intraventricular expansion of hemorrhage.

The macroscopic primary and secondary injuries described above reflect a complex series of microscopic cellular cascades initiated by the trauma. Mechanical deformation of neurons induces ion homeostasis disruptions, excessive release of glutamate and other neurotransmitters, intracellular calcium release, and the activation of cytotoxic cascades. Other complex delayed post-TBI processes include microglial activation, the release of inflammatory cytokines, and alterations in cerebral blood flow.

Evidence from experimental models suggests that TBI generates widespread neuropathologic changes in diverse cortical areas, subcortical nuclei, and white matter tracts. Neuronal damage and cell loss may

Telegram: @medical_k

www.konkur.in

progress over weeks to months after the initial insult in selectively vulnerable regions of the prefrontal cortex, hippocampus, thalamus, striatum, amygdala, and forebrain nuclei. Damage to ascending biogenic amine and cholinergic pathways may also influence the pathophysiologic processes contributing to neuropsychiatric presentations and the long-term outcome of patients with TBI. Furthermore, network-wide disruptions may result from Wallerian degeneration, diaschisis, or repair and regeneration mechanisms, such as synaptogenesis and axonal sprouting, altering network organization.

Blast Injuries

TBI from blast exposure occurs via several mechanisms. Primary blast injury results from the initial pressure wave of the explosion causing mechanical tissue damage and the release of heat, acoustic, and electromagnetic energies. Further injury may also be caused by the reflection of the pressure wave when it hits the skull. Primary blast injuries are unique to blasts. Of note, air–fluid interfaces of the tympanic membrane, heart, lungs, and gastrointestinal tract are potentially susceptible to blasts. Lung injury accounts for a high percentage of blast fatalities due to the disruption of the alveoli–capillary interface.

Telegram: @medical_k

www.konkur.in

FIGURE 2.5–1. Diffuse axonal injury. Magnetic resonance images consistent with the presence of diffuse axonal injury at the gray–white matter junction and frontal intracerebral hemorrhages.

Secondary mechanisms of injury may result from the release of high-energy fragments that may penetrate the skull, eye, or other body parts. Tertiary injury refers to injuries occurring from acceleration/deceleration or blunt-force injuries (e.g., from being thrown from the blast and hitting a solid object). Tertiary injury may result in a closed TBI via a similar mechanism to that of a motor vehicle accident. Quaternary injury is caused by toxic or radiological substances emitted from the blast. Gas inhalation or toxin-induced burns may result from this type of injury.

The growing number of TBIs incurred by soldiers deployed to the wars in Iraq and Afghanistan has heightened interest in understanding mechanisms of blast injury. Research groups are actively investigating thresholds required to induce blast-related TBI and the potential for unique neuropsychiatric outcomes associated with blasts. For instance, the Translational Research Center for TBI and Stress Disorders (TRACTS), a multi-VA cohort study of previously deployed, post-9/11

Telegram: @medical_k

www.konkur.in

veterans, is actively collecting structured histories of blast and other TBI exposures and longitudinal psychiatric, cognitive, and neuroimaging data to understand long-term outcomes of blast injuries and optimize the assessment of blast-related TBI.

NEUROIMAGING AND LABORATORY INVESTIGATIONS

This section provides a brief summary of neuroimaging techniques, serum biomarkers, electrophysiologic studies, and neuroendocrine evaluations of brain alterations associated with TBI. These modalities have contributed to current understandings of the pathophysiology of injury and neural circuits implicated in its acute and chronic neuropsychiatric sequelae.

Neuroimaging

CT and MRI are routinely incorporated into the clinical evaluations of patients with TBI. Common data elements guiding technical considerations and definitions of TBI-related neuroimaging findings were published in 2010 and have aided in the standardization of data reporting for clinical care and outcomes research.

CT is the most efficient means of detecting injuries requiring neurosurgical intervention. Thus, CT remains the initial study of choice in the emergency room (ER). Structural abnormalities visualized on CT include skull fractures, epidural or subdural hematomas, subarachnoid hemorrhage, intraparenchymal contusions, and mass effect producing herniation. The Marshall and Rotterdam CT classification systems utilize these CT abnormalities to predict outcomes (e.g., mortality) following more severe TBIs.

Telegram: @medical_k

www.konkur.in

FIGURE 2.5–2. Proton magnetic resonance spectroscopy (dorsal–rostral cingulate gyrus PRESS CSI).

MRI is more sensitive than CT for visualizing the extent of acute and chronic post-traumatic lesions (Fig. 2.5–1), such as small hemorrhages associated with traumatic axonal injury. MRI is also the study of choice for visualizing volumetric changes (e.g., hippocampal atrophy) over time. The use of diffusion-weighted imaging (DWI), apparent diffusion coefficient (ADC), gradient echo (GRE), and susceptibility-weighted imaging (SWI) sequences also improves the detection of axonal injury. Finally, CT angiography (CTA), MR angiography (MRA), and catheter angiography may be required to visualize traumatic vascular injuries, such as arterial dissections and traumatic aneurysms.

CT and routine MRI lack the sensitivity to identify the whole extent of the pathologic changes associated with TBI. Structural volumetric MRI studies, however, provide quantitative data on volumetric changes observed in gray matter, white matter, and cerebrospinal fluid. Volumetric MRI may be particularly useful for monitoring the progression of atrophy over time.

Diffusion tensor imaging (DTI) enhances the sensitivity of MRI to detect white matter changes after TBI. DTI provides an objective measure of

Telegram: @medical_k

www.konkur.in

directional water diffusion in space (e.g., fractional anisotropy [FA]), which in white matter regions reflects the integrity of myelin sheaths. DTI reveals changes in the white matter that correlate with the severity of TBI and with the functional outcome at the time of hospital discharge. Diffusion tensor tractography, which allows visualization and analysis of specific white matter pathways, may extend the potential of DTI in TBI. However, DTI and tractography techniques are primarily reserved for the research setting due to varying methodologies among investigators and lacking normative data.

Functional imaging studies, such as functional MRI (fMRI), positron emission tomography (PET), single-photon emission computed tomography (SPECT), and magnetic resonance spectroscopy (MRS), are also used in research settings to detect in vivo brain changes not captured by structural imaging. Both task-based and resting-state fMRI has been used to explore the integrity of neural networks subserving cognitive, emotional, and behavioral functions post TBI. For instance, in task-based fMRI studies of working memory and attention, individuals with TBI show different patterns of regional brain activation than healthy controls, even when performance on these cognitive tasks does not substantially differ from normal. This suggests that injury-related changes in the allocation of working memory and attentional resources might underlie some of the cognitive complaints after mild head injury.

In addition, Fluorodeoxyglucose (FDG) - PET and SPECT examine regional differences in metabolism and blood flow, respectively. Like fMRI, FDG-PET and SPECT may identify circuits involved in processing cognitive and emotional information, including regions activated during the implementation and monitoring of behavioral responses.

MRS techniques enable the simultaneous generation of maps of metabolite distributions over wide brain regions (Fig. 2.5–2). Multislice short echo time (TE) H_1-MRS allows for the in vivo evaluation of the metabolic profiles of large brain regions, including the neocortex, deep white matter, and basal ganglia. Specific metabolites studied with H_1-MRS include *N*-acetyl aspartate (NAA), a marker of neuron density and metabolism; choline-containing compounds (Cho), which reflect phospholipid metabolism; creatine-containing compounds (Cre), which reflect the cellular energetic status; myoinositol (mI), a putative glial cell marker; the sum of glutamate and glutamine (Glx); lactic acid (Lac); and other peaks. In the research setting, MRS has demonstrated associations

Telegram: @medical_k

www.konkur.in

between metabolic abnormalities and cognitive, emotional, and behavioral changes in patients with otherwise normal-appearing white matter after TBI.

Biomarkers

The identification of cerebrospinal fluid and serum biomarkers of TBI severity and prognostication has inspired much research. However, the interpretation of biomarker levels requires consideration of their specificity for brain tissue damage, temporal kinetics, and optimal cut-off values.

S100B, a calcium-binding protein involved in cell cycle progression and differentiation, is the most studied of these biomarkers. Serum S100B measurements have been incorporated into some national guidelines for triaging CT imaging in the ER following a mild TBI. Compared to other biomarkers, its relatively shorter half-life may enable serial sampling to detect the progression of secondary injury in the acute setting. However, this marker is nonspecific for cerebral injury, having also been studied as a biomarker for idiopathic psychiatric disorders, for instance. Glial fibrillary acidic protein (GFAP), a protein expressed in astrocytes, is more specific to brain tissue but is cleared less rapidly than S100B.

Recently, investigators of the Collaborative European Neurotrauma Effectiveness Research (CENTER-TBI) study compared the incremental value of measuring serum biomarkers to clinical CT decision-making rules for predicting day-of-injury CT abnormalities. Compared to other serum biomarkers (S100B, neuron-specific enolase, ubiquitin C-terminal hydrolase-L1, neurofilament light chain, total tau), GFAP had the highest discriminative value for predicting CT abnormalities, with a 99% likelihood of improved discrimination of CT-positive patients compared to clinical decision-making rules. GFAP also enhanced the prediction of CT abnormalities in a subset of patients with mild TBI. These research efforts may contribute to our understanding of TBI prognostication and severity categorization.

Electrophysiologic Studies

Conventional electroencephalography (EEG) recordings are currently used in trauma intensive care units for monitoring procedures and for brain death diagnosis. EEG is also invaluable in the diagnosis of status epilepticus and is the primary diagnostic procedure to localize a post-traumatic epileptic focus. The use of nasopharyngeal, anterior temporal,

Telegram: @medical_k

www.konkur.in

or sphenoidal leads increases the chance of finding an abnormality on routine EEG. Video-EEG monitoring and 24-hour ambulatory recordings aid in the differential diagnosis of patients presenting with unclear paroxysmal behavioral disturbances. Quantitative EEG (Q- EEG) is currently used as an adjunctive diagnostic technique in the evaluation of slow-wave abnormalities associated with brain injuries and in the diagnosis of post-traumatic temporal lobe epilepsy.

Polysomnography permits the diagnosis of sleep disturbances that may occur in patients with TBI. These include sleep-disordered breathing, nocturnal epilepsy, rapid-eye-movement sleep behavior disorder, sleep-related movement disorders, and narcolepsy. The latter may also require a multiple sleep latency test.

Visual-, auditory-, and somatosensory-evoked potentials help localize the level of injury to the central nervous system. Auditory-evoked potentials are particularly effective in detecting brain stem pathology. More complex electrophysiologic responses may provide insight into the integrity of neural systems subserving cognitive and emotional functions post TBI. For example, one study using P50 physiology found evidence of deficits in sensory gating mechanisms in patients with TBI.

Neuroendocrine Testing

Hypopituitarism may contribute to the neuropsychiatric sequelae in the acute and chronic phases of TBI. The pooled prevalence estimate of hypopituitarism following TBI is 29%. However, rates vary widely depending upon TBI severity, time post injury, hormones of study, and testing methodologies.

Hypopituitarism may result from primary or secondary injury mechanisms. In terms of the former, traumatic forces may directly injure the pituitary gland, stalk, hypothalamus, and/or their complex vasculatures. In terms of the latter, elevated intracranial pressure, hypotension, and hypoxia may lead to pituitary ischemia and infarction.

During the acute phase following a mild-complicated, moderate, or severe TBI, screening for hypocortisolism (via early morning cortisol) may prevent hypotension, hyponatremia, and increased vasopressor needs. A posterior pituitary injury may also be suspected in patients presenting with potentially life-threatening hypernatremia and hypotonic polyuria from diabetes insipidus. Conversely, the syndrome of inappropriate antidiuretic hormone (SIADH) may cause hyponatremia in the acute setting.

Telegram: @medical_k

www.konkur.in

In the chronic phase, the risk of developing hormonal deficiencies appears to be highest within the first 12 months postinjury; however, some deficiencies may spontaneously remit while others begin at later time points. The emergence of the syndrome of growth hormone deficiency (GHD) in adults—characterized by decreased strength, energy, and sense of well-being—highlights the potential importance of such deficiencies. Estimated rates of GHD following TBI range from 10% to 30%, making it likely the most common endocrinopathy. Rates of luteinizing hormone (LH), follicle-stimulating hormone (FSH), adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), and prolactin abnormalities range from 2% to 17%. About 3% to 5% of patients with TBI may show multiple neuroendocrine abnormalities.

Currently available recommendations for screening in the subacute and chronic phases apply to mild-complicated, moderate, and severe TBIs. Recommendations for appropriate testing after mild, uncomplicated TBI require further research. According to some guidelines, screening for anterior pituitary deficiencies with dynamic ACTH testing (i.e., ACTH stimulation test), TSH levels, and FSH/LH levels is indicated at 3, 6, and 12 months. While GHD may be the most common anterior pituitary hormone abnormality post TBI, dynamic growth hormone testing (e.g., insulin tolerance test or, more recently, macimorelin test) is generally not recommended until 12 months postinjury, as its deficiency may be transient or appear later in the recovery course. After 12 months, if no hormonal deficiencies develop, then repeat testing is unnecessary in the absence of clinical symptoms.

CATEGORIZATION OF TRAUMATIC BRAIN INJURY SEVERITY

Head injuries span a wide range of severity, from patients who die at the time of trauma to those who do not require medical evaluation or assistance. Severity categorization, while arbitrary in several respects, provides a useful heuristic to predict the likelihood of persistent deficits and group patients into relatively homogenous strata for research purposes.

Most commonly, indices of TBI severity are based on the estimated durations of loss of consciousness (LOC) and post-traumatic amnesia

Telegram: @medical_k

www.konkur.in

(PTA); presence or absence of neuroimaging findings; and Glasgow Coma Scale (GCS) scores. (see Table 2.5–1).

The GCS gives a quantitative estimate of the level of consciousness and neurologic status based on patterns of eye-opening, as well as best verbal and motor responses. GCS scores between 13 and 15 define mild brain injury; scores between 9 and 12 define moderate injury; and scores between 3 and 8 define severe injury. The best score in the 24 hours postinjury is a more useful indicator than the initial score immediately after injury (e.g., during a 45-second period of LOC that then resolves).

LOC refers to a period immediately after the injury where the patient is unresponsive and not awake. PTA refers to loss of memory for events preceding the injury or the injury itself (retrograde amnesia) and/or an inability to produce new memories immediately after the injury (anterograde amnesia). The term alteration of consciousness (AOC) typically refers to the disruption in brain function associated with mild TBI (discussed in the mild TBI section below); in the severity classification system presented in Table 2.5–1, it may also refer to cognitive deficits following resolution of PTA after a mild-complicated, moderate, or severe TBI.

Table 2.5–1.
Grading of TBI Severity

Severity	GCS	LOC	PTA	AOC	Neuroimaging
Mild	13–15	0–30 minutes	0–24 hours	0–24 hours	Normal
Complicated mild	13–15	0–30 minutes	0–24 hours	0–24 hours	Abnormal
Moderate	9–12	>30 minutes and <24 hours	>24 hours and <7 days	>24 hours; severity based on other criteria	Normal or abnormal
Severe	<9	>24 hours	>7 days		Normal or abnormal

AOC, alteration of consciousness (dazed, confused, unable to answer simple questions, disoriented); GCS, Glasgow Coma Scale (refers to best score within 24 hours post injury); LOC, loss of consciousness; PTA, post-traumatic amnesia.
Adapted from the VA/DoD Clinical Practice Guideline for the Management of Concussion-Mild Traumatic Brain Injury Version 2.0. (2016), with the addition of complicated mild TBI definitions.

Finally, neuroimaging studies (CT or MRI) may demonstrate the presence of structural brain lesions in some patients otherwise meeting the criteria for a mild TBI—these TBIs are then classified as mild-complicated. The trajectory of recovery following a mild-complicated TBI is akin to a moderate TBI, leading some researchers and clinicians to classify this subtype as a moderate TBI.

Caveats

Telegram: @medical_k

www.konkur.in

There are several limitations to the above classification scheme worthy of mention. Durations of LOC, PTA, and AOC are useful for predicting the presence of abnormal imaging findings and persistent functional impairments post TBI. However, their arbitrary durations may prevent clinicians from viewing TBI severity as occurring on a spectrum. Instead, patients with mild TBI may also be conceptualized as having relatively briefer and less severe manifestations of the acute post-traumatic encephalopathy (discussed further below) that, by definition, fully recovers without sequelae. Other markers of injury, such as serum biomarkers, may improve the predictive value of this classification scheme, particularly for mild TBI.

Furthermore, establishing the durations of LOC, PTA, and AOC from retrospective self-report is challenging, especially when the TBI occurred decades earlier. Memory gaps occurring during a period of PTA may be misinterpreted as an LOC. In addition, patients and/or observers may not disentangle the effects of TBI from other potential causes of altered mental status, such as alcohol or substance intoxication, iatrogenic sedation, pain medications, or other neurologic complications (e.g., seizures, hypoxic–ischemic brain injury), and even severe emotional trauma.

Clinical Assessment of TBI Severity

In clinical practice, obtaining a step-by-step inquiry into what happened before, during, and after the injury, as well as obtaining observer accounts of the injury and any available records, may assist with determining the presence, severity, and duration of mental status alterations. This method of assessment may also assist with determining whether a patient was truly not awake and unresponsive (i.e., had LOC) after the injury. Other useful information may include descriptions of the medical care the patient received in the acute and subacute time frame after the injury; whether neuroimaging demonstrated abnormalities or was even performed; any concurrent alcohol or substance use at the time of the injury; and the course of cognitive and functional recovery postinjury.

From a practical standpoint, standardized questionnaires of TBI history, such as the Boston Assessment of TBI-Lifetime or Ohio State University TBI Identification Method, are rather lengthy for clinical purposes. Referral to neuropsychology, behavioral neurology and neuropsychiatry, or other

Telegram: @medical_k

www.konkur.in

TBI subspecialists may further assist with diagnostic clarification and symptom evaluation.

COGNITIVE MANIFESTATIONS AND SEQUELAE OF TBI

Regional vulnerabilities to closed head injury translate into relative patterns of cognitive impairments and recovery of cognitive domains following TBI. The following sections provide an overview of these cognitive sequelae. Of note, these cognitive impairments begin immediately after the injury and may persist in accordance with injury severity (and other individual factors – see "Major and Minor Neurocognitive Disorder due to TBI"). Also, emotional and behavioral changes following TBI (particularly moderate and severe TBI) often co-occur with cognitive impairment and may reflect damage to shared neural circuitry. However, neuropsychiatric sequelae have been separated in this chapter for the purpose of clarity.

Acute Traumatic Encephalopathy

The term "acute traumatic encephalopathy" refers to the hierarchical recovery of cognitive domains and mental states emerging in the acute period following mild-complicated/moderate or severe TBIs. This nosology is typically employed to characterize the cognitive sequelae occurring immediately after a TBI requiring acute hospitalization. While patients with mild, uncomplicated TBI may also experience similar patterns of cognitive impairments (e.g., PTA), their durations are brief, and, by definition, recovery is relatively full (see Fig. 2.5–3). Persistent cognitive symptoms following mild TBI are discussed in more detail in a separate section.

Post-Traumatic Disorders of Consciousness

As stated above, when a patient experiences LOC, they are not responsive, their eyes are closed, and they are not awake. In the case of mild TBI, this may be transient. For severe TBIs, persistent and widespread damage, including to the reticular activating system and/or thalamocortical circuitry, may lead to a protracted disorder of consciousness, such as coma, persistent vegetative state, or minimally conscious state.

Telegram: @medical_k

www.konkur.in

Coma is characterized by a lack of voluntary movement, behaviors limited to reflex activity; closed eyes; and absent sleep–wake cycles. A persistent vegetative state implies re-emergence of the sleep–wake cycle and spontaneous periods of eye-opening. Minimally conscious states are characterized by inconsistent but clearly present behavioral responses to environmental stimuli (i.e., visual tracking).

FIGURE 2.5–3. The stages and typical outcomes of the acute traumatic encephalopathy. Reprinted with permission from the Textbook of Traumatic Brain Injury, Third Edition, (Copyright © 2019). American Psychiatric Association. All Rights Reserved.

Post-Traumatic Confusional State

After emerging from a disorder of consciousness, patients can experience a post-traumatic confusional state akin to delirium. As such, patients demonstrate impaired simple and sustained attention and may experience perceptual disturbances (i.e., illusions or hallucinations), delusional thoughts, psychomotor agitation or retardation, and affective lability. Symptoms usually have an acute onset and a fluctuating course. Importantly, affective fluctuations and psychosis occurring during this confusional state should be distinguished from discrete episodes of idiopathic mood or psychotic disorders.

Telegram: @medical_k

www.konkur.in

Clinical Vignette: Post-traumatic Acute Confusional State

A 19-year-old man was admitted to a trauma center after a motorcycle accident. He presented with a right epidural hematoma and bilateral contusions in the anterior temporal lobes. He also had a scalp laceration and right maxillary and zygomatic fractures. The postresuscitation GCS score was 8. Following the surgical evacuation of the hematoma, the patient was transferred to the intensive care unit. Two days later, the patient became restless and agitated. He removed his intravenous (IV) lines and monitoring devices and tried to get out of bed. He was disoriented, incoherent, and aggressive. His behavior suggested that he was experiencing frightening visual hallucinations. He appeared to grab at nonexistent objects in the environment and picked at the bedclothes. He responded well to a short course of a low-dose atypical antipsychotic agent.

Other potential conditions may also lead to the development of acute encephalopathy/delirium in patients with TBI and require consideration in the differential diagnosis. Other causes may include acute hydrocephalus, nonconvulsive seizures or status epilepticus, electrolyte imbalance, infections, medications (e.g., barbiturates, opiates, or steroids), and drug or alcohol withdrawal.

Post-Traumatic Amnesia

PTA, as in the above-mentioned classification scheme, refers to the period of recovery that most prominently features an impaired ability to form new memories after the injury and a loss of memory immediately before or during the event, despite the relative recovery of arousal and simple attention. Inability to remember the traumatic event, events immediately preceding the trauma, and the inability to form new memories after the trauma reflects injury to hippocampal systems subserving mnemonic functioning.

The duration and severity of PTA may be assessed using the Galveston Orientation and Amnesia Test (GOAT), which evaluates orientation to person, place, and time, as well as awareness of the accident and its consequences. Alternatively, retrospective structured questionnaires have shown an excellent correlation with this prospective determination.

Telegram: @medical_k

www.konkur.in

Of note, measures of PTA duration tend to blur this phase of recovery with the duration of the post-traumatic confusional state, as attentional impairments occurring in the context of an encephalopathy/delirium also impede memory formation. Despite this, the duration of PTA has proved to be a good predictor of disability, vocational outcome, and severity of comportment changes following TBI.

Post-Traumatic Dysexecutive Syndrome

Following recovery from PTA, executive dysfunction tends to predominate (and frequently persists). This is due to the predilection of close head injuries for frontal–subcortical circuitry and their concomitant white matter connections.

Executive functions disrupted by TBI include goal formation, planning, selection of adequate response patterns, monitoring of ongoing behavior, and control of other cognitive domains. When confronted with demanding or novel environments, the adaptive functioning of patients with TBI is also often impaired.

Bedside tests of executive function—such as the Frontal Assessment Battery, Oral Trail Making Test, the Executive Interview 25, elements of the clock-drawing test, and verbal or figural fluency tests—may be employed to screen for executive deficits and/or their progression over time.

If a more detailed evaluation is appropriate, there are several neuropsychological tasks specifically designed to quantify executive deficits. The Wisconsin Card Sorting Test, the Goldberg Executive Control Battery, the Tower of London Test, and the Trail Making Test can measure impairments in goal formation, set-shifting, and monitoring of behavioral responses.

TBI-related impairments in executive attentional control may also manifest as restricted verbal or visuospatial attentional spans and altered vigilance patterns (i.e., sustained attention deficits). The most consistent findings, however, are associated with performance in the most demanding tasks (e.g., in divided attention paradigms such as the Paced Auditory Serial Addition Task).

During this acute (or chronically persisting) dysexecutive phase of recovery, patients and family members still frequently report “memory” problems. However, the nature of the memory impairment shifts from an inability to form new memories, as in PTA, to difficulty with retrieving

Telegram: @medical_k

www.konkur.in

memories, reflecting impaired executive function. Additional impairments may include faulty sequencing of events and inefficient encoding and storage strategies.

TBI also frequently affects executive control of language and social cognition (the latter is discussed further below). Patients with TBI may demonstrate higher-order language alterations and present with a defective narrative discourse, a lack of semantic coherence, and impaired pragmatics of communication. All of these result in impoverished and disorganized language and in reduced communication proficiency.

Other Cognitive Sequelae of Moderate–Severe TBI

Mild-complicated, moderate, and severe TBIs are more likely to produce persistent cognitive deficits than mild, uncomplicated TBIs. In addition to the deficits in arousal, attention, memory, and executive domains discussed above, processing speed is frequently impaired during acute and chronic recovery phases. Slowed processing speed may be conceptualized as resulting from damage to white matter tracts required for efficient information processing.

Patients post TBI, particularly those with right hemisphere involvement, frequently exhibit unawareness (anosognosia) or denial of deficits. Unawareness of deficits impedes realistic goal setting; interferes with the rehabilitation progress; and may put patients at risk of additional TBIs if they fail to recognize the need to take precautions to compensate for cognitive and other deficits.

While impairments in primary visuospatial, praxis, and language functions are not classically associated with closed TBI, focal damage from penetrating injuries or other complications may result in additional cognitive impairments beyond those typical for closed head injuries. For instance, a bullet passing through the right parietal lobe may produce visuospatial dysfunction and hemineglect. A large subdural hematoma compressing left parietal regions may produce apraxia or aphasia syndromes. Furthermore, subcortical forms of cortical syndromes may occur, such as subcortical aphasia manifesting from injury to left thalamic circuits.

Importantly, peripheral injuries, motivational syndromes, and primary motor or sensory impairments must be considered when interpreting the nature and extent of cognitive impairments. Neuropsychiatric and

Telegram: @medical_k

www.konkur.in

neuropsychological consultation can assist with the evaluation of these deficits and the development of rehabilitation strategies to aid in recovery.

Major or Mild Neurocognitive Disorder Due to TBI

Major or mild neurocognitive disorder due to TBI may be characterized by the incomplete recovery and persistence of cognitive impairments occurring during the "acute traumatic encephalopathy." Thus, these protracted cognitive impairments may manifest as chronic disorders of consciousness; persistent alterations of arousal and attention (as seen in the acute post-traumatic confusional state); impaired new memory formation (as seen in acute PTA); persistent executive and processing speed abnormalities; and/or other chronic focal deficits resulting from additional injuries. For closed head injuries, visuospatial, praxis, and primary linguistic functions may be relatively preserved. Although beyond the scope of this chapter, post-traumatic parkinsonism or dystonia are also possible.

Clinical Vignette: Major Neurocognitive Disorder Due to TBI

A 40-year-old man sustained severe injuries in a motor vehicle accident and experienced a protracted coma of 1-month duration. MRI performed 2 weeks postinjury revealed the presence of widespread diffuse axonal injury. At 15-month follow-up, the patient presented with a mild left hemiparesis, right hemidystonia, and a left lower motor neuron facial palsy. Neuropsychological testing showed profoundly impaired frontal lobe functions and processing speed. Although the assessment was limited by apathy and slowed processing speed, his visuospatial, episodic memory, and linguistic skills were mildly impaired. Treatment with methylphenidate led to modest improvements in speed of information processing speed and apathy.

Of note, the degrees of neurobehavioral and functional recovery (and hence, the likelihood of developing a persistent cognitive disorder) are influenced by several factors unique to the individual experiencing the TBI. Beyond the severity of intracranial pathology, other negative prognosticators include older age; lower premorbid cognitive reserve; poorer socioeconomic statuses; limited social support; participation in legal or work compensation proceedings pertaining to the injury; and pre-

Telegram: @medical_k

www.konkur.in

or postinjury neurologic/psychiatric conditions. Several genetic factors influencing preinjury cognitive and sensorimotor functions, injury-related inflammatory and vascular responses, and postinjury repair mechanisms may also play a role in cognitive outcome. For instance, several studies have demonstrated associations between the APOE-epsilon4 allele and a poor clinical outcome, implying genetic susceptibility to the effect of brain injury.

Mild Traumatic Brain Injury

The categorization of “mild” TBI implies that this form of head injury is at the least end of the severity spectrum of TBI. However, mild TBI severity can be quite broad, ranging from momentary confusion or disorientation to hours of PTA (see Table 2.5–1). The term “concussion” falls within the mild TBI categorization and can be used to imply the least severe form of TBI.

Akin to moderate and severe TBI, LOC and PTA may occur in the context of a mild TBI. AOC also can occur without associated LOC or PTA. While AOC definitions vary, patients present as dazed, confused, disoriented to time of day or current location, perseverative, incoherent, and unable to answer simple questions (e.g. that one plus two equals three). Note that AOC may easily be confused with surprise, fear, or substance intoxication.

While essentially all researchers and clinicians agree that moderate and severe TBI can produce significant and permanent cognitive changes, controversy exists as to whether mild TBI can as well. Patients may report concentration and memory deficits during the first weeks following mild TBI, and some studies have found objective cognitive deficits persisting up to 3 to 6 months postinjury. However, most of these patients spontaneously recover within the first 3 months.

The presence, severity, and functional contributions of persistent cognitive impairments occurring in the context of repetitive, subconcussive head injuries are also controversial. Protracted cognitive deficits are more frequent in patients with mild-complicated TBI. Of note, although CT is more likely to be performed in the ER than MRI, the latter has greater sensitivity for detecting evidence of shear injury. The development of serum biomarkers may also influence severity grading and prognostication of mild TBI. The long-term outcomes for patients with multiple mild TBIs and subconcussive blows are active areas of research.

Telegram: @medical_k

www.konkur.in

Psychiatric disorders preceding mild TBI are also associated with the presence and severity of prolonged concussive symptoms. It is unclear whether this association represents a predisposition to psychiatric disorders more generally or premorbid disruptions to neurocircuitry that lower reserve in response to the injury.

Persistent symptoms following mild TBI, or postconcussive symptoms, may be categorized according to cognitive (e.g., slowed processing speed, attentional difficulties, executive dysfunction, and memory problems), affective (e.g., depression, anxiety, irritability), somatic (e.g., headache, photo- and phonophobia, dizziness, imbalance), or sleep–arousal (e.g., fatigue, insomnia) domains. However, these symptoms are nonspecific for brain injuries. For instance, similar types of symptoms are reported in healthy and orthopedically injured subjects. Furthermore, a patient with untreated obstructive sleep apnea may also experience daytime fatigue, insomnia, and irritability.

For patients with prolonged (i.e., lasting for at least 3 months beyond the initial injury) postconcussive symptoms, reviewing the history of the initial injury and available medical records may provide insights into the severity of TBI. Additional inquiries may include whether neurosurgical interventions were required; neuroimaging was performed; medical complications or alcohol/substance use contributed to mental status alterations; and inpatient hospitalization or rehabilitation was required. Of note, cognitive impairments post TBI begin immediately after the injury and tend to improve with time; for patients with symptoms beginning sometime after the TBI occurred, the causality of the TBI is less clear.

TREATMENT OF COGNITIVE IMPAIRMENTS

Treatment strategies for post-TBI cognitive impairments require consideration of injury severity (e.g., mild vs. severe), timing postinjury (e.g., acute hospitalization vs. subacute inpatient rehabilitation), goals of treatment (e.g., enhancing rehabilitation vs. compensating for chronic impairments), and the medical/psychiatric comorbidities of the patients. The literature guiding management decisions also varies in terms of subject characteristics, settings, time postinjury, and outcomes of interest. With these limitations in mind, the following section briefly summarizes interventions aimed at enhancing cognitive recovery and/or facilitating neural network reorganization in the acute and chronic periods following a

Telegram: @medical_k

www.konkur.in

TBI of sufficient severity to require hospitalization. A brief overview of psychiatric management of persistent postconcussive symptoms is also provided.

Optimal treatment approaches for cognitive impairments following a mild-complicated, moderate, or severe TBI often involve combinations of environmental, cognitive training, and/or pharmacologic interventions. For instance, environmental interventions used to enhance rehabilitation during the post-traumatic confusional state may include providing consistent staffing patterns; developing predictable schedules for activities; minimizing environmental disruptions; proactively addressing internal sources of disruptions (e.g., hunger, fatigue); allowing rest periods; utilizing external reminders or cues; and educating family members.

In terms of cognitive rehabilitation, strategies with a good evidence base for efficacy in TBI include direct attention training, memory strategy training and compensatory strategies (such as notebook use), and pragmatic conversation training. Metacognitive training, including self-monitoring and regulating strategies, may remediate executive function, memory, and attention deficits. In addition, a comprehensive rehabilitation approach involving training in emotional, social, and functional skills in addition to cognitive skills may enhance outcomes.

Pharmacologic interventions for disorders of consciousness and other post-TBI cognitive disturbances typically target catecholaminergic and cholinergic neurotransmitter pathways. Methylphenidate, a dopamine and norepinephrine reuptake inhibitor, may target hypoarousal, speed of information processing, motivational deficits, and fatigue. This medication may also have beneficial effects for depressive symptoms. Of note, studies have not provided support for the commonly held concern that methylphenidate decreases the seizure threshold in patients with acquired brain injuries

Studies of amantadine, a drug with complex pharmacologic effects on dopaminergic, cholinergic, and glutamatergic NMDA receptors, have shown mixed results for enhancing attentional and other cognitive impairments in the subacute and chronic periods post TBI. In the inpatient rehabilitation setting, amantadine is commonly utilized to enhance recovery from a disorder of consciousness, based on the results of a multicenter, randomized controlled trial (RCT) of 184 patients in vegetative or minimally conscious states. Of note, patients in this study were 4 to 16

Telegram: @medical_k

www.konkur.in

weeks postinjury, and the benefits of amantadine (200 to 400 mg/day for 4 weeks) over placebo dissipated after amantadine's discontinuation.

Cholinesterase inhibitors (e.g., donepezil) may target motivation, arousal, and memory deficits. In terms of the latter, a recent multi-VA trial comparing rivastigmine 9.5 mg/24-hour patches to placebo for chronic memory deficits in 94 veterans (with TBIs of mixed severities) was negative. However, the inclusion of subjects with high rates of concurrent opioid and anxiolytic/hypnotic use, mixed TBI severities, and relatively intact functional and cognitive statuses producing a ceiling effect may account for these negative findings.

Persistent Postconcussive Symptoms

For persistent symptoms following a mild TBI, a general approach to psychiatric management includes providing education on the expected course of improvement post mild TBI (complete resolution of symptoms in approximately 90% of patients within 12 months of a single, uncomplicated mild TBI) and the treatment of comorbid psychiatric conditions. As the evidence supporting pharmacologic management of persistent cognitive symptoms following mild TBI is limited to small RCTs and uncontrolled studies, these symptoms should rarely be treated with cognitive enhancers alone. On the other hand, medications with anticholinergic or other cognitively harmful side effects, adverse metabolic effects, and sedating properties should be tapered off, discontinued, and/or replaced. Other causes of cognitive impairments, such as obstructive sleep apnea, vitamin deficiencies, or another neurodegenerative process, should be considered in the differential diagnosis. Finally, referrals to specialists may assist in further assessment, treatment, and/or rehabilitation of cognitive, somatic, and sleep complaints, as appropriate.

TBI AND LATER-LIFE NEURODEGENERATIVE DEMENTIA

Overall, most of the evidence—including retrospective, prospective, and meta-analytic studies—indicates that TBI increases the risk of developing neurodegenerative disorders later in life. The mechanisms by which TBI, including mild TBI, increase and/or accelerate the onset of various dementias are unclear. In predisposed individuals, the injury may

Telegram: @medical_k

www.konkur.in

accelerate or augment the aggregation of pathologic proteins. Alternatively, the injury may lower cognitive reserve. In some cases, reverse causation could also be true-for example, the TBI could reflect an already present neurodegenerative process impairing impulse control and balance. Furthermore, one large epidemiologic study found that TBI increases the risk of subsequent ischemic stroke; as cerebrovascular disease is a known risk factor for vascular neurodegenerative dementias, this could potentially represent another pathway for TBI to predispose to several types of dementia.

The preponderance of evidence gleaned from epidemiologic studies indicates that TBI confers a greater risk of developing Alzheimer disease (AD). Some of the pathology of AD (primarily amyloid deposits) may be overrepresented in the brains of individuals with TBI. However, most of these neuropathologic analyses were carried out in cases with severe TBI who died within a few days of trauma. Recently, amyloid-beta PET performed on 241 subjects enrolled in the Alzheimer's Disease Neuroimaging Initiative showed that TBI history was associated with greater amyloid-beta deposition, more pronounced cortical thinning, and a 3- to 4-year earlier age of cognitive impairment onset.

Lifetime TBI history has also been linked to non-Alzheimer, neurodegenerative dementias. Researchers utilizing data from 609 subjects in the National Alzheimer Coordinating Center (NACC) found an age of onset accelerating effect of TBI on several different dementia diagnoses, including mild cognitive impairment, AD, Parkinson disease and related disorders, and frontotemporal dementia. Overall, subjects with self-reported TBI (including single or repetitive TBI, with or without losses of consciousness) were 3.25 years younger, on average, at their first cognitive decline assessment than subjects without TBI, independently of sex, race, attained education, APOE genotype, and clinical diagnosis. Another large, retrospective database analysis demonstrated a synergistic effect of TBI and post-traumatic stress disorder (PTSD) on Parkinson disease risk in U.S. veterans. Advances in neuroimaging, cerebrospinal fluid biomarkers, and serum biomarkers of neurodegeneration may provide new insights into the association of TBI with Alzheimer, Parkinson disease, and other neurodegenerative dementias in living subjects.

Chronic Traumatic Encephalopathy

Telegram: @medical_k

www.konkur.in

In addition to facing higher risks of AD and other neurodegenerative disorders, individuals with repeated mild TBI may develop a unique cognitive disorder known as chronic traumatic encephalopathy (CTE), a dementia syndrome not explainable by an alternative pathophysiologic process. Media coverage of cases of CTE in professional athletes has heightened interest in the relationship between TBI and dementia. This line of research has important implications for military service members, given the higher rates of repetitive TBI in this population compared to the general public.

Modern descriptions of CTE may represent a different condition from the classically described CTE. Classic CTE, also known as dementia pugilistica and initially described in professional boxers, primarily manifests with parkinsonism and nonprogressive cognitive deficits. Modern CTE presents with prominent psychiatric symptoms, and the cognitive deficit tends to progress, though parkinsonism occurs in both conditions.

Clinical descriptions of modern CTE do not clearly distinguish it from other types of dementia. Thus far, no distinguishing pattern of cognitive deficits has been described in CTE; this differs from other dementia subtypes such as AD, where early memory involvement is prominent, or behavioral variant frontotemporal dementia, which tends to present with executive function deficits. The presence of early prominent psychiatric symptoms also does not distinguish CTE from other dementia types—psychiatric changes are common in all types of dementia and may present as an initial symptom. Even motor deficits are not unique to CTE; for instance, motor deficits occur in about one in five patients with AD, the prototypical cortical dementia. A history of TBI is also not specific to CTE, as TBI appears to increase the risk for conventional dementia

At this time, CTE is only definitively diagnosed at autopsy. The pathognomonic CTE finding is the presence of irregular, phosphorylated tau aggregates in neurons and astrocytes around small vessels at the depths of the cortical sulci. Part of the difficulty in determining whether CTE represents a clinically distinct dementia syndrome is due to the postmortem ascertainment of cases, which means that the clinical phenomenology is often determined by a retrospective interview with family members rather than with detailed examination and testing during life. Currently, prospective studies of individuals with repeated TBI, such

Telegram: @medical_k

www.konkur.in

as professional athletes, are underway, which may help clarify the phenomenology of CTE and validate clinical criteria.

NEUROPSYCHIATRIC DISTURBANCES FOLLOWING TRAUMATIC BRAIN INJURY

The following sections summarize the frequencies, presentations, and management of selected neuropsychiatric disorders post TBI. These disorders are intricately linked to functional, cognitive, and psychosocial outcomes.

The fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) classifies many of the neurobehavioral consequences of TBI as disorders due to another medical condition, in this case, TBI. Contemporary research supports the notion that the relationship between TBI and neuropsychiatric disorders is indeed bidirectional: not only can TBI directly cause these disorders, but they appear to increase the risk of TBI as well.

Individuals with premorbid psychiatric disorders have a 70% higher risk of experiencing TBI, possibly because conditions such as substance use disorders, attention-deficit/hyperactivity disorder (ADHD), mania, and psychosis may place them in situations in which TBIs are more likely to occur. Thus, the development of cognitive and psychiatric disorders post TBI must be considered in the context of the individual's pre-existing psychiatric/medical history, cognitive status, genetic/epigenetic predispositions, and social functioning.

GENERAL MANAGEMENT PRINCIPLES

Before proceeding with summaries of individual disorders, several management principles applicable to all post-TBI neuropsychiatric disorders are worthy of mention. Akin to the treatment of cognitive impairments, treatment strategies for post-TBI neuropsychiatric disorders are best approached from a multidisciplinary perspective. Pharmacologic interventions are ideally employed as adjunctive to nonpharmacologic ones. There is also a paucity of high-quality RCTs providing a solid scientific basis for psychiatric treatments post TBI. Furthermore, studies in this population vary in terms of injury severities, times post injury, and other sample characteristics. Currently, anecdotal cases, small

Telegram: @medical_k

www.konkur.in

uncontrolled trials, and clinical experience comprise the only evidence bases supporting daily treatment decisions.

Nonpharmacologic therapies—that is, psychotherapy, environmental and behavioral interventions—should be prioritized wherever possible. Given the limited evidence base for many interventions, clinicians must make sure to avoid iatrogenic harms related to medications.

Finally, care must be taken when increasing medications—"start low and go slow." However, adequate dosage and duration should be trialed prior to tapering off or adding adjunctive medications. A partial response to a specific agent may require augmentation therapy, ideally with a drug whose mechanism of action and side-effect profile does not mimic the former's. Finally, clinicians should frequently reassess brain-injured patients for side effects and interactions with other medications.

Agitation and Aggression

Agitation is defined as excessive, usually nonproductive, motor activity associated with inner tension. Agitation is frequently used to describe various behaviors without reference to the patient's subjective experience or intention, such as yelling or pulling out lines. On the other hand, aggression refers to overtly threatening or injurious behaviors directed toward another person or object. Aggressive behaviors tend to be reactive and impulsive, as opposed to proactive, when occurring in the context of TBI-related cognitive impairments.

Agitation and aggression pose frequent and significant problems in acute hospital and rehabilitation settings. In the acute phase of recovery, agitation, and aggression may occur during the post-traumatic confusional state. In the chronic setting, aggression and agitation may impede care and reflect protracted impairments in impulse control or affective lability. The identification of iatrogenic or other medical complications that may contribute to aggression, agitation, or delirium should precede treatment initiation.

Typical environmental strategies for agitation and aggression may include frequent reorientation, placing the patient in a private room, and reducing ambient noise. Applied behavioral analysis and management techniques may identify and intervene upon triggers and possible reinforcements. Other nonpharmacologic interventions include caregiver support and education, supportive psychotherapy, and cognitive behavioral therapy (CBT) tailored to the patient's cognitive status.

Telegram: @medical_k

www.konkur.in

Standardized measures of agitation and aggression (i.e., the Overt Aggression Scale [OAS]) may track response or nonresponse to possible interventions.

Pharmacologic therapy should be considered adjunctive to nonpharmacologic strategies. Evidence from animal studies suggests that both typical (e.g., haloperidol) and atypical neuroleptics (e.g., risperidone) might have a negative impact on cognitive recovery. One animal study demonstrated that haloperidol, but not olanzapine, impaired cognitive performance in rats post TBI. In general, a prudent strategy for treating acute agitation in the context of TBI is to avoid anything that could worsen the patient's cognition—and thus ability to control their behavior—such as anticholinergic drugs, other deliriogenic medications like benzodiazepines, and, possibly, typical antipsychotics. Finally, care must be taken to ensure that aggression and agitation are not induced by iatrogenic side effects (e.g., akathisia from antipsychotics).

Pharmacologic treatments for chronic agitation or aggression following mild-complicated, moderate and severe TBI include amantadine, beta-blockers (e.g., propranolol and pindolol), and selective serotonin reuptake inhibitors (SSRIs) (e.g., sertraline). Anticonvulsants may be considered despite limited data supporting their efficacy and safety in this population. Recently, RCTs of amantadine (200 mg per day) and carbamazepine (up to 400 mg per day) for post-TBI neuropsychiatric symptoms failed to find significant differences between active and placebo groups on most measures of irritability, aggression, and anger. On the other hand, the placebo response rates observed in these studies highlight the benefits of nonpharmacologic aspects of treatment on TBI-associated agitation and aggression, such as developing therapeutic alliances and tracking symptoms.

Of note, while prophylactic administration of antiseizure medications (ASMs) for the first 7 days following severe TBI effectively reduces the incidence of seizures during this timeframe, longer administration of ASMs or administration in mild or moderate TBI has no effect on the subsequent development of post-traumatic epilepsy. As ASMs can have significant side effects and may potentially inhibit the neuroplasticity needed for optimal recovery, clinicians should avoid prophylactic use of ASMs beyond 7 days postinjury in patients with severe TBI and avoid prophylactic use completely in patients with mild or moderate TBI.

Telegram: @medical_k

www.konkur.in

Comportment Changes

Patients with TBI may experience deficits in comportment, defined as the set of mental processes facilitating contextually appropriate social adaptation and judgment. Clinically, caregivers may report the patient's "personality" has changed. For example: "Before the injury, he/she was polite and introverted. Now he/she curses, blurts out hurtful comments, and hits people when he/she is told no in public."

The famous history of Phineas Gage exemplifies the potentially devastating impact of TBI on comportment and social cognition. Gage was a 25-year-old construction foreman for a railroad company when he suffered a severe, penetrating TBI from a blast at a railroad construction site. A 43-inch long, 13.5-pound iron rod passed through the left frontal lobe before exiting the top of his skull. Gage was able to talk and ambulate away from the accident with assistance from coworkers. However, his physician described Gage as inconsiderate, capricious, obstinate, and profane after the accident. Despite having a relatively intact intellect, "He was no longer Gage." Ultimately, Gage was dismissed from this job, but he was able to work in various others before his death from status epilepticus.

FIGURE 2.5–4. Frequency of mood disorder due to traumatic brain injury with major depressive features.

Telegram: @medical_k

www.konkur.in

Broadly speaking, TBI-induced changes in comportment reflect injury to the prefrontal neural circuitry required for modulating reward/punishment-based decision making, emotional expression and generation, and insight. In the case of Phineas Gage, modern imaging techniques have demonstrated rod-inflicted damage to the orbitofrontal and medial prefrontal cortical regions that contribute to these functions.

Treatment strategies for impaired social cognition prioritize behavioral interventions. Providing psychoeducation to the patient and family is an integral component of management. Therapeutic interventions may include recalling premorbid emotional events and using stimuli that trigger strong emotions to assist with reconnecting to these emotions. Role-playing and image interpretation can assist with social skills training. In addition, partner training has been shown to improve communication appropriateness and effectiveness. Finally, behavioral analysis may quantify the frequency of unwanted behaviors and identify modifiable triggers.

Pharmacologic interventions may target disinhibited, agitated, or aggressive behaviors. SSRIs may reduce sexual drive and are utilized for disinhibited behaviors in other neuropsychiatric conditions. Anticonvulsants, like those used for mania, are other options for managing disinhibition and aggression. Furthermore, addressing cognitive impairments may concomitantly improve behavioral control. More research is needed to guide pharmacologic strategies targeting comportment changes following TBI.

Clinical Vignette: Comportment Changes due to TBI

A 42-year-old construction worker fell from the second floor of a new building. He spent 3 days in a coma and remained amnestic and disoriented for approximately 3 weeks. A CT scan showed bilateral orbitofrontal and anterior temporal hemorrhagic contusions. Six months after the injury, he exhibited a significant personality change. His wife complained of his frequent and often inappropriate sexual demands and stressed his lack of intimacy. He also became easily upset, shouting and making threats when he felt provoked. He was less sensitive to other people's feelings. A trial of sertraline and the maintenance of a numerical record of outbursts resulted in significantly reduced irritability, outbursts, and hypersexuality.

Telegram: @medical_k

www.konkur.in

Depressive Disorders

Depressive disorders are common neuropsychiatric complications of TBI. The frequency of post-TBI depression ranges from 6% to 77% (Fig. 2.5–4). This variability in the reported frequency of depressive disorders, particularly major depression, may reflect the lack of uniformity in the psychiatric diagnosis, sampling times postinjury, and TBI severities.

The risk of developing a depressive disorder appears to be highest in the first year. Approximately 29.4%, 19.6%, and 1% of patients are estimated to meet DSM-IV criteria for major depressive disorder (MDD), depressive disorder not otherwise specified, and dysthymic disorder, respectively, at 12 months postinjury. In comparison, the annual rate of MDD in the general population has been quoted at 6.7%.

Approximately 25% of those without depression in the first year will go on to develop it in the second year, and the risk of depression remains elevated for decades. Furthermore, post-TBI depression tends to be persistent, with one study finding that two-thirds of patients experience symptoms for 1 year or longer. Overall, patients with TBI are at increased risk of developing recurrent depressive disorders throughout their lifetimes compared to patients without TBI.

The DSM-5 classifies depressive disorders associated with TBI as “Depressive Disorder due to Traumatic Brain Injury” with the following subtypes: (1) “with depressive features” (prominent depressed mood but full criteria for a major depressive episode are not met), (2) “with major depressive-like episode” (if the full criteria for a major depressive episode are met), or (3) “with mixed features” (manic or hypomanic symptoms present but not predominant). The standard DSM-5 criteria have a high sensitivity and specificity for identifying depressed patients when compared with alternative diagnostic criteria. One study found that the three symptoms of hopelessness, feeling worthless, and anhedonia best differentiated depressed from nondepressed patients.

Other conditions requiring consideration in the differential diagnosis of post-TBI depression include adjustment disorder with depressed mood; apathetic syndromes; emotional lability or pathologic laughing and crying (PLC); delirium occurring in the context of a post-traumatic confusional state or another cause; and expressive dysprosodia (i.e., impaired ability to utilize intonation and inflection to convey meaning in language associated with right hemispheric injury). Patients with adjustment disorders develop short-lived and relatively mild emotional disturbances

Telegram: @medical_k

www.konkur.in

within 3 months of a stressful life event, and symptoms do not persist longer than 6 months after the stressful event or its consequences cease.

It is well known that age and severity of brain injury are major determinants of recovery from TBI. However, mood disorders have consistently shown independent deleterious effects on recovery of patients with TBI. Patients with post-TBI depression are more likely to have poorer executive function, social integration, and vocational outcomes. Importantly, post-TBI depression appears to increase the risk of subsequent suicide. Thus, the identification, treatment, and/or prevention of depression represent essential elements of post-TBI care.

Clinical Vignette: Post-TBI Depression

A 42-year-old engineer had a motor vehicle accident when returning from a convention. He had multiple injuries, including a diaphragmatic rupture and a left frontotemporoparietal subdural hematoma. When admitted to the hospital, the patient was hypotensive and hypoxic. With the urgent intervention of two surgical teams, he underwent repair of his diaphragm and evacuation of the subdural hematoma. The patient remained in a coma during the following 72 hours. PTA lasted for almost 3 weeks. At this point, the neurologic examination disclosed a right hemiparesis, a left lateral rectus palsy, mild hypophonia, and dysarthria. Forty days after the accident, he transferred to a specialized rehabilitation unit. Once his PTA had cleared, neuropsychological tests neared normal limits. The patient conveyed a profoundly depressed mood and feelings of hopelessness. He stated that he would never be able to recover, that his career was ruined, and that it would have been better if he had died in the accident. He had no appetite and refused to participate in physical rehabilitation. He also had significant sleep problems. Treatment of depression was initiated with sertraline at a dosage of 50 mg per day. After 3 weeks, the patient's mood significantly improved, and he became involved in the rehabilitation program. At 6-month follow-up, he was no longer depressed and had returned to work.

The relationships between depression and psychosocial stressors are often bidirectional. Data from a longitudinal cohort study suggests that pathological processes associated with the brain injury contribute, at least

Telegram: @medical_k

www.konkur.in

in part, to the development of mood disorders. In this study, patients with TBIs of mixed severities were recruited from three academic centers (n = 158) and compared to an orthopedic injury control group (n = 27) with similar demographic characteristics, psychiatric histories, and functional impairments. At 3, 6, and 12 months of follow-up, patients with TBI exhibited a significantly greater frequency of mood disorders than the comparison group of patients with orthopedic trauma (Fig. 2.5–5). In the TBI group, 54% of patients developed a mood disorder at some time during the first year after injury, compared to 22% of patients with multiple traumatic injuries but without central nervous system involvement. In addition, the frequency of MDD was significantly greater in the TBI versus the control group. Thus, mood disorders were significantly more frequent in patients who suffered TBIs than in patients with similar background characteristics who underwent similar levels of stress (e.g., motor vehicle accidents) but who did not sustain a brain injury.

The pathologic mechanisms initiated by TBI and contributing to depression risk remain unclear. In one series, post-TBI major depression was associated with reduced gray matter volume in the lateral aspects of the left prefrontal cortex (Fig. 2.5–6). Major depression could result from the deactivation of more lateral and dorsal frontal cortex and increased activation in ventral limbic and paralimbic structures.

FIGURE 2.5–5. Frequency of mood disorders among patients with traumatic brain injury (TBI) compared to controls with orthopedic injuries. The frequency of mood disorders was significantly greater in TBI patients than in a comparison group of patients with orthopedic trauma.

Faulty prefrontal modulation of medial limbic structures could explain the co-occurrence of anxiety and aggression in this cohort. In a subgroup

Telegram: @medical_k

www.konkur.in

analysis, MDD was significantly associated with the presence of anxiety disorders (Fig. 2.5–7). Furthermore, major depression was also associated with the occurrence of aggressive behavior, as categorized by the OAS. Of the 30 patients with major depression, 17 (57%) demonstrated significant aggressive behavior compared with 10 of 44 patients who showed the same level of aggression without mood disorder during the first year after TBI (p = .004) (Fig. 2.5–7).

In addition to the injury itself, several non-injury factors do appear to influence post TBI depression risk. These factors include personal histories of mood and anxiety disorders, impaired social functioning, current or past alcohol use, unemployment, and poverty. In this same longitudinal cohort, patients with post BI major depression we more likely to have personal histories of mood disorders than non-depressed patients. Groups did not differ significantly in respect to types or severities of brain injuries, family histories of psychiatric disorders, or degrees of physical impairments. Patients with major depression had significantly poorer premorbid social functioning than the nondepressed group, and poor social functioning was the strongest and most consistent clinical correlate of major depression during follow-up (Fig. 2.5–8).

As limited data regarding the treatment of depression in the TBI population exist, clinical care generally follows principles derived from the treatment of idiopathic MDD. Psychotherapeutic interventions with some evidence for TBI-related depression include CBT, mindfulness-based CBT, behavioral activation, problem-solving therapy, acceptance and commitment therapy, and supportive psychotherapy. However, most evidence is derived from small and uncontrolled studies. There is not enough data supporting the efficacy of one psychotherapy over another. One RCT found that both CBT and supportive psychotherapy equally improved depression following TBI. Of note, psychotherapies may require tailoring to suit the cognitive and physical needs of the patient. For example, patients with post-TBI cognitive impairments may benefit from receiving written summaries of session contents, handouts or visual aids, simplified instructions, and caregiver support.

Selection among competing antidepressants is usually guided by their side-effect profiles. In general, it is best to choose drugs with minimal anticholinergic properties, sedative effects, and lowering of the seizure threshold. Currently, SSRIs are considered first-line therapies. The most studied SSRI in the TBI population is sertraline. However, the two largest

Telegram: @medical_k

www.konkur.in

RCTs of sertraline to date have not supported its efficacy for the treatment of post-TBI depression. In the most recent of these two RCTs, sertraline was associated with more side effects and dropouts than placebo. Despite being the "largest" trials for post-TBI depression, the number of subjects in both studies (n = 52 and n = 62) were still relatively small.

Additional evidence supporting the use of sertraline and other SSRIs (e.g., escitalopram, citalopram, and fluoxetine) for post-TBI depression are derived from small RCTs or uncontrolled studies. Methylphenidate may benefit depression, cognition, and fatigue, according to small RCTs. Tricyclic antidepressants (TCAs) are not preferred due to their side-effect profiles, including lowering of the seizure threshold and anticholinergic activities. Other antidepressants used in the treatment of idiopathic MDD (e.g., selective serotonin and norepinephrine inhibitors) may be reasonable alternatives despite lacking systematic investigations in the TBI population. Bupropion, while not absolutely contraindicated in TBI, can lower the seizure threshold; using the lowest effective dose, the extended- or sustained-release formulation, and careful monitoring may help reduce the risk.

FIGURE 2.5–6. Frontal gray matter volumes in traumatic brain injury (TBI) patients with major depression. Magnetic resonance imaging volumetric studies showing that, after controlling for age and severity of trauma, left frontal gray matter volumes are significantly decreased in the group of depressed TBI patients compared with the nondepressed group.

ECT is not contraindicated in patients with TBI and may be considered if other methods of treatment prove to be unsuccessful, though there are

Telegram: @medical_k

www.konkur.in

no systematic studies of its effects. ECT should be administered with the lowest possible effective energy, using brief-pulse, nondominant unilateral currents, and with an interval of 2 to 5 days between treatments. Neurostimulation therapies such as repetitive transcranial magnetic stimulation (rTMS) and transcranial direct current stimulation (tDCS) are also options, although evidence for the latter is inconsistent. A recent meta-analysis of three RCTs and two quasi-experimental pre- and postintervention studies found a positive pooled effect of rTMS on post-TBI depression severity. However, studies to date have utilized heterogeneous stimulation parameters and research methodologies. Furthermore, rTMS should be used with caution, as it may increase the risk of seizure.

Prevention is regarded as more effective than treatment. The prevention of post-TBI depression has received little attention compared to other medical conditions. One RCT compared sertraline 100 mg/day versus placebo for the prevention of depression in 94 patients in the subacute recovery period of TBI. In this study, the hazard of developing depression during 24 weeks of treatment was four times greater in the placebo than sertraline group, and the number needed to treat with sertraline to prevent depression at 24 weeks was 5.9, 95% confidence interval (CI) [3.1, 7.1]. However, another RCT comparing sertraline 50 mg/day versus placebo for 3 months in the subacute recovery period did not find a significant difference in the number of patients who developed depressive episodes between groups. Additional studies of preventive interventions are needed.

FIGURE 2.5–7. Coexistent anxiety and aggression among depressed traumatic brain injury (TBI) patients. Frequency of anxiety and aggressive disorders among depressed TBI patients, nondepressed TBI patients, and patients with orthopedic injuries. Major depressive disorder following TBI was significantly associated with the presence of anxiety disorders and aggressive behavior.

Pathologic Laughing and Crying

PLC manifests as sudden and uncontrollable affective outbursts which may be congruent or incongruent with the patient's mood and can occur spontaneously or may be triggered by minor stimuli. Patients recognize the emotional displays as unrelated or excessive to the underlying mood. Affective displays in PLC are not necessarily reflective of a pervasive alteration of mood or specific vegetative symptoms associated with a major depressive episode.

One study examined the prevalence and clinical correlates of this disorder, assessed using the Pathological Laughter and Crying Scale, in a group of 92 consecutive patients with TBI. Eleven percent of the patients developed PLC during the first year after TBI. PLC was associated with the presence of anxiety disorders and frontal lobe lesions involving the lateral and ventral aspects of the prefrontal region (Fig. 2.5–9). In addition, patients with PLC had significantly more frequent aggressive outbursts and poorer social functioning.

Treatment options for PLC in TBI remain understudied; however, based on their efficacy for this condition in other neurologic disorders and their generally benign side-effect profile, SSRIs represent a reasonable first-line strategy. However, treatment response varies greatly among brain-injured patients, with some showing a rapid response at relatively low doses while others require more time and higher doses. Combination

Telegram: @medical_k

www.konkur.in

therapy with dextromethorphan and quinidine is another option, but quinidine may inhibit the metabolism of other medications. In addition, the proprietary combined pill is quite expensive and may impose a financial burden on some patients.

Apathy

Apathy consists of impairment of motivation, initiation, interest, activity, emotional responsiveness, and/or spontaneity. Apathy, regardless of the underlying etiology, frequently occurs comorbidly with depression, but the two conditions constitute distinct entities with different implications for prognosis and treatment. While patients with apathy often do not appear distressed by their symptoms, apathy can markedly impair patients' ability to participate in rehabilitation therapies, function in the community, and maintain interpersonal relationships.

FIGURE 2.5–8. Comparison of Social Functioning Examination (SFE) scores of major depressed and non-depressed patients during the first year following traumatic brain injury. Higher scores are associated with greater impairment. Poor social functioning was the strongest and most consistent clinical correlate of major depression during follow-up.

Apathy is a frequent complication of TBI: studies have quoted prevalence ranges nearing 75%. Studies investigating potential associations between severity of TBI and apathy have produced conflicting results some studies have found no relationship, but others have found that more severely injured patients are more likely to show

Telegram: @medical_k

www.konkur.in

apathy. One imaging study in patients with TBI found that patients with apathy showed damage to the left hemisphere, specifically in the frontal lobe, anterior cingulate, insula, corpus callosum, and corona radiata, consistent with these regions' involvement in emotion and goal-directed behavior.

Currently, treatments for apathy after TBI are lacking an evidence base. Providing psychoeducation on the nature of apathy and why it does not represent laziness or withdrawal of love may improve caregivers' understanding of the condition and expected treatment outcomes. As patients with apathy may participate in and enjoy activities initiated by others, even if they do not initiate them on their own behalf, family members and friends can provide a structured environment and utilize verbal or visual reminders to encourage the person with apathy to engage in activities. Based on case reports and case series, pharmacologic agents with prodopaminergic activity (e.g., methylphenidate, amantadine, bromocriptine, bupropion) may be trialed as well. Some studies in the general population suggest that SSRIs can worsen apathy, although others have found the opposite. In general, rigorous studies examining treatments for apathy post TBI are greatly needed.

FIGURE 2.5–9. Emotional deregulation following traumatic brain injury. Frontal lobe lesions involving the lateral and ventral aspects of the prefrontal region in a patient with recurrent episodes of pathologic crying consistent with a diagnosis of pathologic laughing and crying.

Bipolar and Related Disorders

Bipolar mood disorders are relatively less frequent compared to depressive disorders post TBI. Estimated rates of bipolar-type disorders in the first-year postinjury range from 2% to 9%. The diagnosis of mania following TBI is based on the DSM-5 criteria for bipolar and related disorders due to TBI, with three subtypes: (1) “with manic features” (full criteria not met for a manic or hypomanic episode), (2) “with manic- or hypomanic-like episode” (full criteria met), and (3) “with mixed features” (depressive symptoms present but not predominant). As in the case of depressive disorders, the mania must appear to stem directly from the physiologic consequences of the brain injury. The diagnosis only requires that the predominant mood be elevated, euphoric, or irritable and accompanied by abnormally elevated energy and/or activity. This does not require the same specificity of the syndrome as a manic episode or a major depressive episode.

A 1987 study reported on 20 patients who developed manic syndromes after closed head trauma. There was a significant association between

Telegram: @medical_k

www.konkur.in

mania and the presence of post-traumatic seizures, predominantly focal onset with impaired awareness (temporal lobe epilepsy). There was no association, however, with a family history of bipolar disorder among first-degree relatives.

FIGURE 2.5–10. Family history of mood disorder among patients with manic syndromes due to traumatic brain injury (TBI). The frequency of family history of mood disorders is significantly higher among patients with bipolar disorder compared to patients with secondary mania, TBI patients without mood disorders, and healthy controls. However, family history of mood disorders was greater among patients with secondary mania compared to TBI patients without mood disorders and healthy controls.

One study found that patients with TBI showed a higher rate of secondary mania during the year after traumatic injury than patients with orthopedic injuries. Although manic episodes lasted only approximately 2 months, the presence of an elevated, expansive, or irritable mood had a mean duration of 5.7 months. Manic syndromes were significantly associated with hyperactivity, disinhibition, aggressive behavior, and hypersexuality. Secondary mania was not related to the type or severity of brain injury, degree of physical or intellectual impairment, level of social functioning, or the presence of family or personal history of psychiatric disorder (Fig. 2.5–10). The development of abnormal electrical activation patterns in limbic networks, functional changes in aminergic inhibitory systems, and the presence of aberrant regeneration patterns may all play a role in the genesis of post-TBI mania.

Telegram: @medical_k

www.konkur.in

The differential diagnosis of mania following TBI should include substance/medication-induced bipolar and related disorder, delirium, and comportment change due to TBI. Impairments in social cognition, conversational pragmatics, and executive dysfunction may appear “manic like.” Affective and behavioral manifestations may also feature prominently in delirium (including during the acute post-traumatic confusional state). Substance-induced mood disorder occurs following intoxication or withdrawal from drugs and is another important differential diagnosis among patients with TBI, who frequently have a prior history of substance abuse.

There have been no systematic studies for the treatment of secondary mania. Thus, it is reasonable to treat along the lines of idiopathic bipolar disorder. Some researchers have theorized that lithium and valproate have neuroprotective effects, which would certainly constitute an important therapeutic advantage among brain-injured populations; however, there is currently no evidence to support if this actually occurs, as data from a controlled trial of valproate in TBI failed to identify a beneficial effect on cognitive and functional outcomes. Patients with persistent cognitive impairments following TBI may also be more susceptible to neurologic side effects of lithium and anticonvulsants. The role of the anticonvulsant lamotrigine for post-TBI bipolar disorder has not been studied. Although data is limited to case reports, atypical antipsychotics (e.g., quetiapine, olanzapine) may also be considered.

www.konkur.in

Clinical Vignette: Bipolar Disorder Due to TBI

A 31-year-old married man with two children was struck in the head when a welding tank exploded, sending large and small pieces of metal in all directions. He experienced intracerebral bleeding in the right basal ganglia and white matter surrounding the anterior horn of the right lateral ventricle. Months after the injury, he became manic, staying up all night, selling things he owned for ridiculously low prices, and buying a new car he could not afford. He believed that he would become a famous songwriter and exhibited hypersexual behavior. He was admitted to a hospital, where he was treated successfully with low-dose lithium and olanzapine. He remained euthymic for approximately 6 months, and he discontinued his medications. Although he continued to experience significant behavioral changes, manic symptoms did not recur during a 2-year follow-up period.

Trauma- and Stressor-Related Disorders

PTSD, the prototypical trauma-related disorder, is characterized by recurrent intrusive recollections, distressing dreams, and flashbacks of the traumatic event. Patients with PTSD show features of increased arousal such as difficulty falling or staying asleep, exaggerated startle response, and irritability. Patients lose interest in social activities and avoid thoughts, feelings, or circumstances associated with the event.

Telegram: @medical_k

www.konkur.in

Clinical Vignette: PTSD Following TBI

A 33-year-old nurse was assaulted while walking to her job in a small hospital. She received several blows to her head and was admitted unconscious to the ER. A CT scan showed a depressed skull fracture and right temporal and parietal contusions. She regained consciousness during the first 12 hours of admission and was confused and disoriented for the following 3 days. After this, she had an uneventful course and a good recovery. One month after trauma, she received a complete neuropsychiatric evaluation. She complained of intrusive recollections of the moments preceding the assault, which were associated with great psychological distress, sweating, and palpitations. She was also disturbed by nightmares in which she suddenly found herself in an intensive care unit connected to a ventilator, incapable of talking or asking for help. She avoided the hospital's surroundings and was unable to walk alone. She also complained of decreased concentration and memory impairments. The results of her neuropsychological tests, however, fell within the normal range. A course of modified prolonged exposure (PE) therapy greatly improved the distress associated with intrusive memories and the frequency of nightmares.

Individuals who sustain a TBI are more likely to develop PTSD than those who suffer other types of traumatic injuries. Veterans who experienced a TBI show a threefold greater rate of PTSD than those without a TBI; civilians with TBI have almost twice the likelihood of developing PTSD as those with other types of traumatic injuries. Estimates of how many individuals with TBI have comorbid PTSD vary widely, from 12% to 30% in civilians and from 12% to 89% in veterans. In addition to variance introduced by different methods of assessment, part of the uncertainty lies in the overlap between PTSD and TBI symptoms, such as impaired concentration/attention and executive function and poor sleep.

Some researchers have speculated that TBI is incompatible with the development of PTSD, because amnesia for the traumatic event would be protective. More recent studies have not born this out. It is possible that even patients with moderate or severe TBI can encode trauma memories at an implicit level, and these memories can influence ongoing emotions

Telegram: @medical_k

www.konkur.in

and behaviors. Lack of declarative memory of the traumatic event could also interfere with attempts to place the trauma in the context of an overall life story and mobilize coping resources to address it.

TBI may predispose to PTSD by causing damage to neural circuits responsible for modulating fear responses. Cognitive deficits from PTSD could impair the ability to effectively utilize coping skills to deal with PTSD. Conversely, ongoing psychological stressors from PTSD could impair cognitive recovery from the TBI. Alternately, the types of incidents that result in TBI could produce more feelings of fear and helplessness than those responsible for other types of injuries.

The combination of TBI and PTSD appears to worsen outcomes compared to either one alone. Patients with PTSD at 6 months following severe TBI had significantly more impaired community reintegration than TBI patients without PTSD. Individuals with TBI complicated by PTSD self-assess their cognitive and health status as worse than those with TBI alone, and some data suggests that the combination of PTSD and TBI impairs objective cognitive performance more than TBI alone. Patients with both disorders report more symptoms of PTSD than those with PTSD alone and experience greater PTSD symptom severity.

Currently, guidelines for the treatment of PTSD in the general population favor psychotherapeutic interventions, such as PE or cognitive processing therapies (CPTs), over pharmacologic ones. Similarly, CBT for insomnia (CBT-I) is favored over pharmacologic interventions for PTSD-related insomnia. While more research is needed to assess the efficacy of these interventions for patients with TBI, particularly moderate and severe TBI, preliminary studies suggest that evidence-based psychotherapies for PTSD may still be useful in this population. However, therapies may require modifications for patients with persistent cognitive and physical impairments. For instance, exposure therapies may require reconstructing memories to offset amnesia, simplification of homework, and more frequent repetition.

Given their safety and tolerability in patients with TBI, SSRIs represent a reasonable first-line treatment strategy in PTSD associated with TBI. An open-label study of prazosin—effective for PTSD-related nightmares in the general population—in patients with TBI found improvements in cognitive performance, sleep, and headaches; however, the largest RCT to date of prazosin versus placebo for PTSD-related nightmares was negative. Given the possibility of adverse cognitive side effects,

Telegram: @medical_k

www.konkur.in

anticholinergic medications and benzodiazepines should be avoided. Finally, consideration of other conditions contributing to poor sleep quality and PTSD symptoms, such as obstructive sleep apnea, should be incorporated into psychiatric management.

Anxiety Disorders

The available data suggests that post-TBI anxiety disorders are common; may take the form of any anxiety-spectrum disorder; and tend to co-occur with depression. Of the individual anxiety disorders, generalized anxiety disorder may be the most common following TBI, but data has been inconsistent. A meta-analysis of 22 studies, comprised of 1,145 subjects with TBIs of mixed severities and postinjury durations, estimated the prevalence of generalized anxiety disorder to range from 2% to 28%, with a pooled estimate of 11%.

Rates of panic disorder following TBI range from 6% to 14%. One study found that TBI conferred double the risk of developing panic disorder compared to other traumatic injuries. TBI also doubled the risk of developing agoraphobia, with 7% of patients with TBI experiencing this condition.

The estimated prevalence of specific phobias post TBI, while based on limited data, appears to be similar to that of the general population (1–10% versus 8–12%, respectively). One study found that among patients who experienced TBI due to a motor vehicle accident, the specific phobias that subsequently developed involved transportation. Another group found that a substantial proportion of individuals with TBI experience a phobic-like fear of falling, which at times may interfere with activities. One study found that 5% of patients with TBI developed social anxiety disorder, twice the rate of those who experienced other types of injuries. Although obsessive-compulsive disorder is no longer classified with other anxiety disorders by the DSM-5, its estimated prevalence (1% to 5%) does not appear significantly elevated above that of the general population.

Previous experimental and clinical studies on the neurobiology of anxiety disorders have emphasized the etiologic role of disrupted prefrontal modulation of limbic and paralimbic circuits involving medial and orbital prefrontal cortices, the amygdala, and the hippocampus. A recent meta-analysis of structural and functional neuroimaging correlates of syndromal post-TBI anxiety found a broad range of regional and circuit alterations reported among studies. Although the most frequently

Telegram: @medical_k

www.konkur.in

implicated regional alterations involved components of the default mode network, the methodologic heterogeneity and a limited number of included studies prevent definitive conclusions. Additional investigations on the neurobiological correlates of anxiety disorders post TBI are needed.

The evidence base for the treatment of anxiety disorders in TBI remains preliminary. As with trauma-related disorders in TBI, SSRIs are likely the best first-line pharmacotherapy, and medications that could worsen cognition in this vulnerable population, such as benzodiazepines and drugs with anticholinergic effects, should be avoided. Few studies specifically examining psychotherapy (e.g., CBT) for TBI-related anxiety suggest this may be effective as well.

Substance-Related and Addictive Disorders

Substance-related and addictive disorders are major risk factors for the occurrence of TBI and major determinants of the clinical and psychosocial outcomes post TBI. A prospective study of 197 patients with TBI showed that 42% had blood alcohol levels consistent with legal intoxication at the time of admission to the emergency department and that blood alcohol levels suggested a history of problem drinking among these patients. The authors also observed that the frequency of alcohol abuse and associated disorders diminished immediately after TBI but increased again at 1-year follow-up, although not to preinjury levels. Although alcohol use significantly decreased during the first year after injury, about 25% of the patients reported alcohol-related problems. As expected, preinjury problematic alcohol use predicted alcohol-related problems after TBI.

In one study, 60% of patients with alcohol use disorders prior to TBI had resumed problematic alcohol use within 1 year of their injury. Patients who relapsed had significantly less education, showed significantly more severe injury as demonstrated by lower GCS scores and a greater frequency of moderate and severe injuries, had significantly higher frequencies of focal lesions on their initial CT or MRI scans and showed impaired cognitive performance on memory and executive tasks.

Conceivably, the combined effects of traumatic injury and the toxicity of chronic substance abuse (particularly alcohol) might produce greater disruption of the neural circuits involved in mood regulation, motivation, and reward processing. In turn, these changes could result in more severe psychopathology, uncontrolled addictive behavior, and poor psychosocial outcome. One study found that inmates with head injuries had higher

Telegram: @medical_k

www.konkur.in

levels of alcohol and marijuana use, a significantly higher frequency of depression, anxiety, and suicidal thinking, as well as more difficulties in concentrating and controlling violent behavior.

Substance use disorders are associated with worse post-TBI outcomes. Individuals with TBI who abuse substances show worse cognitive performance, higher rates of incident depression, decreased employment, and poorer rehabilitation participation in the years following injury than patients with TBI alone. One large study found that, among individuals with TBI, those who had consumed alcohol around the time of their injury were 20% more likely to die of their injuries and were less likely to be able to return home at hospital discharge.

The optimal treatment strategy for comorbid substance use disorders and TBI remains to be determined. One study of systematic motivational counseling (SMC) to treat substance abuse comorbidity among patients with TBI found that the SMC group showed significant improvements in motivational structure and a significant reduction in negative affect and the use of addictive substances. However, two RCTs of a brief motivational interviewing and educational intervention targeting alcohol use disorders among patients with TBI did not find effects on alcohol consumption, but one of the studies did indicate that the intervention increased awareness of the negative consequences of alcohol use. Physical disabilities, such as those which may accompany TBI, can pose barriers to substance abuse treatment, as many treatment programs do not accommodate them.

The evidence supporting pharmacologic intervention for alcohol or substance use is limited in the TBI population. A 12-week pilot RCT demonstrated that topiramate significantly reduced the number of drinks per week compared to placebo in veterans with mild TBI and alcohol use disorder. However, topiramate may induce adverse cognitive effects in patients with moderate and severe TBI. Another recent trial comparing valproate and naltrexone in veterans with and without TBI did not find one to be superior to the other; however, patients with moderate and severe TBI were more likely to relapse than those without TBI. Expanding substance abuse treatment access for these patients remains critical.

Psychotic Disorders

According to DSM-5 criteria, psychotic disorder due to TBI consists of prominent hallucinations or delusions occurring as a direct physiologic

Telegram: @medical_k

www.konkur.in

consequence of the TBI. Symptoms occurring exclusively in the context of delirium are excluded.

The reported incidence of psychosis following TBI varies widely. Retrospective reviews of World War II records found a rate of 7%, while one prospective study in an inpatient rehabilitation setting found that 64% of individuals with moderate or severe TBI experienced hallucinations and/or delusions at some point in their postinjury course. Psychotic symptoms were associated with poorer sleep and worse cognitive impairment and tended to occur earlier in the post-TBI recovery period.

Much of the literature on psychosis following TBI takes the form of case studies. Nineteen published reports describe patients with delusions only, including Capgras syndrome, delusional jealousy, Cotard syndrome, Fregoli syndrome, and somatic delusions. Seventy-one published reports describe patients with psychotic symptoms thought to resemble those of schizophrenia—that is, hallucinations and delusions; almost all of these patients experienced auditory hallucinations, one in five also experienced visual hallucinations, 85% experienced delusions (most commonly persecutory), and 43% experienced negative symptoms. On average, these 90 patients developed psychotic symptoms 3.3 years after the TBI. Thus, attributing psychosis directly to the TBI is challenging.

Care must be taken to consider other causes of psychosis, including iatrogenic effects, substance intoxication/withdrawal symptoms, epilepsy-related psychoses, and causes of delirium. Psychotic symptoms occurring during an acute post-traumatic confusional state should not be labeled as “psychotic disorder due to TBI” or another idiopathic psychotic disorder.

In line with the current hypothesis on the pathophysiology of psychotic disorders, post-traumatic psychosis has been associated with the presence of cognitive disturbance and imaging and EEG abnormalities in the frontal and temporal lobes. In addition, post-traumatic psychosis has been associated with seizure disorder in approximately one-third of cases.

A related clinical problem is whether TBI constitutes a risk factor for later schizophrenia. A recent meta-analysis of nine studies with a total of 180,859 persons found an elevated risk of subsequent development of schizophrenia in individuals who had experienced a TBI (RR 1.65, 95% CI 1.17–2.32). Individuals with a family history of schizophrenia appeared to face a particularly heightened risk after TBI; conversely, a family history of schizophrenia also represented a risk factor for experiencing a TBI,

Telegram: @medical_k

www.konkur.in

suggesting the possibility of a complex interaction between the two disorders.

To date, no clinical trials have examined the pharmacotherapy of psychosis due to TBI. By extrapolation from the treatment of idiopathic psychosis, atypical antipsychotic medications will likely represent the mainstay of treatment. Psychosocial treatments useful in patients with schizophrenia, such as psychoeducation of patients and family, vocational rehabilitation, psychotherapy, and assertive community treatment, may also help patients with psychosis due to TBI, though no studies have yet explored this.

FUTURE DIRECTIONS

In summary, cognitive and neuropsychiatric disturbances frequently complicate functional outcomes and quality of life following TBI. While the above sections briefly describe these disturbances and several treatment strategies, the evidence base supporting daily clinical decisions requires much expansion. Future research is needed to improve the identification of neuropsychiatric disorders, predict functional outcomes, optimize available treatments, and understand the relationships between TBI and neurodegeneration.

Ongoing research efforts are attempting to address some of these knowledge gaps. For instance, point-of-care serum biomarker devices are being investigated for the enhancement of TBI prognostication and case definitions in the acute setting. Other exciting areas of research involve the applications of noninvasive neurostimulation techniques to treat disorders of consciousness, cognitive impairments, and neuropsychiatric disorders. Studies of TBI-related sleep disturbances are increasingly demonstrating the detrimental impact of poor sleep on functional outcomes and longitudinal neurodegeneration risk. Current efforts to characterize the prevalence, risk factors, and clinical features of CTE will hopefully guide the clinical management of suspected cases.

The complex interplay between post-TBI neuronal degeneration and repair processes may produce long-lasting changes in neuronal activity and circuitry. Mechanisms of secondary injury continue to be investigated for potential targets of interventions that may reduce injury progression. Moreover, research efforts to characterize the functional changes

Telegram: @medical_k

www.konkur.in

observed in neuronal networks may provide insight into the neurologic substrates of post-TBI cognitive and behavioral deficits.

Multicenter consortia are critical for future study of the longitudinal course of mild TBI, relationships between TBI and neurodegeneration, and the development of biomarkers and other predictors of recovery postinjury. The Transforming Research and Clinical Knowledge in TBI (TRACK-TBI) study is an NINDS-funded, multicenter TBI data repository of neuroimaging, blood biospecimens, and detailed clinical outcomes post TBI. Similarly, the previously mentioned TRACTS cohort study collects a repository of neuroimaging, blood specimens, and cognitive and psychiatric outcomes for the purpose of investigating the longitudinal course of blast-related and other TBIs in post-9/11 veterans. Large, multicenter data sets obtained from these and other consortia promote the advancement of precision medicine by improving TBI classification and outcomes, particularly for mild TBI.

Finally, insights gleaned from research are made clinically applicable by the providers directly caring for patients with TBI. Additional efforts to incorporate principles of TBI pathophysiology and management into medical student and postgraduate education are needed to ensure that clinicians are attuned to the transdisciplinary needs of these patients.

2.6 Neuropsychiatric Aspects of Movement Disorders

LAURA MARSH, M.D., AND RUSSELL L. MARGOLIS, M.D.

Most often, and consistent with the focus of this chapter, the term *movement disorders* refers to a group of central nervous system (CNS) diseases that primarily involve neurodegeneration of the basal ganglia, cerebellum, or both. From the clinical perspective, however, movement disorders mark the crossroads of the fields of psychiatry and neurology and underscore the importance of interdisciplinary care and perspectives. This is because psychiatric and cognitive abnormalities figure prominently in many patients, resulting in excess morbidity and caregiver burden. Diagnosis and treatment of neuropsychiatric conditions in patients with primary movement disorders are also challenged by the interplay of motor, cognitive, and psychiatric features over the course of the disease and their degree of overlap at the time of an examination. Examples are the masked face of parkinsonism and flat affect in depressive disorders. Furthermore, management of psychiatric disorders in patients with movement disorders is potentially complex; treatments of motor symptoms can exacerbate or cause cognitive or psychiatric symptoms, and, conversely, psychiatric treatments may result in adverse motor and cognitive side effects. Appreciation of the distinctive motor, cognitive, mood, and behavioral aspects of the various movement disorders and their underlying pathophysiology helps to target therapies that are effective and limited in their risks.

Comparative Nosology

Classification of Movement Disorders. Several approaches are used to classify movement disorders (Table 2.6–1). From the phenomenologic standpoint, movement disorders are generally grouped into three main categories. Parkinsonian disorders are characterized by reduced amplitude of movements (hypokinesia), slowness of movements

Telegram: @medical_k

www.konkur.in

(bradykinesia), and difficulty initiating movements (akinesia). Dyskinetic disorders are characterized by increased motor activity and excessive (hyperkinetic) involuntary movements such as tremor, chorea, ballism, tics, dystonia, or myoclonus. Ataxias involve gait disturbances, dysmetria, and dysdiadokinesis. Nosologically, the phenomenologic scheme is problematic because clinical features overlap across diseases. In addition, syndromes frequently involve several types of movement abnormalities, such as akinesia, dystonia, and tremor in Wilson disease (WD), while others, such as focal dystonia, consist of a single movement abnormality. Classification schemes based on neuropathologic findings generally distinguish diseases in which the primary pathology involves the basal ganglia from diseases that primarily affect cerebellum, cerebral cortex, or motor neurons. Again, common clinical features and neuronal system involvement across different neuropathologic groups limit this approach. An etiologic classification has the advantage of linking a syndrome directly to its cause and directing attention at specific modes of pathogenesis, treatment, and prevention. However, the cause of many diseases is unknown (e.g., idiopathic Parkinson disease [PD]), and an etiologic nosology can lead to confusion since entities with clinical similarities are separated into different categories.

Classification of Psychiatric Disturbances Associated with Movement Disorders. In accordance with the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5), psychiatric disturbances associated with movement disorders can generally be classified as "due to another medical condition," such as depression due to Huntington disease (HD), psychotic disorder secondary to dementia with Lewy bodies (DLBs), or anxiety disorder secondary to PD. Additional qualifiers designate specific features of the presentation, such as *with hallucinations or with major depressive–like episode*. The prominence of psychiatric and cognitive manifestations in movement disorders, however, points out the arbitrariness of this scheme; it could be equally valid for many of the movement disorders to be classified as neurocognitive disorders with associated movement and psychiatric phenomena, for example, probable major neurocognitive disorder with Lewy bodies, with behavioral disturbance. For that reason, many research studies establish diagnoses using the DSM phenomenologic criteria for idiopathic psychiatric conditions, that is, from the revised fourth edition of DSM (DSM-IV-TR), and now the DSM-5, while ignoring the criterion stating that the disturbance is "not attributable to the physiological effects of a substance or to another medical condition." Another shortcoming of the DSM nosologic system is that its terminology does not capture the nuances of many psychiatric disturbances. Examples are the disruptive perseverative behaviors seen with HD or pathologic laughter or crying syndromes that may occur with progressive supranuclear palsy (PSP).

Bedside Assessment of Movement Disorders

Emotion, cognition, and movement are controlled by a series of inter-related and interdependent circuits involving the basal ganglia and frontal–subcortical circuits. It is therefore not surprising that patients with motor abnormalities often have emotional or cognitive disorders and

Telegram: @medical_k

www.konkur.in

patients with disorders of emotion or cognition frequently have motor abnormalities.

While often relegated to the specialty of neuropsychiatry, the careful appraisal and appreciation of movement abnormalities and movement disorders in psychiatric patients should be considered an important aspect of general psychiatric practice. First, side effects of many psychiatric medications include abnormal movements, some of which may be long-lasting or even permanent. Second, some patients demonstrate abnormal movements before exposure to psychiatric drugs, underscoring the need for baseline motor screening in all patients. Abnormal movements in such patients may indicate the presence of gross congenital disorders (such as cerebral malformations), developmental disorders without gross brain malformation (such as the “soft signs” seen in patients with schizophrenia or autism), neurodegenerative disorders (such as HD or PD), other cerebral insults (including strokes and tumors), or even normal aging. Third, powerful emotions can lead to abnormal movements in otherwise healthy individuals as well as those with CNS disturbances (e.g., tremulousness with anxiety). Fourth, primary psychiatric disorders may present with movement abnormalities, as illustrated by motor slowing seen with depression or the motor hyperactivity with mania. When the motor examination is accompanied by an adequate history and suspicion, overlapping motor and psychiatric signs can be recognized and distinguished according to the relative influences of a primary motor disorder, a psychiatric disturbance, a drug effect, or some interaction among them. For example, an older adult patient with melancholic depression may walk slowly with a hunched posture, but also display unilateral upper extremity rigidity, bradykinesia, and a rest tremor, suggesting a diagnosis of PD and the need for additional treatment beyond antidepressant agents.

In patients with known movement disorders, the initial history and physical examination should confirm the presence of the diagnosed movement disorder. The causes, course, and treatment of the different movement disorders are diverse, but most share similar features. Given this, there is frequent misdiagnosis of movement disorders; only 75% to 80% of patients with parkinsonism are correctly diagnosed with idiopathic PD during life by movement disorder specialists and the rate of misdiagnosis is probably higher among nonspecialists. Examples of

Telegram: @medical_k

www.konkur.in

disorders that mimic PD, especially early in their course, are PSP and DLB, as well as medication-induced parkinsonism.

A second goal of the motor examination is to evaluate the extent of deficits relative to the reported impairment. Complaints of motor dysfunction can be exaggerated in patients with depression, whereas dementia or lack of insight, as is often the case with HD, can contribute to denial of illness or impulsive behaviors that increase the risk of falls. Finally, as mentioned above, serial motor examinations provide a barometer of motor side effects caused by agents used to treat psychiatric conditions.

Table 2.6–2.
Screening Examination for Motor System Dysfunction

Gait-observe walking, including on tiptoes and heels, and turning
Station-observe balance, pull test
Abnormal movements—with patient sitting at rest and with arms outstretched, observe limbs, trunk, face, and head for abnormal and excessive movements or hypokinesia
Coordination-rapid finger tapping, finger-to-nose test
Tone-passive movement of limbs and neck
Strength

The main elements of a motor function screen (Table 2.6–2) include assessment of gait, involuntary movements, coordination, muscle tone, and strength, as discussed further in the chapter on neuropsychological assessment. Gait provides clues to the presence of upper versus lower motor neuron disease (MND), sensory loss, and cerebellar versus extrapyramidal pathology and should first be observed when a patient walks to the examining room. Ability to rise independently from a chair and without pushing off the armrests is a common but nonspecific screen for gait difficulties and increased fall risk in the geriatric population. Balance should be examined separately. Hyper- and hypokinetic movement abnormalities can be observed during the interview while the patient rests comfortably in a chair. The five main types of abnormal hyperkinetic involuntary movements are tremor, chorea, myoclonus, tics, and dystonia. Having the patient hold their arms outstretched will reveal forms of nonrest tremor, other adventitious movements, and motor

Telegram: @medical_k

www.konkur.in

weakness. Finger-to-nose testing permits examination of large proximal arm movements, kinetic tremor, and dysmetria. Hypokinesia, characteristic of parkinsonian syndromes, is manifest by bradykinesia and akinesia. There is a relative absence of spontaneous movements or gestures, slowed movements, decreased arm swing, and diminished facial expressiveness (masked face) and spontaneous blinking. Gait disturbances are related to difficulties initiating and sustaining movements and turning. Coordination can be assessed with finger-thumb tapping. Motor tone is tested by passive movement of an extremity or the neck while the patient is at rest. When assessing tone, the examiner should note whether there is increased resistance to the passive movements, and whether that resistance is active, spastic, or “lead pipe” in character. Cogwheeling, a feature of a tremor, is often mistaken for a measure of tone.

PARKINSON DISEASE

Introduction and Definition

PD is a progressive neurodegenerative disorder that is associated with loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc). The hallmarks of the disease are its triad of motor features—resting tremor, rigidity, and akinesia/bradykinesia (inability to initiate movement and slowness of movement, respectively). Gait and postural disturbances also characterize the disease. Parkinsonism or parkinsonian syndromes are less specific and nonetiologic terms that refer to the clinical appearance of PD. Examples are parkinsonism secondary to antidopaminergic medications, without pathology of the substantia nigra, or atypical parkinsonian syndromes such as multiple system atrophy (MSA).

History

Descriptions of parkinsonian syndromes are found in the earliest medical writings. Idiopathic PD is named after James Parkinson, a general practitioner in London who wrote about *paralysis agitans* as a distinct disease separate from other causes of tremor in his classic 1817 article, “Essay on the Shaking Palsy.” Parkinson’s description of six cases highlighted the cardinal motor signs that remain characteristic of the

Telegram: @medical_k

www.konkur.in

disease today. Parkinson's case descriptions included neuropsychiatric as well as other physical changes, such as constipation. However, his conclusion of the "senses and intellect being uninjured" led to relatively less emphasis on these aspects of PD. Subsequent descriptions recognized memory loss and other neuropsychiatric features, but it is only relatively recently that these have received greater attention. It is worth noting that profound akinesia and speech difficulties may have limited evaluation of the mental state in patients with PD until effective treatment with levodopa became available in the 1960s, thus leaving psychiatric disorders often unrecognized. Although anticholinergic belladonna alkaloids were used to treat PD in the 19th century, the discovery that dopaminergic precursors reversed reserpine-induced parkinsonism led to the treatment of PD with levodopa, still the gold standard of antiparkinsonian medications.

Epidemiology

Parkinsonian syndromes frequently present in older adults and their prevalence increases with advancing age, affecting up to 15% of individuals up to age 74 and over half of those over age 85. The most common parkinsonian syndrome is PD. It is the second most common neurodegenerative disease after Alzheimer disease (AD), and it affects over 1% of the population over age 55 and nearly 3% of the population over age 70. Worldwide, an estimated 4 to 6 million people have PD. The mean age of onset for PD is 60 years of age and 80% of individuals develop the disorder between the ages of 40 to 70 years. About 5% of patients have symptom onset before age 40 and, in such cases, the disease is classified as young onset PD. Juvenile onset occurs in less than 1% of cases. The wide range in the age of onset of PD contributes to misdiagnosis, especially in younger patients.

Lewy bodies are cytoplasmic inclusions with a dense eosinophilic core surrounded by a clear halo. (Photographs courtesy of The Morris K. Udall Parkinson's Disease Research Center and the Alzheimer's Disease Research Center at Johns Hopkins and Drs. Olga Pletnikova and Juan Troncoso.)

Sex and ethnic differences in the frequency of PD can be an important source of variation because of the association of PD with genetic and environmental factors. Taken together, prevalence studies indicate some age-range–associated differences in PD prevalence by geographic location and sex. For example, prevalence among individuals in their eighth decade is higher in European, North American, and Australian populations relative to Asians. Prevalence of PD, with and without dementia, is higher in men as compared to women. With increasing age, incidence of PD increases in both sexes. Across all age groups, incidence is consistently higher among males, with differences in age-specific pooled male:female incidence ratios achieving statistical significance among those between 60 to 79 years of age. Incidence of PD has been reported as lower among African Americans than Caucasians; discrepant

Telegram: @medical_k

www.konkur.in

rates may be a function of socioeconomic factors, such as access to health care and perception of the disease.

Etiology

The neuropathologic hallmarks of PD include progressive loss of dopaminergic neurons in the ventral tier of the SNpc and intraneuronal aggregation of the α-synuclein protein in the form of Lewy bodies and Lewy neurites (Fig. 2.6–1A). When approximately 60% to 80% of the SNpc neurons degenerate and dopamine production is inadequate, the motor symptoms of PD emerge. What leads to selective and progressive cell death is unknown. Transformation of α-synuclein, a presynaptic protein, to fibrillary and oligomeric forms and their aggregation appears central to neurotoxicity. As such, PD belongs to the family of neurodegenerative disorders referred to as synucleinopathies, which also includes DLB and MSA.

A prevailing theory of the pathophysiology of PD, referred to as the Braak hypothesis, suggests that initial symptoms of PD involve nondopaminergic neuronal degeneration in the enteric nervous system, olfactory bulb, and other brain regions (e.g., raphe nuclei, locus coeruleus, and dorsal motor nucleus of the vagus) followed by rostral progression to the SNpc over many years. This phase, beginning up to 20 years before onset of motor symptoms, is termed “prodromal.” Clinical studies support the Braak hypothesis in that nonmotor symptoms, such as depressive and anxiety disturbances, olfactory dysfunction, rapid eye movement sleep behavior disorder (RBD), constipation, and autonomic disturbances, often precede onset of motor symptoms by several years. These conditions represent potential risk markers for PD and provide a basis for alternative therapeutic interventions that modulate noradrenergic, serotonergic, glutamatergic, and other pathways

Research over the last two decades demonstrates that the contribution of genetic factors to the pathophysiology of PD is much greater than previously expected. Most cases of PD (>85%) are regarded as sporadic (not inherited), but, now, over 20 monogenic forms of PD are described and genome-wide association studies (GWAS) have identified over 100 loci as risk factors for PD. Taken together, it appears that most cases of PD result from effects of multiple predisposing genetic factors, possibly in combination with select environmental insults. Proposed mechanisms of neuronal degeneration include α-synuclein misfolding and aggregation,

Telegram: @medical_k

www.konkur.in

mitochondrial dysfunction, oxidative stress, excitotoxicity, perturbations of neuronal cytoskeleton and axonal transport, neuroinflammation, and programmed cell death.

Though several risk factors have been proposed, the only unequivocal risk factor for PD is increasing age. Dopaminergic cell loss also occurs with normal aging, but the loss is less severe and involves different subpopulations of SNpc neurons than PD. Toxins associated with parkinsonism include viral infection of the CNS and industrial exposures, including manganese, carbon monoxide, organophosphates, and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Higher prevalence in industrialized regions and associations with well water consumption, farming, and rural living may reflect exposure to neurotoxins contained in pesticides and other agricultural agents that contain homologs of MPTP. By contrast, other environmental factors and behaviors, such as caffeine use and cigarette smoking, are associated with a reduced risk to develop PD.

Familial forms of PD are present in about 15% of individuals with the disease. Studies of large family and twin samples with heritable parkinsonian conditions have led to identification of over 20 causative genes, to date. One of the most prevalent genes associated with familial and sporadic PD is leucine-rich repeat kinase 2 (LRRK2), identified in 2004 and inherited in an autosomal dominant pattern. The locus for LRRK2, called PARK8, is located on chromosome 12q12. Its most common pathogenic mutation, G2019S, is found in up to 5% of Caucasian patients with familial PD. In Ashkenazi Jews and African Arabs, G2019S mutations are present in up to 30% of familial PD cases and 13% to 40% of sporadic PD cases. The G2385R LRRK2 variant is the most common genetic risk factor identified among Asian people, accounting for 23% of familial cases as well as 4% to 9% of early and typical late-onset cases. Most LRRK2 carriers with PD resemble noncarriers with PD, though LRRK2 carriers who develop PD may have a more benign course than noncarriers with PD. The LRRK2 protein has a number of functions; its proposed mechanism in PD is thought to involve dysregulation of kinase and GTPase activities.

The α-synuclein gene (SNCA) mutation, located on chromosome 4q21-q23, was the first mutation identified in association with autosomal dominant PD. Although SNCA mutations are a rare cause of PD, the study of α-synuclein led to the discovery that it is a major component of

Telegram: @medical_k

www.konkur.in

Lewy bodies and demonstrated the role of protein aggregation in the pathophysiology of PD. Since patients with sporadic PD, who have normal α-synuclein genes, have Lewy bodies that stain positive for α-synuclein and ubiquitin, neuronal cell death in PD is attributed to abnormal accumulations of these proteins. Gene mutations on chromosome 6 that code for Parkin (PARK2), a protein involved in the ubiquitination pathway, are the most common inherited defect and are associated with a juvenile autosomal recessive form of early-onset PD. Alterations in gene loci on chromosome 4 that affect ubiquitin processing (UCH-L1) and on chromosome 1 that affect β-glucocerebrosidase and lysosomal function (GBA) are also linked to PD. While rare, other identified genes are associated with autosomal dominant and autosomal recessive parkinsonian syndromes, the latter including the oncogene DJ-1 (PARK7), the MAPT (tau) gene, progranulin (PGRN), FBXO7 (PARK-15), and PINK1.

Current models of basal ganglia/cortical physiology suggest the presence of five adjacent but anatomically distinct frontocorticostriatothalamic loops with motor, oculomotor, limbic, anterior cingulate, and prefrontal targets and that dysfunction of these neural loops is linked to the motor and nonmotor features in PD and other basal ganglia disorders. A common feature of these cortical–subcortical loops is their projection from higher-level cortical areas to the basal ganglia via striatal areas with outflow through the internal globus pallidum (Gpi) or its histologic analog, the substantia nigra pars reticulata (SNpr) (Fig. 2.6–2). Gpi/SNpr outputs then project to specific areas of the thalamus that complete the loops through projections to the original cortical area. Within each loop, the striatonigral component includes a “direct” pathway that projects directly from striatum to Gpi/SNpr and an “indirect” pathway that flows from the striatum through the subthalamic nucleus (STN) to reach Gpi/SNpr.

Motor Manifestations. Human and animal models of PD demonstrate that loss of SNpc dopaminergic neurons affects frontocorticostriatothalamic circuits sufficiently to result in PD motor manifestations. The best studied of these neuronal circuits is the “motor circuit” as illustrated in Figure 2.6–2. In PD, dopaminergic degeneration appears to have differential effects on the nigrostriatal pathway. Projections from SNpc to striatal targets are inhibitory in the dopamine

Telegram: @medical_k

www.konkur.in

type 1 (D1) receptor–mediated direct path and excitatory in the D2 receptor–mediated indirect path. Normal movement results from coordinated regulation of thalamocortical excitation by the direct and indirect pathways, with the presence of nigrostriatal dopaminergic projections tending toward increased movement by facilitation of the direct pathway and inhibition of the indirect pathway. Loss of dopamine results in hypokinetic symptoms secondary to overactivity of the STN and Gpi via the indirect path, which increases inhibitory input to the thalamus and then reduces the excitatory thalamocortical activity that ordinarily facilitates motor movements. Hyperkinetic movements, such as levodopa-induced dyskinesias, occur with overactivation of the direct pathway.

Cognitive Manifestations. Nearly all patients with PD experience some degree of cognitive change, with deficits ranging from slightly abnormal with minimal impact to very severe and disabling and different rates of progression. While there is considerable heterogeneity across patients, a typical cognitive profile early in the course of PD involves preserved intellectual abilities with mild-to-moderate impairments in memory retrieval, executive functions, and visuospatial functions. Word-finding difficulties may be present, but language functions are generally intact. Mild cognitive impairment in PD (PD-MCI), affecting about 80% of PD patients, is defined on the basis of single- or multidomain (e.g., mild memory and executive dysfunction) deficits on neuropsychological testing that are not associated with significant interference with functional independence. The symptoms are frustrating and may preclude gainful employment, especially with disease progression but awareness is usually retained so that compensatory strategies can be used to mitigate the impact of cognitive and motor deficits on daily functioning. PD-MCI is demonstrated in about 20% of patients upon diagnosis of PD and in 40% to 50% after 5 years. The neuropathologic underpinnings of cognitive dysfunction in PD are complex and not fully understood. Executive dysfunction in PD, primarily associated with frontal lobe dysfunction and disrupted frontostriatal networks, may also involve dysfunction of nonmotor neural circuits, including mesocortical and mesolimbic dopaminergic and nondopaminergic projections that subserve memory, motivational, and response inhibition functions. Bradyphrenia may be associated with noradrenergic cell loss.

Telegram: @medical_k

www.konkur.in

FIGURE 2.6–2. Corticostriatalthalamic circuits. In the motor circuit, the supplementary motor area and primary motor cortices in frontal regions project mainly to putamen and then "directly" to Gpi or "indirectly" via the external globus pallidus (Gpe) and then the STN to reach Gpi. Excitatory (glutamatergic) cortical projections generally decrease Gpi activity through the direct pathway and increase Gpi activity through the indirect pathway. Inhibitory (GABAergic) Gpi projections to thalamus and excitatory thalamocortical projections result in net excitation (increased motor activity) or net inhibition (decreased movement) through the direct and indirect pathways, respectively. Dopamine has differential inhibitory and excitatory effects on the nigrostriatal pathway.

Over time, risk for developing dementia in PD (PD-dementia) is sixfold higher in comparison to the general population after controlling for age, gender, and educational level. Point prevalence is estimated to be 24% to 30%; prevalence is lower within the first 5 years after diagnosis (<5%) and increases with disease duration, affecting over 80% of patients followed for 20 years. In patients with PD-MCI, an estimated 20% to 60% progress to dementia within 5 years, but there is considerable heterogeneity and severity of PD-dementia. The risk of PD-dementia is associated with increasing age, a family history of dementia, depression, and more severe

Telegram: @medical_k

www.konkur.in

motor dysfunction. Neuropathologic and imaging studies in patients with PD-dementia are associated with neuronal loss in cholinergic cells of the basal forebrain, implicating cholinergic deficits in PD-related cognitive impairment. Cortical Lewy bodies may also be associated with dementia. The histopathologic changes of AD—neurofibrillary tangles and senile plaques—are seen in some patients with PD and dementia.

Psychiatric Manifestations. Other than PD itself, there are no known specific risk factors for psychiatric disturbances in PD. Though psychological reactions to the experience of living with PD can influence occurrence of depression, most evidence suggests that depressive disorders, like motor and cognitive features, are related to the underlying disease processes of PD. Most compelling is evidence that depressive and anxiety disorders frequently develop *before* the onset of motor symptoms, suggesting that these mood phenomena are either neurologic signs of the disease (i.e., prodromal PD) or a risk or causative factor for development of PD. Cross-sectional studies do not show consistent relationships between depression onset and severity to age onset or duration of PD, motor severity, disease subtype (tremor dominant vs. akinetic-rigid), or disease stage. Several studies link depression with excessive serotonergic loss from the midbrain raphe. Depression in PD is also associated with decreased blood flow in frontal regions, a finding also seen in idiopathic depression. In apathetic syndromes, noradrenergic dysfunction is implicated by the relationship between bradyphrenia and neuronal loss in the locus coeruleus. Noradrenergic dysfunction is also evident in anxiety disorders, including an imbalance in noradrenergic/dopaminergic tone. Psychosis in PD is often associated with dopaminergic therapy, which may lead to hypersensitivity of mesocortical and mesolimbic dopaminergic receptors. Other factors related to the incidence of psychosis are cognitive impairment, disease severity, mood disorders, impaired visual acuity, other psychoactive medications, and delirium. An association of psychosis with cognitive impairment and mood disorders implicates more widespread brain pathology involving other neurotransmitter systems, including cholinergic deficits or a serotonergic/dopaminergic imbalance.

Diagnosis and Clinical Features

Telegram: @medical_k

www.konkur.in

Motor Manifestations. Motor manifestations of PD initially affect one side of the body and gradually progress to the contralateral side, though remaining asymmetric. A slow (3- to 6-Hz) classic resting tremor is often the presenting feature of PD, but other types of tremor may be present and 20% to 30% of cases have no tremor at all. Bradykinesia and akinesia are the most disabling aspects of PD and contribute to problems with dexterity and gait. Patients typically walk in a flexed forward posture without swinging their arms. The gait is slow and shuffling with small steps and a tendency to fall forward and hasten the rate of walking (festination). Difficulty initiating movements leads to start hesitation and “freezing.” For example, a patient may suddenly be unable to move their legs while walking or their hands when reaching into a purse. Deteriorated handwriting, weakness, and clumsiness in one limb are also common initial symptoms of bradykinesia. Rigidity is appreciated as increased muscle tone on examination. Patients may note muscle cramps, weakness, or stiffness as the first indication of rigidity.

In the absence of a biologic marker for PD, its diagnosis is based on the clinical examination and associated history and course. Most experts require presence of two of the three cardinal motor signs to diagnose PD along with a robust response to an initial trial of levodopa. Early in its course, PD can be difficult to diagnose since signs of the disease may be subtle and not even perceived by the patient. Parkinsonian signs can also be a feature of normal aging or other parkinsonian syndromes. The initial symptoms in up to 20% of patients are nonmotor, including fatigue, musculoskeletal complaints, and depression. Other nonmotor somatic symptoms of PD include sialorrhea, dysarthria, visual and genitourinary dysfunction, sleep disturbances, sweating, seborrhea, edema, constipation, paresthesias, and hyposmia. As mentioned, the prodromal phase may be characterized by depression, anxiety, and musculoskeletal discomfort. Heightened vigilance for emerging clinical signs of PD during this phase might result in earlier disease detection, especially in older adults who present with new-onset depression or anxiety.

Cognitive Manifestations. Cognitive impairment in PD ranges from mild executive dysfunction to dementia and affects nearly all patients with PD. Commonly, cognitive decline is not obvious clinically and scores on tests that screen for dementia, such as the Mini Mental State Examination (MMSE), remain in the “normal” or nondemented range for some patients

Telegram: @medical_k

www.konkur.in

who nonetheless have dementia. The concept of “subcortical dementia” has been used to describe the cognitive impairment that is frequently associated with the various movement disorders characterized primarily by subcortical neuropathology. Executive dysfunction is especially common, resulting from deficits that affect the ability to process new information and anticipate, plan, initiate, maintain, and change behaviors. Memory, visuospatial skills, information processing speed, attention, explicit recall, spatial planning, perseveration, verbal fluency, and poverty of thought are also affected. Compared to patients with AD, recognition memory, aphasia, agnosia, apraxia, and higher language functions are relatively spared. Some patients with PD, however, demonstrate wider involvement of cortical functions, including aphasia, apraxia, and memory deficits, and may have a cognitive presentation indistinguishable from AD. Task forces, commissioned by the Movement Disorder Society, delineated consensus diagnostic criteria for PD-MCI and PD-dementia and procedures that can be used to identify and distinguish cognitive decline in PD at its earliest stages. These diagnostic criteria and procedures, while subject to refinement with further research, including validation, benefit clinical care and research by facilitating communication about the clinical cognitive syndromes in PD.

Psychiatric Manifestations. Psychiatric disturbances affect up to 90% of patients at some point during the course of PD and more than one psychiatric disturbance is often present. Early in the disease process, adult-onset anxiety and depressive disorders precede the obvious onset of motor symptoms in up to 30% of patients.

DEPRESSION. Normal psychological reactions to the illness can result in low mood, grief, demoralization, frustration, and embarrassment. Depressive disorders in PD involve more pervasive mood changes and generally resemble idiopathic forms of depression.

Reported prevalence ranges from 20% to 90%, with an average reported frequency of 40% to 50%. Up to half of those with depression, in most studies, have major depression. The majority of PD patients with depression have nonmajor depressive syndromes that are variably referred to as minor depression, persistent depressive disorder (dysthymia), or subsyndromal depression. Nonmajor forms of depression often progress to major depression if untreated. Anxiety symptoms and

Telegram: @medical_k

www.konkur.in

comorbid anxiety syndromes such as panic disorder are especially prominent, but self-blame, guilt, delusions, a negative self-attitude, self-destructive thoughts, a sense of failure, and anhedonia may be less evident. Suicide can occur, but at a similar rate as for the general population. Other psychological, vegetative, and autonomic features of depression are also common, but early morning awakening, anergia, and retardation occur at comparable rates in nondepressed patients with PD. Depression is not consistently associated with a family history of mood disorders.

APATHY. Apathy occurs in at least 25% of patients and often coexists with depression. It manifests as indifference and a lack of motivation, initiative, perseverance, interest in new things, or concern for ones health. In most cases, apathy is not distressing to the patient, but the absence of spontaneous effort and interest can be frustrating for caregivers, who may perceive the patient as depressed. Inactivity, deconditioning, and fatigue contribute to further loss of function and increased disability and suffering. Other neurologic signs and symptoms such as akinesia, hypomimia, hypophonia, cognitive dysfunction, and bradyphrenia can confound recognition of apathy. Selective serotonin reuptake inhibitors (SSRIs), the most frequently prescribed antidepressants for patients with PD, can also cause apathy, though this has not been demonstrated in PD specifically.

ANXIETY. Difficulties initiating movements can frequently lead to anxiety-provoking circumstances in the course of living with PD, but pathologic anxiety is still more common in PD compared to other parkinsonian syndromes. Particularly common are generalized anxiety disorder, social phobia, and panic disorder, which have a prevalence of 25% in some series. In general, anxiety syndromes in PD resemble those in idiopathic conditions and frequently co-occur with depression. There are also anxiety disturbances unique to PD, particularly anxiety associated with fluctuations in levodopa levels and motor function, although there is not always a strict temporal relationship between anxiety and motor “off” states. Some patients describe episodic panic attack–like states that develop at the same time every day and can be associated with motor deficits. Sleep difficulties are very common and seem to aggravate daytime anxiety.

www.konkur.in

PSYCHOSIS. Psychosis affects about 25% to 40% of patients, with increased prevalence as the disease progresses. The temporal pattern and clinical profile of PD psychotic symptoms in PD differs from other psychotic disorders such as substance-induced psychosis or schizophrenia. Lack of standardized diagnostic criteria for PD-associated psychosis contributed to variability in reported prevalence. As studies were often restricted to visual hallucinations, the most common psychotic symptom in PD, new criteria for PD-psychosis were proposed for in 2007 by a National Institutes of Health (NIH)-sponsored work group.

In PD, psychotic symptoms include hallucinations and delusions. Atypical symptoms, referred to as minor psychotic phenomena, affect over two-thirds of patients and include sense of presence, passage hallucinations, and illusions. It is a misnomer to refer to minor symptoms as “benign,” as they, like other psychotic symptoms in PD, are associated with more depressive symptoms and worse quality of life. While visual hallucinations are most common, and are often related to dopaminergic medications, other sensory modalities can be involved. Typically, in earlier stages of PD, visual hallucinations include well-delineated animals or people that occur in a clear sensorium. They are not necessarily distressing, and insight may be retained. Later in the disease course, some patients experience persistent hallucinations and/or delusions in a clear sensorium but with diminished insight. Aggression, delusional jealousy and other paranoid accusations, delusional fears about eating or medications, inappropriate sexual behaviors, and confusion are frequent manifestations that can be difficult to manage and may require hospitalization. Some patients develop chronic paranoid syndromes that resemble schizophrenia. Hallucinations and delusions also occur with major depression, mania, or anxiety disorders, and may be overlooked when patients are especially agitated. Fragmented sleep, vivid dreams, and nightmares may herald the onset of chronic psychosis. Hallucinations and delusions associated with advanced PD are a major reason for nursing home placement. Another category includes hallucinations or delusions in the context of delirium related to antiparkinsonian medications and/or other causes.

IMPULSE CONTROL DISORDERS. Impulse control disorders (ICDs), most commonly pathologic gambling, hypersexuality, uncontrolled spending, and binge eating, are observed in up to 14% of patients with PD. About

Telegram: @medical_k

www.konkur.in

one-third of affected patients have more than one ICD. Sporadic cases of hypersexuality were reported in the medical literature in the 1970s, after the introduction of levodopa. However, ICDs are most strongly associated with use of dopamine agonists for PD (e.g., pramipexole, ropinirole, and rotigotine) or for other indications, such as restless legs syndrome, underscoring the importance of patient (and family) education plus close monitoring for ICDs whenever dopamine agonists are prescribed. While not all individuals taking dopamine agonists develop ICDs, monitoring is especially prudent when there are other risk factors associated with development of ICDs, including younger age of PD onset, unmarried status, family history of problem gambling, cigarette smoking, caffeine use, and a novelty-seeking temperament.

In most cases, ICDs resolve after the offending medications are discontinued, but there can be devastating social consequences, including serious financial loss, bankruptcy, divorce, other legal problems, and loss of employment. Similar to other addictive disorders, ICDs may elude detection or, when referred for psychiatric care, the link to a potential side effect of PD medications is not appreciated. In part, this is because ICD behaviors can begin as early as a few months after starting dopamine agonists, but may also develop only after years of treatment, such as when the dose is increased, or when levodopa and dopamine agonists are used together. In the absence of a collateral informant, patients are unlikely to divulge their uncontrollable urges to engage in sexual activity, gamble, or spend excessively, and the behaviors may be unusual or idiosyncratic. For example, hypersexuality, seen in 2% to 6% of patients with PD, usually presents as an increase from baseline sexual activity, but paraphilias including transvestitism, pedophilia, and flagrant promiscuity are reported. Spending may involve purchases of large quantities of unnecessary items, for example, lamps, or excessive and reckless generosity. Such behaviors may be misinterpreted as a way of “coping” with PD.

Other significantly disruptive behaviors, often referred to as compulsive behaviors, are associated with antiparkinsonian treatment, namely levodopa. Punding refers to intense time-consuming preoccupation and fascination with seemingly meaningless rituals or stereotyped activities, for example, arranging and rearranging objects. Hobbyism involves intense time-consuming preoccupation with specific hobbies or activities, for example, endlessly working on projects or hobbies, or computer

Telegram: @medical_k

www.konkur.in

addiction. Walkabout refers to excessive aimless walking or driving. The dopamine dysregulation syndrome is a challenging condition involving an addiction-like overuse of dopaminergic medications that exceeds what is needed to control motor symptoms and persists despite harmful side effects. The dopamine agonist withdrawal syndrome (DAWS), also challenging to manage, includes addiction-like withdrawal symptoms (anxiety, panicky feelings, diaphoresis, irritability, dysphoria, drug craving, pain, and fatigue) when dopamine agonists are eliminated. Mania or euphoric syndromes are generally related to dopaminergic medications and are often associated with mood swings and on–off phenomena, but can also reflect a premorbid (pre-PD) mood disorder. Emotionalism refers to fleeting states of heightened and excessive sentimentality, often with pathologic tearfulness (also referred to as pseudobulbar affect) that can be precipitated by a variety of emotions; it can be a feature of a depressive disorder.

PREMORBID PERSONALITY. There is controversy over whether certain premorbid personality characteristics prevail in patients with PD. Observers have noted premorbid personality features that include industriousness, cautiousness, perfectionism, and punctuality in individuals who ultimately develop PD, with persistence of these traits over the course of the illness. One argument is that these traits represent a consequence of premorbid reductions in dopaminergic tone.

Pathology and Laboratory Examination. Unlike other common neurodegenerative disorders, there are no accepted neuropathologic criteria for PD. Most neuropathologists agree that dopaminergic neuronal loss in the SNpc is a requisite finding. However, the pathologic process precedes the clinical presentation since classic motor signs of PD are not evident until there is 70% to 80% loss of nigral neurons. In addition to dopaminergic cell loss, Lewy bodies, which are intraneuronal aggregates of the protein α-synuclein, are present in most forms of PD (Fig. 2.6–1B) and are seen in the substantia nigra, locus coeruleus, dorsal vagal nucleus, and nucleus basalis of Meynert. Lewy bodies are not specific to PD, and are seen in a variety of conditions, including AD. PD is also accompanied by degeneration of noradrenergic neurons in the locus coeruleus, serotonergic neurons in the dorsal raphe, and cholinergic neurons in the nucleus basalis and their attendant projection systems.

www.konkur.in

Alzheimer type neuropathologic changes (i.e., senile plaques and neurofibrillary tangles) are present in some patients with PD and dementia. Differential degrees of pathology among affected neuronal systems are thought to underlie the heterogeneous motor, cognitive, and psychiatric features of PD.

It is important to rule out other causes of parkinsonism. Laboratory tests should be conducted to rule out WD and hypothyroidism. Neuropsychological testing can help clarify the extent of cognitive deficits, evaluate cognitive status in potential candidates for neurosurgical treatments, or establish alternative diagnoses. Dementia is an exclusionary criterion for surgical therapies since it is associated with a poor motor outcome and limits compliance. A cognitive profile atypical for PD also predicts a poor outcome. Structural neuroimaging studies may help exclude other diagnoses, such as vascular disease, normal pressure hydrocephalus, and other Parkinsonian conditions, but are generally not needed to diagnose classic PD. Brain magnetic resonance imaging (MRI) is expected to be normal in PD. Functional imaging with dopamine transporter single photon emission computerized tomography (DaT SPECT) or PET can be used to assess presynaptic dopaminergic integrity as a marker of disease progression or diagnose PD in unclear cases, for example, presence of atypical signs and a poor response to levodopa, a prominent essential tremor (ET), or parkinsonism from dopamine antagonist medications. Decreased dopaminergic uptake in the putamen is characteristic of PD, but subclinical dopaminergic changes are also evident in some at-risk relatives of kindreds with familial PD.

Differential Diagnosis. Several clinical features help distinguish PD from other parkinsonian disorders. PD progresses more slowly, postural instability is a later finding, and has an excellent and sustained response to levodopa. Alternative diagnoses, such as PSP or MSA, are suggested by rapid progression with development of postural instability and early falls (within 3 years), a poor or transient response to levodopa, orthostatic hypotension and other signs of autonomic dysfunction, early dysphagia, and supranuclear gaze palsy. Early hallucinations, unrelated to treatment, and early dementia suggest a diagnosis of DLB or AD with associated PD or with parkinsonism. Myoclonic jerks, pyramidal signs (e.g., Babinski sign), and cerebellar signs (e.g., wide-based gait), are not features of PD,

Telegram: @medical_k

www.konkur.in

but are seen in other parkinsonian disorders. Other non-PD–associated findings include alien limb syndrome or ideomotor apraxia.

It is always important to consider alternative diagnoses to depression. Apathetic syndromes, dementia, or delirium can all result in changes in mood that are usually more apparent to families than the patient. The differential diagnosis of depression in PD also includes bipolar disorder, adjustment disorders, anxiety syndromes, psychosis, pathologic tearfulness (emotional incontinence), substance abuse or dependence, mood lability associated with parkinsonian motor fluctuations, and increased medical debility. Independent of a depressive disorder, sleep disturbances and daytime fatigue in PD can impair function and lead patients to feel discouraged. PD-related depression is also frequently associated with anxiety disorders (e.g., panic disorder) and dementia. The somatic and autonomic symptoms of anxiety can overlap with features of other medical conditions. Psychosis in the early stages of PD suggests alternative diagnoses, such as DLB or AD with extrapyramidal features. In some cases, pre-existing psychopathology emerges with dopaminergic treatment.

Course and Prognosis. PD is clinically heterogeneous. In each case, there is a different clinical presentation, age onset, natural history, and response to levodopa. Many cases of PD can be subdivided into either a tremor predominant form, or one characterized by prominent gait disorder and postural instability, the former having a more benign prognosis. Heterogeneity in clinical onset, progression, and levodopa response also influence the natural history of PD. This includes the onset of motor fluctuations and other treatment-related complications, longevity, and functional impairment. The rate and course of cognitive deterioration is also highly variable, ranging from mild to severe. Successful treatment of depression improves motor status but medical treatment of motor symptoms does not usually improve depressive syndromes. Even in the absence of depression, antidepressant medications and ECT have been shown to improve motor function. As in the general population, anxiety disorders often coexist with depressive episodes, but anxiety disorders tend to be chronic. The need for nursing home placement, often triggered by psychosis, is associated with a higher mortality rate.

Treatment

www.konkur.in

Motor Symptoms

PHARMACOLOGIC TREATMENTS. Current treatment options for PD provide only symptomatic relief of the motor deficits; there are no known neuroprotective or regenerative strategies, though this is an active area of research. Consequently, the gold standard of treatment for PD remains levodopa, which increases the life expectancy among patients with PD and significantly improves function and quality of life. During early stages, anticholinergic medications such as trihexyphenidyl or benztropine, amantadine, and selegiline provide mild-to-moderate reductions in motor symptoms. Anticholinergic medications are used primarily to reduce tremor; their adverse effects, for example, cognitive impairment, urinary retention, and lack of benefit on bradykinesia limit their utility in the treatment of PD. Dopamine agonists, such as pramipexole, ropinirole, and pergolide, and/or levodopa may then be added to address progressive disability. Dopamine agonists are especially effective early treatments that can delay initiation of levodopa therapy. Postural instability does not usually respond to antiparkinsonian medications.

There is debate over when to begin levodopa therapy since it is associated with dose-limiting motor side effects (in addition to psychosis). Initially, there is tremendous improvement in motor function. As PD progresses (along with the underlying neurodegeneration), higher levodopa doses are required to achieve similar benefit and the duration of the motor response wanes. A roller coaster–like experience of fluctuating motor effects then replaces the sustained motor benefits: patients experience states of improved motor function after taking dopaminergic medications (the “on” state) followed by reduced mobility or even immobility when the medication effects subside (the “off” state). Patients also develop abnormal involuntary hyperkinetic choreiform or dystonic movements during the “on” state, referred to as drug-induced dyskinesias. Agents that inhibit dopamine metabolism via catechol-o-methyltransferase inhibition, such as tolcapone and entacapone, can reduce motor fluctuations.

Psychiatric Disturbances Related to Fluctuating Effects of Dopaminergic Therapy. Emotional influences can trigger or intensify the “on–off” motor fluctuations and drug-induced dyskinesias, themselves, can be distressing or embarrassing. In the extreme, “on–off” fluctuations

Telegram: @medical_k

www.konkur.in

with dyskinesias range from states of complete immobility or “freezing” to severe writhing. Fluctuating motor states can also be accompanied by nonmotor phenomena such as akathisia, anxiety, dysphoria, autonomic symptoms, irritability, apathy, hallucinosis, psychosis, screaming, and cognitive slowing during “off” periods and hypersexuality, hypomania, and thought racing during “on” periods.

SURGICAL TREATMENTS. Before availability of levodopa in the 1960s, neurosurgical procedures were standard treatments for tremor and rigidity in PD. More refined stereotactic neurosurgical therapies currently used for PD involve high-frequency deep brain stimulation (DBS) of the STN and globus pallidus pars interna (Gpi) or ablative procedures that target the GPi (pallidotomy) or thalamus (thalamotomy). Both improve motor function because they reduce the hyperactivity of the STN and its efferent targets, thus partially restoring thalamic outflow. Thalamotomy and thalamic DBS are indicated for disabling tremor. STN DBS and pallidal interventions also improve tremor, but are mainly indicated for severe dyskinesias, bradykinesia/akinesia, and rigidity. The procedures are aimed at alleviation of contralateral symptoms, but bilateral benefits are seen for dyskinesias and bradykinesia. In 2018, U.S. Food and Drug Administration (FDA) approved unilateral high-intensity focused ultrasound (FUS) of the STN or thalamus for treatment of tremor-dominant PD. The indications were subsequently expanded to include bradykinesia, rigidity, and dyskinesias. Embryonic cell transplantation of dopamine neurons, first performed in the 1980s, remains experimental, as are trials on surgical delivery of gene therapies.

Neuropsychiatric Effects of Neurosurgical Therapy for PD. Initial studies showed limited, if any, adverse cognitive effects after ablative or DBS procedures when surgical candidates underwent careful screening for dementia. Some pallidotomy studies found changes in executive function, memory, verbal fluency, and attentional set shifting, but lesion size may have been influential. Stimulation parameters, laterality and site-specific effects, electrode placement, and stimulation sites may also affect cognitive outcomes.

While many patients report improved quality of life after surgery, acute stimulation with DBS can be associated with profound depressive or manic symptoms, including in patients with no prior psychiatric history. In

Telegram: @medical_k

www.konkur.in

some patients, pre-existing disorders, such as depression, anxiety, or drug dependence, and interpersonal conflicts worsen and can overshadow motoric benefits. DBS treatment-emergent sexually deviant behaviors, gambling, mood lability, apathy, and aggression are also described. Reductions in anxiety and depression, unrelated to improved motor status, are reported after unilateral pallidotomy, whereas depression and apathy are reported after bilateral pallidotomy. Pallidotomy studies show no consistent effects on depression or anxiety, but a history of a prior or active affective disturbance at the time of surgery may be associated with development of a mood disorder.

COGNITIVE MANIFESTATIONS. Several large randomized controlled trials on treatments of cognitive impairment or dementia in PD or DLB have been conducted. Presence of cholinergic deficits in PD and their relationship to dementia suggests a role for cholinesterase inhibitors. Intervention trials for PD-related dementia or DLBs show that cognition and psychiatric symptoms, including psychosis, improved with donepezil and rivastigmine, though the data are more limited for galantamine. Cholinesterase inhibitors are not always well tolerated; the most common side effects are nausea, vomiting, anorexia, dizziness, drowsiness, and insomnia and may be more common with rivastigmine. Memantine, while well tolerated, has not demonstrated consistent benefit, though perhaps more so in DLB. A recent systematic review indicates that both cholinesterase inhibitors and memantine result in slight improvement in global impression, but cognitive performance improved only with cholinesterase inhibitors.

A few studies investigated treatment of PD-MCI, though inconsistent definitions of PD-MCI confound interpretation of the results. Cholinesterase inhibitors appear to have some potential benefits, but targeted treatment of noradrenergic deficits may also be beneficial. Cognitive rehabilitation programs are increasingly recognized as beneficial to cognitive performance and functional abilities in patients with PD, including as adjunctive therapy to medications. In addition, patients and families benefit from education about cognitive deficits in PD, especially their consequences on executive functioning and strategies for minimizing distress related to selective cognitive impairments, and, later in the course, dementia.

Telegram: @medical_k

www.konkur.in

PSYCHIATRIC MANIFESTATIONS. A first step in the treatment of psychiatric disorders is to evaluate the contribution of the antiparkinsonian medications, fluctuating medication effects, other medical conditions, cognitive deficits, and caregiver and other psychosocial variables to the presenting problem. The common occurrence of more than one psychiatric disturbance also influences treatment. Sleep is commonly disrupted in PD, independent of psychiatric problems, and addressing it alone can reduce daytime mood lability, psychosis, and motor impairments. Initial treatment involves consideration of the antiparkinsonian regimen, sleep hygiene practices, and use of a low-dose sedating antidepressant or hypnotic such as trazodone (e.g., 25 to 100 mg). Benzodiazepines can be used judiciously but are not considered first-line therapy for anxiety, agitation, or sleep disturbances because of their effects on cognition, falls, and interdose withdrawal symptoms. Patient and caregiver education, especially about the psychiatric condition and its overlap with parkinsonian features, and supportive therapy are cornerstones of effective treatment. Parkinson support groups can be invaluable sources of education and community support. Speech, physical, and occupational therapies can help maximize function, which facilitates socialization and quality of life. Even early in the disease, and then periodically as the disease progresses, rehabilitative therapies provide patients and caregivers opportunities to develop new strategies and skills that enhance communication, gait, balance, and daily self-care and function as new impairments emerge. Regular exercise helps motor symptoms and overall well-being.

DEPRESSION. For many years, despite the prevalence and seriousness of PD-related depression, published controlled trials on antidepressant treatment in PD were of poor quality. More recent research on various modalities to treat depression in PD provides some guidance, though there remains a need for larger, well-designed trials including behavioral and pharmacologic treatments. The most recent systematic review and meta-analysis indicates that pharmacologic treatments, especially using serotonin reuptake inhibitors (citalopram, sertraline, fluoxetine, and paroxetine), and CBT, result in significant improvements in depressive symptoms in both major and nonmajor depressive syndromes. Longer-term benefits of these treatments have not been assessed. However, a randomized controlled trial of CBT for PD depression demonstrated

Telegram: @medical_k

www.konkur.in

efficacy of individual CBT as monotherapy or in combination with antidepressant medication, including for reducing residual symptoms in patients already treated with antidepressants. In-person and remote telephone- or video-based modalities for delivering CBT are all shown to be efficacious. Tricyclic antidepressants (nortriptyline, desipramine, and doxepin) showed a large pooled effect that was not statistically significant. Trials of nonantidepressant medications (pramipexole, pergolide, atomoxetine, and memantine) were not efficacious. rTMS studies showed improvement in depressive symptoms, but were not sufficiently powered to yield firm conclusions.

As with primary depression, antidepressant selection is usually based on consideration of side-effect profiles. Serotonin reuptake inhibitors can aggravate motor symptoms, but this is not especially common. Use of selegiline with antidepressants carries the risk of inducing a serotonin syndrome or hypertensive reactions, but most patients tolerate this combination. In clinical practice, ECT is safe and effective for depression in PD, especially in the context of psychotic symptoms.

ANXIETY. In spite of the high prevalence of anxiety disturbances in PD and their impact, there is limited treatment data for this population. The most extensive data shows improvement of anxiety symptoms with CBT, though impact on specific anxiety disorders was not assessed. In the one randomized controlled medication trial, bromazepam, a long-acting benzodiazepine, improved psychological and somatic anxiety symptoms. While benzodiazepines can be effective in reducing anxiety, their unfavorable effects on alertness, cognition, and gait, and fall risk should discourage their use, with careful evaluation of known risks and putative benefits before prescribing even for short-term use. SSRI antidepressants have been shown to improve anxiety when measured as a secondary outcome in depression treatment trials in patients with PD. Buspirone, a nonbenzodiazepine anxiolytic with partial 5-HT agonism, has been used in PD but its specific effects on anxiety are not obvious. Gabapentin is used for treatment of anxiety disorders, but its use in PD has not been examined. The utility of antipsychotic medications as adjunctive therapy is also not known.

APATHY. Studies on treatment of apathy in PD are limited, in part because of practical and conceptual barriers, such as lack of established

Telegram: @medical_k

www.konkur.in

diagnostic criteria or a gold-standard assessment scale, and confounding conditions. Treatment of comorbid depression is an obvious initial approach, but there may be residual or SSRI-induced apathy. Antidepressants that inhibit dopamine or norepinephrine reuptake are suggested by neurochemical theories of apathy. If depression is not an issue, dopaminergic agents, including levodopa, dopamine receptor agonists, selegiline, amphetamines, and amantadine, have been most consistently effective; the absence of cognitive dysfunction predicts a better response. Among PD patients without dementia or comorbid depression, apathy improved in double-blind placebo-controlled trials of medications that either enhanced acetylcholine (rivastigmine) or stimulated D2 or D3 receptors (piribedil). In Alzheimer and PD, cholinesterase inhibitors may reduce apathy. Subthalamic DBS can induce or aggravate apathy in some patients

PSYCHOSIS. Treatment of psychosis in PD is challenged by the delicate balancing act between the use of medications that can relieve psychosis without aggravating motor or cognitive dysfunction and medications that improve motor symptoms without exacerbating the mental status. Caregiver safety is also an issue because of immobility, directed aggression, and combativeness during care. Reducing or simplifying the antiparkinsonian regimen usually involves elimination of anticholinergics, amantadine, and selegiline; in addition, when there is psychosis, levodopa is generally preferred to dopamine agonists or controlled-release levodopa. When higher doses of levodopa are required or disruptive symptoms persist, treatment usually requires addition of an atypical antipsychotic.
