Staphylococcal Meningitis Meningitis due to susceptible strains of *S. aureus* or coagulase-negative staphylococci is treated with nafcillin (Table 143-3). Vancomycin is the drug of choice for methicillin-resistant staphylococci and for patients allergic to penicillin. In these patients, the CSF should be monitored during therapy. If the CSF is not sterilized after 48 h of intravenous vancomycin therapy, then either intraventricular or intrathecal vancomycin, 20 mg once daily, can be added.

Gram-Negative Bacillary Meningitis The third-generation cephalosporins—cefotaxime, ceftriaxone, and ceftazidime—are equally efficacious for the treatment of gram-negative bacillary meningitis, with the exception of meningitis due to *P. aeruginosa*, which should be treated with ceftazidime or meropenem (Table 143-3). A 3-week course of intravenous antibiotic therapy is recommended for meningitis due to gram-negative bacilli.

ADJUNCTIVE THERAPY

The release of bacterial cell-wall components by bactericidal antibiotics leads to the production of the inflammatory cytokines IL-1β and TNF-α in the SAS. Dexamethasone exerts its beneficial effect by inhibiting the synthesis of IL-1β and TNF-α at the level of mRNA, decreasing CSF outflow resistance, and stabilizing the blood-brain barrier. The rationale for giving dexamethasone 20 min before antibiotic therapy is that dexamethasone inhibits the production of TNF-α by macrophages and microglia only if it is administered before these cells are activated by endotoxin. Dexamethasone does not alter TNF-α production once it has been induced. The results of clinical trials of dexamethasone therapy in meningitis due to *H. influenzae, S. pneumoniae*, and *N. meningitidis* have demonstrated its efficacy in decreasing meningeal inflammation and neurologic sequelae such as the incidence of sensorineural hearing loss.

A prospective European trial of adjunctive therapy for acute bacterial meningitis in adults found that dexamethasone reduced the number of unfavorable outcomes (15 vs 25%, $p = .03$) including death (7 vs 15%, $p = .04$). The benefits were most striking in patients with pneumococcal meningitis. Dexamethasone (10 mg intravenously) was administered 15–20 min before the first dose of an antimicrobial agent, and the same dose was repeated every 6 h for 4 days. These results were confirmed in a second trial of dexamethasone in adults with pneumococcal meningitis. Therapy with dexamethasone should ideally be started 20 min before, or not later than concurrent with, the first dose of antibiotics. It is unlikely to be of significant benefit if started >6 h after antimicrobial therapy has been initiated. Dexamethasone may decrease the penetration of vancomycin into CSF, and it delays the sterilization of CSF in experimental models of *S. pneumoniae* meningitis. As a result, to assure reliable penetration of vancomycin into the CSF, children and adults are treated with vancomycin in a dose of 45–60 mg/kg per day. Alternatively, vancomycin can be administered by the intraventricular route. In clinical trials, dexamethasone has also been shown to reduce rates of death and hearing loss with no adverse effects in patients with meningococcal meningitis.

One of the concerns for using dexamethasone in adults with bacterial meningitis is that in experimental models of meningitis, dexamethasone therapy increased hippocampal cell injury and reduced learning capacity. This has not been the case in clinical series. The efficacy of dexamethasone therapy in preventing neurologic sequelae is also different between high- and low-income countries. Three large randomized trials in low-income countries (sub-Saharan Africa, Southeast Asia) failed to show benefit in subgroups of patients. The lack of efficacy of dexamethasone in these trials has been attributed to late presentation to the hospital with more advanced disease, antibiotic pretreatment, malnutrition, infection with HIV, and treatment of patients with probable, but not microbiologically proven, bacterial meningitis. The results of these clinical trials suggest that patients in sub-Saharan Africa and those in low-income countries with negative CSF Gram's stain and culture should not be treated with dexamethasone.

INCREASED INTRACRANIAL PRESSURE

Emergency treatment of increased ICP includes elevation of the patient's head to 30–45°, intubation, hyperventilation ($Paco_2$ 25–30 mmHg), and mannitol. Patients with increased ICP should be managed in an intensive care unit; accurate ICP measurements are best obtained with an ICP monitoring device.

Treatment of increased ICP is discussed in detail in Chap. 318.

PROGNOSIS

Mortality rate is 3–7% for meningitis caused by *H. influenzae, N. meningitidis*, or group B streptococci; 15% for that due to *L. monocytogenes*; and 20% for *S. pneumoniae*. In general, the risk of death from bacterial meningitis increases with (1) decreased level of consciousness on admission, (2) onset of seizures within 24 h of admission, (3) signs of increased ICP, (4) young age (infancy) and age >50, (5) the presence of comorbid conditions including shock and/or the need for mechanical ventilation, and (6) delay in the initiation of treatment. Decreased CSF glucose concentration (<2.2 mmol/L [<40 mg/dL]) and markedly increased CSF protein concentration (>3 g/L [> 300 mg/dL]) have been predictive of increased mortality and poorer outcomes in some series. Moderate or severe sequelae occur in ~25% of survivors, although the exact incidence varies with the infecting organism. Common sequelae include decreased intellectual function, memory impairment, seizures, hearing loss and dizziness, and gait disturbances.

VIRAL MENINGITIS

CLINICAL MANIFESTATIONS

Immunocompetent adult patients with viral meningitis usually present with headache, fever, and signs of meningeal irritation coupled with an inflammatory CSF profile (see below). Headache is almost invariably present and often characterized as frontal or retroorbital and frequently associated with photophobia and pain on moving the eyes. Nuchal rigidity is present in most cases but may be mild and present only near the limit of neck anteflexion. Constitutional signs can include malaise, myalgia, anorexia, nausea and vomiting, abdominal pain, and/or diarrhea. Patients often have mild lethargy or drowsiness; however, profound alterations in consciousness, such as stupor, coma, or marked confusion, do not occur in viral meningitis and suggest the presence of encephalitis or other alternative diagnoses. Similarly, seizures or focal neurologic signs or symptoms or neuroimaging abnormalities indicative of brain parenchymal involvement are not typical of viral meningitis and suggest the presence of encephalitis or another CNS infectious or inflammatory process.

ETIOLOGY

Using a variety of diagnostic techniques, including CSF PCR, culture, and serology, a specific viral cause can be found in 60–90% of cases of

TABLE 143-4 Viruses Causing Acute Meningitis in North America

COMMON	LESS COMMON
Enteroviruses (coxsackieviruses, echoviruses, and the numbered enteroviruses)	Herpes simplex virus 1
Varicella-zoster virus	Human herpesvirus 6
Herpes simplex virus 2	Cytomegalovirus
Epstein-Barr virus	Lymphocytic choriomeningitis virus
Arthropod-borne viruses (notably WNV)	Mumps
HIV	Zika and other non-WNV arboviruses

Abbreviation: WNV, West Nile virus.

viral meningitis. The most important agents are enteroviruses (including echoviruses and coxsackieviruses in addition to numbered enteroviruses), varicella-zoster virus (VZV), HSV (HSV-2 > HSV-1), HIV, and arboviruses **(Table 143-4)**. CSF cultures are positive in 30–70% of patients, with the frequency of isolation depending on the specific viral agent. Approximately two-thirds of culture-negative cases of "aseptic" meningitis have a specific viral etiology identified by CSF PCR testing (see below).

EPIDEMIOLOGY

Viral meningitis is not a nationally reportable disease; however, it has been estimated that the incidence is at least 75,000 cases per year in the United States. In temperate climates, there is a substantial increase in cases during the nonwinter months, reflecting the seasonal predominance of enterovirus and arthropod-borne virus (arbovirus) infections in the summer and fall, with a peak monthly incidence of about 1 reported case per 100,000 population.

LABORATORY DIAGNOSIS

CSF Examination The most important laboratory test in the diagnosis of viral meningitis is examination of the CSF. The typical profile is a pleocytosis, a normal or slightly elevated protein concentration (0.2–0.8 g/L [20–80 mg/dL]), a normal glucose concentration, and a normal or mildly elevated opening pressure (100–350 mmH_2O). Organisms are *not* seen on Gram's stain of CSF. The total CSF cell count in viral meningitis is typically 25–500/μL, although cell counts of several thousand/μL are occasionally seen, especially with infections due to lymphocytic choriomeningitis virus (LCMV) and mumps virus. Lymphocytes are typically the predominant cell. Rarely, PMNs may predominate in the first 48 h of illness, especially with infections due to echovirus 9, West Nile virus (WNV), eastern equine encephalitis (EEE) virus, or mumps. A PMN pleocytosis occurs in 45% of patients with WNV meningitis and can persist for a week or longer before shifting to a lymphocytic pleocytosis. PMN pleocytosis with low glucose may also be a feature of cytomegalovirus (CMV) infections in immunocompromised hosts. Despite these exceptions, the presence of a CSF PMN pleocytosis in a patient with suspected viral meningitis in whom a specific diagnosis has not been established should prompt consideration of alternative diagnoses, including bacterial meningitis or parameningeal infections. The CSF glucose concentration is typically normal in viral infections, although it may be decreased in 10–30% of cases due to mumps or LCMV. Rare instances of decreased CSF glucose concentration occur in cases of meningitis due to echoviruses and other enteroviruses, HSV-2, and VZV. As a rule, a lymphocytic pleocytosis with a low glucose concentration should suggest fungal or tuberculous meningitis, *Listeria* meningoencephalitis, or noninfectious disorders (e.g., sarcoid, neoplastic meningitis).

A number of tests measuring levels of various CSF proteins, enzymes, and mediators—including C-reactive protein, lactic acid, lactate dehydrogenase, neopterin, quinolinate, IL-1β, IL-6, soluble IL-2 receptor, β_2-microglobulin, and TNF—have been proposed as potential discriminators between viral and bacterial meningitis or as markers of specific types of viral infection (e.g., infection with HIV), but they remain of uncertain sensitivity and specificity and are not widely used for diagnostic purposes.

Polymerase Chain Reaction Amplification of Viral Nucleic Acid Amplification of viral-specific DNA or RNA from CSF using PCR amplification has become the single most important method for diagnosing CNS viral infections. In both enteroviral and HSV infections of the CNS, CSF PCR has become the diagnostic procedure of choice and is substantially more sensitive than viral cultures. HSV CSF PCR is also an important diagnostic test in patients with recurrent episodes of "aseptic" meningitis, many of whom have amplifiable HSV DNA in CSF despite negative viral cultures. The FilmArray Meningitis/Encephalitis panel (BioFire Diagnostics) includes HSV-1, HSV-2, enteroviruses, VZV, human herpesvirus 6 (HHV-6), and human *Parechovirus*. The panel does not include CMV, WNV, LCMV, or Epstein-Barr virus (EBV). CSF PCR tests are available for WNV but are not as sensitive as detection of WNV-specific CSF IgM. PCR is also useful in the diagnosis of CNS infection caused by *Mycoplasma pneumoniae,* which can mimic viral meningitis and encephalitis. PCR of throat washings may assist in diagnosis of enteroviral and mycoplasmal CNS infections. PCR of stool specimens may also assist in diagnosis of enteroviral infections (see below).

Viral Culture The sensitivity of CSF cultures for the diagnosis of viral meningitis and encephalitis, in contrast to its utility in bacterial infections, is generally poor. In addition to CSF, specific viruses may also be isolated from throat swabs, stool, blood, and urine. Enteroviruses and adenoviruses may be found in feces; arboviruses, some enteroviruses, and LCMV in blood; mumps and CMV in urine; and enteroviruses, mumps, and adenoviruses in throat washings. During enteroviral infections, viral shedding in stool may persist for several weeks. The presence of enterovirus in stool is not diagnostic and may result from residual shedding from a previous enteroviral infection; it also occurs in some asymptomatic individuals during enteroviral epidemics.

Serologic Studies The basic approach to the serodiagnosis of viral meningitis is identical to that for viral encephalitis **(see Chap. 142)**. Serologic studies are important for the diagnosis of arboviruses such as WNV; however, these tests are less useful for viruses such as HSV, VZV, CMV, and EBV that have a high seroprevalence in the general population.

CSF oligoclonal γ globulin bands occur in association with a number of viral infections. The associated antibodies are often directed against viral proteins. Oligoclonal bands also occur commonly in certain noninfectious neurologic diseases (e.g., multiple sclerosis) and may be found in nonviral infections (e.g., neurosyphilis, Lyme neuroborreliosis).

Other Laboratory Studies All patients with suspected viral meningitis should have a complete blood count and differential, liver and renal function tests, erythrocyte sedimentation rate (ESR), C-reactive protein, electrolytes, glucose, creatine kinase, aldolase, amylase, and lipase. Neuroimaging studies (MRI preferable to CT) are not absolutely necessary in patients with uncomplicated viral meningitis but should be performed in patients with altered consciousness, seizures, focal neurologic signs or symptoms (see "Differential Diagnosis" below), atypical CSF profiles, or underlying immunocompromising treatments or conditions.

DIFFERENTIAL DIAGNOSIS

The most important issue in the differential diagnosis of viral meningitis is to consider diseases that can mimic viral meningitis, including (1) untreated or partially treated bacterial meningitis; (2) early stages of meningitis caused by fungi, mycobacteria, or *Treponema pallidum* (neurosyphilis), in which a lymphocytic pleocytosis is common, cultures may be slow growing or negative, and hypoglycorrhachia may not be present early; (3) meningitis caused by agents such as *Mycoplasma, Listeria* spp., *Brucella* spp., *Coxiella* spp., *Leptospira* spp., and *Rickettsia* spp.; (4) parameningeal infections; (5) neoplastic meningitis;

and (6) meningitis secondary to noninfectious inflammatory diseases, including medication-induced hypersensitivity meningitis, SLE and other rheumatologic diseases, sarcoidosis, Behçet's syndrome, and the uveomeningitic syndromes. Studies in children >28 days of age suggest that the presence of CSF protein >0.5 g/L (sensitivity 89%, specificity 78%) and elevated serum procalcitonin levels >0.5 ng/mL (sensitivity 89%, specificity 89%) were clues to the presence of bacterial as opposed to "aseptic" meningitis. A variety of clinical algorithms for differentiating bacterial from aseptic meningitis have been developed. One such prospectively validated system, the *bacterial meningitis score*, suggests that the probability of bacterial meningitis is 0.3% or less (negative predictive value 99.7%, 95% confidence interval 99.6–100%) in children with CSF pleocytosis who have (1) a negative CSF Gram's stain, (2) CSF neutrophil count <1000 cells/μL, (3) CSF protein <80 mg/dL, (4) peripheral absolute neutrophil count of <10,000 cells/μL, and (5) no prior history or current presence of seizures.

SPECIFIC VIRAL ETIOLOGIES

Enteroviruses (EVs) **(Chap. 210)** are the most common cause of viral meningitis, accounting for >85% of cases in which a specific etiology can be identified. Cases may either be sporadic or occur in clusters. EV71 has produced large epidemics of neurologic disease outside the United States, especially in Southeast Asia, but most recently reported cases in the United States have been sporadic. Enteroviruses are the most likely cause of viral meningitis in the summer and fall months, especially in children (<15 years), although cases occur at reduced frequency year-round. Although the incidence of enteroviral meningitis declines with increasing age, some outbreaks have preferentially affected older children and adults. Meningitis outside the neonatal period is usually benign. Patients present with sudden onset of fever; headache; nuchal rigidity; and often constitutional signs, including vomiting, anorexia, diarrhea, cough, pharyngitis, and myalgias. The physical examination should include a careful search for stigmata of EV infection, including exanthems, hand-foot-mouth disease, herpangina, pleurodynia, myopericarditis, and hemorrhagic conjunctivitis. The CSF profile is typically a lymphocytic pleocytosis (100–1000 cells/μL) with normal glucose and normal or mildly elevated protein concentration. However, up to 15% of patients, most commonly young infants rather than older children or adults, have a normal CSF leukocyte count. In rare cases, PMNs may predominate during the first 48 h of illness. CSF reverse transcriptase PCR (RT-PCR) is the diagnostic procedure of choice and is both sensitive (>95%) and specific (>100%). CSF RT-PCR has the highest sensitivity if performed within 48 h of symptom onset, with sensitivity declining rapidly after day 5 of symptoms. RT-PCR of throat washings or stool specimens may be positive for several weeks, and positive results can help support the diagnosis of an acute enteroviral infection. The sensitivity of routine enteroviral RT-PCRs for detecting EV71 is low, and specific testing may be required. Treatment is supportive, and patients usually recover without sequelae. Chronic and severe infections can occur in neonates and in individuals with hypo- or agammaglobulinemia.

Arbovirus infections **(Chap. 215)** occur predominantly in the summer and early fall. Arboviral meningitis should be considered when clusters of meningitis and encephalitis cases occur in a restricted geographic region during the summer or early fall. In the United States, the most important causes of arboviral meningitis and encephalitis are WNV, St. Louis encephalitis virus, and the California encephalitis group of viruses. In WNV epidemics, avian deaths may serve as sentinel infections for subsequent human disease. A history of tick exposure or travel or residence in the appropriate geographic area should suggest the possibility of Colorado tick fever virus or Powassan virus infection, although nonviral tick-borne diseases, including RMSF and Lyme neuroborreliosis, may present similarly. Arbovirus meningitis is typically associated with a CSF lymphocytic pleocytosis, normal glucose concentration, and normal or mildly elevated protein concentration. However, ~45% of patients with WNV meningitis have CSF neutrophilia, which can persist for a week or more. The rarity of hypoglycorrhachia in WNV infection, the absence of positive Gram's stains, and the negative cultures help distinguish these patients from those with bacterial meningitis. Definitive diagnosis of arboviral meningitis is based on demonstration of viral-specific IgM in CSF or seroconversion. The prevalence of CSF IgM increases progressively during the first week after infection, peaking at >80% in patients with neuroinvasive disease; as a result, repeat studies may be needed when disease suspicion is high and an early study is negative. CSF RT-PCR tests are available for some viruses in selected diagnostic laboratories and at the Centers for Disease Control and Prevention (CDC), but in the case of WNV, sensitivity (~70%) of CSF RT-PCR is less than that of CSF serology. WNV CSF RT-PCR may be useful in immunocompromised patients who may have absent or reduced antibody responses.

HSV meningitis **(Chap. 197)** has been increasingly recognized as a major cause of viral meningitis in adults, and overall, it is probably second in importance to enteroviruses as a cause of viral meningitis, accounting for 5% of total cases overall and undoubtedly a higher frequency of those cases occurring in adults and/or outside of the summer-fall period when enterovirus infections are increasingly common. In adults, the majority of cases of uncomplicated meningitis are due to HSV-2, whereas HSV-1 is responsible for 90% of cases of HSV encephalitis. HSV meningitis occurs in ~25–35% of women and ~10–15% of men at the time of an initial (primary) episode of genital herpes. Of these patients, 20% go on to have recurrent attacks of meningitis. Diagnosis of HSV meningitis is usually by HSV CSF PCR because cultures may be negative, especially in patients with recurrent meningitis. Demonstration of intrathecal synthesis of HSV-specific antibody may also be useful in diagnosis, although antibody tests are less sensitive and less specific than PCR and may not become positive until after the first week of infection. Although a history of or the presence of HSV genital lesions is an important diagnostic clue, many patients with HSV meningitis give no history and have no evidence of active genital herpes at the time of presentation. Most cases of recurrent viral or "aseptic" meningitis, including cases previously diagnosed as Mollaret's meningitis, are due to HSV.

VZV meningitis **(Chap. 198)** should be suspected in the presence of concurrent chickenpox or shingles. However, it is important to recognize that VZV is being increasingly identified as an important cause of both meningitis and encephalitis in patients without rash. The frequency of VZV as a cause of meningitis is extremely variable, ranging from as low as 3% to as high as 20% in different series. Diagnosis is usually based on CSF PCR, although the sensitivity of this test is not as high as for the other herpesviruses. VZV serologic studies complement PCR testing, and the diagnosis of VZV CNS infection can be made by the demonstration of VZV-specific intrathecal antibody synthesis and/or the presence of VZV CSF IgM antibodies, or by positive CSF cultures.

EBV infections **(Chap. 199)** may also produce aseptic meningitis, with or without associated infectious mononucleosis. The presence of atypical lymphocytes in the CSF or peripheral blood is suggestive of EBV infection but may occasionally be seen with other viral infections. EBV is almost never cultured from CSF. Serum and CSF serology help establish the presence of acute infection, which is characterized by IgM viral capsid antibodies (VCAs), antibodies to early antigens (EAs), and the absence of antibodies to EBV-associated nuclear antigen (EBNA). CSF PCR is another important diagnostic test, although false-positive results may reflect viral reactivation associated with other infectious or inflammatory processes or the presence of latent viral DNA in lymphocytes recruited due to other inflammatory conditions.

HIV meningitis should be suspected in any patient presenting with a viral meningitis with known or suspected risk factors for HIV infection. Meningitis may occur following primary infection with HIV in 5–10% of cases and less commonly at later stages of illness. Cranial nerve palsies, most commonly involving cranial nerves V, VII, or VIII, are more common in HIV meningitis than in other viral infections. Diagnosis can be confirmed by detection of HIV genome in blood or CSF. Seroconversion may be delayed, and patients with negative HIV serologies who are suspected of having HIV meningitis should be monitored for delayed seroconversion. **For further discussion of HIV infection, see Chap. 208.**

Mumps **(Chap. 213)** should be considered when meningitis occurs in the late winter or early spring, especially in males (male-to-female ratio 3:1). With the widespread use of the live attenuated mumps vaccine in the United States since 1967, the incidence of mumps meningitis has fallen by >95%; however, mumps remains a potential source of infection in nonimmunized individuals and populations, but also in those who have been vaccinated but may have waning immunity. Rare cases (10–100/100,000 vaccinated individuals) of vaccine-associated mumps meningitis have been described, with onset typically 2–4 weeks after vaccination. The presence of parotitis, orchitis, oophoritis, pancreatitis, or elevations in serum lipase and amylase is suggestive of mumps meningitis; however, their absence does not exclude the diagnosis. Clinical meningitis has been estimated to occur in 10–30% of patients with mumps parotitis. Mumps infection confers lifelong immunity, so a documented history of previous infection excludes this diagnosis. A CSF pleocytosis that can exceed 1000 cells/μL is present in 25% of patients with mumps meningitis. Lymphocytes predominate in 75%, although CSF neutrophilia occurs in 25%. Hypoglycorrhachia occurs in 10–30% of patients and may be a clue to the diagnosis when present. Diagnosis is typically made by culture of virus from CSF or by detecting IgM antibodies or seroconversion. CSF PCR is available in some diagnostic and research laboratories.

LCMV infection **(Chap. 215)** should be considered when aseptic meningitis occurs in the late fall or winter and in individuals with a history of exposure to house mice (*Mus musculus*), pet or laboratory rodents (e.g., hamsters, rats, mice), or their excreta. Some patients have an associated rash, pulmonary infiltrates, alopecia, parotitis, orchitis, or myopericarditis. Laboratory clues to the diagnosis of LCMV, in addition to the clinical findings noted above, may include the presence of leukopenia, thrombocytopenia, or abnormal liver function tests. Some cases present with a marked CSF pleocytosis (>1000 cells/μL) and hypoglycorrhachia (<30%). Diagnosis is based on serology and/or culture of virus from CSF.

TREATMENT

Acute Viral Meningitis

Treatment of almost all cases of viral meningitis is primarily symptomatic and includes use of analgesics, antipyretics, and antiemetics. Fluid and electrolyte status should be monitored. Patients with suspected bacterial meningitis should receive appropriate empirical therapy pending culture results (see above). Hospitalization may not be required in immunocompetent patients with presumed viral meningitis and no focal signs or symptoms, no significant alteration in consciousness, and a classic CSF profile (lymphocytic pleocytosis, normal glucose, negative Gram's stain) if adequate provision for monitoring at home and medical follow-up can be ensured. Immunocompromised patients; patients with significant alteration in consciousness, seizures, or the presence of focal signs and symptoms suggesting the possibility of encephalitis or parenchymal brain involvement; and patients who have an atypical CSF profile should be hospitalized. Oral or intravenous acyclovir may be of benefit in patients with meningitis caused by HSV-1 or -2 and in cases of severe EBV or VZV infection. Data concerning treatment of HSV, EBV, and VZV meningitis are extremely limited. Seriously ill patients should probably receive intravenous acyclovir (15–30 mg/kg per day in three divided doses), which can be followed by an oral drug such as acyclovir (800 mg five times daily), famciclovir (500 mg tid), or valacyclovir (1000 mg tid) for a total course of 7–14 days. Patients who are less ill can be treated with oral drugs alone. Patients with HIV meningitis should receive antiretroviral therapy **(Chap. 208)**. There is no specific therapy of proven benefit for patients with arboviral encephalitis, including that caused by WNV.

Patients with viral meningitis who are known to have deficient humoral immunity (e.g., X-linked agammaglobulinemia) and who are not already receiving either intramuscular γ globulin or intravenous immunoglobulin (IVIg) should be treated with these agents. Intraventricular administration of immunoglobulin through an Ommaya reservoir has been tried in some patients with chronic enteroviral meningitis who have not responded to intramuscular or intravenous immunoglobulin.

Vaccination is an effective method of preventing the development of meningitis and other neurologic complications associated with poliovirus, mumps, measles, rubella, and varicella infection. A recombinant zoster vaccine (RSV, Shingrix) contains recombinant VZV glycoprotein E in combination with an adjuvant ($ASO1_B$) and has greater efficacy in preventing zoster in adults aged ≥70 years than the previously recommended live attenuated vaccine (Zostrax). The Advisory Committee on Immunization Practices recommends the use of the recombinant zoster vaccine in immunocompetent adults aged ≥50 years and in immunodeficient or immunosuppressed adults ≥19 years of age.

PROGNOSIS

In adults, the prognosis for full recovery from viral meningitis is excellent. Rare patients complain of persisting headache, mild mental impairment, incoordination, or generalized asthenia for weeks to months. The outcome in infants and neonates (<1 year) is less certain; intellectual impairment, learning disabilities, hearing loss, and other lasting sequelae have been reported in some studies.

SUBACUTE MENINGITIS

CLINICAL MANIFESTATIONS

Patients with subacute meningitis typically have an unrelenting headache, stiff neck, low-grade fever, and lethargy for days to several weeks before they present for evaluation. Cranial nerve abnormalities and night sweats may be present. **This syndrome overlaps that of chronic meningitis, discussed in detail in Chap. 144 but is included here because the meningeal pathogens of subacute meningitis can also present as an acute meningitis.**

ETIOLOGY

Common causative organisms include *M. tuberculosis, C. neoformans, H. capsulatum, C. immitis*, and *T. pallidum*. Initial infection with *M. tuberculosis* is acquired by inhalation of aerosolized droplet nuclei. Tuberculous meningitis in adults does not develop acutely from hematogenous spread of tubercle bacilli to the meninges. Rather, millet seed–sized (miliary) tubercles form in the parenchyma of the brain during hematogenous dissemination of tubercle bacilli in the course of primary infection. These tubercles enlarge and are usually caseating. The propensity for a caseous lesion to produce meningitis is determined by its proximity to the SAS and the rate at which fibrous encapsulation develops. Subependymal caseous foci cause meningitis via discharge of bacilli and tuberculous antigens into the SAS. Mycobacterial antigens produce an intense inflammatory reaction that leads to the production of a thick exudate that fills the basilar cisterns and surrounds the cranial nerves and major blood vessels at the base of the brain.

Fungal infections are typically acquired by the inhalation of airborne fungal spores. The initial pulmonary infection may be asymptomatic or present with fever, cough, sputum production, and chest pain. The pulmonary infection is often self-limited. A localized pulmonary fungal infection can then remain dormant in the lungs until there is an abnormality in cell-mediated immunity that allows the fungus to reactivate and disseminate to the CNS. The most common pathogen causing fungal meningitis is *C. neoformans*. This fungus is found worldwide in soil and bird excreta. *H. capsulatum* is endemic to the Ohio and Mississippi River valleys of the central United States and to parts of Central and South America. *C. immitis* is endemic to the desert areas of the southwest United States, northern Mexico, and Argentina.

Syphilis is a sexually transmitted disease that is manifest by the appearance of a painless chancre at the site of inoculation. *T. pallidum* invades the CNS early in the course of syphilis. Cranial nerves VII and VIII are most frequently involved.

LABORATORY DIAGNOSIS

The classic CSF abnormalities in tuberculous meningitis are as follows: (1) elevated opening pressure, (2) lymphocytic pleocytosis (10–500 cells/μL), (3) elevated protein concentration in the range of 1–5 g/L, and (4) decreased glucose concentration in the range of 1.1–2.2 mmol/L (20–40 mg/dL). *The combination of unrelenting headache, stiff neck, fatigue, night sweats, and fever with a CSF lymphocytic pleocytosis and a mildly decreased glucose concentration is highly suspicious for tuberculous meningitis.* The last tube of fluid collected at LP is the best tube to send for a smear for acid-fast bacilli (AFB). If there is a pellicle in the CSF or a cobweb-like clot on the surface of the fluid, AFB can best be demonstrated in a smear of the clot or pellicle. Positive smears are typically reported in only 10–40% of cases of tuberculous meningitis in adults. Cultures of CSF take 4–8 weeks to identify the organism and are positive in ~50% of adults. Culture remains the gold standard to make the diagnosis of tuberculous meningitis. Nucleic acid amplification tests for the detection of *M. tuberculosis* DNA should be sent on CSF if available. The XpertMTB/RIF Ultra and the Xpert MTB/RIF are used most commonly, but the consensus of opinion is that the sensitivity, and thus the risk of false-negative results, has not been defined.

The characteristic CSF abnormalities in fungal meningitis are a mononuclear or lymphocytic pleocytosis, an increased protein concentration, and a decreased glucose concentration. There may be eosinophils in the CSF in *C. immitis* meningitis. Large volumes of CSF are often required to demonstrate the organism on India ink smear or grow the organism in culture. If spinal fluid examined by LP on two separate occasions fails to yield an organism, CSF should be obtained by high-cervical or cisternal puncture.

The cryptococcal polysaccharide antigen test is a highly sensitive and specific test for cryptococcal meningitis. A reactive CSF cryptococcal antigen test establishes the diagnosis. The detection of the *Histoplasma* polysaccharide antigen in CSF establishes the diagnosis of a fungal meningitis but is not specific for meningitis due to *H. capsulatum*. It may be falsely positive in coccidioidal meningitis. The CSF complement fixation antibody test is reported to have a specificity of 100% and a sensitivity of 75% for coccidioidal meningitis.

The diagnosis of syphilitic meningitis is made when a reactive serum treponemal test (fluorescent treponemal antibody absorption test [FTA-ABS] or microhemagglutination assay–*T. pallidum* [MHA-TP]) is associated with a CSF lymphocytic or mononuclear pleocytosis and an elevated protein concentration, or when the CSF Venereal Disease Research Laboratory (VDRL) test is positive. A reactive CSF FTA-ABS is not definitive evidence of neurosyphilis. The CSF FTA-ABS can be falsely positive from blood contamination. A negative CSF VDRL does not rule out neurosyphilis. A negative CSF FTA-ABS or MHA-TP rules out neurosyphilis.

TREATMENT

Subacute Meningitis

Empirical therapy of tuberculous meningitis is often initiated based on a high index of suspicion without adequate laboratory support. Initial therapy is a combination of isoniazid (300 mg/d), rifampin (10 mg/kg per day), pyrazinamide (30 mg/kg per day in divided doses), ethambutol (15–25 mg/kg per day in divided doses), and pyridoxine (50 mg/d). When the antimicrobial sensitivity of the *M. tuberculosis* isolate is known, ethambutol can be discontinued. If the clinical response is good, pyrazinamide can be discontinued after 8 weeks and isoniazid and rifampin continued alone for the next 6–12 months. A 6-month course of therapy is acceptable, but therapy should be prolonged for 9–12 months in patients who have an inadequate resolution of symptoms of meningitis or who have positive mycobacterial cultures of CSF during the course of therapy. Dexamethasone therapy is recommended for HIV-negative patients with tuberculous meningitis. The dose is 12–16 mg/d for 3 weeks, and then tapered over 3 weeks.

Meningitis due to *C. neoformans* in non-HIV, nontransplant patients is treated with induction therapy with amphotericin B (AmB) (0.7 mg/kg IV per day) plus flucytosine (100 mg/kg per day in four divided doses) for at least 4 weeks if CSF culture results are negative after 2 weeks of treatment. Therapy should be extended for a total of 6 weeks in the patient with neurologic complications. Induction therapy is followed by consolidation therapy with fluconazole 400 mg/d for 8 weeks. Organ transplant recipients are treated with liposomal AmB (3–4 mg/kg per day) or AmB lipid complex (ABLC; 5 mg/kg per day) plus flucytosine (100 mg/kg per day in four divided doses) for at least 2 weeks or until CSF culture is sterile. Follow CSF yeast cultures for sterilization rather than the cryptococcal antigen titer. This treatment is followed by an 8- to 10-week course of fluconazole (400–800 mg/d [6–12 mg/kg] PO). If the CSF culture is sterile after 10 weeks of acute therapy, the dose of fluconazole is decreased to 200 mg/d for 6 months to a year. Patients with HIV infection are treated with AmB or a lipid formulation plus flucytosine for at least 2 weeks, followed by fluconazole for a minimum of 8 weeks. HIV-infected patients may require indefinite maintenance therapy with fluconazole 200 mg/d. Meningitis due to *H. capsulatum* is treated with AmB (0.7–1.0 mg/kg per day) for 4–12 weeks. A total dose of 30 mg/kg is recommended. Therapy with AmB is not discontinued until fungal cultures are sterile. After completing a course of AmB, maintenance therapy with itraconazole 200 mg two or three times daily is initiated and continued for at least 9 months to a year. *C. immitis* meningitis is treated with either high-dose fluconazole (1000 mg daily) as monotherapy or intravenous AmB (0.5–0.7 mg/kg per day) for >4 weeks. Intrathecal AmB (0.25–0.75 mg/d three times weekly) may be required to eradicate the infection. Lifelong therapy with fluconazole (200–400 mg daily) is recommended to prevent relapse. AmBisome (5 mg/kg per day) or amphotericin B lipid complex (ABLC; 5 mg/kg per day) can be substituted for AmB in patients who have or who develop significant renal dysfunction. The most common complication of fungal meningitis is hydrocephalus. Patients who develop hydrocephalus should receive a CSF diversion device. A ventriculostomy can be used until CSF fungal cultures are sterile, at which time the ventriculostomy is replaced by a ventriculoperitoneal shunt.

Syphilitic meningitis is treated with aqueous penicillin G in a dose of 3–4 million units intravenously every 4 h for 10–14 days. An alternative regimen is 2.4 million units of procaine penicillin G intramuscularly daily with 500 mg of oral probenecid four times daily for 10–14 days. Either regimen is followed with 2.4 million units of benzathine penicillin G intramuscularly once a week for 3 weeks. The standard criterion for treatment success is reexamination of the CSF. The CSF should be reexamined at 6-month intervals for 2 years. The cell count is expected to normalize within 12 months, and the VDRL titer to decrease by two dilutions or revert to nonreactive within 2 years of completion of therapy. Failure of the CSF pleocytosis to resolve or an increase in the CSF VDRL titer by two or more dilutions requires retreatment.

144 Chronic and Recurrent Meningitis

Avindra Nath, Walter J. Koroshetz, Michael R. Wilson

Chronic inflammation of the meninges (pia, arachnoid, and dura) can produce profound neurologic disability and may be fatal if not successfully treated. Chronic meningitis is diagnosed when a characteristic neurologic syndrome exists for >4 weeks and is associated with a persistent inflammatory response in the cerebrospinal fluid (CSF) (white cell count >5/μL). The causes are varied, and appropriate treatment depends on identification of the etiology. Five categories of disease account for most cases of chronic meningitis: (1) meningeal infections, (2) malignancy, (3) autoimmune inflammatory disorders, (4) chemical meningitis, and (5) parameningeal infections. In addition, there is increasing recognition that some patients with recurrent meningitis may have monogenic autoinflammatory disorders.

CLINICAL PATHOPHYSIOLOGY

Neurologic manifestations of chronic meningitis (Table 144-1) are determined by the anatomic location of the inflammation and its consequences. Persistent headache, clinical signs of hydrocephalus, cranial neuropathies, radiculopathies, and cognitive or personality changes are the cardinal features. Meningeal signs are uncommon in chronic meningitis. These manifestations can occur alone or in combination. When they appear in combination, it may be indicative of widespread dissemination of the inflammatory process along CSF pathways. In some cases, the presence of an underlying systemic illness points to the probable cause of the meningitis (Fig. 144-1). The diagnosis of chronic meningitis is usually made when the clinical presentation prompts the physician to examine the CSF for signs of inflammation. CSF is produced by the choroid plexus of the cerebral ventricles, exits through the foramina in the fourth ventricle into the subarachnoid space surrounding the brain and spinal cord, circulates around the base of the brain and over the cerebral hemispheres, and is resorbed by arachnoid villi projecting into the superior sagittal sinus where it mixes with blood in the venous sinuses. Recently, a cerebral lymphatic system has been identified that drains the dura mater (Chap. 435); however, its role in chronic meningitis has not been studied. CSF flow provides a pathway for rapid spread of infectious and other infiltrative processes over the brain, spinal cord, cranial, and spinal nerve roots. Spread from the subarachnoid space into brain parenchyma may occur via the arachnoid cuffs that surround blood vessels that penetrate brain tissue (Virchow-Robin spaces). Microorganisms can travel along these perivascular spaces to enter the brain.

TABLE 144-1 Symptoms and Signs of Chronic Meningitis

SYMPTOM	SIGN
Chronic headache	± Papilledema
Neck or back pain/stiffness	Brudzinski's or Kernig's sign of meningeal irritation
Change in personality	Altered mental status—drowsiness, inattention, disorientation, memory loss, frontal release signs (grasp, suck, snout), perseveration
Facial weakness	Peripheral seventh CN paresis
Double vision	Paresis of CNs III, IV, and/or VI
Diminished vision	Papilledema, CN II (optic atrophy/inflammation)
Hearing loss	Eighth CN paresis
Arm or leg weakness	Myelopathy or radiculopathy
Numbness in arms or legs	Myelopathy or radiculopathy
Urinary retention/ incontinence	Myelopathy or radiculopathy Frontal lobe dysfunction (hydrocephalus)
Clumsiness	Ataxia

Abbreviation: CN, cranial nerve.

Intracranial Meningitis In intracranial meningitis, nociceptive nerve fibers of the meninges are stimulated by the inflammatory process, resulting in headache, neck pain, or back pain. Obstruction of CSF pathways at the cerebral aqueduct or arachnoid villi may produce hydrocephalus and signs and symptoms of raised intracranial pressure (ICP), including headache, vomiting, apathy or drowsiness, gait instability, papilledema, visual loss, impaired upgaze, or palsy of the sixth cranial nerve (CN VI). Cognitive and behavioral changes during the course of chronic meningitis may also result from vascular damage due to inflammation around the blood vessels in the subarachnoid space, causing infarction. Inflammatory deposits seeded via the CSF circulation are often prominent around the brainstem and cranial nerves and along the undersurface of the frontal and temporal lobes. Such cases, termed *basal meningitis*, often present as multiple cranial neuropathies (Chap. 452), with some combination of decreased vision (CN II), facial weakness (CN VII), decreased hearing (CN VIII), diplopia (CNs III, IV, and VI), sensory or motor abnormalities of the oropharynx (CNs IX, X, and XII), decreased olfaction (CN I), or decreased facial sensation and masseter weakness (CN V). Involvement of the lower CNs is more common because the inflammatory exudate tends to collect at the base of the brain.

Spinal Meningitis In spinal meningitis, injury may occur to motor and sensory nerve roots as they traverse the subarachnoid space and penetrate the meninges. These cases present as multiple radiculopathies with combinations of radicular pain, sensory loss, motor weakness, and urinary or fecal incontinence. In some cases, chronic inflammation causes arachnoiditis with clumping of the lower nerve roots and thickening of the meninges. Preferential involvement of the lower nerve roots results from inflammatory cells that gravitate to the bottom of the intrathecal space. Meningeal inflammation can encircle and damage the spinal cord, resulting in a myelopathy. Slow progressive involvement of multiple CNs and/or spinal nerve roots is likely due to chronic meningitis. Electrophysiologic testing (electromyography, nerve conduction studies, and evoked response testing) may be helpful in determining whether there is involvement of cranial and spinal nerve roots.

Systemic Manifestations In some patients, evidence of systemic disease provides clues to the underlying cause of chronic meningitis. A complete history of travel, sexual exposure, insect bites, and other modes of exposure to infectious agents should be sought. Infectious causes are often associated with fever, malaise, anorexia, and signs of localized or disseminated infection outside the nervous system. Infectious causes are of major concern in immunosuppressed patients and especially in patients with untreated HIV infection, in whom chronic meningitis is most often caused by *Mycobacterium tuberculosis* or *Cryptococcus neoformans* and may present without headache, fever, or meningeal signs. In this population, a high index of clinical suspicion needs to be maintained even when there is only mild confusion or a nonspecific headache syndrome even in the context of a pauicellular CSF profile. Noninfectious inflammatory disorders most often produce systemic manifestations first, but meningitis may be the initial manifestation. Carcinomatous meningitis, caused by CSF seeding with metastatic cancer cells, may or may not be accompanied by clinical evidence of the primary neoplasm.

APPROACH TO THE PATIENT

Chronic Meningitis

The occurrence of chronic or worsening headache, typically constant and nonfocal, clinical signs of hydrocephalus, cranial neuropathy, radiculopathy, and/or cognitive decline in a patient with or without fever should prompt consideration of a lumbar puncture for evidence of meningeal inflammation. On occasion, the diagnosis is made when a contrast-enhanced imaging study

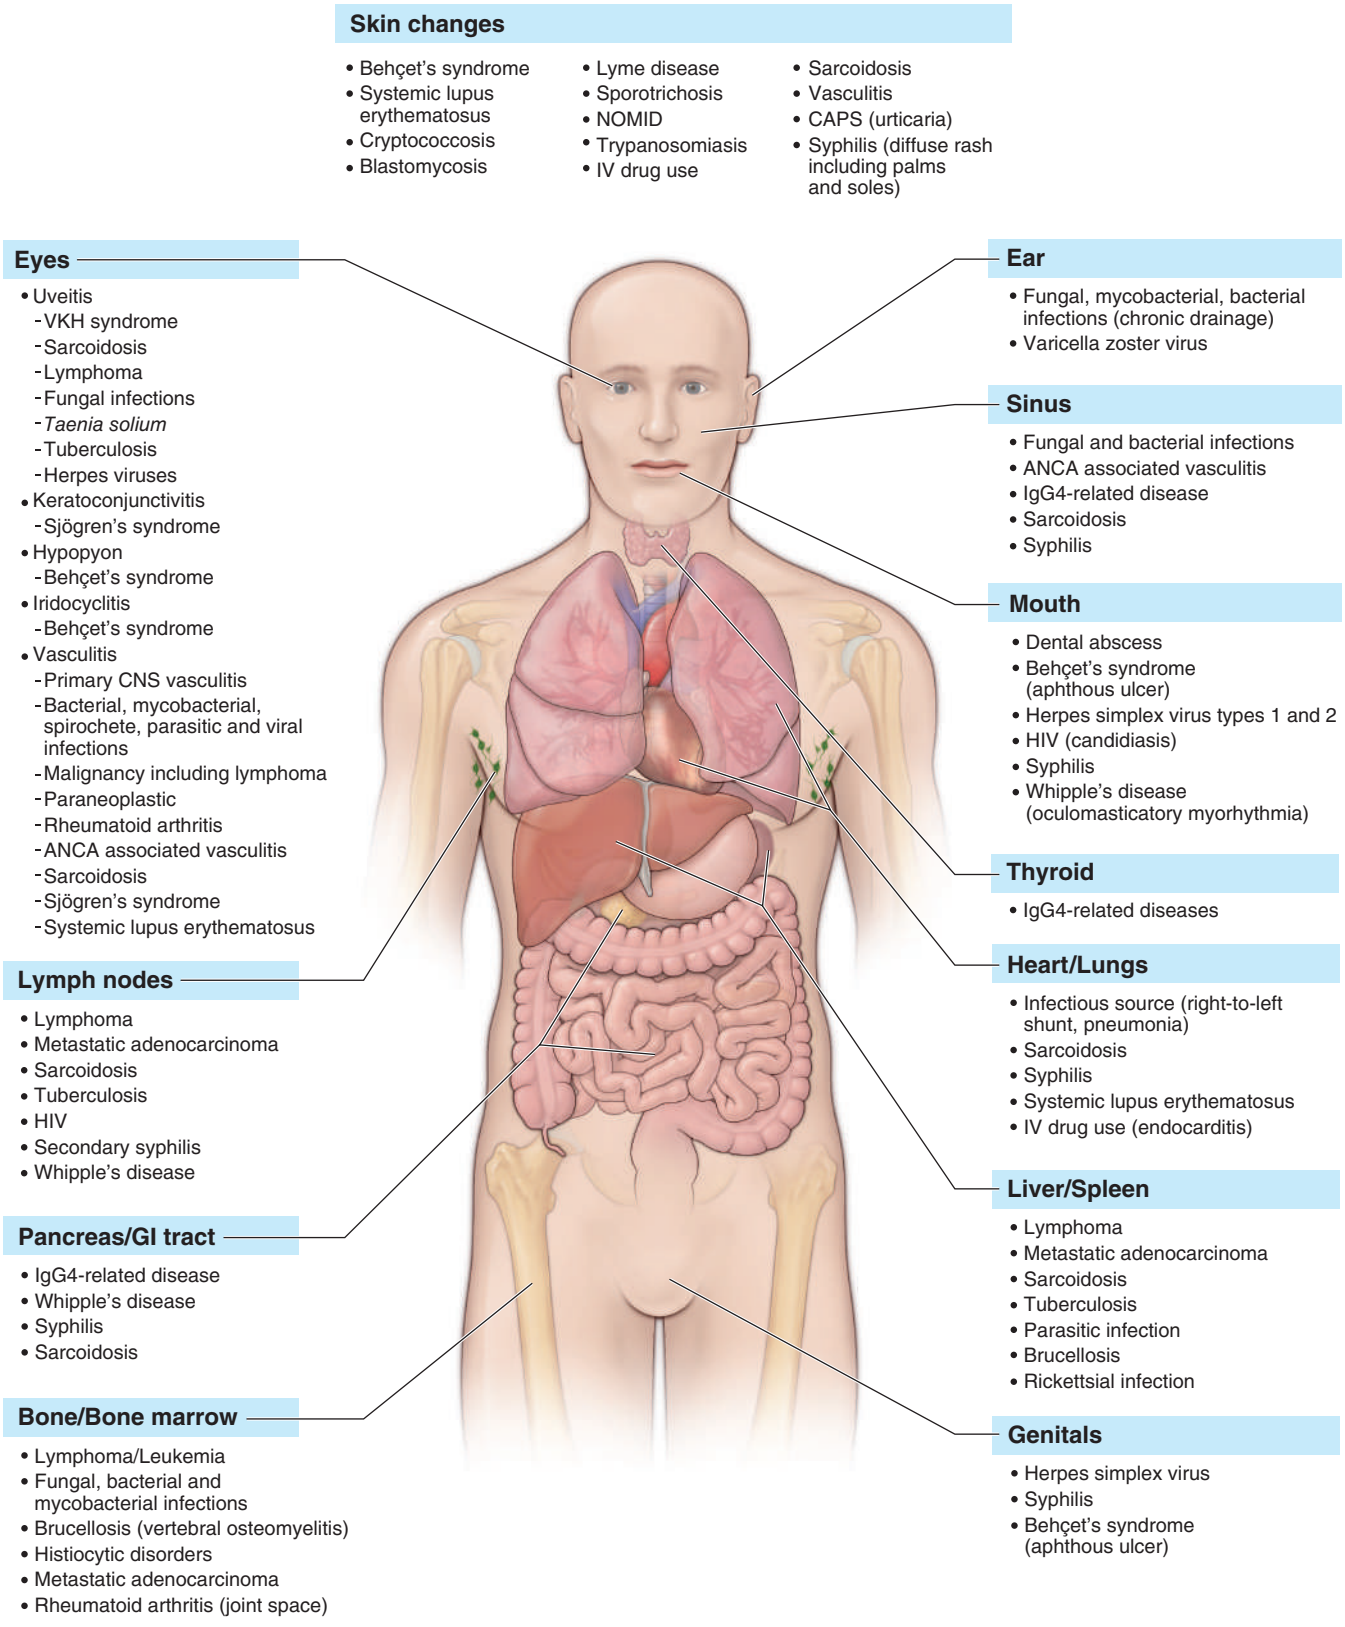

FIGURE 144-1 Systemic manifestations that may provide clues to the etiology of chronic meningitis.

(magnetic resonance imaging [MRI] or computed tomography [CT]) shows leakage of contrast agent into the meninges. Meningeal enhancement is always concerning with the exception of dural enhancement after lumbar puncture, neurosurgical procedures, concussion, or spontaneous CSF leakage. Once chronic meningitis is confirmed by CSF examination, effort is focused on identifying the cause (Tables 144-2 and 144-3) by (1) further analysis of the CSF, (2) diagnosis of an underlying systemic infection or noninfectious inflammatory condition, or (3) pathologic examination of meningeal biopsy specimens.

Two clinical forms of chronic meningitis exist. In the first, the symptoms are chronic and persistent, whereas in the second, there

TABLE 144-2 Infectious Causes of Chronic Meningitis

CAUSATIVE AGENT	CSF FORMULA	HELPFUL DIAGNOSTIC TESTS	RISK FACTORS AND SYSTEMIC MANIFESTATIONS
Common Bacterial Causes			
Partially treated suppurative meningitis	Mononuclear or mixed mononuclear-polymorphonuclear cells	CSF culture and Gram's stain; CSF 16s rRNA PCR	History consistent with acute bacterial meningitis and incomplete treatment
Parameningeal infection	Mononuclear or mixed mononuclear-polymorphonuclear cells	Contrast-enhanced CT or MRI to detect parenchymal, subdural, epidural, or sinus infection	Otitis media, pleuropulmonary infection, right-to-left cardiopulmonary shunt for brain abscess; focal neurologic signs; neck, back, ear, or sinus tenderness
Mycobacterium tuberculosis	Mononuclear cells except polymorphonuclear cells in early infection (commonly <500 WBC/μL); low CSF glucose; high protein	Tuberculin skin test may be negative; interferon gamma release assay; PCR and AFB culture of CSF (sputum, urine, gastric contents if indicated); identify tubercle bacillus on acid-fast stain of CSF or protein pellicle	Exposure history; previous tuberculous illness; immunosuppressed, anti-TNF therapy or AIDS; young children; fever, meningismus, night sweats, miliary TB on x-ray or liver biopsy; stroke due to arteritis
Lyme disease (Bannwarth's syndrome) *Borrelia burgdorferi*	Mononuclear cells; elevated protein	Serum Lyme antibody titer; western blot confirmation; (patients with syphilis may have false-positive Lyme titer)	History of tick bite or appropriate exposure history; erythema chronicum migrans skin rash; arthritis, radiculopathy, Bell's palsy and other cranial neuropathies, meningoencephalitis–multiple sclerosis-like syndrome
Syphilis (secondary, tertiary) *Treponema pallidum*	Mononuclear cells; elevated protein	CSF VDRL; serum VDRL (or RPR); fluorescent treponemal antibody-absorbed (FTA) or MHA-TP; serum VDRL and RPR may be negative in tertiary syphilis due to waning antibody levels or earlier in the disease course due to very elevated antibody levels (prozone effect)	Appropriate exposure history; HIV-seropositive individuals at increased risk of aggressive infection; fever; lymphadenopathy; generalized, nonpruritic, mucocutaneous rash; "dementia"; cerebral infarction due to endarteritis; myelopathy
Uncommon Bacterial Causes			
Actinomyces	Polymorphonuclear cells	Anaerobic culture	Parameningeal abscess or sinus tract (oral or dental focus); pneumonitis
Nocardia	Polymorphonuclear; occasionally mononuclear cells; often low glucose	Isolation may require weeks; weakly acid fast	Associated brain abscess may be present
Brucella	Mononuclear cells (rarely polymorphonuclear); elevated protein; often low glucose	CSF antibody detection; serum antibody detection	Intake of unpasteurized dairy products; exposure to goats, sheep, cows; fever, arthralgia, myalgia, vertebral osteomyelitis
Whipple's disease *Tropheryma whipplei*	Mononuclear cells	Biopsy of small bowel or lymph node; CSF PCR for *T. whipplei;* brain and meningeal biopsy (with PAS stain and EM examination)	Diarrhea, weight loss, arthralgias, fever; dementia, ataxia, paresis, ophthalmoplegia, oculomasticatory myoclonus
Rare Bacterial Causes			
Leptospirosis (occasionally if left untreated may last 3–4 weeks)			
Fungal Causes			
Cryptococcus neoformans and *var. gattii*	Mononuclear cells; count not elevated in some patients with AIDS	India ink or fungal wet mount of CSF (budding yeast); blood and urine cultures; antigen detection in CSF (false negatives can occur in the setting of high antigen titers [prozone effect])	AIDS and immune suppression; pigeon exposure for *C. neoformans*, decaying wood exposure for *C. var. gattii*; skin and other organ involvement due to disseminated infection
Coccidioides immitis	Mononuclear cells (sometimes 10–20% eosinophils); often low glucose	Antibody detection in CSF and serum, antigen detection in CSF	Exposure history—southwestern United States
Candida species	Polymorphonuclear or mononuclear	Fungal stain and culture of CSF	IV drug abuse; postsurgery; prolonged IV therapy; disseminated candidiasis, recent epidural injection
Histoplasma capsulatum	Mononuclear cells; low glucose	Fungal stain and culture of large volumes of CSF; antigen detection in CSF, serum, and urine; antibody detection in serum, CSF	Exposure history—Ohio and central Mississippi River Valley; AIDS; mucosal lesions
Blastomyces dermatitidis	Mononuclear or polymorphonuclear	Fungal stain and culture of CSF; biopsy and culture of skin, lung lesions; antibody detection in serum	Midwestern and southeastern United States; usually systemic infection; abscesses, draining sinus, ulcers
Aspergillus species	Mononuclear or polymorphonuclear	CSF culture	Sinusitis; granulocytopenia or immunosuppression
Sporothrix schenckii	Mononuclear cells	Antibody detection in CSF and serum; CSF culture	Traumatic inoculation; IV drug use; ulcerated skin lesion
Rare Fungal Causes			
Xylohypha (formerly *Cladosporium*) *trichoides* and other dark-walled (dematiaceous) fungi such as *Curvularia; Drechslera; Mucor*; and, after water aspiration, *Pseudallescheria boydii;* iatrogenic *Exserohilum rostratum* infection following spinal blocks and *Fusarium solani* following epidural anesthesia in two clinics in Durango, Mexico, during 2022–2023			

(*Continued*)

TABLE 144-2 Infectious Causes of Chronic Meningitis (Continued)

CAUSATIVE AGENT	CSF FORMULA	HELPFUL DIAGNOSTIC TESTS	RISK FACTORS AND SYSTEMIC MANIFESTATIONS
Protozoal Causes			
Toxoplasma gondii	Mononuclear cells	Biopsy or response to empirical therapy in clinically appropriate context (including presence of antibody in serum)	Usually with intracerebral abscesses; common in HIV-seropositive patients; fever
Trypanosomiasis *Trypanosoma gambiense, T. rhodesiense*	Mononuclear cells; elevated protein	Elevated CSF IgM; identification of trypanosomes in CSF and blood smear	Endemic in Africa; chancre, lymphadenopathy; prominent sleep disorder
Rare Protozoal Causes			
Acanthamoeba sp. causing granulomatous amebic encephalitis and meningoencephalitis in immunocompromised and debilitated individuals; *Balamuthia mandrillaris* causing chronic meningoencephalitis in immunocompetent hosts			
Helminthic Causes			
Cysticercosis (infection with cysts of *Taenia solium*)	Mononuclear cells; may have eosinophils; glucose level may be low	Indirect hemagglutination assay in CSF; Serum serology with enzyme-linked immunoelectrotransfer blot preferred over crude extract ELISA; antigen or PCR testing in CSF	Usually with multiple cysts in basal meninges and hydrocephalus; cerebral cysts, ocular involvement; muscle calcification
Gnathostoma spinigerum	Eosinophils, mononuclear cells	Peripheral eosinophilia	History of eating raw fish; common in Thailand and Japan; ocular involvement; subarachnoid hemorrhage; painful radiculopathy
Angiostrongylus cantonensis	Eosinophils, mononuclear cells	Recovery of worms from CSF	History of eating raw shellfish; common in tropical Pacific regions; often benign; ocular involvement (rare)
Baylisascaris procyonis (raccoon ascarid)	Eosinophils, mononuclear cells	Immunoblot in CSF (Centers for Disease Control and Prevention)	Infection follows accidental ingestion of *B. procyonis* eggs from raccoon feces; ocular involvement; fatal meningoencephalitis
Rare Helminthic Causes			
Trichinella spiralis (trichinosis); *Fasciola hepatica* (liver fluke), *Echinococcus* cysts; *Schistosoma* spp. The former may produce a lymphocytic pleocytosis, whereas the latter two may produce an eosinophilic response in CSF associated with cerebral cysts (*Echinococcus*) or granulomatous lesions of brain or spinal cord.			
Viral Causes			
Mumps	Mononuclear cells	Antibody in serum	No prior mumps or immunization; orchitis; may produce meningoencephalitis; may persist for 3–4 weeks
Lymphocytic choriomeningitis	Mononuclear cells; may have low glucose	Antibody in serum; PCR for LCMV in CSF	Contact with rodents or their excreta; may persist for 3–4 weeks
Enteroviruses	Mononuclear cells; may have low glucose	Virus isolation and/or PCR for enteroviruses from CSF	Congenital hypogammaglobulinemia; history of recurrent meningitis
HIV (acute retroviral syndrome)	Mononuclear cells	PCR for HIV in blood and CSF	HIV risk factors; rash, fever, lymphadenopathy; lymphopenia in peripheral blood; syndrome may persist long enough to be considered as "chronic meningitis"; or chronic meningitis may develop in later stages (AIDS) due to HIV
Human herpes viruses	Mononuclear cells	PCR for HSV, EBV, CMV DNA; CSF antibody for HSV, EBV	Recurrent meningitis due to HSV-2 (rarely HSV-1) often associated with genital recurrences; EBV associated with myeloradiculopathy, CMV with polyradiculopathy

Abbreviations: AFB, acid-fast bacillus; CMV, cytomegalovirus; CSF, cerebrospinal fluid; CT, computed tomography; EBV, Epstein-Barr virus; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; FTA, fluorescent treponemal antibody absorption test; HSV, herpes simplex virus; LCMV, lymphocytic choriomeningitis virus; MHA-TP, microhemagglutination assay–*T. pallidum*; MRI, magnetic resonance imaging; PAS, periodic acid–Schiff; PCR, polymerase chain reaction; RPR, rapid plasma reagin test; TB, tuberculosis; VDRL, Venereal Disease Research Laboratory test.

are recurrent discrete episodes of illness. In the latter group, all symptoms, signs, and CSF parameters of meningeal inflammation resolve completely between episodes either spontaneously or in response to a specific therapy. In such patients, the likely etiologies include Mollaret's meningitis, which is most often due to herpes simplex virus (HSV) type 2; chemical meningitis due to episodic leakage from an epidermoid tumor, craniopharyngioma, or cholesteatoma into CSF; primary autoimmune inflammatory conditions, including Vogt-Koyanagi-Harada syndrome, Behçet's syndrome, systemic lupus erythematosus (SLE), rheumatoid arthritis, neurosarcoidosis, IgG4-related disease, granulomatosis with polyangiitis, and primary central nervous system (CNS) vasculitis; and drug hypersensitivity with repeated administration of the offending agent. With the wider availability of whole genome sequencing, there is also a growing recognition that patients with inherited autoinflammatory syndromes like tumor necrosis factor (TNF) receptor–associated periodic syndrome (TRAPS), cryoporin-associated periodic fever syndrome (CAPS), complement factor I deficiency, and neonatal-onset multisystem inflammatory disorder can have recurrent meningitis.

The epidemiologic history is of considerable importance in diagnosis of chronic meningitis and may provide direction for selection of laboratory studies. Pertinent features include a history of tuberculosis or exposure; past travel to areas endemic for fungal infections (the San Joaquin Valley in California and southwestern states for coccidioidomycosis, midwestern states for histoplasmosis, southeastern states for blastomycosis); travel to the Mediterranean region or ingestion of imported unpasteurized dairy products (*Brucella*); time spent in wooded areas endemic for Lyme disease; exposure to sexually transmitted disease (syphilis, HSV-2); exposure of an immunocompromised host to pigeons and their droppings (*Cryptococcus neoformans*); exposure to decaying wood (*Cryptococcus gattii*); gardening (*Sporothrix schenckii*); ingestion of poorly cooked meat or contact with a household cat (*Toxoplasma gondii*); residence in Thailand or Japan (*Gnathostoma spinigerum*), Latin America (*Paracoccidioides brasiliensis*), or the South Pacific

TABLE 144-3 Noninfectious Causes of Chronic Meningitis

CAUSATIVE AGENTS	CSF FORMULA	HELPFUL DIAGNOSTIC TESTS	RISK FACTORS AND SYSTEMIC MANIFESTATIONS
Malignancy	Mononuclear cells; elevated protein; low glucose	Repeated cytologic examination of large volumes of CSF; CSF exam by polarizing microscopy; clonal lymphocyte markers; deposits on nerve roots or meninges seen on myelogram or contrast-enhanced MRI; meningeal biopsy	Metastatic cancer of breast, lung, stomach, or pancreas; melanoma, lymphoma, leukemia; meningeal gliomatosis; sarcoma; cerebral dysgerminoma
Chemical compounds (may cause recurrent meningitis)	Mononuclear or PMNs; low glucose, elevated protein; xanthochromia from subarachnoid hemorrhage in week prior to presentation with "meningitis"	Contrast-enhanced CT scan or MRI; cerebral angiogram to detect aneurysm. Enhancement and clumping of nerve roots of the cauda equina in arachnoiditis/ pachymeningitis	History of recent injection into the subarachnoid space; history of sudden onset of headache; recent resection of acoustic neuroma or craniopharyngioma; epidermoid tumor of brain or spine, sometimes with dermoid sinus tract; pituitary apoplexy
Primary Inflammation			
CNS sarcoidosis	Mononuclear cells; elevated protein; often low glucose	Serum and CSF angiotensin-converting enzyme levels (insensitive); biopsy of extraneural affected tissues or brain lesion/meningeal biopsy, nodular meningeal and parenchymal enhancement	CN palsy, especially CN VII and CN II, including optic chiasm; hypothalamic dysfunction, especially diabetes insipidus; abnormal chest radiograph; peripheral neuropathy or myopathy; longitudinally extensive transverse myelitis
Vogt-Koyanagi-Harada syndrome (recurrent meningitis)	Mononuclear cells		Recurrent meningoencephalitis with uveitis, retinal detachment, alopecia, lightening of eyebrows and lashes, dysacousia, cataracts, glaucoma
Isolated granulomatous angiitis of the nervous system	Mononuclear cells; elevated protein	Angiography (often normal with small vessel angiitis); meningeal biopsy may be necessary if confined to small vessels. VZV PCR in blood, CSF, and biopsy tissue; microhemorrhages with amyloid beta–related angiitis	Subacute dementia; multiple cerebral infarctions; recent zoster ophthalmicus
Systemic lupus erythematosus	Mononuclear or PMNs	Anti-dsDNA antibody, antinuclear antibodies	Encephalopathy; seizures; stroke; transverse myelopathy; rash; arthritis; thromboembolism; renal and/ or pulmonary complications
Behçet's syndrome (recurrent meningitis)	Mononuclear or PMNs; elevated protein	Rhombencephalitis	Oral and genital aphthous ulcers; iridocyclitis; retinal hemorrhages; pathergic lesions at site of skin puncture
Chronic benign lymphocytic meningitis	Mononuclear cells		Recovery in 2–6 months, diagnosis by exclusion
Mollaret's meningitis (recurrent meningitis)	Large endothelial cells and PMNs in first hours, followed by mononuclear cells	PCR for HSV; MRI/CT to rule out epidermoid tumor or dural cyst	Recurrent meningitis; exclude HSV-2; rare cases due to HSV-1; occasional case associated with dural cyst
Drug hypersensitivity	PMNs; occasionally mononuclear cells or eosinophils	Complete blood count (eosinophilia)	Exposure to nonsteroidal anti-inflammatory agents, sulfonamides, isoniazid, tolmetin, ciprofloxacin, penicillin, carbamazepine, lamotrigine, IV immunoglobulin, OKT3 antibodies, phenazopyridine; improvement after discontinuation of drug; recurrence with repeat exposure
Granulomatosis with polyangiitis (Wegener's)	Mononuclear cells	Chest and sinus radiographs; urinalysis; ANCA antibodies in serum; pachymeningitis on contrast-enhanced MRI	Associated sinus, pulmonary, or renal lesions; CN palsies; skin lesions; peripheral neuropathy
Neonatal-onset multisystem inflammatory disorder	Mononuclear and PMNs	Gain-of-function mutation in *NLRP3* gene leading to elevated IL-1β	Recurrent fever, urticaria, arthralgia, sensorineural hearing loss, papilledema, increased ICP
IgG4-related hypertrophic pachymeningitis	Mild lymphocytic pleocytosis in some cases; normal to mildly increased protein; normal glucose	Serum IgG4 levels frequently elevated; ESR and C-reactive protein; pachymeningitis on contrast-enhanced MRI; meningeal biopsy shows swirling "storiform" fibrosis with lymphocytic infiltrates, obliterative phlebitis and IgG4+ plasma cells	Headache; seizures; focal symptoms from dural involvement in spinal cord/nerve roots, clivus, periorbital, vestibular, and brainstem structures. Systemic IgG4-related disease can involve many tissues including pancreas, thyroid, lungs, retroperitoneum, lacrimal, parotid and submandibular glands, orbits, kidney, aorta, liver
TNF receptor–associated periodic fever syndrome (TRAPS)	Mononuclear cells	Mutation in *TNFRSF1A* gene leading to elevated TNF	Headache, seizures, tinnitus, skin rash, abdominal pain, lymphadenopathy, periorbital edema, joint pain, myalgia
Complement factor I deficiency	PMNs	Mutation in complement factor I gene leading to low serum levels of factor I (or dysfunctional factor I) and C3	Recurrent, steroid-responsive, aseptic, neutrophilic meningitis with or without encephalitis; increased risk for systemic infections with encapsulated bacteria, glomerulonephritis, systemic lupus erythematosus and leukocytoclastic vasculitis
Cryoporin-associated periodic fever syndrome (CAPS)	Mononuclear cells	Heterozygous gain-of-function mutations within the *NLRP3* gene	Fever, urticaria, amyloidosis, arthralgia, sensorineural hearing loss, myalgias, papilledema, vision changes
Other: multiple sclerosis, Sjögren's syndrome, and rarer forms of vasculitis (e.g., Cogan's syndrome)			

Abbreviations: ANCA, antineutrophil cytoplasmic antibodies; CN, cranial nerve; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; HSV, herpes simplex virus; ICP, intracranial pressure; IL, interleukin; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; PMNs, polymorphonuclear cells; TNF, tumor necrosis factor; VZV, varicella-zoster virus.

(*Angiostrongylus cantonensis*); rural residence and raccoon exposure (*Baylisascaris procyonis*); and residence in Latin America, the Philippines, sub-Saharan Africa, or Southeast Asia (*Taenia solium/cysticercosis, schistosomiasis*). CNS meliodosis caused by *Burkholderia pseudomallei* is endemic in South Asia and Australia. Individuals with agammaglobulinemia or those receiving B cell–depleting therapy may be susceptible to chronic enterovirus meningitis.

Focal cerebral signs in a patient with chronic meningitis suggest the possibility of a brain abscess, parameningeal infection, or infarct; identification of a potential source of infection (chronic draining ear, sinusitis, dental abscess, right-to-left cardiac or pulmonary shunt, chronic pleuropulmonary infection) supports this diagnosis. In some cases, diagnosis may be established by recognition and biopsy of unusual skin lesions (Behçet's syndrome, SLE, cryptococcosis, blastomycosis, Lyme disease, sporotrichosis, trypanosomiasis, IV drug use) or enlarged lymph nodes (lymphoma, sarcoid, tuberculosis, HIV, secondary syphilis, or Whipple's disease). Ophthalmologic examination may reveal uveitis (Vogt-Koyanagi-Harada syndrome, sarcoidosis, or CNS lymphoma), keratoconjunctivitis sicca (Sjögren's syndrome), or iridocyclitis (Behçet's syndrome) and is essential to assess visual loss from papilledema. *M. tuberculosis* can cause a wide spectrum of ophthalmologic pathology. If neurocysticercosis is suspected, it is important to rule out an intraocular infection requiring surgical treatment before initiating antihelminthic therapy. Aphthous oral lesions, genital ulcers, and hypopyon (inflammatory cells in the anterior chamber of the eye) suggest Behçet's syndrome. Hepatosplenomegaly suggests lymphoma, sarcoid, tuberculosis, or brucellosis. Arthralgias could be indicative of Lyme disease or Whipple's disease. The latter can also cause gastrointestinal symptoms, including diarrhea and abdominal pain. Herpetic lesions in the genital area or on the thighs suggest HSV-2 infection. A breast nodule; a suspicious hyperpigmented skin lesion; focal bone pain; hard, fixed lymph nodes; or an abdominal mass suggests possible carcinomatous meningitis.

IMAGING

Once the clinical syndrome is recognized as a potential manifestation of chronic meningitis, proper analysis of the CSF is essential. However, if the possibility of raised ICP exists, a brain imaging study should be performed before lumbar puncture. If ICP is elevated because of a mass lesion, brain swelling, or a block in ventricular CSF outflow (obstructive hydrocephalus), then lumbar puncture carries the potential risk of brain herniation. Obstructive hydrocephalus usually requires direct ventricular drainage. In patients with open CSF flow pathways, elevated ICP can still occur due to impaired resorption of CSF by arachnoid villi. In such patients, lumbar puncture is usually safe and may be therapeutic. Indeed, repetitive or continuous lumbar drainage may be necessary to prevent abrupt deterioration and death from raised ICP. In some patients, especially those with cryptococcal meningitis, fatal levels of raised ICP can occur without enlarged ventricles.

Contrast-enhanced MRI or CT studies of the brain and spinal cord can identify meningeal enhancement, parameningeal infections (including brain abscess), encasement of the spinal cord (malignancy, inflammation, or infection), or nodular deposits on the meninges or nerve roots (malignancy, sarcoidosis, or schistosomiasis) **(Fig. 144-2)**. Imaging studies are also useful to guide biopsy of affected meninges. Lastly, a cyst that recurrently causes a chemical meningitis due to a leak may be better visualized in between clinical episodes when a recent leak has not shrunken the cyst volume.

The patterns of enhancement of the different layers of the meninges can be very informative and can be divided into two types: leptomeningeal (pia and arachnoid), when enhancement of the meninges follows the convolutions of the gyri and/or involves the meninges around the basal cisterns; and pachymeningeal (dura), when the enhancement is thick and linear or nodular along the inner surface of the calvarium, falx, or tentorium without extension into the cortical gyri or basal cistern involvement. For example, infectious meningitis presents mostly as leptomeningitis, while lymphomatous meningitis can present as pachymeningitis.

Angiographic studies can identify evidence of cerebral arteritis in patients with chronic meningitis and stroke.

CEREBROSPINAL FLUID ANALYSIS

The CSF pressure should be measured and samples sent for bacterial, fungal, and mycobacterial culture; Venereal Disease Research Laboratory (VDRL) test; cell count and differential; Gram's stain; and measurement of glucose and protein. CSF VDRL is a highly specific, but not particularly sensitive, test for syphilis. If CSF VDRL is negative in an otherwise high-risk patient with positive treponemal antibodies in the serum and an otherwise unexplained CSF pleocytosis, empiric treatment for neurosyphilis may still be appropriate. Wet mount for fungus and parasites, India ink preparation, culture for fastidious bacteria and fungi, assays for cryptococcal antigen and oligoclonal immunoglobulin bands, and cytology should be performed. Other specific CSF tests (Tables 144-2 and 144-3) or blood tests and cultures should be ordered as indicated based on the history, physical examination, or preliminary CSF results (i.e., eosinophilic, mononuclear, or polymorphonuclear meningitis). Rapid diagnosis may be facilitated by serologic tests and polymerase chain reaction (PCR) testing to identify DNA sequences in the CSF that are specific for the suspected pathogen. 16s ribosomal RNA (rRNA) PCR can be used to detect a broad range of bacterial causes of meningitis and can be particularly useful in partially treated meningitis when the yield of culture is low. 18s and 28s rRNA PCR can similarly be useful for detecting a broad range of fungal species. In patients with suspected fungal infections, when other tests are negative, CSF assays for beta-glucans may be a useful adjunct in establishing the diagnosis. Building on progress in parallel deep sequencing and informatics, unbiased metagenomic next-generation sequencing is becoming generally available, representing an efficient and powerful method for diagnosis of challenging infectious cases.

In most categories of chronic (not recurrent) meningitis, mononuclear cells predominate in the CSF. When neutrophils predominate after 3 weeks of illness, the principal etiologic considerations are *Nocardia asteroides*, *Actinomyces israelii*, *Brucella*, *M. tuberculosis* (5–10% of early cases only), various fungi (*Blastomyces dermatitidis*, *Candida* spp., *Histoplasma capsulatum*, *Aspergillus* spp., *Pseudallescheria boydii*, *Cladophialophora bantiana*), and noninfectious causes (SLE, exogenous chemical meningitis). When eosinophils predominate or are present in limited numbers in a primarily mononuclear cell response in the CSF, the differential diagnosis includes parasitic diseases (*A. cantonensis*, *G. spinigerum*, *B. procyonis*, or *Toxocara canis* infection; cysticercosis; schistosomiasis; echinococcal disease; *T. gondii* infection), fungal infections (6–20% eosinophils along with a predominantly lymphocyte pleocytosis, particularly with coccidioidal meningitis), neoplastic disease (lymphoma, leukemia, metastatic carcinoma), or other inflammatory processes (sarcoidosis, hypereosinophilic syndrome).

It is often necessary to broaden the number of diagnostic tests if the initial workup does not reveal the cause. In addition, repeated samples (three or more) of large volumes of lumbar CSF may be required to diagnose certain infectious and malignant causes of chronic meningitis. Lymphomatous or carcinomatous meningitis may be diagnosed by examination of sections cut from a cell block formed by spinning down the sediment from a large volume of CSF. Flow cytometry for malignant cells may also be useful in patients with suspected carcinomatous meningitis. The diagnosis of fungal meningitis may also require large volumes of CSF for culture of sediment. If standard lumbar puncture is unrewarding, a cervical cisternal tap to sample CSF near to the basal meninges may be fruitful. Ventricular fluid may appear sterile in cases with active infection in the lower lumbar space.

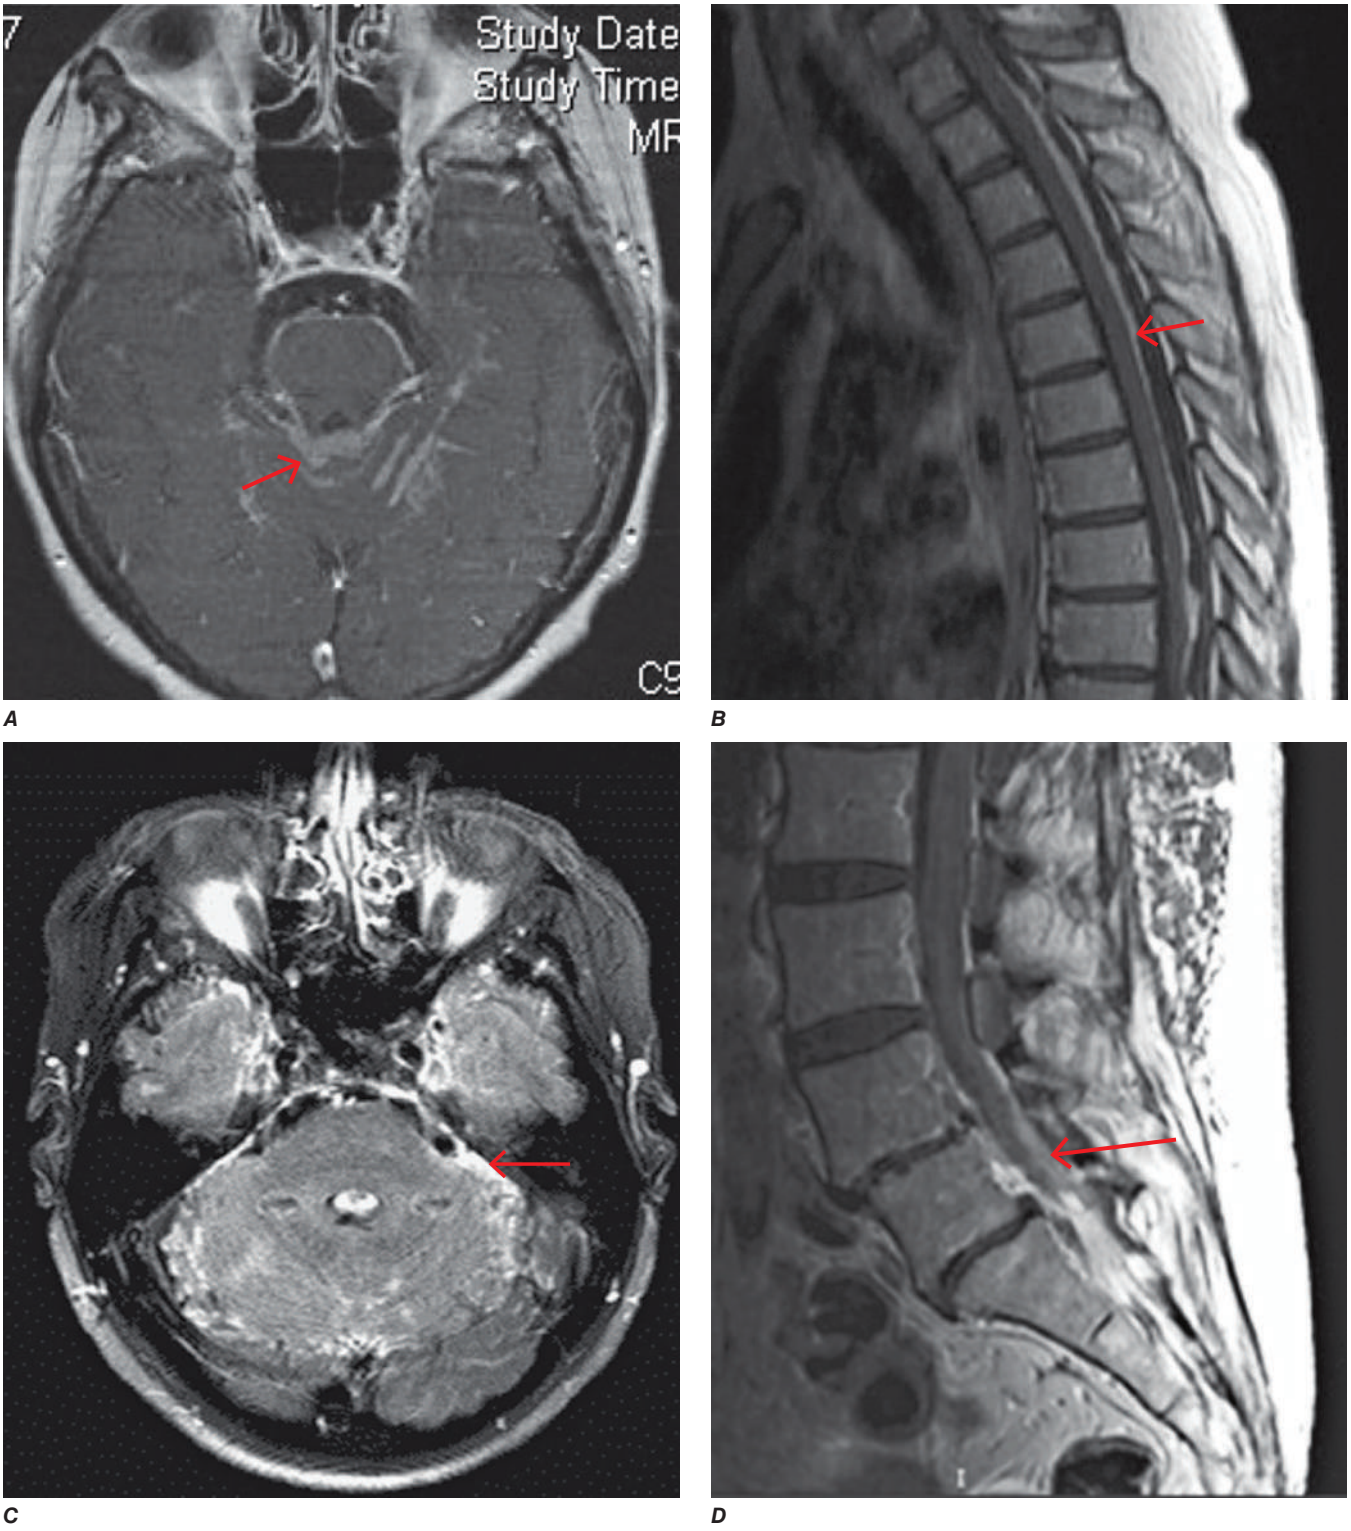

FIGURE 144-2 Chronic meningitis illustrating meningeal enhancement on contrast magnetic resonance imaging scan. ***A*** and ***B*** are images from a patient with chronic meningitis due to carcinoma. ***C*** and ***D*** are from a patient with chronic meningitis due to *Cryptococcus* infection. *Arrows* point to the most prominent areas of meningeal inflammation around the brainstem and cerebellar folia (***A***), cerebellum (***C***), along the dorsal spinal cord (***B***), and clumping of roots in the cauda equina (***D***).

LABORATORY INVESTIGATION

In addition to the CSF examination, an attempt should be made to uncover pertinent underlying illnesses. Tuberculin skin test, chest radiograph, urine analysis and culture, blood count and differential, renal and liver function tests, alkaline phosphatase, sedimentation rate, antinuclear antibody, anti-Ro antibody, anti-La antibody, rheumatoid factor, and IgG4 level are often indicated. In some cases, a thorough search for a systemic site of infection is indicated. Pulmonary foci of infection may be present, particularly with fungal or tuberculous disease. Hence, a CT or MRI of the chest and a sputum examination may be helpful. Abnormalities can be pursued by bronchoscopy or transthoracic needle biopsy. A tuberculin skin test is often placed, although the test has limited specificity and sensitivity for diagnosis of active disease. Where available, gamma interferon release assays may be used to diagnose latent tuberculosis. Liver, bone marrow, or lymph node biopsy may be diagnostic in some cases of miliary tuberculosis, disseminated fungal infection, sarcoidosis, or metastatic malignancy. Positron emission

tomography with fluorodeoxyglucose may be useful in identifying a systemic site for biopsy in patients with suspected carcinomatous meningitis or sarcoidosis when other tests are unrevealing. Genetic testing can identify mutations that cause rare monogenic autoinflammatory disorders or underlying immunocompromised states.

MENINGEAL BIOPSY

If CSF is not diagnostic, then a meningeal biopsy should be strongly considered in patients who are severely disabled, who need chronic ventricular decompression, or whose illness is progressing rapidly. The activities of the surgeon, pathologist, microbiologist, and cytologist should be coordinated so that a large enough sample is obtained and the appropriate cultures and histologic and molecular studies, including electron-microscopic and PCR studies, are performed. The diagnostic yield of meningeal biopsy can be increased by targeting regions that enhance with contrast on MRI or CT. With current microsurgical techniques, most areas of the basal meninges can be accessed for biopsy via a limited craniotomy. In one series, MRI demonstrated meningeal enhancement in 47% of patients undergoing meningeal biopsy; biopsy of an enhancing region was diagnostic in 80% of cases, biopsy of nonenhancing regions was diagnostic in only 9%, and sarcoidosis (31%) and metastatic adenocarcinoma (25%) were the most common conditions identified. Tuberculosis is the most common condition identified in many reports from outside the United States.

APPROACH TO THE ENIGMATIC CASE

In approximately one-third of cases, the diagnosis is not known despite careful evaluation of CSF and potential extraneural sites of disease. A number of the organisms that cause chronic meningitis may take weeks to be identified by cultures. In enigmatic cases, several options are available, determined by the extent of the clinical deficits and rate of progression. It is prudent to wait until cultures are finalized if the patient is asymptomatic or symptoms are mild and not progressive. Unfortunately, in many cases, progressive neurologic deterioration occurs, and rapid treatment is required. Ventricular-peritoneal shunts may be placed to relieve hydrocephalus, but the risk of disseminating the undiagnosed inflammatory process into the abdomen must be considered.

Empirical Treatment Diagnosis of the causative agent is essential because effective therapies exist for many etiologies of chronic meningitis, but if the condition is left untreated, progressive damage to the CNS and cranial nerves and roots is likely to occur. Occasionally, empirical therapy must be initiated when all attempts at diagnosis fail. In general, empirical therapy in the United States consists of antimycobacterial agents, amphotericin B (often combined with flucytosine) for fungal infection, and/or glucocorticoids for noninfectious inflammatory causes. It is important to direct empirical therapy of lymphocytic meningitis at tuberculosis, particularly if the condition is associated with low CSF glucose, since untreated disease can be devastating within weeks. Prolonged anti-TNF therapy and anti–programmed cell death 1 (PD-1) inhibitors can cause reactivation of TB, and such patients who develop chronic meningitis should be treated empirically with antituberculous therapy if the etiology is uncertain. Even with treatment, TB meningitis can carry high rates of morbidity. In the Mayo Clinic series, the most useful empirical therapy was administration of glucocorticoids rather than antituberculous therapy. When proceeding with empiric glucocorticoids, caution should be maintained whenever a transient response to treatment is noted, as some infectious (e.g., tuberculosis and cysticercosis) and noninfectious (e.g., lymphoma) etiologies may temporarily respond to glucocorticoid monotherapy. Carcinomatous or lymphomatous meningitis may be difficult to diagnose initially, but the diagnosis becomes evident with time.

THE IMMUNOSUPPRESSED PATIENT

Chronic meningitis is not uncommon in the course of HIV infection. Pleocytosis and mild meningeal signs often occur at the onset of HIV infection, and occasionally, low-grade meningitis persists. In worldwide populations, *M. tuberculosis* is the most common cause of chronic meningitis, followed by *C. neoformans*. Toxoplasmosis commonly presents as intracranial abscesses and also may be associated with meningitis. Other important causes of chronic meningitis in AIDS include infection with *Nocardia*, *Candida*, or other fungi; syphilis; and lymphoma (Fig. 144-2). With HIV infection, primary CNS lymphomas may arise, which are typically positive for EBV infection. Toxoplasmosis, nocardiosis, cryptococcosis and other fungal infections are important etiologic considerations in individuals with immunodeficiency states other than AIDS, including those due to immunosuppressive medications. Because of the increased risk of chronic meningitis and the attenuation of clinical signs of meningeal irritation in immunosuppressed individuals, CSF examination should be performed for any persistent headache or unexplained change in mental state.

145 Brain Abscess and Empyema

Karen L. Roos, Kenneth L. Tyler

BRAIN ABSCESS

DEFINITION

A brain abscess is a focal, suppurative infection within the brain parenchyma, typically surrounded by a vascularized capsule. The term *cerebritis* is often employed to describe a nonencapsulated brain abscess.

EPIDEMIOLOGY

A bacterial brain abscess is a relatively uncommon intracranial infection, with an incidence of ~0.3–1.3:100,000 persons per year. Predisposing conditions include otitis media and mastoiditis, paranasal sinusitis, pyogenic infections in the chest or other body sites, penetrating head trauma or neurosurgical procedures, and dental infections. In immunocompetent individuals, the most important pathogens are *Streptococcus* spp. (anaerobic, aerobic, and viridans [40%]), Enterobacteriaceae (*Proteus* spp., *Escherichia coli* sp., *Klebsiella* spp. [25%]), anaerobes (e.g., *Bacteroides* spp., *Fusobacterium* spp. [30%]), and staphylococci (10%). In immunocompromised hosts with underlying HIV infection, organ transplantation, cancer, or immunosuppressive therapy, most brain abscesses are caused by *Nocardia* spp., *Toxoplasma*

gondii, Aspergillus spp., *Candida* spp., and *Cryptococcus neoformans*. In Latin America and in immigrants from Latin America, the most common cause of brain abscess is *Taenia solium* (neurocysticercosis). In India and East Asia, mycobacterial infection (tuberculoma) remains a major cause of focal CNS mass lesions.

ETIOLOGY

A brain abscess may develop (1) by direct spread from a contiguous cranial site of infection, such as paranasal sinusitis, otitis media, mastoiditis, or dental infection; (2) following head trauma or a neurosurgical procedure; or (3) as a result of hematogenous spread from a remote site of infection. In up to 25% of cases, no obvious primary source of infection is apparent (cryptogenic brain abscess).

Approximately one-third of brain abscesses are associated with otitis media and mastoiditis, often with an associated cholesteatoma. Otogenic abscesses occur predominantly in the temporal lobe (55–75%) and cerebellum (20–30%). In some series, up to 90% of cerebellar abscesses are otogenic. Common organisms include streptococci, *Bacteroides* spp., *Pseudomonas* spp., *Haemophilus* spp., and Enterobacteriaceae. Abscesses that develop as a result of direct spread of infection from the frontal, ethmoidal, or sphenoidal sinuses and those that occur due to dental infections are usually located in the frontal lobes. Approximately 10% of brain abscesses are associated with paranasal sinusitis, and this association is particularly strong in young males in their second and third decades of life. The most common pathogens in brain abscesses associated with paranasal sinusitis are streptococci (especially *Streptococcus milleri*), *Haemophilus* spp., *Bacteroides* spp., *Pseudomonas* spp., and *Staphylococcus aureus*. Dental infections are associated with ~2% of brain abscesses, although it is often suggested that many "cryptogenic" abscesses are in fact due to dental infections. The most common pathogens in this setting are streptococci, staphylococci, *Bacteroides* spp., and *Fusobacterium* spp.

Hematogenous abscesses account for ~25% of brain abscesses. Hematogenous abscesses are often multiple, and multiple abscesses often (50%) have a hematogenous origin. These abscesses show a predilection for the territory of the middle cerebral artery (i.e., posterior frontal or parietal lobes). Hematogenous abscesses are often located at the junction of the gray and white matter and are often poorly encapsulated. The microbiology of hematogenous abscesses is dependent on the primary source of infection. For example, brain abscesses that develop as a complication of infective endocarditis are often due to viridans streptococci or *S. aureus*. Abscesses associated with pyogenic lung infections such as lung abscess or bronchiectasis are often due to streptococci, staphylococci, *Bacteroides* spp., *Fusobacterium* spp., or Enterobacteriaceae. Enterobacteriaceae and *Pseudomonas aeruginosa* are important causes of abscesses associated with urinary sepsis. Congenital cardiac malformations that produce a right-to-left shunt allow bloodborne bacteria to bypass the pulmonary capillary bed and reach the brain. Similar phenomena can occur with pulmonary arteriovenous malformations. The decreased arterial oxygenation and saturation from the right-to-left shunt and polycythemia may cause focal areas of cerebral ischemia, thus providing a nidus for microorganisms that bypassed the pulmonary circulation to multiply and form an abscess. Streptococci are the most common pathogens in this setting.

Abscesses that follow penetrating head trauma or neurosurgical procedures are frequently due to methicillin-resistant *S. aureus* (MRSA), *Staphylococcus epidermidis*, Enterobacteriaceae, *Pseudomonas* spp., and *Clostridium* spp.

PATHOGENESIS AND HISTOPATHOLOGY

Results of experimental models of brain abscess formation suggest that for bacterial invasion of brain parenchyma to occur, there must be preexisting or concomitant areas of ischemia, necrosis, or hypoxemia in brain tissue. The intact brain parenchyma is relatively resistant to infection. Once bacteria have established infection, brain abscess frequently evolves through a series of stages, influenced by the nature of the infecting organism and by the immunocompetence of the host. The early cerebritis stage (days 1–3) is characterized by a perivascular infiltration of inflammatory cells, which surround a central core of coagulative necrosis. Marked edema surrounds the lesion at this stage. In the late cerebritis stage (days 4–9), pus formation leads to enlargement of the necrotic center, which is surrounded at its border by an inflammatory infiltrate of macrophages and fibroblasts. A thin capsule of fibroblasts and reticular fibers gradually develops, and the surrounding area of cerebral edema becomes more distinct than in the previous stage. The third stage, early capsule formation (days 10–13), is characterized by the formation of a capsule that is better developed on the cortical than on the ventricular side of the lesion. This stage correlates with the appearance of a ring-enhancing capsule on neuroimaging studies. The final stage, late capsule formation (day 14 and beyond), is defined by a well-formed necrotic center surrounded by a dense collagenous capsule. The surrounding area of cerebral edema has regressed, but marked gliosis with large numbers of reactive astrocytes has developed outside the capsule. This gliotic process may contribute to the development of seizures as a sequela of brain abscess.

CLINICAL PRESENTATION

A brain abscess typically presents as an expanding intracranial mass lesion rather than as an infectious process. Although the evolution of signs and symptoms is extremely variable, ranging from hours to weeks or even months, most patients present to the hospital 11–12 days following onset of symptoms. The classic clinical triad of headache, fever, and a focal neurologic deficit is present in <50% of cases. The most common symptom in patients with a brain abscess is headache, occurring in >75% of patients. The headache is often characterized as a constant, dull, aching sensation, either hemicranial or generalized, and it becomes progressively more severe and refractory to therapy. Fever is present in only 50% of patients at the time of diagnosis, and its absence should not exclude the diagnosis. The new onset of focal or generalized seizure activity is a presenting sign in 15–35% of patients. Focal neurologic deficits including hemiparesis, aphasia, or visual field defects are part of the initial presentation in >60% of patients.

The clinical presentation of a brain abscess depends on its location, the nature of the primary infection if present, and the level of the intracranial pressure (ICP). Hemiparesis is the most common localizing sign of a frontal lobe abscess. A temporal lobe abscess may present with a disturbance of language (dysphasia) or an upper homonymous quadrantanopia. Nystagmus and ataxia are signs of a cerebellar abscess. Signs of raised ICP—papilledema, nausea and vomiting, and drowsiness or confusion—can be the dominant presentation of some abscesses, particularly those in the cerebellum. Meningismus is not present unless the abscess has ruptured into the ventricle or the infection has spread to the subarachnoid space.

DIAGNOSIS

Diagnosis is made by neuroimaging studies. Magnetic resonance imaging (MRI) **(Fig. 145-1)** is better than computed tomography (CT) for demonstrating abscesses in the early (cerebritis) stages and is superior to CT for identifying abscesses in the posterior fossa. Cerebritis appears on MRI as an area of low signal intensity on T1-weighted images with irregular postgadolinium enhancement and as an area of increased signal intensity on T2-weighted images. Cerebritis is often not visualized by CT scan, but when present, appears as an area of hypodensity. On a contrast-enhanced CT scan, a mature brain abscess appears as a focal area of hypodensity surrounded by ring enhancement with surrounding edema (hypodensity). On contrast-enhanced T1-weighted MRI, a mature brain abscess has a capsule that enhances surrounding a hypodense center and surrounded by a hypodense area of edema. On T2-weighted MRI, there is a hyperintense central area of pus surrounded by a well-defined hypointense capsule and a hyperintense surrounding area of edema. It is important to recognize that the CT and MRI appearance, particularly of the capsule, may be altered by treatment with glucocorticoids. The distinction between a brain abscess and other focal CNS lesions such as primary or metastatic tumors may be facilitated by the use of diffusion-weighted imaging sequences on which a brain abscess typically shows increased signal due to restricted diffusion of the abscess cavity with corresponding low signal on apparent diffusion coefficient images.

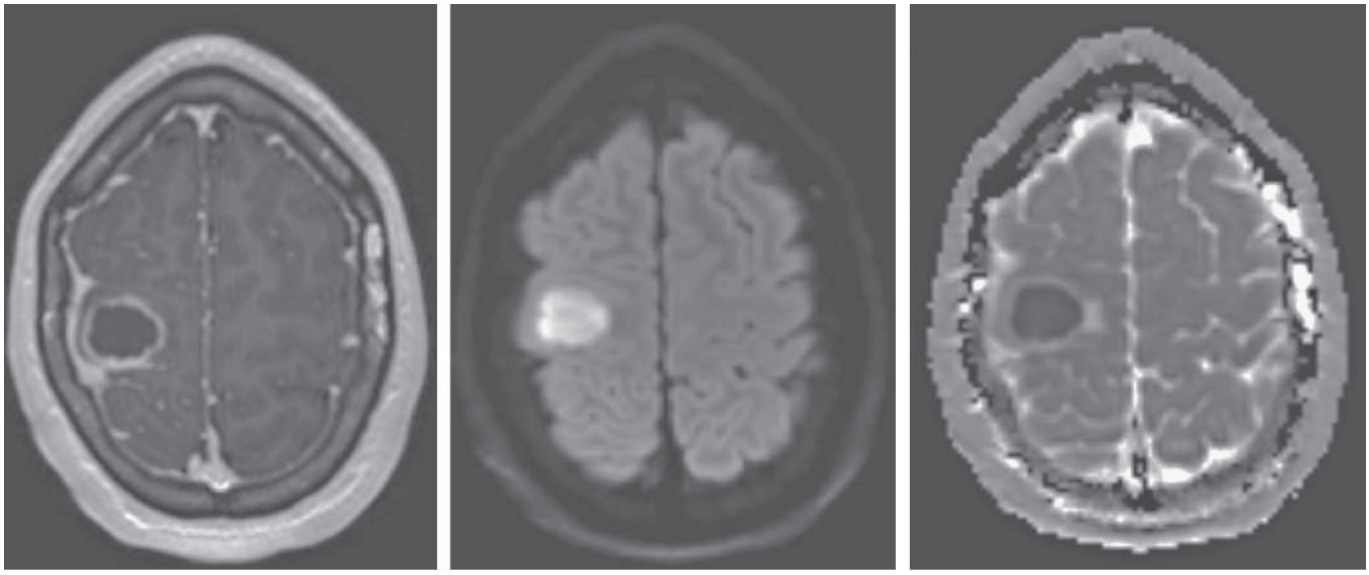

FIGURE 145-1 Pyogenic brain abscess. Note that the abscess wall enhances prominently after gadolinium administration on the magnetic resonance axial T1-weighted image (***A***). The abscess is hyperintense on the diffusion-weighted image (***B***) and dark on the apparent diffusion coefficient (ADC) image (***C***). *(Courtesy of Aaron Kamer, MD; with permission.)*

Microbiologic diagnosis of the etiologic agent is most accurately determined by Gram's stain and culture of abscess material obtained by CT-guided stereotactic needle aspiration. Aerobic and anaerobic bacterial cultures and mycobacterial and fungal cultures should be obtained. Blood cultures are positive in ~10% of cases overall but may be positive in >85% of patients with abscesses due to *Listeria*. About 50% of patients have a peripheral leukocytosis, 60% an elevated erythrocyte sedimentation rate, and 80% an elevated C-reactive protein. Lumbar puncture (LP) should not be performed in patients with known or suspected focal intracranial infections such as abscess or empyema; cerebrospinal fluid (CSF) analysis contributes nothing to diagnosis or therapy, and LP increases the risk of herniation.

DIFFERENTIAL DIAGNOSIS

Conditions that can cause headache, fever, focal neurologic signs, and seizure activity include brain abscess, subdural empyema, bacterial meningitis **(Chap. 143)**, viral meningoencephalitis **(Chap. 142)**, superior sagittal sinus thrombosis **(Chap. 438)**, and acute disseminated encephalomyelitis **(Chap. 456)**. When fever is absent, primary and metastatic brain tumors become the major differential diagnosis. Less commonly, cerebral infarction or hematoma can have an MRI or CT appearance resembling brain abscess.

TREATMENT

Brain Abscess

Optimal therapy of brain abscesses involves a combination of high-dose parenteral antibiotics and neurosurgical drainage. Empirical therapy of community-acquired brain abscess in an immunocompetent patient typically includes a third- or fourth-generation cephalosporin (e.g., cefotaxime, ceftriaxone, or cefepime) and metronidazole **(see Table 143-1 for antibiotic dosages)**. In patients with penetrating head trauma or recent neurosurgical procedures, treatment should include ceftazidime as the third-generation cephalosporin to enhance coverage of *Pseudomonas* spp. and vancomycin for coverage of staphylococci. Meropenem plus vancomycin also provides good coverage in this setting.

Aspiration and drainage of the abscess under stereotactic guidance are beneficial for both diagnosis and therapy. Empirical antibiotic coverage should be modified based on the results of Gram's stain and culture of the abscess contents. Complete excision of a bacterial abscess via craniotomy or craniectomy is generally reserved for multiloculated abscesses or those in which stereotactic aspiration is unsuccessful.

Medical therapy alone is not optimal for treatment of brain abscess and should be reserved for patients whose abscesses are neurosurgically inaccessible, for patients with small (<2–3 cm) or nonencapsulated abscesses (cerebritis), and for patients whose condition is too tenuous to allow performance of a neurosurgical procedure. All patients should receive a minimum of 6–8 weeks of parenteral antibiotic therapy. The role, if any, of supplemental oral antibiotic therapy following completion of a standard course of parenteral therapy has never been adequately studied.

In addition to surgical drainage and antibiotic therapy, patients should receive prophylactic anticonvulsant therapy because of the high risk (~35%) of focal or generalized seizures. Anticonvulsant therapy is continued for at least 3 months after resolution of the abscess, and decisions regarding withdrawal are then based on the electroencephalogram (EEG). If the EEG is abnormal, anticonvulsant therapy should be continued. If the EEG is normal, anticonvulsant therapy can be slowly withdrawn, with close follow-up and repeat EEG after the medication has been discontinued.

Glucocorticoids should not be given routinely to patients with brain abscesses. Intravenous dexamethasone therapy (10 mg every 6 h) is usually reserved for patients with substantial periabscess edema and associated mass effect and increased ICP. Dexamethasone should be tapered as rapidly as possible to avoid delaying the natural process of encapsulation of the abscess.

Serial MRI or CT scans should be obtained on a monthly or twice-monthly basis to document resolution of the abscess. More frequent studies (e.g., weekly) are probably warranted in the subset of patients who are receiving antibiotic therapy alone. A small amount of enhancement may remain for months after the abscess has been successfully treated.

PROGNOSIS

The mortality rate of brain abscess has declined in parallel with the development of enhanced neuroimaging techniques, improved neurosurgical procedures for stereotactic aspiration, and improved antibiotics. In modern series, the mortality rate is typically <15%. Significant sequelae, including seizures, persisting weakness, aphasia, or mental impairment, occur in ≥20% of survivors.

NONBACTERIAL CAUSES OF INFECTIOUS FOCAL CNS LESIONS

ETIOLOGY

Neurocysticercosis is the most common parasitic disease of the CNS worldwide. Humans acquire cysticercosis by the ingestion of food contaminated with the eggs of the parasite *Taenia solium* **(Chap. 242)**. Toxoplasmosis **(Chap. 235)** is a parasitic disease caused by *T. gondii* and acquired from the ingestion of undercooked meat and from handling cat feces.

CLINICAL PRESENTATION

The most common manifestation of neurocysticercosis is new-onset partial seizures with or without secondary generalization. Cysticerci may develop in the brain parenchyma and cause seizures or focal neurologic deficits. When present in the subarachnoid or ventricular spaces, cysticerci can produce increased ICP by interference with CSF flow. Spinal cysticerci can mimic the presentation of intraspinal tumors. When the cysticerci first lodge in the brain, they frequently cause little in the way of an inflammatory response. As the cysticercal cyst degenerates, it elicits an inflammatory response that may present clinically as a seizure. Eventually the cyst dies, a process that may take several years and is typically associated with resolution of the inflammatory response and, often, abatement of seizures.

Primary *Toxoplasma* infection is often asymptomatic. However, during this phase, parasites may spread to the CNS, where they become latent. Reactivation of CNS infection is almost exclusively associated with immunocompromised hosts, particularly those with HIV infection. During this phase, patients present with headache, fever, seizures, and focal neurologic deficits.

DIAGNOSIS

The lesions of neurocysticercosis are readily visualized by MRI or CT scans depending on the stage of the lesion. There are four stages of neurocysticercosis: (1) the vesicular stage, (2) the colloidal stage, (3) the granulonodular stage, and (4) the nodular-calcified stage. Lesions with viable parasites appear as cystic lesions, and the scolex can often be visualized on MRI. Cystic lesions with small nodules (scolex) within the cyst are in the vesicular stage of neurocysticercosis **(Fig. 145-2*A* and *B*)**. There is no significant edema surrounding a lesion in the vesicular stage. Lesions in the colloidal stage demonstrate peripheral enhancement on postcontrast imaging **(Fig. 145-2*C*)** with substantial surrounding edema on T2 images **(Fig. 145-2*D*)**. In the granulonodular stage, on postcontrast imaging, the lesion enhances in a homogenous fashion **(Fig. 145-2*E*)**. On fluid-attenuated inversion recovery (FLAIR) images, there is no surrounding edema **(Fig. 145-2*F*)**. Parenchymal brain calcifications are the most common finding and evidence that the parasite is no longer viable. These chronic lesions are best seen on CT **(Fig. 145-2*G*)** and can be difficult to detect on MRI. The most sensitive technique for the detection of these small calcific foci on MRI is susceptibility-weighted imaging (SWI). If a confirmatory test for neurocysticercosis is needed, the enzyme-linked immunotransfer blot is recommended. A funduscopic exam is also recommended for all patients with suspected neurocysticercosis.

MRI findings of toxoplasmosis consist of multiple lesions in the deep white matter, the thalamus, and basal ganglia and at the gray-white junction in the cerebral hemispheres. With contrast administration, the majority of the lesions enhance in a ringed, nodular, or homogeneous pattern and are surrounded by edema. In the presence of the characteristic neuroimaging abnormalities of *T. gondii* infection, serum IgG antibody to *T. gondii* should be obtained and, when positive, the patient should be treated.

TREATMENT

Infectious Focal CNS Lesions

Anticonvulsant therapy is initiated when the patient with neurocysticercosis presents with a seizure. Anthelmintic therapy is given to patients based on the stage of the lesion(s). Cysticerci appearing as cystic lesions in the brain parenchyma with or without pericystic edema or in the subarachnoid space at the convexity of the cerebral hemispheres should be treated with anticysticidal therapy. Cysticidal drugs accelerate the destruction of the parasites, resulting in a faster resolution of the infection. Albendazole monotherapy is recommended for patients with one to two parenchymal cysts. The dose of albendazole is 15 mg/kg per day in two daily doses for 10–14 days. A combination of albendazole plus praziquantel is recommended for patients with more than two viable cysts. Viable cysts are defined as those in the vesicular or colloidal stages (see above). The recommended dose of praziquantel is 50 mg/kg per day for 10–14 days. Prednisone or dexamethasone is begun prior to anticysticidal therapy to reduce the host inflammatory response to degenerating parasites. Only cysts in the vesicular stage, where the cyst contains living larva (scolex seen on CT or MRI), and cysts in the colloidal stage, as the larva degenerates (edema surrounds the lesion), are treated with anticysticidal therapy. Some, but not all, experts recommend anticysticidal therapy for lesions that are in the granulonodular stage (surrounded by a contrast-enhancing ring). There is universal agreement that calcified lesions do not need to be treated with anticysticidal therapy. Antiepileptic therapy can be stopped once a follow-up CT or MRI scan shows resolution of the lesion and the patient has had no seizures for 24 consecutive months. Long-term antiepileptic therapy is recommended when seizures occur after resolution of edema and resorption or calcification of the degenerating cyst.

CNS toxoplasmosis is treated with a combination of sulfadiazine, 1.5–2.0 g orally qid, plus pyrimethamine, 100 mg orally to load, then 75–100 mg orally qd, plus folinic acid, 10–15 mg orally qd. Folinic acid is added to the regimen to prevent megaloblastic anemia. Therapy is continued until there is no evidence of active disease on neuroimaging studies, which typically takes at least 6 weeks, and then the dose of sulfadiazine is reduced to 2–4 g/d and pyrimethamine to 50 mg/d. Clindamycin plus pyrimethamine is an alternative therapy for patients who cannot tolerate sulfadiazine, but the combination of pyrimethamine and sulfadiazine is more effective.

SUBDURAL EMPYEMA

A subdural empyema (SDE) is a collection of pus between the dura and arachnoid membranes **(Fig. 145-3)**.

EPIDEMIOLOGY

SDE is a rare disorder that accounts for 15–25% of focal suppurative CNS infections. Sinusitis is the most common predisposing condition and typically involves the frontal sinuses, either alone or in combination with the ethmoid and maxillary sinuses. Sinusitis-associated empyema has a striking predilection for young males, possibly reflecting sex-related differences in sinus anatomy and development. It has been suggested that SDE may complicate 1–2% of cases of frontal sinusitis severe enough to require hospitalization. As a consequence of this epidemiology, SDE shows an ~3:1 male/female predominance, with 70% of cases occurring in the second and third decades of life. SDE may also develop as a complication of head trauma or neurosurgery. Secondary infection of a subdural effusion may also result in empyema, although secondary infection of hematomas, in the absence of a prior neurosurgical procedure, is rare.

ETIOLOGY

Aerobic and anaerobic streptococci, staphylococci, Enterobacteriaceae, and anaerobic bacteria are the most common causative organisms of sinusitis-associated SDE. Staphylococci and gram-negative bacilli are often the etiologic organisms when SDE follows neurosurgical procedures or head trauma. Up to one-third of cases are culture-negative, possibly reflecting difficulty in obtaining adequate anaerobic cultures.

PATHOPHYSIOLOGY

Sinusitis-associated SDE develops as a result of either retrograde spread of infection from septic thrombophlebitis of the mucosal veins

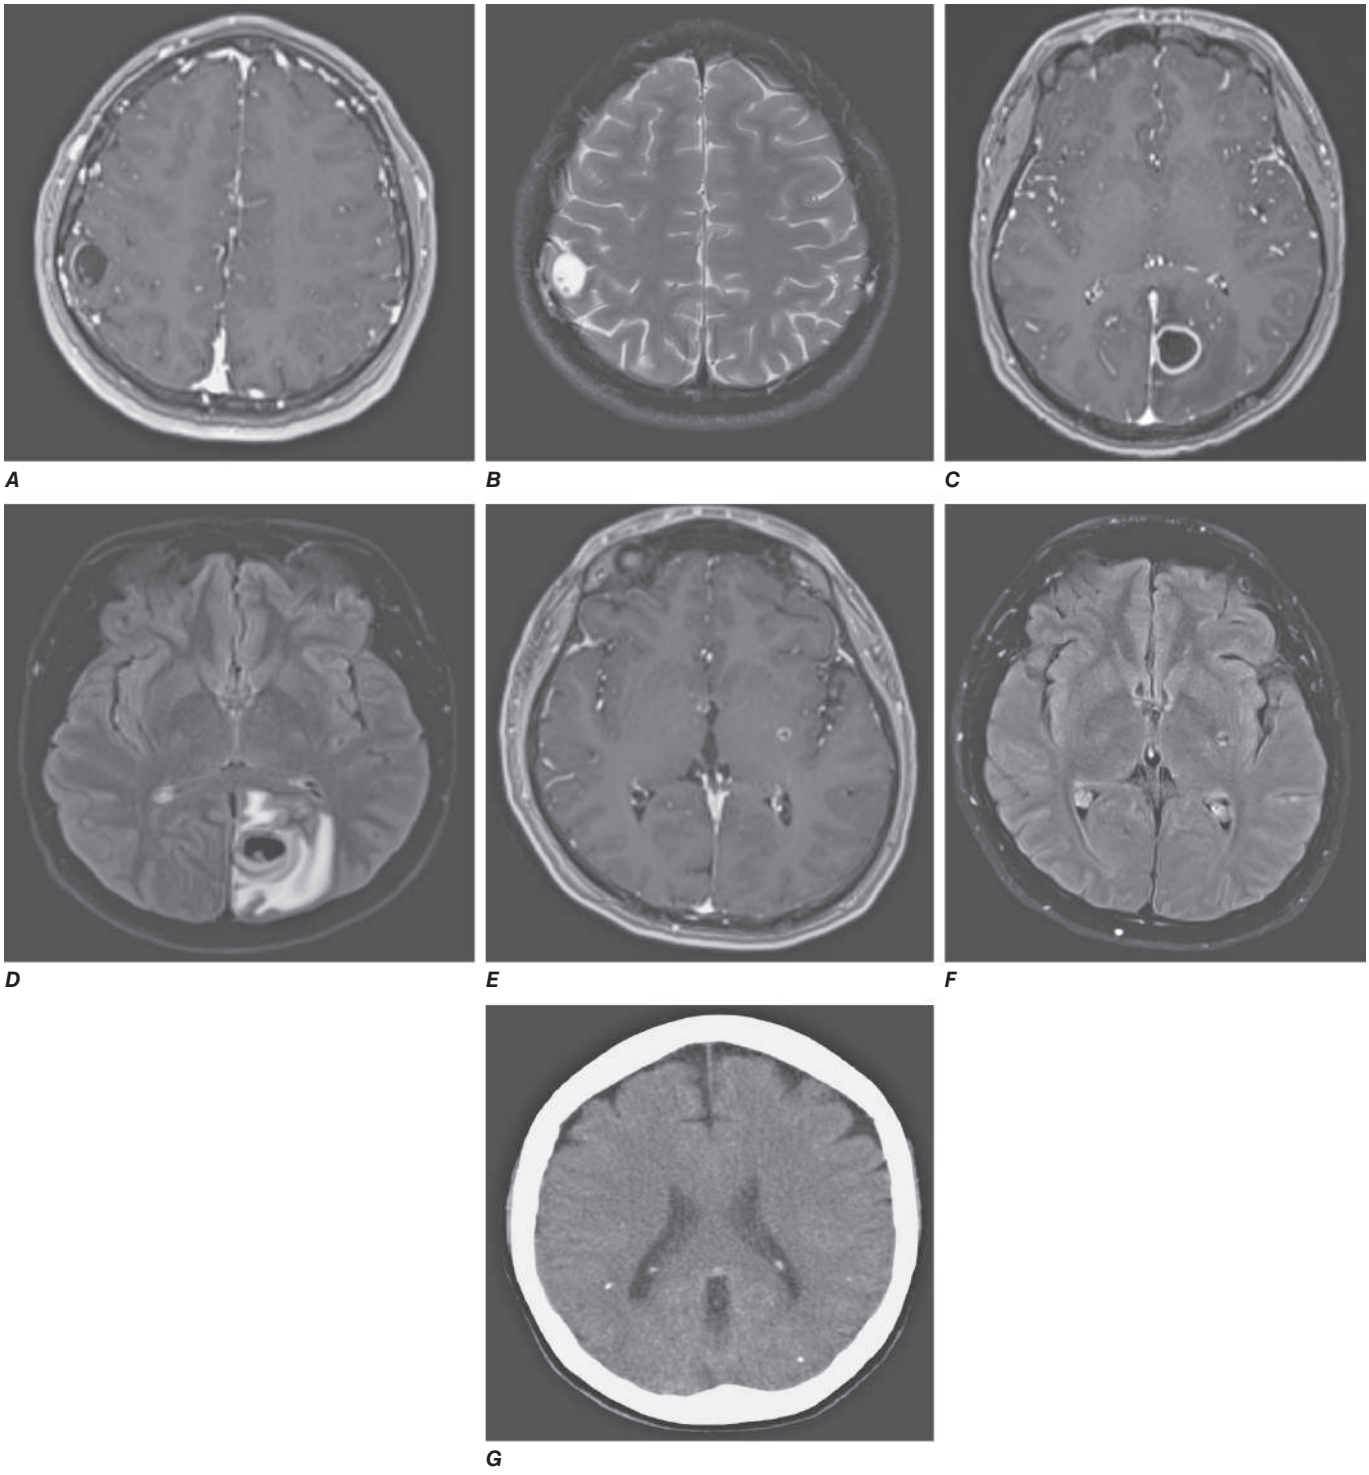

FIGURE 145-2 The four stages of neurocysticercosis. ***A, B.*** The vesicular stage. ***A.*** Postcontrast T1 magnetic resonance image (MRI). Note lesion in right parietal area. Small hypointense nodules within the cyst likely represent scolex. ***B.*** T2 MRI. The cyst is now visualized as a uniform hyperintense lesion with the small hypointense nodules likely representing scolex. No significant edema is present around the lesion on T2, typical for this stage of the disease. ***C, D.*** The colloidal stage. ***C.*** A medial left occipital lesion demonstrates peripheral enhancement on postcontrast imaging. ***D.*** On fluid-attenuated inversion recovery (FLAIR) MRI, the lesion has substantial surrounding hyperintense edema. ***E, F.*** The granulonodular stage. ***E.*** Postcontrast T1-weighted imaging demonstrates enhancing lesions in the left putamen and in the genu of the internal capsule near the foramen of Monro. ***F.*** These lesions demonstrate no surrounding edema on FLAIR imaging, typical for this stage of the disease. ***G.*** The nodular-calcified stage. Computed tomography scan demonstrates typical parenchymal brain calcifications. *(Courtesy of Aaron Kamer, MD; with permission.)*

draining the sinuses or contiguous spread of infection to the brain from osteomyelitis in the posterior wall of the frontal or other sinuses. SDE may also develop from direct introduction of bacteria into the subdural space as a complication of a neurosurgical procedure. The evolution of SDE can be extremely rapid because the subdural space is a large compartment that offers few mechanical barriers to the spread of infection. In patients with sinusitis-associated SDE, suppuration typically begins in the upper and anterior portions of one cerebral hemisphere and then extends posteriorly. SDE is often associated with other intracranial infections, including epidural empyema (40%), cortical thrombophlebitis (35%), and intracranial abscess or cerebritis (>25%). Cortical venous infarction produces necrosis of underlying cerebral cortex and subcortical white matter, with focal neurologic deficits and seizures (see below).

CLINICAL PRESENTATION

A patient with SDE typically presents with fever and a progressively worsening headache. The diagnosis of SDE should always be suspected

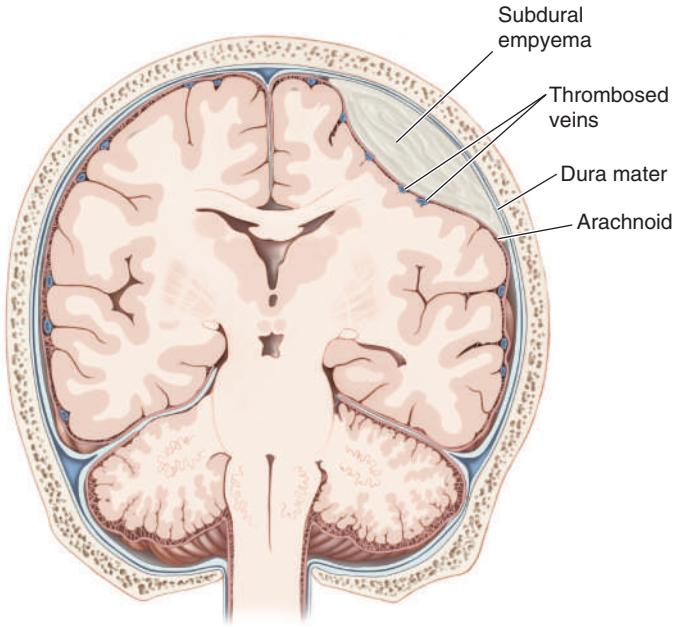

FIGURE 145-3 Subdural empyema.

in a patient with known sinusitis who presents with new CNS signs or symptoms. Patients with underlying sinusitis frequently have symptoms related to this infection. As the infection progresses, focal neurologic deficits, seizures, nuchal rigidity, and signs of increased ICP commonly occur. Headache is the most common complaint at the time of presentation; initially it is localized to the side of the subdural infection, but then it becomes more severe and generalized. Contralateral hemiparesis or hemiplegia is the most common focal neurologic deficit and can occur from the direct effects of the SDE on the cortex or as a consequence of venous infarction. Seizures begin as partial motor seizures that then become secondarily generalized. Seizures may be due to the direct irritative effect of the SDE on the underlying cortex or result from cortical venous infarction. In untreated SDE, the increasing mass effect and increase in ICP cause progressive deterioration in consciousness, leading ultimately to coma.

DIAGNOSIS

MRI **(Fig. 145-4)** is superior to CT in identifying SDE and any associated intracranial infections. The administration of gadolinium greatly improves diagnosis by enhancing the rim of the empyema and allowing the empyema to be clearly delineated from the underlying brain parenchyma. Cranial MRI is also extremely valuable in identifying sinusitis, other focal CNS infections, cortical venous infarction, cerebral edema, and cerebritis. CT may show a crescent-shaped hypodense lesion over one or both hemispheres or in the interhemispheric fissure. Frequently the degree of mass effect, exemplified by midline shift, ventricular compression, and sulcal effacement, is far out of proportion to the mass of the SDE.

CSF examination should be avoided in patients with known or suspected SDE because it adds no useful information and is associated with the risk of cerebral herniation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the combination of headache, fever, focal neurologic signs, and seizure activity that progresses rapidly to an altered level of consciousness includes subdural hematoma, bacterial meningitis, viral encephalitis, brain abscess, superior sagittal sinus thrombosis, and acute disseminated encephalomyelitis. The presence of nuchal rigidity is unusual with brain abscess or epidural empyema and should suggest the possibility of SDE when associated with significant focal neurologic signs and fever. Patients with bacterial meningitis also have nuchal rigidity but do not typically have focal deficits of the severity seen with SDE.

TREATMENT

Subdural Empyema

SDE is a medical emergency. Emergent neurosurgical evacuation of the empyema, either through craniotomy, craniectomy, or burr-hole drainage, is the definitive step in the management of this infection. Empirical antimicrobial therapy for community-acquired SDE should include a combination of a third-generation cephalosporin (e.g., cefotaxime or ceftriaxone), vancomycin, and metronidazole **(see Table 143-1 for dosages)**. Patients with hospital-acquired SDE may have infections due to *Pseudomonas* spp. or MRSA and should receive coverage with a carbapenem (e.g., meropenem) and vancomycin. Metronidazole is not necessary for antianaerobic therapy when meropenem is being used. Parenteral antibiotic therapy should be continued for a minimum of 3–4 weeks after SDE drainage. Patients with associated cranial osteomyelitis may require longer therapy. Specific diagnosis of the etiologic organisms is made based on Gram's stain and culture of fluid obtained via either burr holes or craniotomy; the initial empirical antibiotic coverage can be modified accordingly.

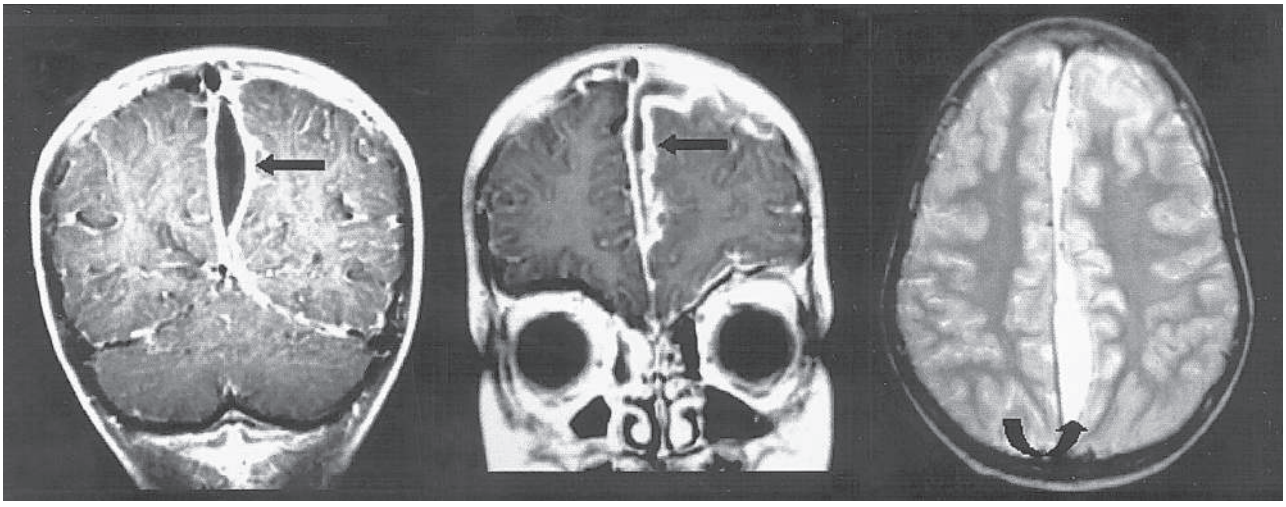

FIGURE 145-4 Subdural empyema. The purulent fluid collection along the left falx and left frontal convexity is hypointense on T1-weighted images (***A***) but markedly hyperintense on the diffusion-weighted (***B***) and the T2 fat-saturation (***C***) magnetic resonance images.

PROGNOSIS

Prognosis is influenced by the level of consciousness of the patient at the time of hospital presentation, the size of the empyema, and the speed with which therapy is instituted. Long-term neurologic sequelae, which include seizures and hemiparesis, occur in up to 50% of cases.

CRANIAL EPIDURAL ABSCESS

Cranial epidural abscess is a suppurative infection occurring in the potential space between the inner skull table and dura **(Fig. 145-5)**.

ETIOLOGY AND PATHOPHYSIOLOGY

Cranial epidural abscess is less common than either brain abscess or SDE and accounts for <2% of focal suppurative CNS infections. A cranial epidural abscess develops as a complication of a craniotomy or compound skull fracture or as a result of spread of infection from the frontal sinuses, middle ear, mastoid, or orbit. An epidural abscess may develop contiguous to an area of osteomyelitis, when craniotomy is complicated by infection of the wound or bone flap, or as a result of direct infection of the epidural space. Infection in the frontal sinus, middle ear, mastoid, or orbit can reach the epidural space through retrograde spread of infection from septic thrombophlebitis in the emissary veins that drain these areas or by way of direct spread of infection through areas of osteomyelitis. Unlike the subdural space, the epidural space is really a potential rather than an actual compartment. The dura is normally tightly adherent to the inner skull table, and infection must dissect the dura away from the skull table as it spreads. As a result, epidural abscesses are often smaller than SDEs. Cranial epidural abscesses, unlike brain abscesses, only rarely result from hematogenous spread of infection from extracranial primary sites. The bacteriology of a cranial epidural abscess is similar to that of SDE (see above). The etiologic organisms of an epidural abscess that arises from frontal sinusitis, middle-ear infections, or mastoiditis are usually streptococci or anaerobic organisms. Staphylococci or gram-negative organisms are the usual cause of an epidural abscess that develops as a complication of craniotomy or compound skull fracture.

CLINICAL PRESENTATION

Patients present with fever (60%), headache (40%), nuchal rigidity (35%), seizures (10%), and focal deficits (5%). Development of symptoms may be insidious, as the empyema usually enlarges slowly in the confined anatomic space between the dura and the inner table of the skull. Periorbital edema and Pott's puffy tumor, reflecting underlying associated frontal bone osteomyelitis, are present in ~40%. In patients with a recent neurosurgical procedure, wound infection is invariably present, but other symptoms may be subtle and can include altered mental status (45%), fever (35%), and headache (20%). The diagnosis should be considered when fever and headache follow recent head trauma or occur in the setting of frontal sinusitis, mastoiditis, or otitis media.

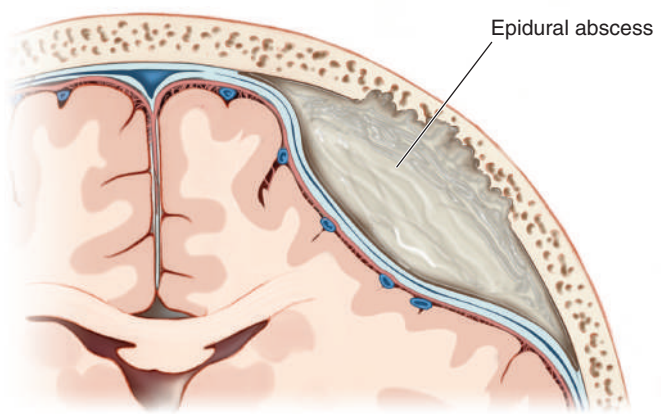

FIGURE 145-5 Cranial epidural abscess is a collection of pus between the dura and the inner table of the skull.

DIAGNOSIS

Cranial MRI with gadolinium enhancement is the procedure of choice to demonstrate a cranial epidural abscess. The sensitivity of CT is limited by the presence of signal artifacts arising from the bone of the inner skull table. The CT appearance of an epidural empyema is that of a lens or crescent-shaped hypodense extraaxial lesion. On MRI, an epidural empyema appears as a lentiform or crescent-shaped fluid collection that is hyperintense compared to CSF on T2-weighted images. On T1-weighted images, the fluid collection may be either isointense or hypointense compared to brain. Following the administration of gadolinium, there is linear enhancement of the dura on T1-weighted images. In distinction to subdural empyema, signs of mass effect or other parenchymal abnormalities are uncommon.

TREATMENT

Epidural Abscess

Immediate neurosurgical drainage is indicated. Empirical antimicrobial therapy, pending the results of Gram's stain and culture of the purulent material obtained at surgery, should include a combination of a third-generation cephalosporin, vancomycin, and metronidazole **(see Table 143-1)**. Ceftazidime or meropenem should be substituted for ceftriaxone or cefotaxime in neurosurgical patients. Metronidazole is not necessary for antianaerobic coverage in patients receiving meropenem. When the organism has been identified, antimicrobial therapy can be modified accordingly. Antibiotics should be continued for 3–6 weeks after surgical drainage. Patients with associated osteomyelitis may require additional therapy.

PROGNOSIS

The mortality rate is <5% in modern series, and full recovery is the rule in most survivors.

SUPPURATIVE THROMBOPHLEBITIS

DEFINITION

Suppurative intracranial thrombophlebitis is septic venous thrombosis of cortical veins and sinuses. This may occur as a complication of bacterial meningitis; SDE; epidural abscess; or infection in the skin of the face, paranasal sinuses, middle ear, or mastoid.

ANATOMY AND PATHOPHYSIOLOGY

The cerebral veins and venous sinuses have no valves; therefore, blood within them can flow in either direction. The superior sagittal sinus is the largest of the venous sinuses **(Fig. 145-6)**. It receives blood from the

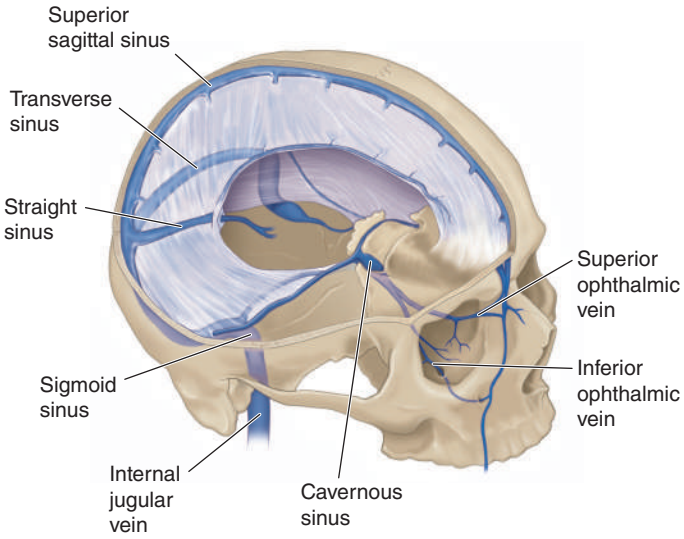

FIGURE 145-6 Anatomy of the cerebral venous sinuses.

frontal, parietal, and occipital superior cerebral veins and the diploic veins, which communicate with the meningeal veins. Bacterial meningitis is a common predisposing condition for septic thrombosis of the superior sagittal sinus. The diploic veins, which drain into the superior sagittal sinus, provide a route for the spread of infection from the meninges, especially in cases where there is purulent exudate near areas of the superior sagittal sinus. Infection can also spread to the superior sagittal sinus from nearby SDE or epidural abscess. Dehydration from vomiting, hypercoagulable states, and immunologic abnormalities, including the presence of circulating antiphospholipid antibodies, also contribute to cerebral venous sinus thrombosis. Thrombosis may extend from one sinus to another, and at autopsy, thrombi of different histologic ages can often be detected in several sinuses. Thrombosis of the superior sagittal sinus is often associated with thrombosis of superior cortical veins and small parenchymal hemorrhages.

The superior sagittal sinus drains into the transverse sinuses (Fig. 145-6). The transverse sinuses also receive venous drainage from small veins from both the middle ear and mastoid cells. The transverse sinus becomes the sigmoid sinus before draining into the internal jugular vein. Septic transverse/sigmoid sinus thrombosis can be a complication of acute and chronic otitis media or mastoiditis. Infection spreads from the mastoid air cells to the transverse sinus via the emissary veins or by direct invasion. The cavernous sinuses are inferior to the superior sagittal sinus at the base of the skull. The cavernous sinuses receive blood from the facial veins via the superior and inferior ophthalmic veins. Bacteria in the facial veins enter the cavernous sinus via these veins. Bacteria in the sphenoid and ethmoid sinuses can spread to the cavernous sinuses via the small emissary veins. The sphenoid and ethmoid sinuses are the most common sites of primary infection resulting in septic cavernous sinus thrombosis.

CLINICAL MANIFESTATIONS

Septic thrombosis of the superior sagittal sinus presents with headache, fever, nausea and vomiting, confusion, and focal or generalized seizures. There may be a rapid development of stupor and coma. Weakness of the lower extremities with bilateral Babinski's signs or hemiparesis is often present. When superior sagittal sinus thrombosis occurs as a complication of bacterial meningitis, nuchal rigidity and Kernig's and Brudzinski's signs may be present.

The oculomotor nerve, the trochlear nerve, the abducens nerve, the ophthalmic and maxillary branches of the trigeminal nerve, and the internal carotid artery all pass through the cavernous sinus (see Fig. 452-7). The symptoms of *septic cavernous sinus thrombosis* are fever, headache, frontal and retroorbital pain, and diplopia. The classic signs are ptosis, proptosis, chemosis, and extraocular dysmotility due to deficits of cranial nerves III, IV, and VI; hyperesthesia of the ophthalmic and maxillary divisions of the fifth cranial nerve and a decreased corneal reflex may be detected. There may be evidence of dilated, tortuous retinal veins and papilledema.

Headache and earache are the most frequent symptoms of *transverse sinus thrombosis*. A transverse sinus thrombosis may also present with otitis media, sixth nerve palsy, and retroorbital or facial pain (*Gradenigo's syndrome*). Sigmoid sinus and internal jugular vein thrombosis may present with neck pain.

DIAGNOSIS

The diagnosis of septic venous sinus thrombosis is suggested by an absent flow void within the affected venous sinus on MRI and confirmed by contrast-enhanced magnetic resonance venography, CT venography, or the venous phase of cerebral angiography. The diagnosis of thrombophlebitis of intracerebral and meningeal veins is suggested by the presence of intracerebral hemorrhage but requires the venous phase of cerebral angiography for definitive diagnosis.

TREATMENT

Suppurative Thrombophlebitis

Septic venous sinus thrombosis is treated with antibiotics, hydration, and removal of infected tissue and thrombus in septic lateral or cavernous sinus thrombosis. The choice of antimicrobial therapy is based on the bacteria responsible for the predisposing or associated condition. Optimal duration of therapy is unknown, but antibiotics are usually continued for 6 weeks or until there is radiographic evidence of resolution of thrombosis. Anticoagulation with unfractionated or low-molecular-weight heparin is recommended for aseptic venous sinus thrombosis and in the treatment of septic venous sinus thrombosis complicating bacterial meningitis in patients who have progressive neurologic deterioration despite antimicrobial therapy and intravenous fluids. The presence of a small intracerebral hemorrhage from septic thrombophlebitis is not an absolute contraindication to heparin therapy. Successful management of aseptic venous sinus thrombosis has been reported with surgical thrombectomy, catheter-directed urokinase therapy, and a combination of intrathrombus recombinant tissue plasminogen activator (rtPA) and intravenous heparin, but there are not enough data to recommend these therapies in septic venous sinus thrombosis.

146 Infectious Complications of Bites

Nongnooch Poowanawittayakom, Lawrence C. Madoff

The skin is an essential component of nonspecific immunity, protecting the host from potential pathogens in the environment. Breaches in this protective barrier thus represent a form of immunocompromise that predisposes the patient to infection. Bites and scratches from animals and humans allow the inoculation of microorganisms past the skin's protective barrier into deeper, susceptible host tissues.

Each year in the United States, millions of animal-bite wounds are sustained. The vast majority are inflicted by pet dogs and cats, which number >100 million; the annual incidence of dog and cat bites has been reported as 300 bites per 100,000 population. Other bite wounds are a consequence of encounters with animals in the wild or in occupational settings. While many of these wounds require minimal or no therapy, a significant number result in infection, which may be life-threatening. The microbiology of bite-wound infections in general reflects the oropharyngeal flora of the biting animal, although organisms from the soil, the skin of the animal and the victim, and the animal's feces may also be involved.

DOG BITES

In the United States, dogs bite >4.7 million people each year and are responsible for 80% of all animal-bite wounds, an estimated 15–20% of which become infected. Each year, 800,000 Americans seek medical

attention for dog bites; of those injured, 386,000 require treatment in an emergency department, with >1000 emergency department visits each day and ~43 deaths per year. Most dog bites are provoked and are inflicted by the victim's pet or by a dog known to the victim. These bites are frequently sustained during efforts to break up a dogfight. Children are more likely than adults to sustain canine bites, with the highest incidence of 6 bites per 1000 population among boys 5–9 years old. Victims are more often male than female, and bites most often involve an upper extremity. Among children <4 years old, two-thirds of all these injuries involve the head or neck. Infection typically manifests 8–24 h after the bite as pain at the site of injury with cellulitis accompanied by purulent, sometimes foul-smelling discharge. Septic arthritis and osteomyelitis may develop if a canine tooth penetrates synovium or bone. Systemic manifestations (e.g., fever, lymphadenopathy, and lymphangitis) also may occur. The microbiology of dog-bite wound infections is usually mixed and includes *Pasteurella* species, β-hemolytic streptococci, *Staphylococcus* species (including methicillin-resistant *Staphylococcus aureus* [MRSA] and *Staphylococcus intermedius*), *Neisseria* species (commonly *Neisseria weaveri*, formerly known as CDC group M-5), *Eikenella corrodens*, and *Capnocytophaga canimorsus*. Many wounds also include anaerobic bacteria such as *Bacteroides*, *Fusobacterium*, *Prevotella*, and *Porphyromonas* species.

While most infections resulting from dog-bite injuries are localized to the area of injury, many of the microorganisms involved are capable of causing systemic infection, including bacteremia, meningitis, brain abscess, endocarditis, and chorioamnionitis. These infections are particularly likely in hosts with edema or compromised lymphatic drainage in the involved extremity (e.g., after a bite on the arm in a woman who has undergone mastectomy) and in patients who are immunocompromised by medication or disease (e.g., glucocorticoid use, systemic lupus erythematosus, acute leukemia, or hepatic cirrhosis). In addition, dog bites and scratches may result in systemic illnesses such as rabies **(Chap. 214)** and tetanus **(Chap. 157)**.

Infection with *Capnocytophaga canimorsus* (and other *Capnocytophaga* species) following dog-bite wounds (or licking of preexisting wounds) may result in fulminant sepsis, disseminated intravascular coagulation, and renal failure, particularly in hosts who have impaired hepatic function, who have undergone splenectomy, or who are immunosuppressed. This thin gram-negative rod is difficult to culture on most solid media but grows in a variety of liquid media. It may require up to 14 days of incubation to grow on blood cultures. The bacteria are occasionally seen within polymorphonuclear leukocytes on Wright-stained smears of peripheral blood from septic patients. Tularemia **(Chap. 175)** also has been reported to follow dog bites.

CAT BITES

Although less common than dog bites, cat bites and scratches result in infection in more than half of all cases. Because the cat's narrow, sharp canine teeth penetrate deeply into tissue, cat bites are more likely than dog bites to cause septic arthritis and osteomyelitis; the development of these conditions is particularly likely when punctures are located over or near a joint, especially in the hand. Women sustain cat bites more frequently than do men. These bites most often involve the hands and arms. Both bites and scratches from cats are prone to infection from organisms in the cat's oropharynx. *Pasteurella multocida*, a normal component of the feline oral flora, is a small gram-negative coccobacillus implicated in the majority of cat-bite wound infections. Like that of dog-bite wound infections, however, the microflora of cat-bite wound infections is usually mixed. However, the median time from bite to the appearance of signs and symptoms of wound infection is much shorter when compared to dog bites. Other microorganisms causing infection after cat bites are similar to those causing dog-bite wound infections.

The same risk factors for systemic infection following dog-bite wounds apply to cat-bite wounds. *Pasteurella* infections tend to advance rapidly, often within hours, causing severe inflammation accompanied by purulent drainage with adenitis; *Pasteurella* may also be spread by respiratory droplets from animals, resulting in pneumonia or bacteremia. Like dog-bite wounds, cat-bite wounds may result in the transmission of rabies or in the development of tetanus. Infection with *Bartonella henselae* causes cat-scratch disease **(Chap. 177)** and is an important late consequence of cat bites and scratches. Tularemia **(Chap. 175)** also has been reported to follow cat bites. Occasionally, sporotrichosis **(Chap. 225)** has been associated with scratches or bites by animals, especially domestic cats.

OTHER ANIMAL BITES

Infections have been attributed to bites from many animal species. Often these bites are sustained as a consequence of occupational exposure (farmers, laboratory workers, veterinarians) or recreational exposure (hunters and trappers, wilderness campers, owners of exotic pets). Generally, the microflora of bite wounds reflects the oral flora of the biting animal. Most members of the cat family, including feral cats, harbor *P. multocida*. Bite wounds from aquatic animals such as alligators or piranhas may contain *Aeromonas hydrophila*. Shark, moray eel, and barracuda bites, like other injuries sustained in saltwater, are often associated with infections with marine *Vibrio* species. Venomous snakebites **(Chap. 471)** result in severe inflammatory responses and tissue necrosis—conditions that render these injuries prone to infection. The snake's oral flora includes many species of aerobes and anaerobes, such as *Pseudomonas aeruginosa, Serratia marcescens, Proteus* species, *Staphylococcus epidermidis, Salmonella* species, *Bacteroides fragilis*, and *Clostridium* species. Bites from nonhuman primates are highly susceptible to infection with pathogens similar to those isolated from human bites (see below). Bites from Old World monkeys (*Macaca*) may also result in the transmission of B virus (*Macacine herpesvirus 1, Herpesvirus simiae, Cercopithecine herpesvirus*), a cause of serious infection of the human central nervous system. *Actinobacillus lignieresii* has often been reported in infected wounds of humans bitten by horses, pigs, and sheep. Bites of seals, walruses, and polar bears may cause a chronic suppurative infection known as *seal finger*, which is probably due to one or more species of *Mycoplasma,* including *Mycoplasma phocacerebrale,* colonizing these animals.

Small rodents, including rats, mice, and gerbils, as well as animals that prey on rodents may transmit *Streptobacillus moniliformis* (a microaerophilic, pleomorphic gram-negative rod) or *Spirillum minor* (a spirochete); these organisms cause a clinical illness known as *rat-bite fever*. The vast majority of cases in the United States are streptobacillary, whereas *Spirillum* infection occurs mainly in Asia.

In the United States, the risk of rodent bites is usually greatest among laboratory workers or inhabitants of rodent-infested dwellings (particularly children). Rat-bite fever is distinguished from acute bite-wound infection by its typical manifestation after the initial wound has healed. Streptobacillary disease follows an incubation period of 3–10 days. Fever, chills, myalgias, headache, and severe migratory arthralgias are usually followed by a maculopapular rash, which characteristically involves the palms and soles and may become confluent or purpuric. Complications include endocarditis, myocarditis, meningitis, pneumonia, and abscesses in many organs. *Haverhill fever* is an *S. moniliformis* infection acquired from contaminated milk or drinking water and has similar manifestations. Streptobacillary rat-bite fever was frequently fatal in the preantibiotic era. The differential diagnosis includes Rocky Mountain spotted fever, Lyme disease, leptospirosis, and secondary syphilis. The diagnosis is made by direct observation of the causative organisms in tissue or blood, by culture of the organisms on enriched media, or by serologic testing with specific agglutinins.

Spirillum infection (referred to in Japan as *sodoku*) causes pain and purple swelling at the site of the initial bite, with associated lymphangitis and regional lymphadenopathy, after an incubation period of 1–4 weeks. The systemic illness includes fever, chills, and headache. The original lesion may eventually progress to an eschar. The infection is diagnosed by direct visualization of the spirochetes in blood or tissue or by animal inoculation.

HUMAN BITES

Human bites may be self-inflicted; may be sustained by medical personnel caring for patients; or may take place during fights, domestic abuse, or sexual activity. The risk of infection in human-bite wounds

depends on the depth of the wound. The risk of wound infection ranges from about 2% in superficial wounds to over 25% in deep bite wounds such as clenched-fist injuries. Human-bite wounds become infected more frequently (~10–15% of the time) than do bites inflicted by other animals. These infections reflect the diverse oral microflora of humans, which includes multiple species of aerobic and anaerobic bacteria. Common aerobic isolates include viridans streptococci, *S. aureus*, *E. corrodens* (which is particularly common in clenched-fist injury; see below), and *Haemophilus influenzae*. Anaerobic species, including *Fusobacterium nucleatum* and *Prevotella*, *Porphyromonas*, and *Peptostreptococcus* species, are isolated from 50% of wound infections due to human bites; many of these isolates produce β-lactamases. The oral flora of hospitalized and debilitated patients often includes Enterobacteriaceae in addition to the usual organisms. Hepatitis B, hepatitis C, herpes simplex virus infection, syphilis, tuberculosis, actinomycosis, and tetanus have been reported to be transmitted by human bites; it is biologically possible to transmit HIV through human bites, although the risk is quite low. In general, postexposure prophylaxis should be considered for bites involving severe trauma with extensive tissue damage and the presence of blood in saliva. There is essentially no risk of transmission if the skin is intact.

Human bites are categorized as either *occlusional* injuries, which are inflicted by actual biting, or *clenched-fist* injuries, which are sustained when the fist of one individual strikes the teeth of another, causing traumatic laceration of the hand. For several reasons, clenched-fist injuries, which are sometimes referred to as "fight bite" and which are more common than occlusional injuries, result in particularly serious infections. The deep spaces of the hand, including the bones, joints, and tendons, are frequently inoculated with organisms in the course of such injuries. The clenched position of the fist during injury, followed by extension of the hand, may further promote the introduction of bacteria as contaminated tendons retract beneath the skin's surface Moreover, medical attention is often sought only after frank infection develops. Patients with clenched-fist injury should undergo careful physical examination of the area, including the extensor tendons.

APPROACH TO THE PATIENT

Animal or Human Bites

A careful history should be elicited, including the type of biting animal, the type of attack (provoked or unprovoked), and the amount of time elapsed since injury. Local and regional public-health authorities should be contacted to determine whether an individual species could be rabid and/or to locate and observe the biting animal when rabies prophylaxis may be indicated **(Chap. 214)**. Suspicious human-bite wounds should provoke careful questioning regarding domestic or child abuse. Details on antibiotic allergies, immunosuppression, splenectomy, liver disease, mastectomy, and immunization history should be obtained. The wound should be inspected carefully for evidence of infection, including redness, exudate, and foul odor. The type of wound (puncture, laceration, or scratch); the depth of penetration; and the possible involvement of joints, tendons, nerves, and bones should be assessed. It is often useful to include a diagram or photograph of the wound in the medical record. In addition, a general physical examination should be conducted and should include an assessment of vital signs as well as an evaluation for evidence of lymphangitis, lymphadenopathy, dermatologic lesions, and functional limitations. Injuries to the hand warrant consultation with a hand surgeon for the assessment of tendon, nerve, and muscular damage. Radiographs should be obtained in penetrating wounds to evaluate the evidence of fracture or retained foreign body such as a tooth fragment. Culture and Gram's staining of all infected wounds are essential; anaerobic cultures should be undertaken if abscesses, devitalized tissue, or foul-smelling exudate is present. A small-tipped swab may be used to culture deep punctures or small lacerations. It is also reasonable to culture samples from apparently uninfected wounds due to bites inflicted by animals other than dogs and cats, since the microorganisms causing disease are less predictable in these cases. The microbiology laboratory should be notified if fastidious organisms such as *E. corrodens* are under consideration in human bites. The white blood cell count should be determined, and the blood cultured if systemic infection is suspected.

TREATMENT

Bite-Wound Infections

WOUND MANAGEMENT

Wound closure is controversial in bite injuries. Many authorities prefer not to attempt primary closure of wounds that are or may become infected, choosing instead to irrigate these wounds copiously, debride devitalized tissue, remove foreign bodies, and approximate the wound edges. All abscesses should be drained. Delayed primary closure may be undertaken after the risk of infection is over. Small uninfected wounds may be allowed to close by secondary intention. Puncture wounds due to cat bites should be left unsutured because of the high rate at which they become infected. Facial wounds are usually sutured after thorough cleaning and irrigation because of the importance of a good cosmetic result in this area and because anatomic factors such as an excellent blood supply and the absence of dependent edema lessen the risk of infection. In general, wounds >12 h old (for bites to the arm or leg) or >24 h old (for bites to the face) should not be closed primarily and may require prophylactic antibiotics (see below).

ANTIBIOTIC THERAPY

Established Infection Antibiotics should be administered for all established bite-wound infections and should be chosen in light of the most likely potential pathogens, as indicated by the biting species and by Gram's stain and culture results **(Table 146-1)**. For dog and cat bites, antibiotics should be effective against *S. aureus, Pasteurella* species, *C. canimorsus*, streptococci, and oral anaerobes. For human bites, agents with activity against *S. aureus, H. influenzae*, and β-lactamase-positive oral anaerobes should be used. The combination of an extended-spectrum penicillin with a β-lactamase inhibitor (amoxicillin/clavulanic acid, ampicillin/sulbactam) appears to offer the most reliable coverage for these pathogens. Third-generation cephalosporins (ceftriaxone, cefpodoxime) also offer substantial coverage when given in conjunction with a drug that provides anaerobic coverage (clindamycin or metronidazole). The choice of antibiotics for penicillin-allergic patients (particularly those in whom immediate-type hypersensitivity makes the use of cephalosporins hazardous) is more difficult and is based primarily on in vitro sensitivity since data on clinical efficacy are inadequate. The combination of an antibiotic active against gram-positive cocci and anaerobes (such as clindamycin or metronidazole) with trimethoprim-sulfamethoxazole or a fluoroquinolone, which is active against many of the other potential pathogens, would appear reasonable. Moxifloxacin, a fluoroquinolone with anaerobic coverage, can also be considered as a single agent. In vitro data suggest that azithromycin alone provides coverage against most commonly isolated bite-wound pathogens; however, this agent has variable activity against *P. multocida*, *E. corrodens,* and fusobacteria and thus should be avoided unless no alternative agent is available. Empirical use of agents active against MRSA should be considered in high-risk situations while culture results are awaited.

Antibiotics are generally given for about 5–7 days and for no more than 14 days, but the response to therapy must be carefully monitored. Failure to respond should prompt a consideration of diagnostic alternatives and surgical evaluation for possible drainage or debridement. Complications such as osteomyelitis or septic arthritis mandate a longer duration of therapy.

TABLE 146-1 Management of Wound Infections Following Animal and Human Bites

BITING SPECIES	COMMONLY ISOLATED PATHOGENS	PREFERRED ANTIBIOTIC(S)[a]	ALTERNATIVE IN PENICILLIN-ALLERGIC PATIENT	PROPHYLAXIS ADVISED FOR EARLY UNINFECTED WOUNDS	OTHER CONSIDERATIONS
Dog	*Staphylococcus aureus, Pasteurella* spp. (mainly *P. multocida* and *P. canis*), anaerobes, *Capnocytophaga canimorsus*	Amoxicillin/clavulanate (875/125 mg PO q12h) or ampicillin/sulbactam (3.0 g IV q6h) or Ceftriaxone 2 g IV once daily plus metronidazole 500 mg q8h	Clindamycin[b] or metronidazole plus either TMP-SMX (1 DS tablet PO bid) or ciprofloxacin (500 mg PO bid)	Sometimes[c]	Consider rabies prophylaxis.
Cat	*P. multocida, S. aureus*, anaerobes	Amoxicillin/clavulanate, ampicillin/sulbactam, or ceftriaxone plus metronidazole as above	Clindamycin or metronidazole plus TMP-SMX as above or fluoroquinolone	Usually[d]	Consider rabies prophylaxis. Carefully evaluate for joint/bone penetration.
Human, occlusional	Viridans streptococci, *S. aureus, Haemophilus influenzae*, anaerobes *Eikenella corrodens*[e]	Amoxicillin/clavulanate plus TMX-SMX if consider including MRSA coverage or ampicillin/sulbactam or ceftriaxone plus metronidazole (consider adding vancomycin if MRSA coverage required)	TMP-SMX plus metronidazole	Always	
Monkey	As for human bite	As for human bite	As for human bite	Always	For macaque monkeys, consider B virus prophylaxis with acyclovir.
Snake	Snake oral flora including *Pseudomonas, Morganella* spp., *E. coli,* group D streptococci, *Salmonella* spp., anaerobic organisms including *Bacteroides fragilis, Clostridium* spp.	Piperacillin/tazobactam 3.375 g IV q6–8h	Clindamycin or metronidazole plus a fluoroquinolone	Evidence does not support the benefit. Can consider in regions with high rates of infection such as Brazil.	Administer antivenin for venomous snakebite. Tetanus prophylaxis.
Rodent	Rat bite fever; *Streptobacillus moniliformis, Spirillum minus, Streptobacillus notomytis, Leptospira* spp., *P. multocida*	Penicillin VK (500 mg PO qid) or ceftriaxone IV	Doxycycline (100 mg PO bid)	Sometimes	
Aquatic animal (alligator, piranha, shark, moray eel, barracuda)	*Aeromonas hydrophila*, marine *Vibrio* spp. (*Vibrio vulnificus*)	Third-generation cephalosporin (e.g., ceftriaxone, 1 g IV q24h) plus doxycycline (100 mg PO bid)	Clindamycin or metronidazole plus levofloxacin (750 mg PO qd) plus doxycycline	Always	Obtain prompt surgical consultation, as risk for necrotizing infection is high with *Aeromonas* and *Vibrio* spp.

[a]Antibiotic choices should be based on culture data when available. These suggestions for empirical therapy need to be tailored to individual circumstances and local conditions. MRSA empirical coverage is based on individual risk factors. IV regimens should be used for hospitalized patients. A single IV dose of antibiotics may be given to patients who will be discharged after initial management. [b]Avoid monotherapy for aerobic coverage due to poor activity against *Pasteurella* spp. Risk of *Clostridioides difficile* infection. [c]Cat bite may leave small external wounds but deep puncture wounds. [d]Prophylactic antibiotics are suggested for severe or extensive wounds, facial wounds, and crush injuries; when bone or joint may be involved; delayed wound care >8 h; and when comorbidity is present (see text). Prophylactic antibiotic duration is generally between 3 and 5 days. [e]*Eikenella corrodens* is resistant to penicillinase-resistant penicillin, first and second generation cephalosporins, clindamycin, metronidazole, and aminoglycosides in vitro.

Abbreviations: DS, double-strength; TMP-SMX, trimethoprim-sulfamethoxazole.

Management of *C. canimorsus* bacteremia requires an initial treatment with a 2-week course of IV antibiotics such as penicillin G (2 million units IV every 4 h) or IV ampicillin/sulbactam (3.0 g every 6 h) along with supportive measures. Once the patient is improved, then a switch to oral antibiotics can be considered. Alternative agents for the treatment of *C. canimorsus* infection include cephalosporins or carbapenems. Serious infection with *P. multocida* (e.g., pneumonia, sepsis, or meningitis) also should be treated with IV penicillin G. Alternative agents include a second- or third-generation cephalosporin or ciprofloxacin. Penicillin resistance is uncommon.

Bites by venomous snakes **(Chap. 471)** may not require antibiotic treatment. Because it is often difficult to distinguish signs of infection from tissue damage caused by the envenomation, many authorities continue to recommend treatment directed against the snake's oral flora—i.e., the administration of broadly active agents such as ceftriaxone (1–2 g IV every 24 h) or ampicillin/sulbactam (3.0 g IV every 6 h).

Seal finger appears to respond to doxycycline (100 mg twice daily for a duration guided by the response to therapy).

Presumptive or Prophylactic Therapy The use of antibiotics for patients presenting early (within 8 h) after bite injury is controversial. Although symptomatic infection frequently will not yet have manifested at this point, many early wounds will harbor pathogens, and many will become infected. Studies of antibiotic prophylaxis for wound infections are limited and have often included only small numbers of cases in which various types of wounds have been managed according to various protocols. A meta-analysis of eight randomized trials of prophylactic antibiotics in patients with dog-bite wounds demonstrated a reduction in the rate of infection by 50% with prophylaxis. However, in the absence of sound clinical trials, many clinicians base the decision to treat bite wounds with empirical antibiotics on the species of the biting animal; the location, severity, and extent of the bite wound; and the existence of comorbid conditions in the host. All human- and monkey-bite wounds should be treated presumptively because of the high rate of infection. Most cat-bite wounds, particularly those involving the hand, should consider prophylactic antibiotics. Other factors favoring treatment for bite wounds include severe injury, as in crush wounds; potential bone or joint involvement; involvement of the hands or genital region; host

immunocompromise, including that due to diabetes mellitus, liver disease, or splenectomy; involvement of extremities with underlying venous and/or lymphatic compromise; and prior mastectomy on the side of an involved upper extremity. When prophylactic antibiotics are administered, they are usually given for 3–5 days.

Rabies and Tetanus Prophylaxis Rabies prophylaxis, consisting of both passive administration of rabies immune globulin (with as much of the dose as possible infiltrated into and around the wound) and active immunization with rabies vaccine, should be given in consultation with local and regional public-health authorities for some animal bites and scratches as well as for certain nonbite exposures **(Chap. 214)**. Rabies is endemic in a variety of animals, including dogs and cats, in many areas of the world. In the United States, although the majority (90%) of rabid animals reported each year are wild (including raccoons, skunks, foxes, and bats), most rabies prophylaxis is given because of close contact with domestic animals. More cats than dogs are reported rabid each year. Many local health authorities require the reporting of all animal bites.

A tetanus booster immunization should be given if the patient has undergone primary immunization but has not received a booster dose in the past 5 years. Patients who have not previously completed primary immunization should be immunized and should also receive tetanus immune globulin. Elevation of the site of injury is an important adjunct to antimicrobial therapy. Immobilization of the infected area, especially the hand, also is beneficial.

Hepatitis B Prophylaxis Hepatitis B virus can be transmitted, albeit rarely, by exposure of nonintact skin to blood-free saliva. The mainstay of postexposure prophylaxis is active immunization with hepatitis B vaccine, but, in certain circumstances, hepatitis B immune globulin is recommended in addition to vaccine for added protection **(Chap. 350)**.

Acknowledgment

The authors would like to acknowledge Drs. Sandeep S. Jubbal and Florencia Pereyra for their prior contributions to this chapter.

Section 3 Clinical Syndromes: Health Care–Associated Infections

147 Infections Acquired in Health Care Facilities

Mini Kamboj, Tara N. Palmore

Health care–associated infections affect at least 3% of hospitalized patients at any given time. Through concerted efforts, national rates of some nosocomial infections were declining before the onset of the COVID-19 pandemic, but infection control challenges related to the pandemic reversed years of progress. The past few years have also seen a rise in incidence of multidrug-resistant infections, which are challenging to treat and contain. However, newer tools combined with evidence-based methods of infection prevention and control are robust and can succeed. This chapter reviews the epidemiology, prevention, and control of health care–associated infections and recent challenges faced by health care epidemiologists.

ORGANIZATION, RESPONSIBILITIES, AND OVERSIGHT OF INFECTION PREVENTION AND CONTROL PROGRAMS

Infection prevention and control programs are composed of infection preventionists supervised by an experienced team lead. These typically include a doctoral-level (MD/DO/PhD) health care epidemiologist who may report to the chief medical officer or chief quality officer. The number of staff required in an infection prevention and control program depends on the size and complexity of the health care facility and its patients.

Infection prevention and control programs are responsible for a broad range of activities, including surveillance and reporting of nosocomial infections; preventing and thwarting transmission of nosocomial pathogens through use of isolation and education; reducing device-associated infections through evidence-based interventions; collaborating with occupational health to manage infectious exposures; preparing for and managing emerging infectious diseases; and investigating and controlling outbreaks. The team collects and analyzes infection data and reports those data to institutional stakeholders, such as the multidisciplinary Infection Control Committee. Infection preventionists usually perform the mandatory reporting of select nosocomial infection data to the National Healthcare Safety Network that is managed by the Centers for Disease Control and Prevention (CDC). Such reporting is required by the U.S. Centers for Medicare and Medicaid Services and affects facilities' reimbursement for the care they have provided, i.e., nonpayment for care related to preventable nosocomial infections.

SURVEILLANCE

Surveillance to detect and prevent health care–associated infections focuses on outcomes, processes, and other related measures that directly or indirectly influence the risk of contracting them. Examples of outcomes include surgical site infections and hospital-onset *Clostridioides difficile* infections. Key process measures include compliance with evidence-based practices that reduce the risk of infection, such as hand hygiene, central line insertion care, and maintenance practices for indwelling devices. Finally, health care personnel influenza immunization rates are an example of a related measure that is tracked at a local, regional, and national level to gauge efforts toward reducing the risk of nosocomial influenza in acute and long-term care settings.

Detecting health care–associated infections using a case-finding strategy is a labor- and resource-intensive process. Most U.S. hospitals rely on laboratory-based surveillance as the fundamental data collection methodology, supplemented with clinical reviews by infection preventionists.

Widespread adoption of automated surveillance systems to collect, analyze, and combine infection and antimicrobial prescription data from diverse sources within electronic records has improved surveillance efficiency and scalability. Challenges with reliability, interfacility standardization, and the need for considerable human input to refine and ensure comprehensive data flow and adjudication of infection definitions continue to leave considerable room for improvement in electronic surveillance. Leveraging natural language processing models for health care–associated infection surveillance should further enhance existing systems. Surveillance data interpretation can be complex as hospitals apply health care–associated infection metrics for diverse purposes, including monitoring disease trends, detecting outbreaks, driving quality improvement, and meeting mandated reporting requirements to state and federal agencies, and as a vital part of value-based care measures.

Because of its role as the nation's mandatory reporting mechanism for health care–associated infections, the CDC's National Healthcare Safety Network benchmarks and tracks health care–associated infections and provides the measures and analytical tools that allow comparison across facilities. Infection rates are expressed as standardized infection ratios, calculated by dividing the number of observed infections by the number of predicted infections.

EPIDEMIOLOGIC BASIS AND GENERAL MEASURES FOR PREVENTION AND CONTROL

Patients in health care facilities are vulnerable to transmission of pathogens from other patients, visitors, staff, or the inanimate health care environment. Health care personnel may convey multidrug-resistant organisms between patients and the environment on their hands or on shared patient care equipment (e.g., stethoscopes or portable imaging machines). Spread can also occur from contaminated plumbing, person to person via a respiratory route (e.g., influenza or group A *Streptococcus* from health care personnel), or via contamination of food, water, or medications.

Infections that arise within the first 48–72 h after admission are generally considered community acquired or, if the patient was transferred from another facility, attributed to the transferring institution. Those occurring henceforth are considered health care associated, or nosocomial. Patient factors that increase vulnerability to nosocomial infection include presence of an invasive device, immune deficiency (congenital or acquired), renal insufficiency, diabetes, and other major comorbidities.

When patients' own microbiota have been altered by exposure to antibiotics or other medications, they become more susceptible to colonization with multidrug-resistant organisms. Colonized patients serve as unintentional reservoirs for transmission of resistant organisms to other patients or to the hospital environment, including shared equipment. Patients can develop nosocomial infections from these transmitted pathogens (cross-transmission) or from their own microbiota.

Hand hygiene and environmental cleaning are essential interventions to interrupt transmission. Hand hygiene can be performed either with soap and water or alcohol-based hand gel, with special requirements for care of patients who have diarrhea (see "Health Care–Associated Diarrhea," below). Environmental cleaning and disinfection are focused on frequently touched surfaces, such as doorknobs, bed rails, and objects in the bathroom, and are similarly adjusted for disinfectant-resistant pathogens when necessary.

COLONIZATION

Nosocomial bacteria or yeast that are transmitted to a patient may be unintentionally ingested, leading to colonization with the organism, a carrier state. Patients whose microbiota have been altered by antibiotics are more susceptible to colonization with nosocomial organisms. Colonization pressure, the proportion of patients in a ward who are colonized, is a risk factor for spread of resistant organisms. Patients who are immunocompromised or whose immune barriers have been breached by surgery or invasive devices, are at increased risk of infection from the nosocomial organisms with which they are colonized.

OUTBREAK INVESTIGATION AND RESPONSE

Transmission in a health care facility may be detected via careful surveillance or by notification from a clinician or laboratory. Investigation typically involves molecular typing of bacterial or fungal (less commonly viral) isolates to ascertain whether they are, in fact, closely related and represent an outbreak. The gold standard for these comparisons is whole genome sequencing, which has high resolution for determining clonality and, in the case of bacteria, conveys valuable information about plasmid-carried resistance genes.

Once transmission has been established, outbreak investigation involves a series of steps including drafting a case definition, finding cases, reviewing medical records, performing descriptive epidemiology, and developing a hypothesis regarding the source of the outbreak. Control measures are implemented while surveillance (including environmental cultures in some cases) is conducted. Communicating with patients, staff, facility leaders, and public health is integral to the outbreak response.

NOSOCOMIAL AND DEVICE-RELATED INFECTIONS

Invasive procedures and indwelling devices deliver supportive care and can save lives, but they provide potential portals of entry for pathogens. Infections in patients who undergo surgery or have indwelling devices are important targets for prevention in health care facilities.

Postsurgical infections occur more frequently when surgery is performed in the setting of emergencies, tissue damage from trauma or radiation, uncontrolled infection elsewhere in the body, malnutrition, chemotherapy, and other conditions that impair wound healing.

Routine perioperative checklists enumerate activities that reduce the risk of surgical site infections **(Table 147-1)**.

After years of decline due to prevention efforts, rates of device-related and other nosocomial infections rose during the COVID-19 pandemic. These infections are a substantial cause of morbidity and mortality for hospitalized patients and are often due to antimicrobial-resistant infections.

CATHETER-ASSOCIATED URINARY TRACT INFECTIONS

Catheter-associated urinary tract infections occur more frequently in patients with critical illness, older age, and female sex. Sterile and atraumatic insertion of catheters and preservation of a closed drainage system help prevent contamination. Infections are preventable largely by concerted efforts to avoid the placement of indwelling urinary catheters and by reevaluating daily the duration of their use.

The presence of asymptomatic bacteriuria, or bacteria without symptoms of urinary tract infection, often leads to improper antimicrobial treatment in patients with indwelling urinary catheters. Apart from pregnant patients, most others need not undergo urine culture or treatment for asymptomatic bacteriuria. Diagnostic stewardship efforts include guidelines to reduce collection of urinalysis and culture from patients in whom these studies are not indicated to avoid subsequent inappropriate treatment of asymptomatic bacteriuria. In the elderly, this often occurs in the setting of nonspecific symptoms, such as confusion, that are not related to asymptomatic bacteriuria. Improper treatment of asymptomatic bacteriuria is often followed by improper testing for "clearance" of bacteriuria, which results in a vicious cycle of escalating antimicrobial use and resistance.

HEALTH CARE–ASSOCIATED PNEUMONIA

Hospital-acquired pneumonia is often due to aspiration of oral or gastric contents or, less commonly, hematogenous transmission from a remote source. Because of changes in patients' microbiota in medical facilities, bacterial causes of nosocomial pneumonia are frequently antimicrobial resistant. The most likely pathogens involved in nosocomial pneumonia and its treatment are discussed in **Chaps. 131 and 147**.

Ventilator-associated pneumonia is a subset of nosocomial pneumonia that occurs in up to 10% of ventilated patients. Mechanical ventilation can be complicated by a variety of infectious and noninfectious problems that are encompassed under the term *ventilator-associated*

TABLE 147-1 Evidence-Based Bundled Measures to Reduce the Risk of Select Device- and Procedure-Related Infections

Prevention of Surgical Site Infections
Treat active infections prior to surgery
Administer prophylactic antibiotics within 1 h before surgery and discontinue immediately after surgery
Wear surgical attire that covers hair, mouth, and nose
Perform hand hygiene with an antiseptic agent
Perform antisepsis of the surgical site with chlorhexidine/alcohol solutions whenever possible
If hair must be removed, clip rather than shave (to avoid skin microtrauma)
Implement operating room asepsis, minimizing movement into and out of the room
Maintain operating room air at positive pressure, with moderate humidity (20–60%) and at least 20 air changes per hour
Prevention of Ventilator-Associated Pneumonia
Attempt to avoid intubation using high-flow nasal oxygen or noninvasive positive-pressure ventilation
Elevate head of bed to 30–45 degrees to reduce risk from gastric contents
Brush teeth daily
Use aseptic care of all respiratory care equipment
Avoid use of tap water for rinsing any respiratory care equipment
Follow strategies to promote earlier extubation:
• Minimize sedation
• Provide early exercise and mobilization
• Provide early enteral feeding
• Assess readiness for extubation on a daily basis
Prevention of Catheter-Associated Urinary Tract Infection
Place indwelling catheters only when strictly necessary, e.g., to relieve obstruction, and not for convenience
Use aseptic equipment and technique for catheter insertion and urinary tract instrumentation
Minimize urinary tract instrumentation
Minimize manipulation of or entry into urinary catheter systems, and avoid catheter irrigation
Reevaluate daily the need for continued use of an indwelling urinary catheter in each patient
Use alternative methods to avoid indwelling catheters, e.g., bladder scans, condom catheters, intermittent catheterization
Prevention of Catheter-Associated Central Line Infections
Optimize nurse-to-patient ratio
Consider alternatives to central line (e.g., peripheral IV, midline catheter)
Catheter insertion
• Use a checklist to ensure adherence to insertion bundle
• Use hand hygiene
• Use maximum sterile barrier precautions and aseptic technique
• Use chlorhexidine-alcohol antisepsis to prepare the site
• Use ultrasound guidance
• Use an all-inclusive catheter insertion kit
• The subclavian vein is least prone and the femoral vein most prone to infection in the intensive care unit (ICU) setting
Catheter maintenance
• Administer daily chlorhexidine gluconate baths to ICU patients with central lines
• Scrub the hub with alcohol
• Cleanse the catheter site with chlorhexidine-based antiseptic with every dressing change, at a minimum every 7 days (earlier if site is soiled or dressing disrupted)
• Use disinfectant caps
• Apply chlorhexidine-impregnated dressings
• Reevaluate daily the need for continued use of each central line in each patient

events. Ventilator-associated pneumonia can prolong the duration of ventilation and intensive care unit (ICU) stay or even prove fatal. Like other device-related infections, ventilator-associated pneumonia is preventable by limiting use of the invasive device (Table 147-1).

CATHETER-ASSOCIATED BLOODSTREAM INFECTIONS

Central venous catheters represent another major target for infection prevention. Although they are often necessary for patient care, central lines are foreign objects that lie in direct contact with the bloodstream. Without meticulous care, each health care personnel interaction with the catheter serves as a potential contamination event. Catheter-associated bloodstream infections triple a patient's risk of in-hospital death. Similar to other device-related infections, the rate of catheter-related bloodstream infections had declined in the years leading up to 2020, when infection control gains were lost with the onset of the pandemic.

Preventing catheter-associated bloodstream infections begins with aseptic insertion technique using a bundle, or checklist, of evidence-based steps (Table 147-1). Catheter maintenance practices are important for ongoing prevention of infection and include meticulous, aseptic technique in handling the catheter. Daily full-body cleansing with 2% chlorhexidine gluconate is effective for preventing bloodstream infections, particularly central line infections, in the ICU and are standard of care. Although studies outside the ICU show mixed results, some hospitals utilize the baths for all patients with central lines because of the treatment's low side effect profile and the potential impact of the intervention.

TRANSMISSION-BASED PRECAUTIONS

Standard precautions are the basic set of practices that health care personnel should follow to minimize exposure to potentially infectious material and prevent pathogen transmission while caring for all patients in all health care settings. The key elements of standard precautions are applied based on the situational risk and include hand hygiene; respiratory etiquette; personal protective equipment use depending on the potential for exposure to blood, body fluid, or infectious material; and safe injection practices.

Additional pathogen-specific prevention measures are called transmission-based precautions. When patients harbor a suspected or confirmed communicable disease, transmission-based precautions are used to prevent spread in the health care setting. The fundamental modes of pathogen transmission inform the recommended prevention methods categorized by the World Health Organization (WHO) and CDC into contact, droplet, and airborne precautions.

Contact precautions utilize hand hygiene and barrier methods (gown and gloves) to prevent the spread of ubiquitous pathogens in a colonized or infected person's immediate environment, for example, *C. difficile* and multidrug-resistant organisms. Institutions differ in use of contact precautions for ubiquitous resistant organisms such as methicillin-resistant *Staphylococcus aureus*.

Droplet precautions are implemented when a patient has respiratory symptoms or a confirmed respiratory infection with a pathogen that is transmitted from person to person. Protective equipment includes a gown, gloves, eye protection, and a mask or respirator, given recent evidence that respiratory viruses are spread by both droplets (respiratory particles ≥ 100 microns in size) and aerosols (sprays of particles <100 microns). The principal mode of respiratory pathogen spread is by inhalation of respiratory particles emitted by an infected person during sneezing, coughing, talking, and breathing. Host factors such as infection stage, symptoms, immune status, and environmental conditions, including ventilation and humidity, influence pathogen transmissibility. Respiratory droplets remain suspended in the air only briefly and travel short distances.

Airborne transmission occurs via tiny particles 100 that can travel larger distances and remain suspended in the air for an extended duration. Measles, tuberculosis, varicella, and COVID-19 are infectious agents that pose a major risk of airborne transmission. *Airborne precautions* require respirators and placement of the infected individual in a negative-pressure airborne isolation room with a minimum air flow

rate of 12 air changes per hour with direct exhaust outside the building or recirculation through a high-efficiency particulate air (HEPA) filter and respirator use.

Some conditions may merit combinations of these precautions (e.g., patients with varicella and SARS-CoV-2 are placed in contact and airborne precautions).

EMERGING INFECTIOUS DISEASES

EPIDEMICS, EMERGING INFECTIOUS DISEASES, AND AGENTS OF BIOTERRORISM

Preparedness for newly evolved and reemerging human pathogens is critical to infection prevention and control activities. The 21st century has witnessed the emergence of several infectious threats and two major pandemics: 2009 H1N1 swine influenza and 2019 SARS-CoV-2, with their vast worldwide impact and, in the case of SARS-CoV-2, millions of deaths. The changing of global ecosystems from deforestation, climate change, and extensive urbanization with a rising world population has increased the proximity between humans and wildlife. The confluence of these factors can generate conditions that favor mutational viral evolution and, ultimately, cross-species spillover of otherwise geographically confined zoonotic illnesses, as was seen with the outbreaks of Ebola in 2014, Zika in 2016, SARS-CoV-2, and the 2022–2023 international monkeypox (mpox) epidemic.

Another emerging challenge relates to socio-behavioral perceptions and beliefs linked to vaccines; the perpetuation of misinformation through social media around childhood and adult immunizations has amplified vaccine hesitancy, threatening the maintenance of safe vaccination rates and herd immunity. The most urgent threat is from highly contagious illnesses such as measles, mumps, polio, and varicella. The current global rise in measles cases has disproportionately affected unvaccinated or partially vaccinated individuals. Therefore, addressing vaccine access, misinformation, and declining immunization rates is critical to avert outbreaks of vaccine-preventable illnesses with a high public health impact.

Finally, health care personnel awareness of intentional human threats from potential agents of bioterrorism such as *Bacillus anthracis* and variola virus is essential. Natural smallpox is no longer a hazard; routine vaccination against smallpox ended in the United States in 1971. However, there is a possibility of laboratory-maintained variola outside of the WHO-approved repositories. In the event of an accidental or intentional release, vaccination is the primary strategy to stop smallpox spread. Two currently licensed vaccines for smallpox prevention are the replication-competent vaccinia virus vaccine, ACAM2000, and the live, nonreplicating modified vaccinia Ankara vaccine. Both vaccines are also recommended for prevention of mpox in high-risk groups. *B. anthracis* is a category A pathogen with a high case fatality rate and potential for mass casualty if aerosolized. After the U.S. inhalational anthrax cases in 2001 from mailed letters containing anthrax spores that resulted in five deaths, protocols for a mass disaster related to *B. anthracis* exposure have been a biodefense preparedness priority.

VIRAL RESPIRATORY INFECTIONS WITH PANDEMIC POTENTIAL

Safety protocols for patients and health care personnel from new and reemerging contagious respiratory illnesses including novel influenza A viruses, Middle East respiratory syndrome coronavirus (MERS-CoV), and other novel coronaviruses are vital. Adopting an integrated all-hazard screening approach to identify and implement infection control measures, initiate diagnostic testing, and safely deliver care is critical. Lessons from the COVID-19 pandemic underscore the importance of maintaining par levels of personal protective equipment, testing supplies, and essential therapeutics. Regular training of frontline health care personnel on appropriate donning and doffing of personal protective equipment ensures readiness to handle patients with contagious illnesses safely. Testing for novel pathogens may only be available through public health laboratories; however, developing the capability for laboratory-developed tests and existing infrastructures to rapidly adopt testing protocols ensures timely diagnosis, contact investigations, and postexposure management, which is critical for effective containment. Health care facilities should leverage a structured information-sharing approach through hospital incident command system activation. From a public health standpoint, robust surveillance mechanisms, clear and concise guidelines for clinicians and the public, and alignment among federal agencies, state and local public health, and commercial laboratories are critical to ensure testing capacity and vaccine and therapeutics access.

HIGHLY PATHOGENIC AVIAN INFLUENZA

Among the potential pandemic pathogens, avian influenza A (H5 and H7 strains) has an exceptionally high impact due to its constant viral evolution and potential for adaptation to transmit effectively in humans. The most immediate pandemic threat is posed by highly pathogenic H5N1 avian influenza, with ~900 known human infections worldwide since 2003 and a case fatality rate of ~50%. Sustained person-to-person transmission of this group of viruses has not occurred thus far. H5N1 began circulating in North American wild birds and poultry in late 2021, with subsequent detections in mammals, including U.S. dairy cattle herds and barn cats, in multiple U.S. states and numerous cases of animal-to-human transmission.

The recommended prevention measures against novel influenza in hospitals are similar to those against other high-consequence pathogens, including contact and airborne precautions and eye protection. Close contacts should receive antiviral prophylaxis with oseltamivir. Regarding diagnostics, influenza targets on commercial multiplex reverse transcriptase polymerase chain reaction (PCR) panels are insufficient for strain identification and additional, dedicated testing in public health laboratories from nasopharyngeal swabs, washes, and conjunctival swabs is required to establish the diagnosis in the appropriate clinical and epidemiologic context.

MPOX

Previously a geographically constrained virus endemic to West Africa mpox Clade II virus caused s global outbreak in 2022. On its heels, in central Africa, cases of Clade I, endemic to that region, soared. The virus is zoonotic, and spreads from person to person through close contact of mucosal surfaces or nonintact skin with open lesions or via contaminated inanimate objects such as bed linens. The role of respiratory transmission without close physical contact is less well established. Despite initial concerns, health care–associated transmission of mpox in nonendemic countries is rare, with multiple reported occupational transmissions after direct inoculation from needlestick injuries. Postexposure prophylaxis with the JYNNEOS or ACAM2000 vaccine series is recommended for high-risk exposures.

VIRAL HEMORRHAGIC FEVER PREPAREDNESS

During the 2014–2015 West African Ebola epidemic, symptomatic returning travelers presented to U.S. hospitals, resulting in occupational Ebola infections in two nurses at one facility. These and other events led to formation of a national network of Regional Emerging Special Pathogen Treatment Centers at large hospitals that have built specially engineered containment wards and trained staff to care for patients with suspected or confirmed Ebola, Marburg, or other viral hemorrhagic fever diseases. A series of additional hospitals are prepared to receive and provide temporary care for such patients prior to transferring them to these treatment centers. Finally, all medical facilities and emergency services should have plans for managing patients with highly contagious diseases who may present unexpectedly.

HEALTH CARE–ASSOCIATED DIARRHEA

CLOSTRIDIOIDES DIFFICILE INFECTION

Diarrhea that begins in health care facilities or is attributable to recent care in a health care facility is considered health care associated. *C. difficile* infection **(Chap. 139)** is not only the most frequent cause but also the most frequent hospital-acquired infection in the United States. *C. difficile* colitis has symptoms that can range in severity from mild diarrhea to life-threatening toxic megacolon. Receipt of antibiotics is the most common cause of *C. difficile* infection, making antimicrobial

stewardship the first-line measure for its prevention. Restricting use of antibiotics that are highly associated with subsequent *C. difficile* infection, such as quinolones and clindamycin, has been shown to reduce the incidence of the disease. Longitudinal genomic surveillance shows that patients who enter the hospital already colonized with *C. difficile* are by far the most likely to develop the infection during their hospital stay.

Patients who have suspected or confirmed *C. difficile* infection are placed in contact isolation to contain spores that infected patients shed in high numbers and that heavily contaminate their skin and environment. These spores are hardy, survive for a prolonged time in the health care environment, and can be transmitted on hands of health care personnel, on surfaces, or on shared patient care equipment. Because alcohol-based hand gel and standard hospital cleaners do not kill *C. difficile* spores, handwashing with soap and water is preferred to mechanically remove them, and sporicidal disinfectants such as bleach are used to clean the rooms of infected patients.

NOROVIRUS

Norovirus is another important cause of health care–associated diarrhea that can be transmitted among patients and staff and cause outbreak in facilities. A nonenveloped virus that is poorly inactivated by alcohol-based hand gel and standard hospital cleaners, norovirus is also addressed with handwashing with soap and water and bleach cleaning.

Another potential cause of health care–associated diarrhea is a foodborne outbreak, which can start with symptomatic food handlers or point-source food contamination that originates outside the facility.

TUBERCULOSIS

Tuberculosis **(Chap. 183)** requires special infection prevention and occupational health measures. Early identification, isolation, and testing of patients who may have active tuberculosis are critical steps in tuberculosis control in health care facilities. Patients with suspected or confirmed tuberculosis should be managed with airborne precautions (see "Transmission-Based Precautions"). Health care personnel managing patients with infectious tuberculosis use fit-tested particulate respirators, known in the United States and Canada as N95 respirators because they filter 95% of airborne particles, or powered air-purifying respirators that draw air through a HEPA filter into a hood.

Health care personnel should undergo preemployment screening for tuberculosis, preferably with an interferon-γ release assay rather than a tuberculin skin test due to its higher positive predictive value. Staff with positive tests should be evaluated further with symptom screening and chest imaging to assess for active or latent tuberculosis. Staff who have latent tuberculosis should be encouraged to undergo treatment to reduce the risk of reactivation and transmission to patients. In hospitals with high caseloads and local prevalence of tuberculosis, follow-up testing may be performed routinely among staff in certain disciplines. In most facilities, follow-up testing is event driven, such as following exposure to a patient with active tuberculosis.

FUNGAL INFECTIONS

MOLD INFECTIONS

Some immunocompromised hospitalized patients are highly susceptible to nosocomial mold infections, which are usually acquired through inhalation. Patients who will experience prolonged neutropenia during treatment of leukemia and stem cell transplant recipients require protective isolation rooms that are specially engineered with positive-pressure, HEPA-filtered airflow and sealed seams to repel mold spores, which, at 2–4 microns in size, are ubiquitous in dust and air currents. Vulnerable patients should wear masks when leaving their rooms to go to areas of the hospital that lack such measures. Exposure to hospital construction is a well-described risk factor for invasive fungal infections among immunosuppressed patients; thus, all construction sites within the hospital must employ negative airflow, HEPA filtration, sealed walls, and sticky doormats to minimize leakage of particles containing mold spores into patient care areas.

CANDIDA INFECTIONS

Candida infections represent the vast majority of health care–associated fungal infections. Many of these arise from endogenous sources in patients who are immunosuppressed, have undergone surgery, or have invasive devices in place. Although *Candida albicans* represent a majority of *Candida* infections, antifungal prophylaxis may select out non-albicans species such as *Candida glabrata*.

Candida auris Some *Candida* infections are attributed to exogenous transmission. *Candida auris* was first isolated in Japan in 2009 and subsequently emerged as a global nosocomial pathogen. Since the first U.S. case was identified in 2015, the incidence has increased steadily, with a sharp acceleration during the COVID-19 pandemic. *C. auris* has become an increasing cause of candidiasis in hospitals and in long-term care facilities where patients are mechanically ventilated. A multidrug-resistant species that is adapted to the health care environment, *C. auris* survives for extended periods on surfaces, and rapid recontamination from colonized persons makes sustained disinfection challenging.

Shared medical equipment such as glucometers, ultrasound machines, blood pressure cuffs, and axillary temperature probes are potential sources of transmission between patients, and thorough disinfection after each use is vital to prevent the spread of *C. auris*. Hand hygiene and contact precautions should be followed strictly when caring for a colonized or infected patient. The organism is resistant to some hospital disinfectant cleaners and requires use of select disinfectants. *C. auris* is of substantial public health concern, such that efforts to contain its spread require collaboration among infection control, public health, and laboratory experts on a facility, local, and regional basis. Patients transferred from long-term care facilities are often screened for *C. auris* by PCR or culture and isolated pending the results of screening **(Fig. 147-1)**.

THE HEALTH CARE BUILT ENVIRONMENT

Patients, staff, and visitors continually shed microorganisms into the built environment of a health care facility (surfaces and plumbing). Organisms are also introduced via the external environment, including potable water. Patients who are immunologically vulnerable may acquire pathogens from the built environment. Health care facilities must reduce their risk through adherence to current guidelines and through surveillance for such infections.

ENVIRONMENTAL CLEANING

Floors and frequently touched surfaces in health care facilities should be cleaned often with disinfectant cleaners in order to reduce the burden of communicable bacteria, viruses, and fungi. Patient care equipment (e.g., stethoscopes, portable x-ray cartridges) should be disinfected between patients to avoid becoming point sources for transmission of multidrug-resistant pathogens. Sporicidal cleaners and ultraviolet C light are often used as adjunctive methods for inactivating *C. difficile* spores and other tenacious pathogens. Clinical trial data suggest that standard cleaning plus adjunctive ultraviolet C may reduce nosocomial transmission of pathogens over cleaning alone.

WATER SAFETY

Waterborne infections arising from wastewater (drains and toilets) as well as potable water (sinks, showers, and fountains) pose a potential risk to vulnerable patients in health care facilities. Because many of these infections are preventable, hospitals are required to have a water management plan to anticipate and reduce risk to patients.

Tap water is not sterile, and contamination of potable hospital water and plumbing occurs most frequently when waterborne organisms (e.g., *Legionella pneumophila,* nontuberculous mycobacteria, and many others) colonize the biofilm within the pipes or cooling towers of a health care facility. Low disinfectant levels, warm temperature ranges, and stagnation of water promote organism growth, which can lead to transmission to patients via aerosols or droplets. Immunosuppressed patients are the most susceptible to waterborne infections; pneumonia in this patient population should be thoroughly investigated to include testing for waterborne infection.

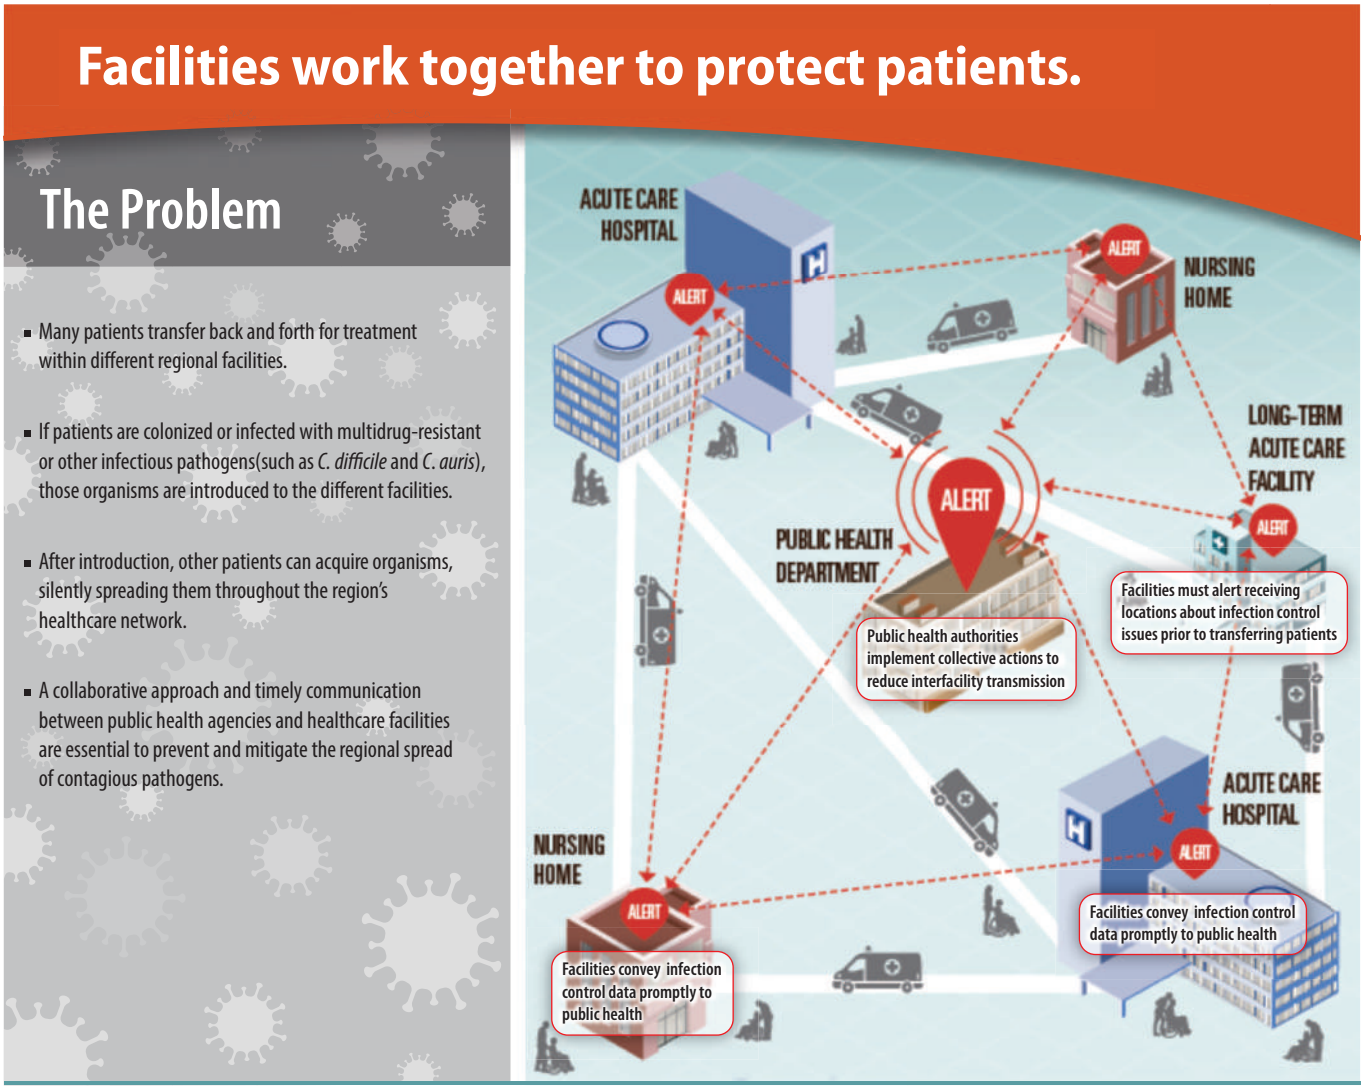

FIGURE 147-1 Regional spread and control of antimicrobial resistance. *(Modified from https://archive.cdc.gov/#/details?url=https://www.cdc.gov/vitalsigns/stop-spread/infographic.html.)*

In the case of nosocomial Legionnaires disease, detection of a single case should prompt a thorough investigation. In facilities with no history of an outbreak, routine hospital water testing for *L. pneumophila* is not strictly necessary if robust clinical surveillance is in place. Institutions that have had nosocomial cases should conduct regular water testing for the organism as part of their water management plan.

Wastewater drains in health care facility sinks, tubs, and showers, as well as toilets, serve as silent reservoirs for multidrug-resistant gram-negative organisms and can cause protracted outbreaks. These bacteria reach patients via transmission in droplets or aerosols of contaminated water from splashback, plumbing fixtures, or toilet flushing. Maneuvers to reduce risk include installing lids on toilets and angling sink faucets so water does not land directly on the drain.

Contamination of medications and medical devices can also lead to nosocomial outbreaks. In the past decade, outbreaks of nontuberculous mycobacterial infections among cardiac surgery patients have been linked to operative heater-cooler units that aerosolized the organisms from contaminated water tanks.

ANTIBIOTIC-RESISTANT BACTERIA

Implementing measures to stop the spread of multidrug-resistant organisms is a key priority for public health agencies and health care epidemiologists. Globally, 1.27 million deaths were attributed to antibiotic-resistant infections in 2019, with the highest rates in sub-Saharan Africa. According to recent estimates, infections due to methicillin-resistant *S. aureus* (MRSA) and extended-spectrum β-lactamase (ESBL) infections are the most common multidrug-resistant organism infections in U.S. hospitals. While improved infection prevention measures have led to a substantial reduction in MRSA, vancomycin-resistant *Enterococcus* (VRE), carbapenem-resistant *Acinetobacter*, and multidrug-resistant *Pseudomonas* infections, the prevalence of carbapenem-resistant Enterobacterales and ESBL-producing Enterobacterales has not declined. Infections due to multidrug-resistant organisms, which frequently colonize the human gastrointestinal and respiratory tracts, are associated with higher morbidity and mortality and other adverse clinical consequences such as extended hospital stays, transmission risk, and added health care costs. Without meticulous environmental disinfection, many of these organisms can establish enduring reservoirs in the hospital environment, effectively transmitting between patients and posing the risk of horizontal gene transfer among co-colonizing strains. Coordination of care during interfacility transfer of known patients with MDRO colonization is paramount to ensure timely implementation of infection prevention and control measures (Fig. 147-1).

Regardless of pathogen, frequent health care–related exposure, extended hospital stays, residence in long-term care facilities, multiple comorbid conditions, short- or long-term indwelling devices, and antibiotic exposure are among the key risk factors for multidrug-resistant organism acquisition. Additionally, community determinants can contribute substantially to spread of certain organisms. For example, people who use drugs, prison inmates, and those without stable housing conditions are at a greater risk of MRSA infections.

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS*

Among hospitalized patients, up to a third of MRSA-colonized individuals develop MRSA infection, and the risk in the pediatric ICU can be as high as 47%. MRSA is the most common health care–associated infection in neonatal ICUs. Transmission within facilities occurs through indirect contact with contaminated environments and sometimes from contaminated or colonized health care personnel. Screening, contact precautions, and education can reduce MRSA transmission, but most U.S. hospitals selectively deploy MRSA screening only in high-risk settings, including ICUs; dialysis, burn, and transplant units; and post–acute care facilities. Screening is also the fundamental approach to combat MRSA outbreaks.

Among the preventative practices assessed in ICUs, universal gowns and gloves and decolonization have reduced MRSA acquisition and infections. Universal decolonization is more effective than screening and contact precautions, with or without concurrent targeted decolonization with chlorhexidine bathing and 5-day nasal application of mupirocin. The advantages of decolonizing MRSA carriers extend beyond the hospital stay, and post–hospital discharge measures can reduce the short-term risk of MRSA infections in carriers by 30%. Still, this approach may not achieve sustained benefits over longer time periods.

Preventing postoperative and device-related MRSA infections is an essential surgical quality and safety goal for health care settings. A meta-analysis of 39 studies evaluated nasal decolonization and glycopeptide antibacterial prophylaxis before cardiac and orthopedic surgery, demonstrating a reduced risk of *S. aureus* infections with universal nasal decolonization and all gram-positive surgical site infections with a combined approach of decolonization and targeted antibacterial prophylaxis. Similarly, universal decolonization methods may be effective in non-ICU settings where there is high utilization of invasive devices to lower the risk of associated infections, including MRSA.

VANCOMYCIN-RESISTANT *ENTEROCOCCUS* (VRE)

Soon after VRE emerged in the U.S. in 1987, identifying carriers by screening for gastrointestinal carriage to institute contact precautions proved to be an influential early approach. This commonly applied method successfully controlled the regional spread of this pathogen while its prevalence in health care settings was still low. Initial animal studies and clinical observations established the critical role of antibiotic exposure to vancomycin, third-generation cephalosporins, and anti-anaerobic agents as risk drivers of VRE acquisition and overgrowth. Subsequently, microbiome analysis elucidated that a higher VRE colonization burden often precedes mucosal translocation in susceptible hosts, also influencing the number of bacteria shed in the environment that can facilitate person-to-person spread. Immunocompromised patients with hematologic malignancy, as well as stem cell and liver transplant recipients, are especially vulnerable to VRE colonization and infection. Over the years, VRE has become ubiquitous in many U.S. health care settings. Active surveillance and contact precautions offer minimal benefit in hyperendemic settings. However, the judicious use of antibiotics through robust stewardship measures and bundles incorporating chlorhexidine baths remain effective in reducing the impact of VRE by rendering colonized patients less infectious and decreasing the risk of invasive infection.

MULTIDRUG-RESISTANT GRAM-NEGATIVE BACTERIA

Multidrug-resistant gram-negative bacteria are increasingly common in health care settings. Chromosomally encoded resistance mechanisms and plasmid-carried resistance genes make them particularly challenging therapeutic targets. Multidrug resistance is defined as nonsusceptibility to at least one agent from three distinct antibacterial drug classes. Difficult-to-treat resistance is defined as resistance to all first-line antibacterial agents. Extensively drug-resistant organisms exhibit nonsusceptibility to two or fewer antimicrobials in all categories. Finally, pan-drug resistance is defined by the noneffectiveness of all antimicrobial agents. The rising incidence of drug-resistant gram-negative bacteria has been noted across all types of health care settings, carrying decreased survival compared with susceptible infections from the same species. Carbapenem-resistant Enterobacterales and *Acinetobacter baumanii*, multidrug-resistant *Pseudomonas aeruginosa*, and ESBL-producing *Escherichia coli* and *Klebsiella pneumoniae* are among the top threats.

Extended hospital stays, long-term care facility exposure, antimicrobials, medical devices, mechanical ventilation, and impaired immunity are frequent risk factors for acquisition of multidrug-resistant gram-negative bacteria. Outbreaks mainly occur in long-term care facilities, and hospital-based clusters tend to occur in intensive care, hematology-oncology, and liver transplant units. Inadequate disinfection of duodenoscopes due to their complex design has made them vulnerable to sterilization lapses, resulting in numerous outbreaks of multidrug-resistant gram-negative bacteria.

Aggressive control measures are among the cornerstones of prevention. Given an association between antimicrobial overuse and the emergence of multidrug-resistant gram-negative organisms, antimicrobial stewardship is a pivotal component in the strategies to prevent their emergence and spread. Targeted screening and contact precautions for rapid identification and isolation of gastrointestinal carriers have proven essential for outbreak management. Universal gown and glove use failed to reduce acquisition. Local epidemiology and international travel to hyper endemic areas, especially for medical care, are other important risk factors to consider when deciding on targeted screening practices. Finally, there are no proven decolonization strategies for multidrug-resistant gram-negative bacteria.

DIAGNOSTIC STEWARDSHIP

Diagnostic advances, including molecular technologies and high-throughput automated systems, have vastly enhanced clinical laboratory efficiencies and reduced the time to actionable information. However, rapid, convenient, and unrestricted testing can become problematic when used excessively for medically unnecessary investigations. From a health care–associated infection standpoint, inappropriate testing for *C. difficile* infection and excessive pursuit of urine cultures are pervasive problems in the current health care environment. Estimates show that as much as 40–60% of testing in hospitalized patients may not be medically indicated. Consequently, overtesting for these two common health care–associated infections leads to antibiotic overuse, patient distress,

TABLE 147-2 Diagnostic Stewardship Examples

	KEY FOCUS AREAS
Urine culture	• Educate clinicians on asymptomatic bacteriuria and appropriate indications to suspect urinary tract infection. • Require documentation of patient symptoms at the time of urine culture order placement. • Implement alerts to discourage testing when patient is asymptomatic, with exceptions (pregnancy, urologic procedures, etc.). • Consider algorithms that incorporate pyuria threshold (>10 white blood cells per high-power field) to proceed to culture in nonneutropenic patients. • Educate clinicians on appropriate methods for urine collection, storage, and transport for voided and catheterized urine. Avoid collection from the bag or a catheter that has been in place for an extended time.
Clostridioides difficile testing	• Set clinical criteria for testing: three or more unformed stools in 24 h in the absence of alternate etiology for the diarrhea. • Implement alerts that discourage an ordering clinician from testing when a patient is on laxatives. • Empower laboratory to reject specimens based on Bristol stool scale. • Apply auto-cancellation of test if sample is not received within 24 h or repeated within 7 days after a negative test or 14 days after a positive test. • Educate clinicians on the lack of utility of a test of cure. • Implement a two-step algorithm for testing including a toxin detection method.

TABLE 147-3 Health Care Personnel Immunizations

VACCINE	VACCINE TYPE	ELIGIBILITY	RECOMMENDATIONS
COVID-19	Non-live	All HCP	Per latest CDC recommendations
Influenza	Non-live	All HCP	Once annually
Hepatitis B	Non-live	HCP without serologic evidence of immunity or past infection	Two-dose series (Heplisav-B) or three-dose series (Engerix-B, PreHevbrio, or Recombivax HB)
MMR	Live	HCP without serologic evidence of immunity or past infection	Two doses at a 4-week interval
Varicella	Live	HCP without serologic evidence of immunity, clinician-verified history, or serologic evidence of past infection	Two doses at a 4-week interval
Tetanus-diphtheria-pertussis (TdaP)	Non-live	HCP without immunization in past 10 years Pregnant HCP	Single dose (booster every 10 years) With every pregnancy
Meningococcal	Non-live	Laboratory workers with potential exposure	Men ACWY (booster every 5 years) and MenB (booster at 1 year and every 2–3 years thereafter)

Abbreviations: CDC, Centers for Disease Control and Prevention; HCP, healthcare personnel; MMR, measles, mumps, rubella.

spurious inflation of publicly reported infection rates, and excess health care costs. Clinicians should use interventions implemented through the computerized clinical decision support systems. Lab measures such as reflex or multistep testing algorithms can address the potential harms of overtesting. Interventions based on the electronic health record yield better results than human interventions. Key strategies to reduce inappropriate testing are included in Table 147-2.

OCCUPATIONAL HEALTH

VACCINATION OF HEALTH CARE PERSONNEL

Health care personnel are at higher risk for acquiring certain vaccine-preventable illnesses and for transmitting infection to patients. The goals of vaccination are to provide personal safety, reduce the risk of occupational acquisition or transmission to preserve the workforce during periods of high community transmission, and protect vulnerable patients. Pathogens that pose a substantial risk of occupational transmission for which licensed vaccines are available include respiratory viruses such as influenza, COVID-19, measles and mumps, varicella, pertussis, hepatitis B, and meningococcus.

Vaccine eligibility is assessed at the time of employment, and the schedules for recommended immunizations are shown in Table 147-3. Additional risk-based vaccines may be recommended (e.g., Ebola, vaccinia, hepatitis A). Highly contagious illnesses such as measles and varicella have caused outbreaks in health care settings, disproportionately affecting underimmunized or unimmunized patients and health care personnel. Even with vaccines that have only moderate effectiveness against infection, higher vaccination uptake is associated with a lower risk of respiratory illness among personnel and a lower risk of nosocomial acquisition of these infections, especially in vulnerable patients. Numerous medical professional societies endorse mandatory health care personnel influenza immunization, and many facilities require it.

Health care personnel who provide direct care to patients should be tested for hepatitis B surface antibody 1–2 months after the last dose of the series and reimmunized if antibody levels are <10 mIU/mL. Nonresponders after repeat series are considered susceptible to hepatitis B and should be treated as such in the event of a bloodborne pathogen exposure.

BLOODBORNE PATHOGEN EXPOSURE

Since 1991, the U.S. Occupational Safety and Health Administration has promulgated a standard to regulate exposure to bloodborne pathogens. Advancements in engineering and workplace controls, such as needleless catheter systems, have made the use of medical devices safer, prevented sharps-related injuries, and reduced bloodborne pathogen transmission events. Despite this, exposure to potentially infectious agents in blood and other bodily fluids through contact with skin, eyes, and other mucous membranes remains a significant problem during health care delivery. HIV and hepatitis B and C acquisition after blood exposure are the most common concerning risks; semen, vaginal and rectal fluid, and breast milk can also pose a transmission risk. The risk of bloodborne pathogen transmission after contact with feces, urine, gastric and respiratory secretions, saliva, and sweat that is not contaminated with blood is exceedingly low. Significant exposures involve percutaneous injury or skin puncture with a much lower risk from contamination of nonintact skin and mucous membranes.

TABLE 147-4 Estimated Risk of Bloodborne Pathogen Transmission from Percutaneous Injury

PATHOGEN	RISK
Hepatitis B[a]	6–30%
Hepatitis C	1–3%
HIV[b]	0.3%

[a]Highest for hepatitis B e antigen positive. [b]If on effective treatment and with an undetectable viral load, the risk is negligible.

Among the three pathogens, hepatitis B transmits most effectively, with the estimated risks after percutaneous injury from needlesticks or other sharps shown in Table 147-4.

When managing personnel with a bloodborne pathogen exposure, a thorough history and risk evaluation and baseline serologic testing should be conducted. For significant potential hepatitis B exposures in nonimmune persons, hepatitis B immune globulin should ideally be given within 24 h and can effectively prevent transmission when administered up to 7 days from exposure. HIV postexposure prophylaxis must be started within 72 after possible exposure, and likely has diminishing efficacy the longer initiation is delayed. Serial testing for HIV, hepatitis B, and hepatitis C should be performed 6 weeks and 3 months after exposure, followed by testing for hepatitis C and HIV at 6 months if the exposed person is found to be immune to hepatitis B or received immune globulin.

With widespread vaccination, transmission of hepatitis B from health care personnel to patients is rare. Cases have occurred in the setting of occult hepatitis B with high-grade viremia and invasive procedures. Guidelines set out recommendations for management of clinicians infected with HIV, hepatitis B, and hepatitis C to minimize risks to patients. Unsafe medical device and medication management can spread infection between patients. Outbreaks and transmission events arise from improper disinfection of blood glucose monitors between patient uses, infection control breaches during dialysis, single-dose medication reuse, improper practices with multidose vials, and drug diversion. Such occurrences are entirely preventable with adherence to basic hygiene and patient safety practices.

148 Infections in Transplant Recipients

Jennifer M. Cuellar-Rodriguez, Juan C. Gea-Banacloche

GENERAL CONCEPTS

This chapter discusses infections in recipients of solid organ transplant (SOT), vascular composite allografts (VCAs), and hematopoietic stem cell transplantation (HCT). Despite the notable differences between these procedures, they share the fact that recipients receive immunosuppression (in the case of SOT and VCAs, for life). They become immunocompromised and, consequently, are at increased risk for infection.

Infections in immunocompromised patients may be caused by the common pathogens that affect everybody but also by opportunistic microorganisms that usually do not cause significant illness in healthy people. The physician taking care of transplant recipients should be aware of the risk of unusual pathogens, uncommon presentation of infections, and multiple concomitant infections. In addition, response to treatment may be suboptimal due to the effect of immunosuppressive medication and corticosteroids as well as coexisting medical or surgical complications. Professional societies issue and regularly update guidelines for the diagnosis and management of infections in these patients. For SOT, the reader is referred to the guidelines from the American Society of Transplantation Infectious Diseases Community of Practice and, for HCT, to the guidelines published by the American Society for Transplantation and Cellular Therapy and the European Conference on Infections in Leukemia (ECIL).

In this textbook, there are chapters dedicated to SOT **(Chaps. 271, 309, 325, and 356)**, HCT **(Chap. 119)**, and cellular therapy **(Chap. 483)**, as well as chapters about every one of the pathogens that will be mentioned here. Our goal is to focus on the particulars of infections as they pertain to transplant, as well as to discuss some relevant topics that are not included elsewhere. These include pretransplant evaluation of transplant candidates, assessment of potential donors, infections acquired through the transplant, and prophylaxis of infections.

Understanding the similarities between transplants regarding increased risk of infection (e.g., immunosuppressive agents) is important, as is understanding some of the basic differences. An obvious and relevant difference is that SOT and VCA transplants include surgical procedures, and the operations are extremely challenging. Most early infections are related to complications of the surgery, and sometimes even late infections may have their origin in the operating room. In contrast, early infections after HCT are related to the neutropenia induced by the conditioning regimen. Another difference is that both SOT and VCA transplants require lifelong immunosuppression to prevent rejection. This means the risk of opportunistic infection never goes away. Conversely, immunosuppression is not typically administered after autologous HCT (auto-HCT), and it is only given for a few months after allogeneic HCT (allo-HCT). Finally, both SOT and allo-HCT carry a risk of unfavorable immune reactions: rejection of the transplanted organ and graft-versus-host disease (GHVD), respectively. Both rejection and GVHD are treated by increasing the immunosuppression, with consequent increased risk of infection.

INFECTIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

HCT is a procedure in which a conditioning regimen that eliminates (partially or completely) the recipient's myeloid and lymphoid immune systems is followed by the infusion of hematopoietic stem cells, with subsequent recovery of bone marrow and immune function. It includes two distinct categories: auto-HCT and allo-HCT. Of the approximately 20,000 HCTs performed in the United States every year, 12,000 are autologous and 8000 allogeneic. In both, a conditioning regimen (variable combinations of chemotherapy, radiation, and serotherapy) is administered. This conditioning regimen eliminates the myeloid progenitors and the lymphoid immune system of the patient. Then, hematopoietic stem cells are administered to replenish both the myeloid and the lymphoid immune systems. In the case of autologous transplantation, the stem cells are from the recipient, harvested in advance and cryopreserved until the day of the transplant. This procedure does not correct defects present in the stem cells (e.g., hemoglobinopathies, primary immunodeficiencies) and, in the treatment of cancer, is not expected to cure a malignancy that is refractory to chemotherapy because the autologous stem cells have no anticancer potential. For malignancies still susceptible to chemotherapy, however, the intensive myeloablative conditioning regimen could be curative, while the infusion of autologous cells would effectively "rescue" the bone marrow. Conversely, in allo-HCT, the donor is another person, and their stem cells are free of whatever genetic defect the recipient's stem cells had. This means allo-HCT could, in principle, cure stem cell disorders. The reconstituted myeloid system, for instance, will be free of hemoglobinopathy. The reconstituted immune system should ultimately become immunocompetent. If a malignancy is being treated, there is potential for the new immune system to fight it and even eradicate it, through a now well-defined phenomenon called *graft-versus-leukemia* (GVL) or *graft-versus-tumor* (GVT) effect. From this standpoint, allo-HCT may be considered a form of immunotherapy, and it has been used to cure chemotherapy-refractory malignancies. There is also, unfortunately, the potential for the regenerated immune system to recognize the recipient as "alien" and to mount an immune response against their organs, which is called *graft-versus-host disease* (GVHD) and can be severe and even fatal. GVHD is common, affecting between 35 and 50% of allo-HCT recipients with varying severity (from mild to life-threatening). To prevent GVHD, allo-HCT recipients receive a few months of immunosuppression, which is then slowly tapered. GVHD is not expected to occur after auto-HCT, so no immunosuppression is administered after the stem cell infusion.

The biological difference between auto-HCT and allo-HCT dictates the different indications of each one. The vast majority of auto-HCTs performed are for multiple myeloma and lymphoma, malignancies that do not involve the stem cells. In this situation, the therapeutic intervention is the conditioning regimen, and the function of the infusion of stem cells (the transplant) is to replenish the myeloid progenitors eliminated by the conditioning. A minute fraction of auto-HCT is used or is being studied in select nonmalignant conditions that could potentially benefit from intense immunoablation. Auto-HCT was superior to standard immunosuppression for the treatment of severe systemic sclerosis in a randomized controlled trial and is also being used in selected patients with multiple sclerosis. It is also being investigated in systemic lupus erythematosus, rheumatoid arthritis, polymyositis/dermatomyositis, and Crohn disease.

The most common indication for allo-HCT is acute leukemia, followed by myelodysplastic and myeloproliferative disorders. It is also increasingly used for nonmalignant conditions including aplastic anemia, hemoglobinopathies (e.g., sickle cell disease, thalassemia), and primary immunodeficiency disorders (PIDs; also called inborn errors

of immunity [IEI]) including severe combined immunodeficiencies (SCID), phagocytic disorders such as chronic granulomatous disease, diseases of immune dysregulation such as familial hemophagocytic lymphohistiocytosis, and others.

Different conditioning regimens result in varying degrees of organ toxicity, including mucositis, and variable durations of neutropenia. In the case of allo-HCT, additional factors that impact the risk of infection include the source of stem cells (bone marrow, peripherally collected stem cells, or umbilical cord blood [UCB]) and the degree of human leukocyte antigen (HLA) matching and relatedness between the donor and the recipient (in increasing infection risk: matched sibling donor, matched unrelated donor, haploidentical donor, mismatched donor).

Infections are common after transplant and account for between 15 and 25% of the deaths in the first 100 days after auto-HCT and between 20 and 40% after allo-HCT, depending on the type of transplant. The risk factors for infection include preexisting conditions (intimately associated with the indication for transplant), conditioning regimen with its attendant neutropenia, mucositis and immunosuppression, and (in the case of allo-HCT) immunosuppression to prevent GVHD and, if this occurs, GVHD and its treatment. As mentioned earlier, however, and in distinction to SOT, most allo-HCT recipients do not receive lifelong immunosuppression. A few years after allo-HCT, a patient without chronic GVHD has an essentially normal immune system.

TIMELINE OF INFECTIONS AFTER HCT

Considerable experience over decades of transplantation has resulted in learning what the expected infections are and when they are supposed to occur. Anti-infective prophylaxis derives from this knowledge. Nomenclature varies, but we will consider very early infections (from initiation of the conditioning regimen until resolution of neutropenia), early infections (from neutrophil engraftment until day +100), and late infections (after day +100) **(Table 148-1)**.

Very Early Infections: Preexisting Infections, Baseline Condition, and Neutropenia We consider the "very early" phase of HCT to be the period between the initiation of the conditioning regimen and recovery from neutropenia (neutrophil engraftment). The intensity of the conditioning (which is classified as myeloablative, reduced intensity, and nonmyeloablative) results in different degrees and durations of neutropenia, mucositis, and immunosuppression.

During this time, bacterial infections related to neutropenia and mucosal barrier injury predominate, but one must also consider preexisting infections, both common and frequently known in patients undergoing transplant for PID (e.g., known diarrhea and cholangiopathy caused by cryptosporidiosis in patients with SCID) and potentially unknown and acquired during therapies received prior to transplant (e.g., pulmonary aspergillosis developed during induction therapy of acute myeloid leukemia but asymptomatic pulmonary nodules at the time of transplant). A pretransplant infectious diseases consult is recommended, when possible, as a review of previous records and imaging may be extremely useful for prevention, diagnosis, and management of infection. An etiologic diagnosis for abnormal findings should be pursued. A review of past infection or colonization with resistant pathogens may also provide actionable information, for instance, determining the choice of empirical antibiotics during neutropenic fever.

Fever during neutropenia (neutropenic fever) occurs in a large proportion of HCT recipients, depending on the conditioning regimen. Neutropenic fever is discussed in depth in **Chap. 79**, but a summary follows. Fever during neutropenia is considered infectious in origin even if no infection is identified in most cases. The management centers on the fact that bacterial infections may progress very quickly in the absence of neutrophils, so expediency is critical. A thorough physical exam should be performed, with emphasis on possible bacterial portals of entry (e.g., mouth, perianal region, catheter exit site); blood cultures should be obtained; and broad-spectrum antibiotics including activity against *Pseudomonas aeruginosa* should be initiated. Antibiotic choice varies with prior history (e.g., previous infection with multidrug-resistant [MDR] gram-negative bacteria or methicillin-resistant *Staphylococcus aureus*), the clinical presentation (e.g., localizing symptoms or signs, hemodynamic instability), and the local patterns of resistance. Once antibiotics are started, they are modified depending on new microbiologic data or changes in the clinical status. In general, persistent fever alone is not an indication to modify the antibacterial regimen. However, persistent fever while receiving broad-spectrum antibiotics identifies a subset of patients with higher likelihood of harboring invasive fungal disease (IFD), and a thorough search for IFD or modification of the antifungal regimen is indicated when neutropenic fever continues for >4 days.

Bacterial infections during this time are related to the degree and duration of neutropenia and the extent of the mucositis. Consequently, milder, nonmyeloablative conditioning regimens may result in less very early infections. Antibacterial prophylaxis (typically with a fluoroquinolone such as levofloxacin) decreases the frequency of neutropenic fever and is used by some groups, but there is growing concern about the long-term consequences of this practice (potential for worsening transplant outcome due to microbiome disruption), as well as colonization with resistant bacteria and *Clostridioides difficile* colitis. Currently, antibacterial prophylaxis during HCT is not universal.

Neutropenia during HCT is usually shorter than after induction of remission of acute leukemia. The most common early fungal infection after HCT used to be candidiasis, but now antifungal prophylaxis is almost universal. Prophylaxis with fluconazole decreases the likelihood of invasive candidiasis and improves survival in the allo-HCT setting. Fluconazole prophylaxis is most often used, but if the likelihood of aspergillosis is considered high, an agent with activity against mold, typically posaconazole, is used instead. *Aspergillus* and other molds are uncommon during short neutropenia, but there may be other factors that put the patient at risk. It should be noted that antimicrobial prophylaxis is

TABLE 148-1 Common Sources of Infection After Hematopoietic Stem Cell Transplantation

	PERIOD AFTER TRANSPLANTATION		
INFECTION SITE	VERY EARLY (<1 MONTH)	EARLY (BEFORE 100 DAYS)	LATE (>100 DAYS)
Disseminated	Aerobic bacteria (gram-negative, gram-positive)	*Candida, Aspergillus,* CMV, EBV, *Toxoplasma*	Encapsulated bacteria (*Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis*)
Skin and mucous membranes	HSV, *Candida*	HSV, VZV	VZV, HPV (warts)
Lungs	Aerobic bacteria (gram-negative, gram-positive), *Aspergillus,* other molds	CMV, community-acquired respiratory viruses, *Pneumocystis, Toxoplasma,* molds, adenovirus	Community-acquired respiratory viruses, *Pneumocystis, Nocardia, S. pneumoniae, H. influenzae* NTM (cGVHD)
Gastrointestinal tract	*Clostridioides difficile*	CMV, adenovirus, norovirus	EBV, CMV, norovirus
Genitourinary tract	BK virus	BK virus, adenovirus	
Brain		HHV-6, *Toxoplasma*	*Toxoplasma,* JC virus (rare)
Bone marrow		CMV, *Toxoplasma*	CMV

Abbreviations: cGVHD, chronic graft-versus-host disease; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV-6, human herpesvirus type 6; HPV, human papillomavirus; HSV, herpes simplex virus; NTM, nontuberculous mycobacteria; VZV, varicella-zoster virus.

never completely effective. Breakthrough infections may occur, such as non-albicans *Candida* when fluconazole is used or *Fusarium*, *Mucorales*, or other azole-resistant molds when posaconazole is used.

Risk of early *Pneumocystis jirovecii* pneumonia (PJP) varies with the indication for transplant and prior treatments, as well as with the conditioning regimen. For instance, a patient receiving allo-HCT for sickle cell disease is not at risk for PJP before receiving the conditioning regimen, whereas patients with immunodeficiency or heavily treated for acute lymphoblastic leukemia carry considerable risk. In most cases, prophylaxis against PJP is used. It is well accepted that trimethoprim-sulfamethoxazole (TMP-SMX) is most effective, and it can be used until the infusion of stem cells. After the stem cells are given, the potential for myelotoxicity and delayed engraftment makes other options (e.g., inhaled or intravenous pentamidine) preferable. Atovaquone may be used, but it is expensive, unpalatable, and requires a fatty meal for optimal absorption, which may be difficult during this phase of significant mucositis.

Herpes simplex virus (HSV) reactivation occurs early, associated with the mucositis caused by the conditioning regimen. Acyclovir prophylaxis is standard of care, and it effectively prevents HSV and varicella-zoster virus (VZV). Breakthrough HSV must be differentiated from mucositis caused by chemotherapy, and viral polymerase chain reaction (PCR) should be used. If HSV breaks through acyclovir prophylaxis and absorption is not an issue, acyclovir-resistant HSV should be considered. Decisions must be made clinically, since drug resistance can only be determined definitively by phenotypic testing, which takes weeks. Some instances of low-level resistance may be overcome by switching to high-dose (10 mg/kg per 8 h) IV acyclovir, but if this does not result in clinical improvement, foscarnet 60 mg/kg per 12 h or cidofovir 5 mg/kg weekly should be used.

Cytomegalovirus (CMV) infection is uncommon before engraftment and will be discussed in detail later, but in many centers, HCT recipients who are CMV seropositive start prophylaxis with the antiviral letermovir at the time of transplant. Of note, letermovir has no activity against HSV or VZV, so acyclovir should be administered concomitantly.

Early Infections: Between Neutrophil Engraftment and Day 100—Reactivation of Latent Infections and Complications of GVHD and Its Treatment During this phase, the patient has neutrophils but not a functioning lymphoid immune system. Potential infections include exogenous pathogens (e.g., community-acquired respiratory viruses), acquired when the patient is discharged from the hospital and reenters the community, as well as the reactivation of latent pathogens (e.g., herpesviruses, adenovirus, JC virus, and parasites such as *Toxoplasma gondii*). Despite neutrophil engraftment, the patient's lymphoid immune system was eliminated by the conditioning regimen, and the infused stem cells have not had time to create a functioning immune system. Other factors may impact the risk of infection. In the case of allo-HCT, there is usually ongoing immunosuppression with a calcineurin inhibitor (cyclosporine A or tacrolimus), sirolimus, or mycophenolate mofetil. The conditioning regimen may have included particularly immunosuppressive strategies such as serotherapy with antithymocyte globulin or alemtuzumab, which have a long half-life and may result in prolonged T-cell depletion that persists after engraftment. The source of the stem cells administered also plays a role: peripherally collected stem cells include more mature T cells than bone marrow, and these may offer some protection against latent pathogens. Ex vivo T-cell depletion (CD34 selection) is sometimes used and results in a product with even fewer mature T cells than bone marrow. UCB also lacks effective cellular immunity against infections latent in the recipient. Finally, if the patient develops acute GVHD, high-dose corticosteroids may be added to the immunosuppressive regimen, increasing the risk not only of latent infection reactivation but also of newly acquired bacterial and fungal infections. If GVHD does not respond to steroids, second-line agents may be added, compounding the immunocompromise of the patient.

BACTERIAL INFECTIONS Mucositis and neutropenia have resolved during this phase. Some patients still have a central venous catheter, with the attendant risk of catheter-related bloodstream infection. However, in the absence of GVHD, bacterial infections are relatively uncommon. Conversely, if acute GVHD of the bowel occurs, the patient is at risk of mucosal barrier injury–related bloodstream infection with bowel flora, particularly when high-dose corticosteroids are initiated. *C. difficile* infection is also common during this period and should be aggressively treated.

FUNGAL INFECTIONS Because neutropenia is no longer a factor, fungal infection during this time is usually associated with corticosteroid use, although other immunosuppressive agents used to treat acute GVHD may also increase the risk. Aspergillosis is the most common mold infection, and patients with GVHD on high-dose corticosteroids (i.e., >0.5 mg/kg of prednisone every other day) or on a combination of immunosuppressive agents frequently receive posaconazole prophylaxis, based on the results of a randomized controlled trial. Many authorities recommend monitoring serum posaconazole levels, particularly when absorption may be compromised by severe acute GVHD of the bowel. A level <700 ng/μL is considered subtherapeutic, but experts disagree on what levels are desirable for effective prophylaxis and/or treatment. The use of serologic markers of fungal infection (galactomannan and/or beta-D-glucan) is not recommended in this setting, as the sensitivity of the tests is markedly reduced when on mold-active azoles.

HERPESVIRUSES Herpesviruses may reactivate during this phase, particularly in the setting of T-cell depletion, UCB transplant, or GVHD and its treatment.

HSV and VZV are usually effectively prevented by acyclovir prophylaxis, but acyclovir-resistant HSV may occur (see the previous section). CMV disease may be prevented by prophylaxis or preemptive management and is discussed separately.

Human herpesvirus 6 (HHV-6), the cause of exanthem subitum (sixth disease) in children, is carried latently by most adults and reactivates frequently after HCT. Most of the time, reactivation is asymptomatic and goes undetected, since routine monitoring of HHV-6 is not recommended. However, it can sometimes cause encephalitis, which may be severe and result in significant morbidity and even death. It presents as limbic encephalitis, typically without a fever and initially with a clear sensorium but with short-term memory loss accompanied by tremor or other involuntary movements. It may progress to abnormal mental status, seizures, and coma. The diagnosis is made in the presence of signs and symptoms of encephalitis with detectable HHV-6 in the cerebrospinal fluid (CSF) and no other explanation for the disease. Brain magnetic resonance imaging (MRI) may be normal initially but later shows bilateral involvement of the amygdala on the temporal lobes. It is not clear whether treatment modifies the outcome, as HHV-6 tends to get under control in most patients without any intervention and affected patients frequently suffer significant long-term sequelae despite antiviral treatment. Guidelines recommend treatment with ganciclovir or foscarnet, although some experts recommend combining both antivirals. Other less well-established disease associations with HHV-6 include fever, GVHD, pneumonia, poor graft function, liver enzyme abnormalities, and thrombocytopenia.

Human herpesvirus 7 (HHV-7) is, like CMV and HHV-6, a betaherpesvirus. It may be detected by PCR in the blood of HCT recipients, but it is not known whether it causes any disease or is a co-factor in other infections such as CMV and HHV-6.

BK VIRUS BK virus, a polyomavirus that infects 80–90% of people, is associated with hemorrhagic cystitis after allo-HCT and, very seldomly, nephropathy. The clinical presentation includes dysuria and bladder spasms and hematuria, usually macroscopic. High-level BK viruria is usually present, but this may also happen without symptoms. The increasing use of posttransplant cyclophosphamide as prophylaxis for GVHD may make diagnosis difficult, as cyclophosphamide can cause hemorrhagic cystitis. There is no known effective treatment for BK virus after HCT, but hemorrhagic cystitis, albeit debilitating, is almost always self-limited. In severe cases, intravesical clots may cause obstructive uropathy and require continuous bladder irrigations.

Rarely, BK virus may cause nephropathy after allo-HCT. This entity is discussed in detail in the section on infections after SOT.

RESPIRATORY VIRUSES Besides the reactivation of latent viral infections expected during this period, once the patient is discharged after transplant, they are exposed to community-acquired respiratory viruses, which have significant mortality when they progress from upper respiratory tract infection to pneumonia.

Many respiratory viruses can cause significant morbidity after HCT. SARS-CoV-2, influenza, respiratory syncytial virus (RSV), metapneumovirus, and parainfluenza 3 may cause severe disease more often, but multiple enteroviruses and non–severe acute respiratory syndrome (SARS) coronaviruses may occasionally result in pneumonia. Only a few of these infections are amenable to antiviral treatment. Diagnosis usually relies on molecular methods (PCR of nasopharyngeal swab or nasal wash), but rapid viral culture (shell vial) is still used in some centers.

A general principle of viral infections is that controlling them (especially long term) requires the host's specific immunity, to a degree that bacterial infections do not. In this regard, decreasing the immunosuppression, if possible, is a standard part of the management. Unfortunately, this may not be possible in allo-HCT, particularly if the viral infection occurs in the setting of GVHD. If there is no GVHD, some consideration should be given to decreasing the dose of immunosuppressive drugs such as calcineurin inhibitors or sirolimus, which are usually carefully monitored through blood levels. Specific antiviral treatment recommendations follow.

Coronavirus Disease 2019 (COVID-19) U.S. Food and Drug Administration (FDA)-approved antiviral treatments for SARS-CoV-2 include remdesivir and nirmatrelvir-ritonavir (Paxlovid). In nonvaccinated, never-infected, non-immunocompromised patients with comorbid conditions or older than 60 years with COVID-19, nirmatrelvir-ritonavir given within 3 days of the onset of symptoms resulted in a 90% decrease on the risk of hospitalization or death. More recent studies including people who have been vaccinated and are not at high risk of progression have not confirmed these results. However, many experts still recommend nirmatrelvir-ritonavir for immunocompromised patients. Unfortunately, transplant recipients are frequently receiving medications such as tacrolimus or sirolimus that may make nirmatrelvir-ritonavir use impractical due to drug–drug interactions. The antiviral molnupiravir has an FDA emergency use authorization for the treatment of adults with mild-to-moderate COVID-19 who are at high risk for progression to severe disease and for whom other COVID-19 treatment options are not accessible or clinically appropriate. Most experts would at least consider antiviral treatment of COVID-19 in HCT recipients. Depending on the clinical setting, outpatient administration of IV remdesivir may be a more practical option. Bacterial superinfection is uncommon after COVID-19, but aspergillosis has been described. Risk factors for COVID-19-associated pulmonary aspergillosis include high-dose corticosteroids and hematologic malignancy but not necessarily transplant.

Influenza Virus Influenza may be treated with neuraminidase inhibitors (oseltamivir, zanamivir, or peramivir) or baloxavir, an inhibitor of the polymerase acidic (PA) protein. There are limited data to choose between these two options, but more experience with the former. Amantadine and rimantadine, only active against influenza A, are not currently recommended in the United States because of widespread resistance.

Respiratory Syncytial Virus RSV may be treated off-label with ribavirin, either orally or by inhalation. In RSV, lymphopenia (absolute lymphocyte count [ALC]) has been found to be a risk factor for the development of pneumonia, and some experts recommend using ALC <1000/μL as a guide to initiate early treatment with ribavirin.

Adenovirus Adenovirus occupies a particular place within this group, as it can represent a newly acquired community-acquired infection or be reactivation of latent virus from prior infection. Because adenovirus may be more common in children, some pediatric centers monitor high-risk patients by PCR of stool and/or blood and attempt intervention before established adenovirus disease ensues. Drugs with activity against adenovirus include cidofovir, brincidofovir, and (for some species) ribavirin. The response of established adenovirus disease to antivirals is poor.

As mentioned above, all respiratory viral infections may occasionally cause lower respiratory tract disease. When there is lower respiratory tract with any respiratory virus, a search for co-pathogens (bacterial or fungal) is indicated, as these are frequently present.

TOXOPLASMOSIS *Toxoplasma gondii* infects >2.5 billion people. The prevalence and routine monitoring after HCT vary significantly between countries. Studies from Europe suggest that allo-HCT recipients who have positive *Toxoplasma* serology reactivate frequently (8–21%) and early (95% within the first 6 months). The presentation may be just fever (this, in the presence of a positive *Toxoplasma* PCR, is often called toxoplasmosis infection), but also may include pneumonia (small pulmonary nodules and interstitial pneumonia predominantly at the lung bases), heart disease, brain abscess (single, multiple, or diffuse encephalitis), and disseminated disease sometimes associated with hemophagocytic lymphohistiocytosis. Diagnosis is by blood PCR and/or immunohistochemistry. The standard treatment is with pyrimethamine and sulfadiazine, but TMP-SMX may be equally effective. Atovaquone is a second-line agent, and there are anecdotal reports in advanced HIV of successful use of the combination of azithromycin and clindamycin.

Late Infections (After Day 100) Day 100 post-HCT remains an arbitrary boundary, as this is when tapering of immunosuppression usually begins. Conceptually, immune reconstitution takes place unimpeded by immunosuppressants, so the risk of infection should become progressively less. Most infections at this time are caused by community-acquired pathogens, although late CMV may also occur. The main risk factor for infection is the presence of GVHD and its treatment. Chronic GVHD (cGVHD) results in functional asplenia, and *Streptococcus pneumoniae* is a particularly important pathogen. Late fatal infections are predominantly bacterial, but respiratory viral infections such as influenza are still more common than in age-matched populations. The group at highest risk are patients with cGVHD receiving immunosuppression.

INFECTIONS AFTER SOLID ORGAN TRANSPLANT

RISK FACTORS FOR INFECTION AFTER SOLID ORGAN TRANSPLANT

Infectious complications remain a major cause of morbidity and mortality after SOT. The risk of infection is determined by the interaction of various factors, such as age of the recipient; type of transplant and technical complexities associated with it; other invasive procedures; dose, duration, and temporal sequence of immunosuppressive drugs; epidemiologic exposures of both donor and recipient; use of antimicrobial prophylaxis; donor-recipient serostatus to certain infections (e.g., CMV, Epstein-Barr virus [EBV], toxoplasmosis); and ongoing viral replication (so-called indirect effects). Assessment of a recipient's risk for infection helps tailor specific preventive strategies and workup when an infection is suspected.

Induction immunosuppression is usually administered immediately prior to transplantation. This is followed by maintenance immunosuppression, which frequently consists of triple therapy with a calcineurin inhibitor (cyclosporine A or tacrolimus) or an mTOR inhibitor (sirolimus or everolimus), mycophenolate mofetil, and corticosteroids. Maintenance immunosuppression may be intensified during periods of rejection, and it may be decreased with time, but it is usually continued for life. The amount of immunosuppression the patient is receiving is important in terms of risk of infection.

Age is also an important determinant of susceptibility to infections; it impacts the likelihood of prior exposures to microbial pathogens, either by primary infection or vaccination. History of exposure can have either positive or negative effects. Older patients are more likely to have encountered pathogens that can remain latent and reactivate at the time

of transplant (e.g., tuberculosis [TB]); younger patients have a higher risk of acquiring primary infections after transplant, sometimes from the transplanted organ, which tend to be more severe than those secondary to reactivation of a latent infection (e.g., CMV). In addition, preexisting immunity can have a protective effect against clinical disease (e.g., EBV-associated posttransplant lymphoproliferative disorder [PTLD]).

The type of allograft affects the specific infectious risk due to technical factors associated with the transplant procedure but also inherent to the transplanted organ and risk of rejection. For example, urinary tract infections are most common after kidney transplant, either from catheter placement or ureter stenting. BK virus is ubiquitous, but associated nephropathy (BK virus-associated nephropathy) is most common after kidney transplant and is an important cause of allograft loss. Infection after liver transplant frequently results from leaks of biliary and gastrointestinal anastomoses. Cardiac assist devices in heart transplant recipients are a frequent source of infection. Tracheal anastomotic infections, particularly due to fungi, are a significant complication of lung transplantation. In single-lung transplants, recurrent infections of the native lung, such as gram-negative bacilli or fungi, can extend to the transplanted lung. In small intestine transplant, opportunistic and nonopportunistic viral infections of the gastrointestinal tract are common; these can be severe and even life-threatening (e.g., norovirus).

TIME COURSE OF INFECTIONS AFTER SOLID ORGAN TRANSPLANT (TABLE 148-2)

Despite all the differences in individual risk of infection, some general patterns of infection in the absence of antimicrobial intervention are similar among SOT recipients. This predictable temporal pattern has enabled the institution of specific prophylactic strategies and is useful when developing an infection differential diagnosis.

Early Period: Infections in the First Month After Transplant Infections in this period are generally associated with technical complications of the transplant surgery and are nosocomial. Bacterial infections are most common during this time across all organs. Infections with prior colonizers (e.g., MDR bacteria) can occur, and bacterial prophylactic strategies should take these into account. Antimicrobial prophylaxis is usually started promptly after transplant. Hepatitis C occurs during this period when hepatitis C–positive donors are used. Opportunistic infections can happen in recipients with comorbid immunodeficiencies or those who received immunosuppression before transplant, but in the absence of these risk factors, the development of classic opportunistic infections during this early posttransplant period should alert to the possibility of donor allograft-transmitted infections (e.g., invasive coccidioidomycosis).

Intermediate Period: Infections 1–6 Months After Transplant In the absence of routine antimicrobial prophylaxis, this period is characterized by the presence of classic opportunistic infections, such as *P. jirovecii* and CMV. The incidence of these infections has been significantly reduced or delayed with the use of prophylaxis or preemptive therapy. Reactivation of latent infections such as TB, Chagas' disease, endemic mycoses, and cryptococcosis can occur, so it is important to ascertain the risk before transplant and implement specific prophylactic strategies. Viral infections such as BK virus, adenovirus, RSV, hepatitis B virus, and EBV are common. Invasive fungal infections, specifically *Aspergillus* and other mold infections, can be problematic during this period of heightened immune suppression, but risk varies significantly by type of organ transplanted. Donor-derived infections may still occur.

Late Period: Infections 6 Months After Transplant This period is less well defined. Patients with satisfactory allograft function may develop more severe manifestations of community-acquired infections. Prophylaxes are frequently stopped, since the risk of opportunistic infections is lower than in the earlier period. Patients with poor allograft function due to rejection receive increased immunosuppression and are at higher risk of opportunistic infections for a variable period thereafter. Frequently, antimicrobial prophylaxes are "reset" when an episode of acute rejection ensues. The type of rejection (e.g., cellular or humoral) and its specific management may influence the infection risk. Given that all SOT recipients need lifelong immunosuppression, increased risk of infection persists. Late-onset CMV, nocardiosis, PJP, listeriosis, invasive fungal infections, and EBV-associated PTLD are some examples of opportunistic infections that can be expected in these patients. Patients with ongoing chronic viral reactivation, particularly CMV, are also at increased risk of other opportunistic infections. In addition, lung transplant recipients with chronic graft dysfunction are at high risk of recurrent bacterial pneumonia. Similarly, liver transplant recipients with chronic graft dysfunction frequently develop biliary strictures and recurrent cholangitis. Over time, MDR bacteria can become a problem.

VASCULAR COMPOSITE ALLOGRAFTS

VCAs refer to transplantation as a single functional unit of multiple tissues, such as muscle, blood vessel and nerve bundles, and associated viscera or bone. Face, hand, and uterus are common examples. These procedures are increasing in frequency and complexity, but data regarding infection risk are still scarce and inferred from the known risk of SOT. Due to the highly complex anatomy of the allografts and their natural microbial colonization, bacterial infections are most common. Relevant infection prevention strategies are like those used in SOT, such as updated immunizations pretransplant, donor/recipient serologic screening, and targeted antimicrobial prophylaxis. Planning and in-depth communication between the organ procurement team, the surgical team, and an infectious disease consultant are important so that relevant cultures are obtained and results reported back. Surveillance cultures for targeted microbiologic diagnosis will vary depending on the transplanted tissue. For example, for face transplants, in addition to cultures of respiratory pathogens, sinus cultures for bacteria and fungi are routinely obtained. Similarly, in penile or uterine transplants, sexually transmitted infections such *Chlamydia* or human papillomavirus need to be explicitly ruled out.

Opportunistic infection risk is largely driven by the induction, maintenance, and intensification of immunosuppression due to the frequent rejection episodes. Systemic viral infections, in particular CMV and EBV, have been a significant problem after VCA; similar prevention strategies, as in other high-risk SOT recipients, are recommended. Fungal infections, such as cryptococcus or mucocutaneous candidiasis, may mimic rejection, which underscores the importance of establishing a histopathologic and/or microbiologic diagnosis and reassessing frequently. As the field of VCA continues to evolve, the risk of infectious complications needs to be continually assessed so that in the future we can better define its similarities and differences from other types of transplants.

DONOR-DERIVED INFECTIONS

Donor-derived infections (DDIs) can be expected or unexpected. Expected transmission to the recipient occurs with pathogens that are known to be present in the transplanted organ. Viruses such as CMV, EBV, hepatitis B virus, hepatitis C virus, and BK polyomavirus are examples. Preventive strategies such as targeted antimicrobial prophylaxis and access to highly specific molecular assays minimize the risk of end-organ disease and the overall impact on the recipient despite transmission. Global and regional health and transplantation societies provide detailed recommendations for adequate screening for certain blood and tissue donor-derived pathogens, such as HIV and viral hepatitis, and provide specific guidance for continued surveillance in recipients of donors with a history of IV drug use, unprotected sexual activity, multiple sexual partners, or incarceration within 30 days of potential donation. Recommendations often vary between organizations and countries. Transmission of unexpected infections occurs when pathogens not detected in an organ donor prior to organ recovery are transmitted to recipients. Screening donors for transmissible pathogens requires clinical and epidemiologic history as well as laboratory evaluation. Despite clinical and laboratory screening of potential donors for transmissible diseases, unexpected transmission of infection from donor to recipient remains an inherent risk of transplantation, predominantly of solid organ and composite tissue transplantation. Unexpected donor-derived diseases affect <1%

TABLE 148-2 Common Infections After Solid Organ Transplantation by Site of Infection and Transplant Type

INFECTED SITE	TYPE OF INFECTION	RISK FACTOR	MANAGEMENT
Transplanted organ	Bacterial and fungal infections of the graft, anastomotic site, and surgical wound	Prior colonization of the donor with MDR organisms	Institute targeted antimicrobial treatment as soon as prior colonization is known (peritransplant or immediately posttransplant). Source control (surgical or interventional radiology) and continued directed antimicrobials. Optimal duration after source control is unknown. Usual correlates of adequate treatment are clinical, laboratory, and radiologic resolution.
Surgical incision infection	Bacterial, yeast infections are most common; NTM (rare, mostly thoracic transplants)	Pain, erythema, discharge, or dehiscence of wounds, typically within the first 30 days posttransplant	Collection of microbiologic specimens for culture. Thorough washout and debridement. Imaging to evaluate for the presence of deeper infection. Antimicrobials should be adjusted based on microbiologic results, and duration guided by clinical response.
Intra-abdominal infections in liver transplant recipients	Bacterial and yeast infections	Secondary to biliary anastomoses leaks, or Roux-en-Y hepaticojejunostomy or other anastomoses that increase the risk of intestinal reflux into the biliary system; hepatic necrosis, from hepatic vascular thrombosis	Obtain blood cultures. Deep tissue or fluid cultures obtained intraoperatively or by IR. Source control. Antimicrobials adjusted based on microbiologic results (polymicrobial infections are the norm). Optimal duration of antimicrobials is unknown. Usual correlates of adequate treatment are clinical, laboratory, and radiologic resolution.
Intrahepatic infection in liver transplant	Recurrent cholangitis (bacteria and yeast)	Biliary strictures: anastomotic (acute) or nonanastomotic (chronic allograft rejection)	Biliary drainage and antimicrobials.
Urinary tract infections in kidney transplant	Recurrent cystitis and pyelonephritis (bacteria, in particular Enterobacteriaceae); *Mycobacterium tuberculosis* and yeasts are less frequent causes of UTI but should be suspected when there is pyuria and/or hematuria and negative cultures	Duration of indwelling urinary tract catheters, female recipients, as well as recurrent UTI prior to the transplant	Prompt catheter and ureteral stent removal. Targeted antimicrobials. If recurrent UTI, evaluate for anatomic abnormalities (ureteral reflux, ureterovesical junction stenosis, neurogenic bladder, bladder diverticulum).
Polyomavirus-associated nephropathy in kidney transplant	BK, rarely JC virus	Heightened immunosuppression, male recipient, older age, and a high BK viremia (>10,000 copies/mL)	The only effective intervention is reduction in immunosuppression. An allograft kidney biopsy is necessary when there is suspicion of rejection or a different infection.
Pneumonia and tracheobronchitis in lung transplant	Bacterial infections: severe or recalcitrant community-acquired viral pathogens (RSV, influenza, SARS-CoV-2); invasive mold infections; fungal tracheobronchial infection; NTM pulmonary disease	Pretransplant colonization with resistant organisms, requiring endotracheal intubation prior to the transplant, and mucociliary dysfunction, are significant risk factors for bacterial infections; CLAD is a risk factor for and a result of recurrent viral, bacterial, fungal, and mycobacterial infections	Early antimicrobial therapy if possible. For viral respiratory pathogens, prevention with seasonal annual vaccination is recommended, with monoclonal antibodies when available. In patients with CLAD, respiratory rehabilitation and pulmonary toileting.
Mediastinitis in thoracic organ transplants	Bacterial or *Candida* mediastinitis, with or without sternal osteomyelitis; less common *Nocardia* spp., NTM, or molds	Diabetes mellitus, surgical reoperation, and acute rejection	Deep tissue cultures (intraoperatively). Duration of antimicrobials is unknown. Correlates of adequate treatment are clinical, laboratory, and radiologic resolution.
Myocarditis, pericarditis, and cardiomyopathy in heart transplant	*Toxoplasma gondii* infection	Toxoplasma pretransplant serology D+/R–	Diagnosis is established by the identification of tachyzoites in the endomyocardial biopsy or PCR in tissue and/or pericardial fluid. Preemptive monitoring via blood PCR and TMP-SMX prophylaxis reduce incidence of disease.
	Trypanosoma cruzi	Pretransplant recipient seropositivity (hearts from seropositive donors are not used)	Clinical manifestations are fever, myocarditis, and painful skin lesions. Preemptive monitoring via blood PCR to detect early reactivation is indicated in all previously known seropositive recipients. Antitrypanosomal treatment (benznidazole or nifurtimox) for all patients with reactivation and tissue-invasive disease.
Infectious hyperammonemia syndrome in lung transplant (less commonly in other transplants)	*Ureaplasma* spp. systemic infection (less commonly *Mycoplasma* spp.) that results in encephalopathy due to high ammonia levels >200 μmol/L	Donor lung colonization	Targeted antimicrobial treatment and direct ammonia removal through renal replacement therapy, lactulose, and reducing enteral protein intake. Prevalence in transplanted organs is roughly 10%, and screening should be considered.

Abbreviations: CLAD, chronic lung allograft dysfunction; D+/R–, donor positive, recipient negative (serology); IR, interventional radiology; MDR, multidrug-resistant; NTM, nontuberculous mycobacteria; PCR, polymerase chain reaction; RSV, respiratory syncytial virus; TMP-SMX, trimethoprim-sulfamethoxazole; UTI, urinary tract infection.

of all transplant recipients, and most are infections. (Besides infection, donors may also transmit unsuspected malignancies and other conditions [e.g., hemochromatosis], but these are beyond the scope of this chapter and will not be discussed.) Unexpected DDIs occur predominantly in cadaveric donation, where screening of potentially transmissible infection is hampered by the incomplete assessment of the donor's risk. Almost all become apparent within 90 days of the transplant surgery. Overall mortality is around 15%, but it is much higher (30–50%) in some fungal (e.g., aspergillosis, coccidioidomycosis) and parasitic infections (e.g., strongyloidiasis, toxoplasmosis). The risk of DDI needs to be balanced against the growing number of patients on the transplant waitlist and their associated risks of mortality. The early diagnosis

of a DDI requires a high index of suspicion. Clinicians should be on alert to the possibility of an unexpected transmission. DDI should be considered when opportunistic infections happen outside the expected at-risk period, in the case of infections with no clear epidemiologic risk factors in the recipient, with unusual clinical syndromes, and with persistent undiagnosed fever, especially during the first 90 days. Transplant and infectious disease physicians should be alerted to clusters of infections in recipients from the same donor. When an unexpected DDI is suspected, besides prompt diagnosis and treatment in the recipient, immediate communication with public health authorities and the organ procurement organization is essential to decrease the risk of transmission/disease in other recipients.

Donors with a known or suspected active infection at the time of donation, such as pneumonia, urinary tract infection or bloodstream infection, may transmit the infection to the recipient. Living donors with an identified active infection should ideally be treated and transplantation delayed until infection resolves. In deceased donors, targeted antimicrobial prophylaxis for recipients is highly effective in preventing disease transmission when the infection is due to susceptible bacteria. Bacteremia in deceased donors is not uncommon, and studies have shown that, in adult recipients, donor bacteremia is not associated with adverse outcomes if a feasible treatment option exists. Bacterial meningitis carries a similar risk of transmission. Blood cultures should be obtained to rule out occult bacteremia in deceased donors, but bacteremia is generally not considered a contraindication to organ procurement and transplantation, unless no effective antimicrobial therapy is available. However, if the organ selected for transplantation is not infected or colonized and the donor is not bacteremic, the risk of transmission is low. These scenarios require careful analysis, and decisions should be individualized. The patient should be involved in deciding the acceptance of donors who may entail a higher risk for the recipient.

Meningoencephalitis in SOT recipients can be devastating. Viruses cause most cases, and effective antiviral treatments exist for only a few of these. Parasitic and fungal meningoencephalitis are also associated with significant morbidity and mortality. Development of meningoencephalitis or other neurologic syndrome in an SOT recipient, especially early after transplantation, should raise suspicion for DDI. Meningoencephalitis of unknown etiology in a donor is one of the few remaining absolute contraindications of transplantation. Even in patients in whom the etiology is suspected, caution is advised, and a comprehensive evaluation for infectious causes, with special consideration for opportunistic infection when the donor is from an endemic area, should be undertaken.

TB and endemic mycoses have been well-documented donor-transmitted infections and are associated with significant risk of mortality or graft loss. Routine screening is recommended in areas of endemicity or in other recognized high-risk scenarios for TB, such as incarceration, displacement, or homelessness. Screening in deceased donors is frequently limited by the extent of the medical history and time constraints.

IMPORTANT PATHOGENS IN TRANSPLANT RECIPIENTS

CYTOMEGALOVIRUS

CMV is the most important virus in both SOT and HCT recipients. CMV is usually acquired in early childhood and establishes latency for life in many different cell types, including endothelial cells and dendritic cells. Seropositivity for CMV (defined as positive anti-CMV IgG) varies by geographic region and ranges from 30 to 97%, increasing with age. CMV infection is defined as detection of the virus in the blood (typically by PCR, which has replaced the old pp65 antigenemia test). CMV DNA may be quantified in whole blood or in plasma, with results expressed in international units per microliter (IU/μL), and only results using the same test should be compared. CMV viremia is usually asymptomatic, but SOT recipients may develop a syndrome of fever, malaise, myalgias, moderate leukopenia with occasional atypical peripheral blood lymphocytes, and mild transaminitis concomitant with the detection of CMV in the peripheral blood. This is called CMV syndrome. Tissue-invasive CMV disease is diagnosed by histopathologic proof of invasion by the virus and tissue damage. Pneumonitis is the most feared end-organ disease after allo-HCT, and gastrointestinal disease is the most common, both after SOT and allo-HCT, but many other organs may be affected. Typically, CMV infection precedes development of disease by a few days, but sometimes CMV gastrointestinal disease occurs before the virus may be detected in the blood, or simultaneously. Clinically significant CMV infection is a term used in some clinical trials of CMV prophylaxis and includes invasive disease and/or a viremia level that triggers treatment with antivirals. Before widespread use of interventions aimed at reducing the incidence of CMV end-organ disease (i.e., pneumonitis, carditis, gastroenteritis, hepatitis), this occurred frequently during the first 1–6 months after transplantation and was associated with high morbidity and mortality. In addition, active CMV replication is associated with several "indirect effects," including increased rates of bacterial and fungal infection, increased graft dysfunction, transplant vascular disease, acute rejection, and, after HCT, increased GVHD and increased nonrelapse transplant-related mortality.

Avoiding CMV disease is an important part of transplant medicine. The process starts with donor selection, as the serostatuses of both donor and recipient are the main determinants of the risk of disease. In SOT, the highest risk is seen with a seropositive donor going into a seronegative recipient (D+/R–). In this setting, up to 50% of recipients may become viremic after prophylaxis is stopped, with lung, small bowel, pancreas, and combined kidney-pancreas having higher risks. After HCT, the highest risk is for seropositive recipients (who harbor the virus in many of their tissues) receiving stem cells from seronegative donors (D–/R+), 60–70% of whom may develop CMV viremia. When several donors are available, avoiding high-risk CMV serostatus combinations is part of the selection process. Once the transplant takes place, prevention of CMV disease can be achieved by two different strategies: universal prophylaxis or preemptive management. There are two strategies to prevent CMV disease after transplant: universal prophylaxis, in which every recipient at high risk is given antivirals (usually valganciclovir after SOT or letermovir after allo-HCT) for an arbitrary period (usually 3–6 months after SOT and 100 days after allo-HCT), or preemptive management, in which CMV is monitored in the blood weekly and anti-CMV treatment initiated when a particular level of viremia is detected. Of note, valganciclovir (a prodrug of ganciclovir) is active against HSV and VZV, but letermovir is not, so if letermovir is used, acyclovir or valaciclovir must be added for HSV/VZV prophylaxis. The tolerable level of viremia differs based on type of transplant, timing of the infection, and other factors that increase the risk of CMV disease. In UCB transplant or T-cell-depleted transplants, lower levels of viremia may trigger treatment, as the kinetics of viral replication and risk of progression to end-organ disease may be significantly higher in these patients. Randomized trials comparing both strategies have been performed only after allo-HCT for kidney and liver transplant but are not available for SOT involving other organs. Prophylaxis and preemptive treatment seem similarly effective in terms of overall mortality, and transplant centers may choose one over the other based on considerations such as logistics (more complicated with preemptive therapy) and cost (potentially higher with letermovir). Treatment of significant viremia is with ganciclovir or foscarnet. Cidofovir and maribavir are inferior, and the former is potentially more toxic. Ganciclovir and foscarnet are considered equally effective but differ in toxicity: ganciclovir has significant myelotoxicity, and foscarnet causes electrolyte abnormalities that usually cannot be managed in the outpatient setting, as well as nephrotoxicity. If viremia increases after 2 weeks of optimal antiviral treatment or if it does not decrease, the infection is considered "refractory" or "possibly refractory" CMV, respectively, and testing for genetic resistance to antivirals is recommended. The antiviral maribavir is FDA approved for resistant/refractory CMV, but its efficacy is only moderate, with <20% of patients with resistant/refractory CMV maintaining control of the virus at 16 weeks.

Invasive disease due to CMV varies with the type of transplant. After allo-HCT, CMV pneumonia is the most severe, but it is now uncommon with the use of prophylaxis or preemptive management.

Involvement of the gastrointestinal tract (most commonly CMV colitis, but any segment of the bowel may be affected) is more frequent, in part because the time between asymptomatic viremia and CMV colitis is shorter. After SOT, CMV reactivation may start in the transplanted organ in CMV-seropositive donors (e.g., CMV pneumonia in lung transplant, enteritis in small-bowel transplant). Hepatitis, retinitis, and, rarely, central nervous system (CNS) involvement (myelopathy, encephalopathy) may also occur.

Frequency of CMV monitoring after prophylaxis or treatment is completed is not well established. If available, immune monitoring, via commercially available CMV-specific interferon γ (IFN-γ) release assays that detect CMV-specific T cells in whole blood, may allow for more precise targeting of monitoring and prophylactic strategies.

EPSTEIN-BARR VIRUS

Most adults are infected with EBV, which remains latent in B cells. When an EBV-seropositive donor provides an allograft to an EBV-seronegative recipient (D+/R–), EBV infection (detection of EBV in blood or plasma) is very common. This primary EBV infection may be asymptomatic, present with end-organ disease such as hepatitis or enteritis, or cause a mononucleosis-like febrile illness with or without lymphadenopathy, atypical lymphocytes, and culture-negative exudative pharyngitis. EBV-associated PTLD is a heterogeneous group of clinical syndromes associated with uncontrolled lymphoproliferation (typically of B cells, but cases of natural killer– and T-cell EBV-positive PTLD occur), which ranges from polyclonal proliferation to true lymphoma containing clonal chromosomal abnormalities. The diagnosis requires tissue examination, which may show a polymorphic or monomorphic proliferation of B cells or even frank lymphoma. Risk of PTLD after SOT is greater in EBV-seronegative transplant recipients, who acquire a primary infection through the allograft. Consequently, this scenario is most common in pediatric transplant recipients. Viral burden within the lymphoid tissue of the transplanted organ appears to be a risk factor for PTLD, with intestinal transplant recipients at the highest risk and kidney lowest. EBV-positive PTLD is most frequent in the first year after SOT, but late PTLD incidence increases after 7–10 years and is related to duration of immunosuppression. Late PTLD can present as primary CNS lymphoma and gastrointestinal tract disease. EBV viral load monitoring and radiologic evaluation can assist in early diagnosis. Positron emission tomography/computed tomography (CT) imaging is useful in establishing lymph node or end-organ disease involvement, thus allowing for targeted tissue sampling to establish the diagnosis. In SOT, reduction of immunosuppression is the preferred initial treatment strategy. Rituximab is recommended next if the PTLD cells express CD20. Cytotoxic chemotherapy may be required. For refractory cases, adoptive immunotherapy with EBV-specific T cells, including chimeric antigen receptor T cells and third-party trained T cells, such as tabelecleucel, have been used. All donors and recipients should undergo EBV serologic testing before transplant. Preemptive monitoring of EBV viral load in high-risk (EBV D+/R–) SOT recipients is suggested, and reduction of immunosuppression is recommended in EBV viremic patients. Withdrawal of immunosuppression may trigger graft rejection. Specific viral load cutoffs that should trigger an intervention have not been established; there is considerable interlaboratory variability even with commercial EBV PCR assays. Serial monitoring with the same assay (e.g., whole blood or plasma) and the same laboratory is necessary to establish a trend. Rapidly rising EBV viral load is a significant risk factor for PTLD.

EBV-positive PTLD is an early complication of allo-HCT, occurring in the first 2–4 months. In this case, the virus is usually present in the recipient, and the risk is highest in EBV D–/R+ pair and cord blood stem cell source, although any D/R mismatch (D+/R– or D–/R+) in the setting of T-cell-depleted grafts is recognized as a significant risk. EBV D/R matching is recommended whenever possible. The overall frequency is ~3%, varying between 1% in matched sibling donor transplant to up to 10% in unrelated UCB transplants. The risk depends on the degree of T-cell depletion because it is the T-cell function after transplant (derived from the donor) that will control EBV. The management is like that described above, with the caveats that decreasing immunosuppression after allo-HCT may be difficult or impossible if GVHD is present and that, if the stem cell donor is available and is EBV positive, administration of lymphocytes from the donor (donor lymphocyte infusion) may be a successful strategy, as a significant fraction of the T-cell repertoire is directed against EBV. Donor-derived adoptive immunotherapy with EBV-specific T cells or off-the-shelf commercially available EBV-specific T cells, such as tabelecleucel, are increasingly used as second-line therapy.

POLYOMAVIRUSES

Polyomaviruses have been identified as frequent causes of allograft dysfunction in kidney transplant recipients. BK virus (BKV) and JC virus (JCV) are the most common pathogenic poliomaviruses that infect humans. BKV (most commonly) and JCV have been associated with tubulointerstitial nephritis and nephropathy, usually referred to as polyomavirus-associated nephropathy (PVAN). Ureteric stenosis and hemorrhagic cystitis can also occur. BKV infection is most common in kidney transplant recipients. Viruria is common, but some patients develop viremia, which in the absence of an intervention results in PVAN and allograft loss. The presumptive diagnosis of BKV nephropathy can be established with renal dysfunction and viremia, but acute rejection and PVAN can coexist and can be clinically indistinguishable. Definitive histopathologic diagnosis requires identification of viral cytopathic changes and immunohistochemistry for SV40 antigen or BKV-specific antigen detection in the tissue. Reduction of immunosuppression is the mainstay of treatment. Preemptive monitoring of BKV viral load can aid in the early detection of BK viremia; increasing viral loads are predictive of PVAN, and careful reduction of immunosuppression can prevent renal dysfunction and graft loss.

BKV after allo-HCT was discussed earlier, in the section on early infections after HCT, above.

After PVAN, PML caused by JCV CNS infection is the most common disease caused by polyomaviruses in SOT, although it is significantly less common than in other immunocompromised patients, such as those with advanced HIV. Diagnosis is established by a compatible neurologic syndrome, molecular detection of JC virus in the CSF, and radiologic evidence of demyelinating disease. As with other polyomavirus infections, no effective antiviral therapy exists, and reduction of immunosuppression is commonly employed, with overall poor response rates. Directed T-cell therapies are under development, and immune checkpoint inhibition (e.g., pembrolizumab) has been used successfully in some cases.

FUNGAL INFECTIONS

Invasive fungal infections are a common infectious complication in transplant recipients. Newer antifungals and corticosteroid-sparing immunosuppressive regimens have decreased the overall incidence of invasive fungal infections and improved outcomes. Invasive candidiasis is the most common invasive fungal infection in SOT recipients. Other fungal infections such as invasive aspergillosis, cryptococcosis, and endemic mycoses are also prevalent. In HCT, almost universal antifungal prophylaxis with activity against *Candida* has made mold infections relatively more frequent.

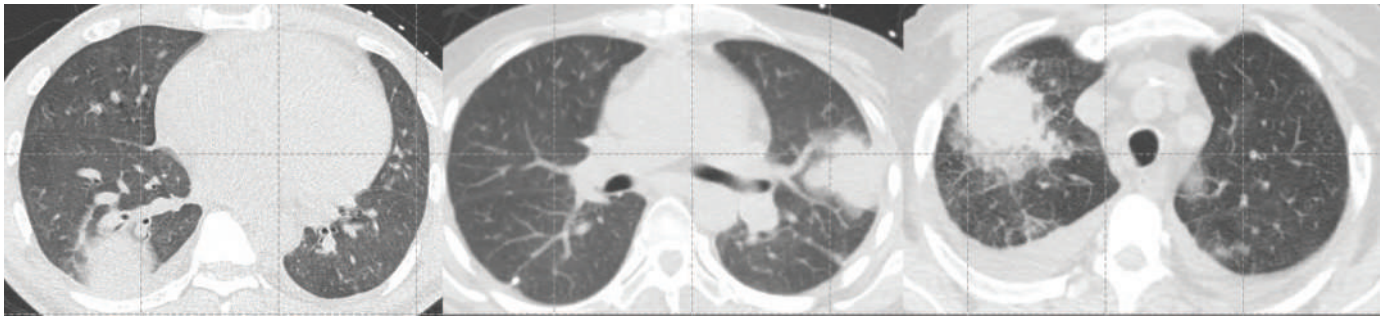
Candidiasis Invasive candidiasis is most often an early complication after SOT. Length of hospitalization, frequent use of broad-spectrum antimicrobials, intravascular catheters, renal replacement therapy, and critical illness are all risk factors for increased incidence of invasive candidiasis. Additionally, the complex nature of abdominal organ transplant surgical procedures increases the risk of invasive candidiasis. In liver transplant recipients, choledochojejunostomy, large-volume transfusion of cellular blood products (including platelets and packed red blood cells), reoperation, and retransplantation are all risk factors for invasive candidiasis. Pancreas transplantation with enteric drainage and small-bowel transplantation are particularly prone to be complicated by candidemia or invasive candidiasis. Targeted antifungal prophylaxis in liver, pancreas, and small-bowel transplant recipients is routine and decreases the incidence of invasive candidiasis.

All forms of invasive candidiasis in transplant recipients merit antifungal treatment, and echinocandins are the initial treatment of

choice, except in CNS disease or urinary tract infection. In addition to antifungal treatment, source control, such as catheter removal, and mechanical drainage of abdominal or surgical collections are the mainstay of successful treatment. Lung transplant recipients are at risk of invasive disease at the site of tracheal anastomosis, which can lead to anastomotic leak. Mycotic aneurisms of the main vessel of the allograft are associated with a high risk of rupture and usually represent a DDI or result from contamination of the preservation fluid. Early diagnosis and aggressive medical and surgical treatment are indispensable for overall survival.

Aspergillus and Other Molds Invasive pulmonary aspergillosis is the most common invasive mold infection in transplant recipients and the overall most common invasive fungal infection in lung transplant recipients. Airway and allograft colonization with *Aspergillus* spp. is a common but also invasive disease. Lung transplant recipients experience the full spectrum of *Aspergillus* spp. pathology, including tracheobronchitis, bronchial anastomotic infections, invasive pulmonary aspergillosis, and disseminated disease. Tracheobronchitis and bronchial anastomotic infections are characterized by ulceration and cartilage invasion. Dissemination, including to the brain, can occur and should be ruled out in all transplant recipients. Risk factors are single-lung transplant, lung transplant for cystic fibrosis, airway ischemia, rejection with increased immunosuppression, and chronic lung allograft dysfunction (CLAD). Risk factors for invasive aspergillosis (IA) in other SOTs include CMV infection and disease and degree of immunosuppression, such as high-dose corticosteroids for rejection. Retransplantation and posttransplant liver or renal hepatic failure, as well as prolonged neutropenia, increase the overall risk of IA.

Targeted antimold prophylaxis in those at high risk of IA is recommended. Monitoring serum galactomannan (GMN) does not perform well in SOT recipients. Targeted diagnostic bronchoalveolar lavage (BAL) GMN and serum GMN are preferred when there is suspicion of invasive disease. CT imaging can assist in the early diagnosis of IA. The CT findings are variable **(Fig. 148-1)**. Whereas dense, well-circumscribed pulmonary nodules, sometimes with halo sign, are characteristic in patients with hematologic malignancies, SOT recipients more frequently present with nonspecific pulmonary findings such as alveolar and centrilobular infiltrates, and the halo sign is almost never seen. Despite early diagnosis and treatment, the mortality associated with IA is still high. Other mold infections in SOT are less frequent but significantly more common than in nontransplant populations.



Aspergillosis after HCT is a complication of prolonged neutropenia or the use of high-dose corticosteroids for the treatment of GVHD. Prophylaxis with posaconazole is frequently used in patients receiving >0.5 mg/kg of prednisone every day or being treated for GVHD with two or more immunosuppressants. Some of the newer treatments for GVHD, such as ibrutinib and ruxolitinib, seem to significantly increase the risk of IA. Presentation is nonspecific with dyspnea, cough, and chest pain. Fever may be absent. Lack of systemic toxicity is frequent in mold infections. Establishing an accurate diagnosis is essential, since most mold infections can have similar presentations, and antifungal susceptibility varies significantly between molds.

Cryptococcosis With prolonged immunosuppression, SOTs are at risk of cryptococcal infection and disease. These tend to occur later after SOT, with most cases occurring between 1 and 3 years after the transplant. Earlier presentation should alert to the possibility of donor-derived cryptococcosis. Advanced liver disease is a risk factor for cryptococcosis, and liver transplant recipients may present earlier after transplant, especially if mental status changes peri-transplant were attributed to hepatic encephalopathy but no microbiologic workup was completed. Other presentations include skin papules or cellulitis, pneumonia, and asymptomatic or minimally symptomatic lung nodules. Both *Cryptococcus neoformans* and *Cryptococcus gattii* are known pathogens in SOT recipients. Serum cryptococcal antigen assay allows early noninvasive diagnosis but requires a high index of suspicion. In patients with CNS disease, both serum and CSF cryptococcal antigen are extremely useful in the early diagnosis of cryptococcal disease. In the evaluation of patients with mental status changes with or without fever or with cryptococcal disease outside of the CNS, patients should undergo a lumbar puncture with CSF opening pressure, as well as cell count and culture. These are useful for the diagnosis of CSF involvement, but also to evaluate the appropriate treatment response. Monitoring of cryptococcal antigen to determine the duration of therapy is not recommended because it may persist despite microbiologic and clinical resolution. Immune reconstitution inflammatory syndrome has been described in SOT recipients when immunosuppression is tapered aggressively in cryptococcal meningitis and may result in worsening of the initial symptoms despite microbiologic cure.

Cryptococcosis is less common after allo-HCT, probably due to the prevalence of antifungal prophylaxis.

Endemic Mycoses SOT recipients are second only to people with advanced HIV in terms of risk of disseminated endemic mycoses. Given its worldwide endemicity, histoplasmosis is the most common, but disseminated coccidioidomycosis, in particular CNS disease, is associated with higher mortality, and patients who survive usually require lifelong antifungal therapy. Invasive forms of all endemic mycoses have been described in transplant recipients.

Pneumocystis jirovecii PJP is an important complication of SOT and allo-HCT, and prophylaxis early after transplant is used routinely. Breakthroughs are uncommon if patients are receiving TMP-SMX but may be seen with second-line prophylaxis such as inhaled pentamidine or atovaquone. Lung transplant recipients retain a lifelong risk of infection. Acute or subacute shortness of breath, with significant hypoxemia, is the most common presentation. Radiologic changes may be subtle and out of proportion to the hypoxemia, with a broad alveolar-arterial gradient. Many radiologic presentations have been described, but the most common are ground-glass opacities. Nodules and atypical

A B C

FIGURE 148-1 Radiologic findings are often nonspecific in transplant recipients. ***A.*** *Nocardia* 3 months after kidney transplant in a patient who was not receiving trimethoprim-sulfamethoxazole. A fine-needle aspirate showed only necrosis, but the bronchoalveolar lavage (BAL) grew *Nocardia cyriacigeorgica.* ***B.*** Tuberculosis 3 months after heart transplant in a patient with known latent tuberculosis infection who was receiving isoniazid prophylaxis. The isolate of *Mycobacterium tuberculosis* was resistant to isoniazid. ***C.*** Aspergillosis in a neutropenic patient receiving allogeneic hematopoietic stem cell transplant for acute myelogenous leukemia. The BAL was positive for galactomannan, but the culture was negative. The mold was later identified as a non-fumigatus *Aspergillus* by next-generation sequencing of a surgical specimen.

consolidations have also been described, especially in patients who receive less effective prophylactic agents, such as inhaled pentamidine or atovaquone. Most patients with PJP have elevated β-D-glucan in serum. The definitive diagnosis is established by identification of *Pneumocystis* trophozoites in a respiratory sample from an induced sputum, a BAL, or a lung biopsy, but microscopy has low sensitivity, and increasingly, PCR in the BAL has become the diagnostic modality of choice. A positive PCR requires clinical interpretation because some patients may be merely colonized. During treatment, an immune reconstitution inflammatory syndrome (IRIS)-like condition can occur, so tapering of immunosuppression is usually not advised in transplant recipients newly diagnosed with PJP. The use of adjuvant corticosteroids in non-HIV patients with severe PJP remains controversial.

MYCOBACTERIAL INFECTIONS

Mycobacterium tuberculosis TB remains a major challenge and public health threat in transplant recipients. Incidence of active TB among SOT recipients is estimated to be 20–75 times higher than in the general population. Incidence varies significantly among different geographic regions and ethnic groups. Most cases occur between 6 and 12 months after the transplant and are associated with very high mortality; many more cases result in graft loss. Donor-derived TB has been also well documented after SOT, and these cases can present earlier after transplant. In contrast, TB after HCT is relatively uncommon and presents early within the first year after allo-HCT. In areas of medium or high endemicity, cases of active TB develop most commonly from reactivation of old foci of infection, but primary infection after transplant can also occur. Disseminated disease is common, and fever is the most common presenting symptom (>90%). In those with only pulmonary involvement, fever is present in ~60%. Involvement of every organ and atypical presentations have been reported (Fig. 148-1). Good-quality data regarding the optimal combinations of drugs and length of therapy are lacking in organ transplant recipients. Decisions are based on case series, recommendations for the general population and other immunocompromised individuals such as people living with HIV, and expert opinion. Most cases require 6–9 months of treatment, but in disseminated disease with CNS involvement, extrapulmonary TB, cavitary TB, or culture positivity after 2 months of treatment, 12–18 months of treatment are recommended. Daily therapy is recommended over intermittent dosing, given signals of higher relapse rates with intermittent dosing and concerns of less reliable immunosuppressive drug levels due to drug–drug interactions that may ultimately result in higher rejection rates or graft loss. Rifamycin-containing regimens are preferred for all types of TB due to the potent sterilizing activity of such regimens. Rifampin, the most used rifamycin, is a potent inducer of the cytochrome P450 enzyme, which increases the metabolism of many drugs, including calcineurin inhibitors (cyclosporine and tacrolimus), mTOR inhibitors (sirolimus and everolimus), and corticosteroids; its use has been frequently associated with acute rejection. Rifampin-based treatment is extremely problematic. Even though there is less experience with the use of rifabutin and it is not available worldwide, rifabutin is a weaker inducer of cytochrome p450, and drug interactions are significantly easier to manage than with rifampin. Other rifamycin-sparing treatment protocols can be used in organ transplant recipients to avoid drug–drug interactions; however, when a rifamycin is not used, shorter courses (6–9 months) should not be used. Use of a rifamycin is also highly desirable in patients with severe, disseminated, or cavitary disease. The initial treatment regimen should follow local recommendations based on local resistance patterns and tailored to available susceptibility data. Newer antituberculous antimicrobials have not been studied in transplant recipients but are promising. Reduction of immunosuppressive therapies, which help control the infection, should be done slowly if at all, as IRIS is a well-known complication of mycobacterial disease. If symptoms worsen with lowering immunosuppression, IRIS should be considered.

Prevention of TB after transplantation relies on adequately identifying those at risk of reactivation or recipients of an organ from a donor who has latent TB infection (LTBI) and treating LTBI. Screening relies on known epidemiologic exposures and probing the individual's immune response to TB antigens. There are two methods available for screening for prior TB exposure (for additional information, see **Chap. 183**), the tuberculin skin test (TST) and the IFN-γ release assays (IGRAs); both assays are less sensitive in immunocompromised hosts. In transplant candidates or recipients, a TST >5 mm is consistent with LTBI. Patients with prior positive bacillus Calmette-Guérin vaccination can have a positive TST from prior vaccination. In these patients, IGRA is preferable. End-stage renal disease, end-stage liver disease, and receipt of prior chemotherapies are all well-known risk factors that can lead to a false-negative TST or indeterminate results in the IGRAs. In patients with indeterminate results, the decision to treat LTBI should be made clinically, according to epidemiologic risk factors based on history. In patients with a negative TST, a second TST should be performed at about 2 weeks to look for a booster effect. An IGRA test can be performed after an initial negative TST in those at risk. In patients with evidence of LTBI by TST or IGRA, active TB should be ruled out before proceeding to transplant. Live donors should undergo a similar screening as recipients. TST and IGRAs may not be available on deceased donors; therefore, risk should be assessed based on a detailed history from the donor's family regarding previous active or latent TB and any treatment received and chest imaging.

All transplant recipients with LTBI should receive treatment. Consideration should be given to time to transplantation, drug–drug interactions with ongoing treatments, and potential toxicities. In patients in whom the transplant is unlikely to occur until at least 4–6 months, shorter courses are suggested (e.g., rifampin for 4 months or isoniazid plus rifapentine for 12 weeks). If the transplant is likely to occur sooner, isoniazid for 9 months is recommended. When possible, LTBI should be treated prior to transplantation; however, the transplant should not be delayed to complete treatment. For liver transplant candidates or HCT candidates receiving chemotherapy, treating prior to transplantation is challenging due to potential hepatoxicity or significant drug–drug interactions. In these patients, it may be safer to begin therapy after transplantation once liver function has normalized or the conditioning regimen has been completed. SOT recipients who received an organ from an untreated donor with known LTBI should also be treated. If a living donor has LTBI, treatment of the donor should prioritize their risk of progression to active TB following national guidelines for the treatment of LTBI.

Nontuberculous Mycobacteria Nontuberculous mycobacteria (NTM) are ubiquitous in the environment, and some species are important opportunistic human pathogens. Transplant recipients are at increased risk of NTM infection. The lungs are the most common site of infection and the most frequently colonized organ. Disease due to NTM can be separated into pulmonary, disseminated, catheter- and cardiac implantable electronic device–associated infection, surgical site deep-seated infection, and skin and soft tissue (SST) infections. Lung followed by heart transplant recipients are at highest risk of post-transplant NTM disease. Because structural lung disease increases the risk of colonization, allo-HCT recipients with cGVHD of the lungs are also at risk. Lung transplant candidates with cystic fibrosis or chronic obstructive pulmonary disease are at increased risk of being colonized or infected by NTMs, and pretransplant isolation of NTM is associated with increased risk of NTM disease after transplant. NTM disease is associated with increased mortality and CLAD. Most common infections are due to *Mycobacterium abscessus* and *M. avium* complex. Diagnosis of NTM disease from nonsterile sites, especially the respiratory tract, can be a challenge. Validation of criteria suggested for the routine diagnosis of pulmonary NTM in immunocompetent individuals is lacking in transplant recipients; however, these provide a useful framework for the diagnosis of pulmonary NTM in transplant recipients. In lung transplant recipients, the threshold for treatment of infection should be lower, given the high rate of infection, secondary dissemination, or development of CLAD. Treatment of NTM is complex and often compromised due to drug–drug interaction and drug toxicities. Species-level identification is necessary to design a treatment regimen. For detailed treatment strategies, the reader is referred

to Chap. 185 and American Thoracic Society/British Thoracic Society guidelines. The length of treatment should be guided by the specific clinical scenario; localized SST infections require shorter treatment durations, whereas pulmonary or disseminated NTMs require at least 1 year (frequently longer).

All patients with NTM infection pretransplant should start treatment before transplantation. Routine screening for NTM infection in lung transplant candidates is recommended, and those found to be colonized or infected should be treated, ideally for at least 3 months prior to proceeding to transplant. Rapidly growing NTMs, especially *M. abscessus,* have been associated with a high risk of deep surgical site infection and with frequent bone involvement. Treatment regimens should be based on species identification and susceptibility testing when appropriate, as well as stabilization of disease before transplant and ability to tolerate the designed regimen. Therapeutic drug monitoring can help to reduce toxicity. Bilateral lung transplant is preferred in those already colonized or infected with NTMs prior to transplant. Despite these measures, the risk of posttransplant infection is high, and the patient should be counseled about this risk.

Some PIDs that result in susceptibility to mycobacterial infection present with disseminated NTM or TB. Without successful replacement of the deficient immune system via allo-HCT, these infections are difficult to treat. Management of these infections is challenging; aggressive antimicrobial treatment is required before, during, and early after transplant. Ideally, infection and associated inflammatory response should be partially controlled prior to transplantation, which usually requires at least 3 months of treatment before the starting conditioning. Drug–drug interactions and drug toxicities in the peri- and posttransplant period are a challenge. In the first few months after engraftment, IRIS-like phenomena are common in patients being treated for active mycobacterial infection at the time of transplantation.

Definitive diagnosis of IRIS is a challenge, as there are no clear diagnostic criteria for this disease. Classically, there is worsening of symptoms or imaging at the site of prior infection that coincides with tapering of immune suppression. Adequate management requires ongoing treatment of the underlying infection, and augmented immunosuppression or anti-inflammatory therapy. Once symptoms are controlled, tapering of immunosuppression should be done slowly, taking into consideration other potential toxicities of ongoing immunosuppression and predisposition to other opportunistic infections.

NOCARDIOSIS

Nocardia is an aerobic gram-positive bacillus found in the soil that infects predominantly immunocompromised people. It is more frequently acquired by inhalation, although skin inoculation also occurs (typical with *Nocardia braziliensis*). The presentation varies from acute with fever, cough, and dyspnea, to subacute or chronic with night sweats and weight loss. Radiologic findings are commonly dense nodules, sometimes with cavitation, but a variety of pulmonary infiltrates may be seen (Fig. 148-1). Dissemination to the CNS occurs in 25% of cases and is frequently asymptomatic. Brain MRI is recommended in all patients with *Nocardia* to rule out brain abscess. Antibiotic susceptibility can be predicted based on species identification, but this may take time. All *Nocardia* species are susceptible to linezolid, so this antibiotic may be administered empirically until identification and susceptibilities are obtained. Most isolates are also susceptible to TMP-SMX, amikacin, and imipenem or meropenem. Combination of two or more antibiotics and long duration of treatment (usually 6–12 months) is recommended by many experts, but comparative trials are not available.

PREVENTION OF INFECTIONS IN TRANSPLANT RECIPIENTS

There are three different and complementary approaches to prevent infections after transplant: minimizing exposures (lifestyle modifications), immunizations, and chemoprophylaxis. Hand hygiene and avoiding sick contacts are some of the most impactful ways to avoid infection. Other suggested lifestyle modifications include recommendations for food and water safety, specifically making sure the drinking water is safe, avoiding raw or poorly cooked eggs and meat, and peeling or carefully washing fruits and vegetables. Hobbies and pets are important components of healthy rehabilitation after transplant, but some specific recommendations can make these safer and reduce the risks of infection. Examples of these are to avoid landscaping, gardening, and

TABLE 148-3 Prophylactic Regimens Commonly Used to Decrease Risk of Infection in Transplant Recipients

RISK FACTOR	ORGANISM	PROPHYLACTIC DRUG	EXAMINATION(S)[a]
Neutropenia, mucositis	*Candida*	Fluconazole	Candida is part of the normal GI flora; everyone with disruption of the mucosal integrity is at risk
Prolonged neutropenia, high-dose corticosteroids, enhanced immunosuppression	*Aspergillus* and other molds	Posaconazole	Blood tests (GMN, β-D-glucan) are less sensitive if triazoles are being administered and are always negative in mucormycosis
Travel to or residence in an area with known risk of endemic fungal infection	*Histoplasma*, *Blastomyces*, *Coccidioides*, *Talaromyces marneffei*	Triazoles considered in context of clinical and laboratory assessment	Chest imaging, antigen testing, serology
Chronic hepatitis B	HBV	Entecavir	HBV serology, HBV DNA
Chronic hepatitis C	HCV	Prophylaxis not used; treat to achieve persistent virological response	HCV serology, HCV RNA
Latent herpesviruses	HSV, VZV, significantly lower efficacy for CMV, EBV	Acyclovir or valacyclovir	Serologic tests for HSV, VZV, CMV, HHV-6, EBV, KSHV (HHV-8); PCR
	CMV	Letermovir (more experience in HCT) or valganciclovir (active against HSV and VZV)	
Exposure (unknown reservoir) or colonization	*Pneumocystis jirovecii*	Trimethoprim-sulfamethoxazole (TMP-SMX) Second line: dapsone, pentamidine, atovaquone	
Parasites	*Toxoplasma gondii* *Strongyloides stercoralis*	TMP-SMX or atovaquone for toxoplasma Ivermectin for *Strongyloides*	Serologic test for *Toxoplasma* and *Strongyloides*
LTBI	*Mycobacterium tuberculosis*	Isoniazid or rifampin in patients with recent seroconversion, positive chest imaging, or recent known exposure and no previous treatment, once active TB is ruled out	TST and/or IGRA; if indeterminate, clinical assessment of exposure and risk

[a]Serologic examination, TST, and IGRAs may be less reliable after transplantation.

Abbreviations: CMV, cytomegalovirus; EBV, Epstein-Barr virus; GI, gastrointestinal; GMN, galactomannan; HBV, hepatitis B virus; HCT, hematopoietic stem cell transplantation; HCV, hepatitis C virus; HHV, human herpesvirus; HSV, herpes simplex virus; IGRA, interferon γ release assay; KSHV, Kaposi's sarcoma–associated herpesvirus; LTBI, latent TB infection; PCR, polymerase chain reaction; TB, tuberculosis; TST, tuberculin skin test; VZV, varicella-zoster virus.

construction sites or to wear protective gear if this is not possible. Using a mask in encounters with high risk of aerosol transmission is recommended. There is a general recommendation against getting new pets for the first 6–12 months after transplant. Avoiding tick and mosquito bites is particularly important. Different professional societies provide advice to transplant recipients. In the United States, the American Society of Transplantation (AST) (*myast.org*) and the Centers for Disease Control and Prevention (*cdc.gov*) are useful resources. Available and required immunizations vary by country, and recommendations are modified as new vaccines and new data become available. Articles published in 2023 are provided in the "Further Reading" section, but updated information may be found in the AST website, and the CDC also presents the guidelines of the Advisory Committee on Immunization Practices. Specific prophylaxes against many infections have been presented in the text; a summary is presented in **Table 148-3**.

Section 4 Therapy for Bacterial Diseases

149 Treatment and Prophylaxis of Bacterial Infections

David C. Hooper, Erica S. Shenoy, Alyssa R. Letourneau, Ramy H. Elshaboury

Antimicrobial agents have had a major impact on human health. Together with vaccines, they have contributed to reduced mortality, extended life span, and enhanced quality of life. Among drugs used in human medicine, however, they are distinctive in that their use promotes the occurrence of drug resistance in the pathogens they are designed to treat as well as in other "bystander" organisms. Indeed, the history of antimicrobial development has been driven in large part by the medical need engendered by the emergence of resistance to each generation of agents. Thus, the careful and appropriate use of antimicrobial drugs is particularly important not only for optimizing efficacy and minimizing adverse effects but also for minimizing the risk of resistance and preserving the value of existing agents. Although this chapter focuses on antibacterial agents, the optimal use of all antimicrobials depends on an understanding of each drug's mechanism of action, spectrum of activity, mechanisms of resistance, pharmacology, and adverse effect profile. This information is applied in the context of the patient's clinical presentation, underlying conditions, and epidemiology to define the site and likely nature of the infection or other condition and thus to choose the best therapy. Gathering of microbiologic information is especially important for refining therapeutic choices based on the documented pathogen and susceptibility data whenever possible; this information also makes it possible to choose more targeted therapy, thereby reducing the risk of selection of resistant bacteria that can occur with use of agents with a broader spectrum of activity than needed for the patient. Durations of therapy are chosen according to the nature of the infection and the patient's response to treatment and are informed by clinical studies when they are available, with the understanding that shorter courses are less likely than longer courses to promote the emergence of resistance. This chapter and the one that follows provide specific information that is necessary for making informed choices among antibacterial agents. The mechanisms of action of antibacterial agents are discussed in detail in the text of this chapter, and mechanisms of resistance are discussed in detail in **Chap. 150**. Both types of mechanisms, which are related to each other, are summarized for the most commonly used groups of agents in **Table 150-1**. A schematic of antibacterial targets is provided in **Fig. 150-1**.

MECHANISMS OF ACTION (SEE TABLE 150-1)

Multiple essential components of bacterial cell structures and metabolism have been the targets of antibacterial agents used in clinical medicine, and the interaction of an agent with its target results in either inhibition of bacterial growth and replication (*bacteriostatic effect*) or bacterial killing (*bactericidal effect*). In general, targets have been chosen because they either do not exist in mammalian cells and physiology or are sufficiently different from their mammalian counterparts to allow selective bacterial targeting. Treatment with bacteriostatic agents is effective when the patient's host defenses are sufficient to contribute to eradication or sufficient reduction of the infecting pathogen. In patients with impaired host defenses (e.g., neutropenia) or infections at body sites with impaired or limited host defenses (e.g., meningitis and endocarditis), bactericidal agents are generally preferred.

INHIBITION OF CELL WALL SYNTHESIS

The bacterial cell wall, which is external to the cytoplasmic membrane and has no counterpart in mammalian cells, protects bacterial cells from lysis under low osmotic conditions. The cell wall is a cross-linked peptidoglycan composed of a polymer of alternating units of *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM), four-amino-acid stem peptides linked to each NAM, and a peptide cross-bridge that links adjacent stem peptides to form a net-like structure. Several steps in peptidoglycan synthesis are targets of antibacterial agents. Inhibition of cell-wall synthesis generally results in a bactericidal effect that is linked to cell lysis. This effect results not only from the blocking of new cell-wall formation but from the uninhibited action of cell wall–remodeling enzymes called *autolysins*, which cleave peptidoglycan as part of normal cell-wall growth and cell division.

In gram-positive bacteria, the peptidoglycan is the most external cell structure, but in gram-negative bacteria, an asymmetric lipid outer membrane is external to the peptidoglycan and contains diffusion channels called *porins*. The space between the outer membrane and the peptidoglycan and cytoplasmic membrane is referred to as the *periplasmic space*. Most antibacterial drugs enter the gram-negative

bacterial cell through a porin channel, since the outer membrane is a major diffusion barrier. Although the peptidoglycan layer is thicker in gram-positive (20–80 nm) than in gram-negative (1 nm) bacteria, peptidoglycan itself constitutes only a limited diffusion barrier for antibacterial agents.

β-Lactams The β-lactam drugs, including penicillins, cephalosporins, monobactams, and carbapenems, target transpeptidase enzymes (also called *penicillin-binding proteins* [PBPs]) involved in the stem-peptide cross-linking step. Inhibitors of β-lactamases—bacterial enzymes that can degrade β-lactams—are used in combination with some β-lactams to expand their spectrum of activity.

Glycopeptides and Lipoglycopeptides The glycopeptides, including vancomycin and teicoplanin, and the lipoglycopeptides, including telavancin, dalbavancin, and oritavancin, bind the two terminal D-alanine residues of the stem peptide, hindering the glycosyltransferase involved in polymerizing NAG–NAM units as well as transpeptidases. Vancomycin also binds to the lipid II intermediate that delivers cell-wall precursor subunits. The additional binding of teicoplanin, telavancin, dalbavancin, and oritavancin to the bacterial cytoplasmic membrane contributes to their increased potency. Both β-lactams and glycopeptides interact with their targets external to the cytoplasmic membrane.

Bacitracin (Topical) and Fosfomycin These agents interrupt enzymatic steps in the production of peptidoglycan precursors in the cytoplasm.

INHIBITION OF PROTEIN SYNTHESIS

Most inhibitors of bacterial protein synthesis target bacterial ribosomes, whose differences from eukaryotic ribosomes allow selective antibacterial action. Some inhibitors bind to the 30S ribosomal subunit and others to the 50S subunit. Most protein synthesis–inhibiting agents are bacteriostatic; aminoglycosides are an exception and are bactericidal.

Aminoglycosides Aminoglycosides (amikacin, gentamicin, kanamycin, netilmicin, streptomycin, tobramycin, and plazomicin) bind irreversibly to 16S ribosomal RNA (rRNA) of the 30S ribosomal subunit, blocking the translocation of peptidyl transfer RNA (tRNA) from the A (aminoacyl) to the P (peptidyl) site and, at low concentrations, causing misreading of messenger RNA (mRNA) codons, and thus cause the introduction of incorrect amino acids into the peptide chain; at higher concentrations, translocation of the peptide chain is blocked. Cellular uptake of aminoglycosides is dependent on the electrochemical gradient across the bacterial membrane. Under anaerobic conditions, this gradient is reduced, with a consequent reduction in the uptake and activity of the aminoglycosides. Spectinomycin is a related aminocyclitol antibiotic that also binds to 16S rRNA of the 30S ribosomal subunit but at a different site. This drug inhibits translocation of the growing peptide chain but does not trigger codon misreading and produces only a bacteriostatic effect.

Tetracyclines Tetracyclines (doxycycline, minocycline, tetracycline) bind reversibly to the 16S rRNA of the 30S ribosomal subunit and block the binding of aminoacyl tRNA to the ribosomal A site, thereby inhibiting peptide elongation. Active transport of tetracyclines into bacterial but not mammalian cells contributes to the selectivity of these agents. Tigecycline, a derivative of minocycline and the only available glycylcycline, acts similarly to the tetracyclines but is distinctive for its ability to circumvent the most common mechanisms of resistance to the tetracyclines. Other new tetracycline derivatives—eravacycline, a fluorocycline, and omadacycline, an aminomethylcycline—like tigecycline are notable for being little affected by prior common tetracycline resistance mechanisms.

Macrolides and Ketolides In contrast to the aminoglycosides and tetracyclines, the macrolides (azithromycin, clarithromycin, and erythromycin) and ketolides (telithromycin) bind to the 23S rRNA of the 50S ribosomal subunit. These agents block translocation of the growing peptide chain by binding to the tunnel from which the chain exits the ribosome.

Lincosamides Clindamycin is the only lincosamide in clinical use. It binds to the 23S rRNA of the 50S ribosomal subunit, interacting with both the ribosomal A and P sites and blocking peptide bond formation.

Streptogramins The only streptogramin in clinical use is a combination of quinupristin, a group B streptogramin, and dalfopristin, a group A streptogramin. Both components bind to 23S rRNA of the 50S ribosome: dalfopristin binds to both the A and P sites of the peptidyl transferase center, and quinupristin binds to a site that overlaps the macrolide-binding site, blocking the emergence of nascent peptide from the ribosome. The combination is bactericidal, but macrolide-resistant bacteria exhibit cross-resistance to quinupristin, and the remaining activity of dalfopristin alone is only bacteriostatic.

Chloramphenicol Chloramphenicol binds reversibly to the 23S rRNA of the 50S subunit in a manner that interferes with the proper positioning of the aminoacyl component of tRNA in the A site. This site of binding is near those of the macrolides and lincosamides.

Oxazolidinones Linezolid and tedizolid are the only oxazolidinones in clinical use. They bind directly to the A site in the 23S rRNA of the 50S ribosomal subunit and block binding of aminoacyl tRNA, inhibiting the initiation of protein synthesis.

Pleuromutilins Lefamulin is the only systemic pleuromutilin in clinical use. It binds to the peptidyl transferase center of the 50S ribosomal subunit and prevents the correct positioning of tRNAs, thereby inhibiting peptide bond formation and protein synthesis.

Mupirocin Mupirocin (pseudomonic acid) is used topically. It competes with isoleucine for binding to isoleucyl tRNA synthetase, depleting stores of isoleucyl tRNA and thereby inhibiting protein synthesis.

INHIBITION OF BACTERIAL METABOLISM

Available inhibitors (antimetabolites) target the pathway for synthesis of folate, which is a cofactor in a number of one-carbon transfer reactions involved in the synthesis of some nucleic acids, including the pyrimidine thymidine and all purines (adenine and guanine), as well as some amino acids (methionine and serine) and acetyl coenzyme A. Two sequential steps in folate synthesis are targeted. The selective antibacterial effect stems from the inability of mammalian cells to synthesize folate; they depend instead on exogenous sources. Antibacterial activity, however, may be reduced in the presence of high exogenous concentrations of the end products of the folate pathway (e.g., thymidine and purines) that may occur in some infections, resulting from local breakdown of leukocytes and host tissues.

Sulfonamides Sulfonamides, including sulfadiazine, sulfisoxazole, and sulfamethoxazole, inhibit dihydropteroate synthetase (DHPS), which adds *p*-aminobenzoic acid (PABA) to pteridine, producing dihydropteroate. Sulfonamides are structural analogues of PABA and act as competing enzyme substrates.

Trimethoprim Subsequent steps in folate synthesis are catalyzed by dihydrofolate synthase, which adds glutamate to dihydropteroate, and dihydrofolate reductase (DHFR), which then generates the final product, tetrahydrofolate. Trimethoprim is a structural analogue of pteridine and inhibits DHFR. Trimethoprim is available alone but is most often used in combination products that also contain sulfamethoxazole and thus block two sequential steps in folate synthesis.

INHIBITION OF DNA AND RNA SYNTHESIS OR ACTIVITY

A variety of antibacterial agents act on these processes.

Quinolones The quinolones include nalidixic acid, the first agent in the class, and newer, more widely used fluorinated derivatives (fluoroquinolones), including norfloxacin, ciprofloxacin, levofloxacin, moxifloxacin, gemifloxacin, and delafloxacin. The quinolones are

synthetic compounds that inhibit bacterial DNA synthesis by interacting with the DNA complexes of two essential enzymes, DNA gyrase and DNA topoisomerase IV, which alter DNA topology. Quinolones trap enzyme–DNA complexes in such a way that they block movement of the DNA replication apparatus and can generate lethal double-strand breaks in DNA, resulting in bactericidal activity. Although mammalian cells also have type II DNA topoisomerases related to gyrase and topoisomerase IV, the structures of the mammalian enzymes are sufficiently different from those of the bacterial enzymes that quinolones have substantially selective antibacterial activity.

Rifamycins Rifampin, rifabutin, and rifapentine are semisynthetic derivatives of rifamycin B and bind the β subunit of bacterial RNA polymerase, thereby blocking elongation of mRNA. Their action is highly selective for the bacterial enzyme over mammalian RNA polymerases.

Nitrofurantoin The reduction of nitrofurantoin, a nitrofuran compound, by bacterial enzymes produces highly reactive derivatives that are thought to cause DNA strand breakage. Nitrofurantoin is used only for the treatment of lower urinary tract infections.

Metronidazole Metronidazole is a synthetic nitroimidazole with activity limited to anaerobic bacteria and certain anaerobic protozoa. Reduction of its nitro group by the electron-transport system in anaerobic bacteria produces reactive intermediates that damage DNA and result in bactericidal activity. Both nitrofurantoin and metronidazole have selective antibacterial activity because the reducing activity needed to produce active derivatives is generated only by bacterial and not mammalian enzymes.

DISRUPTION OF MEMBRANE INTEGRITY

The integrity of the bacterial cytoplasmic membrane—and, in gram-negative bacteria, the outer membrane—is important for bacterial viability. Two bactericidal drugs have membrane targets.

Polymyxins The polymyxins, including polymyxin B and polymyxin E (colistin), are cationic cyclic polypeptides that disrupt the cytoplasmic membrane and the outer membrane (the latter by binding lipopolysaccharides, which are negatively charged).

Daptomycin Daptomycin is a lipopeptide that binds the cytoplasmic membrane of gram-positive bacteria in the presence of calcium, generating a channel that leads to leakage of cytoplasmic potassium ions and membrane depolarization.

PHARMACOKINETICS AND PHARMACODYNAMICS

The term *pharmacokinetics* describes the disposition of a drug in the human body, whereas *pharmacodynamics* describes the drug action on the pathogen in relation to pharmacokinetic factors. An understanding of the principles governing these two areas is required for effective drug selection, dosing, and prevention of toxicities.

PHARMACOKINETICS

The process of drug disposition consists of four principal phases: absorption, distribution, metabolism, and excretion. These phases determine the time course of drug concentrations in serum, tissues, and body fluids.

Absorption When a drug is administered, *absorption* is defined as the percentage of the dose that reaches the vasculature. The fraction of a drug, however, that reaches the systemic circulation or the pharmacologic site of action is termed *bioavailability*. The bioavailability is more relevant when non-IV routes are used—e.g., the oral, IM, SC, and topical routes. For example, since IV administration provides direct access to the systemic circulation, the bioavailability is therefore 100%. IV and oral dosing for highly bioavailable agents can result in equivalent systemic and tissue concentrations; examples of such agents include metronidazole, fluoroquinolones, tetracyclines, and linezolid. Additionally, many factors can influence oral bioavailability, including the timing of food consumption relative to drug administration, drug-metabolizing enzymes, efflux transporters, concentration-dependent solubility, and acid degradation. Underlying conditions such as diarrhea or ileus can also affect the site of drug absorption and thereby alter its bioavailability. Certain orally administered drugs may have lower bioavailability because of the *first-pass effect*—the process by which drugs are absorbed in the small intestine through the portal circulation and directly transported to the liver for metabolism before reaching their intended site of action.

Distribution *Distribution* describes the process of drug transfer reversibly between the general circulation and body tissues and fluids. After absorption into the systemic circulation and the central compartment (the extensively perfused organs), the drug also distributes into the peripheral compartment (less well-perfused tissues). The volume of distribution (Vd) is a pharmacokinetic parameter that describes the amount of drug in the body at a given time relative to the measured serum concentration. Properties such as the drug's lipophilicity, partition coefficient within different body tissues, protein binding, blood flow, penetration of the blood-brain barrier, and pH can affect the Vd and subsequently the concentration in various tissues. Drugs with a small Vd are limited to certain areas within the body (typically extracellular fluid), whereas those with a higher Vd penetrate extensively into tissues and organs. Some antibacterial drugs can bind to serum proteins, resulting in typically lower Vd as only the unbound (free) fraction of the drug distributes into body tissues and fluids. Furthermore, only the unbound fraction of the drug is considered therapeutically active and available to exert antibacterial effects.

Metabolism *Metabolism* is the chemical transformation of a drug by the body. This modification can occur within several areas; the liver is the organ most commonly involved. Drugs are metabolized by enzymes, but enzyme systems have a finite capacity to metabolize a substrate. If a drug is given in a dose at which the concentration does not exceed the rate of metabolism, the metabolic process is generally linear. If the dose exceeds the amount that can be metabolized, drug accumulation and potential toxicity may occur over time. Drugs are metabolized through phase I or phase II reactions. In phase I reactions, the drug is made more polar through dealkylation, hydroxylation, oxidation, and deamination. Polarity increases water solubility and facilitates removal from the body (e.g., renal elimination). Phase II reactions, which include glucuronidation, sulfation, and acetylation, result in larger and more polar compounds than the parent drug. Both phases usually inactivate the parent drug, although some drugs are rendered more active. The hepatic cytochrome P450 (CYP) enzyme system is mostly responsible for phase I reactions. CYP3A4 is a common subfamily within this system that is responsible for the majority of phase I metabolism. Antibacterial drugs can be substrates, inhibitors, or inducers of a particular CYP enzyme. Inducers, e.g., rifampin, can increase the production of CYP enzymes and consequently increase the metabolism of other drugs. Inhibitors, such as macrolides, cause a decrease in enzyme activity and therefore an increase in the concentration of the interacting drug by decreasing the rate of its metabolism.

Excretion *Excretion* describes the body's mechanisms of drug elimination. Drugs can be eliminated through more than one mechanism. Renal clearance is the most common route and includes elimination through glomerular filtration, tubular secretion, and/or passive diffusion. Some agents undergo nonrenal clearance and rely on the biliary tract or the intestine for excretion. Rate of excretion affects the half-life of a drug—i.e., defined as the time it takes for the blood concentration of a drug to decrease by one-half. This value can range from minutes to days. Half-life and overall drug clearance time can be extended if the organ responsible for clearance is impaired. For example, patients with renal or hepatic impairment may require dose adjustments that take delayed clearance into account to prevent drug accumulation and toxicity. For example, the majority of β-lactam agents are cleared predominantly through glomerular filtration, and in the presence of renal impairment, the dosing interval is typically increased to account for the increased half-life.

PHARMACODYNAMICS

The term *pharmacodynamics* describes the relationship between the drug concentrations that determine its efficacy and those that may produce toxic effects. For an antibacterial agent, the pharmacodynamic focus is the level of drug exposure needed for optimal antibacterial effect in relation to the minimal inhibitory concentration (MIC)—the lowest drug concentration that inhibits the growth of a microorganism under standardized laboratory conditions. Antibacterial effect usually correlates with one or more of the following parameters: (1) concentration-dependent killing (defined as the ratio of peak drug concentration to the MIC), (2) time-dependent killing (defined as duration of drug concentrations above the MIC), or (3) the area under the concentration–time curve to the MIC (AUC/MIC), a measure of the overall drug exposure during the dosing interval **(Fig. 149-1)**.

For *concentration-dependent* killing agents, as the designation implies, the higher the drug peak concentration (C_{max}) at the site of action, the higher the rate and extent of bacterial killing. Aminoglycosides fit into the C_{max}/MIC model of pharmacodynamics activity, and a particular measured peak serum concentration is often targeted to achieve optimal killing. In contrast, *time-dependent* killing agents reach a ceiling at which higher concentrations do not result in increased effect(s). Rather, these agents are active against bacteria when the drug concentration exceeds the MIC for a desired period of time. The T > MIC predicts clinical efficacy for all β-lactams. The longer the concentration of the β-lactam remains above the MIC for an infecting pathogen during the dosing interval, the greater the killing effect. Fluoroquinolones and vancomycin exemplify agents for which the AUC/MIC is a predictor of efficacy. For example, studies have found that an AUC/MIC ratio of >30 will maximize killing of *Streptococcus pneumoniae* by fluoroquinolones, whereas AUC/MIC ratios >125 are required to exert their optimal effects against gram-negative pathogens. Finally, for some antibacterial drugs such as aminoglycosides, a *postantibiotic effect*—the delayed regrowth of surviving bacteria after exposure to an antibiotic—supports less frequent dosing, increased drug-free intervals, and likely decreased drug-related toxicities.

APPROACH TO THERAPY

The approach to antibiotic therapy is driven by host factors, site of infection, and local resistance profiles of suspected or known pathogens. Further, national and local drug shortages and formulary restrictions can affect available therapies. Regular monitoring of the patient and collection of laboratory data should be undertaken to streamline antibacterial therapy as appropriate and to investigate the possibility of treatment failure if the patient fails to respond appropriately.

EMPIRICAL AND DIRECTED THERAPY

Therapy is considered *empirical* when the causative agent has yet to be determined and therapeutic decisions are based on the severity of illness, the clinician's assessment of likely pathogens in light of the clinical syndrome, the patient's medical conditions and prior therapy, and relevant epidemiologic factors. For patients with severe illness, empirical therapy often takes the form of an antibacterial combination that provides broad coverage of diverse agents and thus ensures adequate treatment of possible pathogens while additional data are being collected. *Directed* therapy is predicated on identification of the pathogen, determination of its susceptibility profile, and establishment of the extent of the infection. Directed therapy generally allows the use of more targeted and narrower-spectrum antibacterial agents than does empirical therapy.

Information on epidemiology, exposures, and local antibacterial susceptibility patterns can help guide empirical therapy. When empirical treatment is clinically appropriate, care should be taken to obtain clinical specimens for microbiologic analysis before the initiation of therapy and to adjust therapy as new information is obtained about the patient's clinical condition and the causal pathogens. Change to directed therapy can limit unnecessary risks of drug side effects as well as selection for antibacterial resistance and the risk of *Clostridioides difficile* infection and disease.

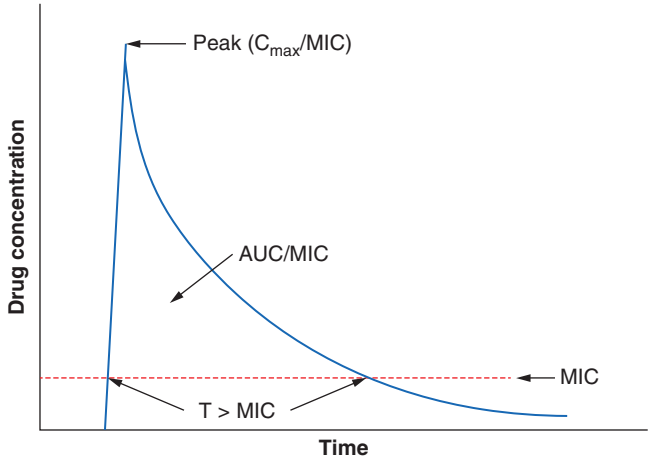

FIGURE 149-1 Pharmacokinetic and pharmacodynamic model predicting efficacy of antibacterial drugs. AUC, area under the time–concentration curve; C_{max}, peak serum concentration of drug; MIC, minimal inhibitory concentration; T > MIC, duration of drug concentrations above the MIC.

SITE OF INFECTION

The site of infection is a consideration in antibacterial therapy, largely because of the differing abilities of drugs to penetrate and achieve adequate concentrations at particular body sites. For example, to be effective in the treatment of meningitis, an agent must (1) be able to cross the blood-brain barrier and reach adequate concentrations in the cerebrospinal fluid (CSF) and (2) be active against the relevant pathogen(s). Dexamethasone, administered with or 15–20 min before the first dose of an antibacterial drug, has been shown to improve outcomes in patients with some types of acute bacterial meningitis, but its use may reduce penetration of some antibacterial agents, such as vancomycin, into the CSF. In this case, rifampin is added because its penetration is not reduced by dexamethasone. Infections at sites where pathogens are protected from normal host defenses, penetration of an antibacterial drug is limited, or local conditions (e.g., low pH) limit activity of some agents include, in addition to meningitis, osteomyelitis, prostatitis, intraocular infections, and abscesses. In such cases, consideration must be given to the route of drug delivery (e.g., intravitreal injections) as well as to interventions to drain, debride, or otherwise reduce bacterial load and necrotic material that can reduce antibacterial activity.

HOST FACTORS

Host factors, including immune function, pregnancy, allergies, age, renal and hepatic function, drug–drug interactions, comorbid conditions, and occupational or social exposures, should be considered.

Immune Dysfunction Patients with deficits in immune function that blunt the response to bacterial infection, including neutropenia, deficient humoral immunity, and asplenia (either surgical or functional), are all at increased risk of severe bacterial infection. Such patients should be treated aggressively and often broadly in the early stages of suspected infection pending results of microbiologic tests. For asplenic patients, treatment should include coverage of encapsulated organisms, particularly *S. pneumoniae*, that may cause rapidly life-threatening infection. For neutropenic patients, initial treatment typically includes antibacterial agents with broad activity against gram-negative bacteria.

Pregnancy Pregnancy affects decisions regarding antibacterial therapy in two respects. First, pregnancy is associated with an increased risk of particular infections (e.g., those caused by *Listeria*). Second, the potential risks to the fetus that are posed by specific drugs must be considered. As for other drugs, the safety of the vast majority of antibacterial agents in pregnancy has not been established, and such agents are grouped in categories B and C by the U.S. Food and Drug Administration (FDA). Drugs in categories D and X are contraindicated in pregnancy or lactation due to established risks. Note that in accordance with the Pregnancy and Lactation Labeling Final Rule (PLLR), drugs submitted to the FDA for approval after 2015 do not use the pregnancy risk categories. The risks associated with antibacterial use in pregnancy and during lactation are summarized in **Table 149-1**.

TABLE 149-1 Risks Associated with Use of Antibacterial Drugs in Pregnancy and Lactation

PREGNANCY CATEGORY[a]	ANTIBACTERIAL DRUG	FETAL RISK RECOMMENDATION[b]	BREAST-FEEDING RISK RECOMMENDATION[b]
B	Azithromycin	Limited human data. Animal data suggest low risk.	Limited human data; probably compatible
	Cephalosporins (including cephalexin, cefuroxime, cefixime, cefpodoxime, cefotaxime, ceftriaxone)	Compatible	Compatible
	Ceftazidime-avibactam	No human data; no fetal harm in animal studies	Ceftazidime is excreted into human milk in low concentrations. Avibactam is excreted into the milk of lactating rats; no human studies have been conducted.
	Ceftolozane-tazobactam	Compatible	Unknown
	Clindamycin	Compatible	Compatible
	Ertapenem	No human data; probably compatible	Limited human data; probably compatible
	Erythromycin	Compatible (except for estolate salt)	Compatible
	Meropenem and meropenem-vaborbactam	No human data. Animal data suggest low risk.	No human data; probably compatible
	Metronidazole	Human data suggest low risk.	Interrupt breast-feeding for 12–24 h after single 2-g dose. Limited human data; potential toxicity in divided doses
	Nitrofurantoin	Human data suggest risk in third trimester.	Limited human data; probably compatible. Higher risk associated with younger infants and those with G6PD deficiency
	Penicillins (including amoxicillin, ampicillin, cloxacillin)	Compatible	Compatible
	Quinupristin-dalfopristin	Compatible. Maternal benefit must far outweigh risk to embryo/fetus.	No human data; potential toxicity
	Vancomycin	Compatible	Limited human data; probably compatible
C	Chloramphenicol	Compatible	Limited human data; potential toxicity
	Fluoroquinolones	Human data suggest low risk.	Limited human data; probably compatible
	Clarithromycin	Limited human data. Animal data suggest high risk.	No human data; probably compatible
	Imipenem-cilastatin	Limited human data. Animal data suggest low risk.	Limited human data; probably compatible
	Linezolid	Compatible. Maternal benefit must far outweigh risk to embryo/fetus.	No human data; potential toxicity
	Telavancin	No human data. Animal studies have revealed evidence of teratogenicity.[c]	No human data. Animal studies have revealed evidence of teratogenicity[c]
	Tedizolid	Limited data. Embryo-fetal studies in mice, rats, and rabbits have demonstrated fetal developmental toxicities. Use only if benefit outweighs risk.	Excreted in the breast milk of rats; unknown in humans; caution use
	Dalbavancin	Limited human data. At high doses in animal studies, delayed fetal maturation, increased embryo and offspring death. Use only if benefit outweighs risk.	Excreted in the breast milk of animals; unknown in humans; caution use
	Oritavancin	Limited human data. Studies in rats and rabbits demonstrated no harm at 25% of recommended human dose. Use only if benefit outweighs risk.	Excreted in the breast milk of rats; unknown in humans; caution use
C/D	Amikacin	Human data suggest low risk.	Compatible
	Gentamicin	Human data suggest low risk.	Compatible
D	Kanamycin	Human data suggest risk.	Limited human data; probably compatible
	Streptomycin	Human data suggest risk.	Compatible
	Sulfonamides	Human data suggest risk in third trimester.	Limited human data; potential toxicity. Avoid in ill, stressed, premature infants and in infants with hyperbilirubinemia or G6PD deficiency.
	Tetracyclines	Contraindicated in second and third trimesters	Compatible
	Tigecycline	Human data suggest risk in second and third trimesters.	No human data; potential toxicity
Not assigned[d]	Cefiderocol	No controlled data in human pregnancy; animal studies have not provided evidence of fetal harm.	Unknown if excreted in human milk; excreted in animal milk.
	Eravacycline	No controlled data in human pregnancy; animal data indicate drug crosses placenta and is associated with risk at higher doses,	Unknown if excreted in human milk; excreted in animal milk. Not recommended during and for a period after treatment.
	Imipenem-cilastatin-relebactam	No controlled data in human pregnancy; animal studies have not revealed teratogenicity but have shown evidence of increased fetal loss.	Imipenem and cilastatin are excreted into human milk; no data on relebactam in human milk. Relebactam is excreted in animal milk. No human data regarding potential effect on infant.
	Lefamulin[e]	No controlled data in human pregnancy; animal studies have revealed evidence of fetal harm.	Unknown if excreted in human milk; excreted in animal milk. Breast-feeding is not recommended during use and for 2 days afterward.

(*Continued*)

TABLE 149-1 Risks Associated with Use of Antibacterial Drugs in Pregnancy and Lactation (Continued)

PREGNANCY CATEGORY[a]	ANTIBACTERIAL DRUG	FETAL RISK RECOMMENDATION[b]	BREAST-FEEDING RISK RECOMMENDATION[b]
	Meropenem-vaborbactam	No controlled data in human pregnancy; animal studies have revealed evidence of fetal harm (related to vaborbactam component).	Meropenem is excreted in human milk; it is unknown if vaborbactam is excreted in human milk. Data on excretion of vaborbactam in animal milk are unknown.
	Omadacycline	No controlled data in human pregnancy; however, as this is a tetracycline class antibiotic, may cause deciduous tooth discoloration and bone growth inhibition in second and third trimester of pregnancy; animal data have demonstrated embryofetal lethality, teratogenicity, and embryofetal toxicity.	Unknown if excreted in human milk; data not available regarding excretion in animal milk. Not recommended during and for a period after treatment.
	Plazomicin	No controlled data in human pregnancy; however, aminoglycoside antibiotics are known to cause fetal harm in pregnancy.	Unknown if excreted in human milk; excreted in animal milk.

[a] *Category B: Either* animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women; *or* animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester. *Category C:* Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. *Category D:* There is positive evidence of human fetal risk based on adverse-reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. [b] Fetal risk recommendation and breast-feeding risk recommendation adapted from GG Briggs et al (eds): *Drugs in Pregnancy and Lactation*, 9th ed. Philadelphia, Lippincott Williams and Wilkins, 2011; and the U.S. Food and Drug Administration (Drugs@FDA). [c] A registry has been established to monitor pregnancy outcomes of pregnant women exposed to telavancin. Physicians are encouraged to register pregnant patients, or pregnant women may enroll themselves by calling 1-855-633-8479. [d] The U.S. Food and Drug Administration is phasing out use of pregnancy categories A, B, C, D, and X. [e] A pregnancy pharmacovigilance program is available: If this drug is inadvertently administered during pregnancy or if a patient becomes pregnant while receiving this drug, healthcare providers or patients should report drug exposure by calling 1-855-5NABRIVA (1-855-56227482) to enroll.

Abbreviation: G6PD, glucose-6-phosphate dehydrogenase.

Allergies Allergies to antibiotics are among the most common allergies reported, and an allergy history should be obtained whenever possible before therapy is chosen. A detailed allergy history can shed light on the type of reaction experienced previously and on whether rechallenge with the same or a related medication is advisable (and, if so, under what circumstances). Allergies to the penicillins are most common. Although as many as 10% of patients may report an allergy to penicillin, studies suggest that >90% of these patients could tolerate a penicillin or cephalosporin. Adverse effects and intolerances **(Table 149-2)** should be distinguished from true allergies to ensure appropriate selection of antibacterial therapy.

Drug–Drug Interactions Patients commonly receive other drugs that may interact with antibacterial agents. A summary of the most common drug–drug interactions, by antibacterial class, is provided in **Table 149-3**.

Exposures Exposures, both occupational and nonoccupational, may provide clues to likely pathogens. When relevant, inquiries about exposure to ill contacts, animals, insects, and water should be included in the history, along with sites of residence and travel within a relevant time frame.

Other Host Factors Age, renal and hepatic function, and comorbid conditions are all considerations in the choice of, and schedule for, therapy. Dose adjustments should be made accordingly. In patients with decreased or unreliable oral absorption, intravenous therapy may be preferred to ensure adequate blood levels of drug and delivery of the antibacterial agent to the site of infection. In general, initial treatment for severe and life-threatening infections is given by intravenous injection to assure prompt and adequate drug delivery.

DURATION OF THERAPY

Whether empirical or directed, the duration of therapy should be established in most clinical situations. Guidelines that synthesize available literature and expert opinion provide recommendations on therapy duration that are based on infecting organism, organ system, and patient factors. For example, the American Heart Association has published guidelines endorsed by the Infectious Diseases Society of America (IDSA) on diagnosis, antibacterial therapy, and management of complications of infective endocarditis. Additional guidelines from the IDSA in collaboration with other specialty societies, such as the Society of Healthcare Epidemiology of America, the American Thoracic Society, and the European Society for Clinical Microbiology and Infectious Diseases, exist for a range of infectious syndromes and specific pathogens. In general, where data on adequate durations of therapy exist, shorter courses are preferred to reduce the likelihood of drug adverse effects and selection of resistant bacteria.

FAILURE OF THERAPY

If a patient does not respond to therapy, investigations often should include imaging and the collection of additional specimens for microbiologic testing as indicated. Failure to respond can be the result of an antibacterial regimen that does not address the underlying causative organism, the development of resistance during therapy, or the existence of a focus of infection at a site poorly penetrated by systemic therapy. Some infections may also require surgical interventions (e.g., large abscesses, myonecrosis). Fever due to allergic drug reactions may complicate assessment of the patient's response to antibacterial treatment.

EXPERT GUIDANCE

Selected websites with the most up-to-date information and guidance for the clinician include the following:

- Johns Hopkins ABX Guide (*www.hopkins-abxguide.org*)
- IDSA Practice Guidelines (*https://www.idsociety.org/practice-guideline/practice-guidelines*)
- One Health Trust Resistance Map (*https://resistancemap.onehealthtrust.org/index.php*)
- Centers for Disease Control and Prevention Antibiotic/Antimicrobial Resistance (*www.cdc.gov/drugresistance/*)

CLINICAL USE OF ANTIBACTERIAL AGENTS

The clinical application of antibacterial therapy is guided by the spectrum of the agent and the suspected or known target pathogen. Infections for which specific antibacterial agents are among the drugs of choice are listed, along with associated pathogens and susceptibility data, in **Table 149-4**. Resistance rates of specific organisms are dynamic and should be taken into account in the approach to antibacterial therapy. While national resistance rates can serve as a reference, the most useful reference for the clinician is the most recent local laboratory antibiogram, which provides details on local resistance patterns, often on an annual or semiannual basis.

β-LACTAMS

The β-lactam class of antibiotics consists of penicillins, cephalosporins, carbapenems, and monobactams. The term *β-lactam* reflects

TABLE 149-2 Common Adverse Reactions to Antibacterial Agents

ANTIBACTERIAL(S)	POTENTIAL ADVERSE EFFECTS	COMMENTS
β-Lactams	Hypersensitivity reactions	Ranges from rash to anaphylaxis. Cross-reactivity among β-lactams is related to chemical structure and side chain similarity.
	Neurotoxicity	More commonly described with cefepime and imipenem, but likely a class effect. Risk is increased in patients with history of seizures, renal impairment, and advanced age.
	Neutropenia/hematologic reactions	May be related to high doses and prolonged duration
Vancomycin	Nephrotoxicity	Risk increases with vancomycin trough levels >20 μg/mL or concomitant administration with other potentially nephrotoxic agents. The effect is usually reversible.
	"Red man syndrome"	Can be managed with a slower vancomycin infusion and pretreatment with antihistamine
Telavancin	QT prolongation	
	Interference with coagulation tests	May falsely affect INR, PT, aPTT. Perform these tests before the next dose of telavancin (when serum drug levels are at their nadir).
	Taste disturbances	
	Nephrotoxicity	
Oritavancin	Interference with coagulation tests	May falsely affect INR, PT, aPTT. Perform these tests at least 24 h after the dose is administered.
	Gastrointestinal distress	
Dalbavancin	Gastrointestinal distress	
Daptomycin	Myopathy	Monitor CPK levels during therapy. Rhabdomyolysis has been reported but appears to be rare.
	Eosinophilic pneumonia	
Aminoglycosides	Nephrotoxicity	Associated with prolonged use; usually reversible
	Ototoxicity	Can cause both vestibular and cochlear toxicity. Ototoxicity may be irreversible.
Fluoroquinolones	QT_c prolongation	Moxifloxacin appears more likely than other quinolones to exert this effect. Risk of arrhythmia increases when these drugs are given concomitantly with other QT_c-prolonging agents.
	Tendinitis	Risk is greater among the elderly and patients receiving steroids.
	Dysglycemia	
	Exacerbation of myasthenia gravis	
Rifampin	Hepatotoxicity	Risk is greater when drug is given with other antituberculosis agents. When rifampin is given alone, LFT values may be transiently elevated without symptoms.
	Orange discoloration of body fluids	
Tetracyclines, including tigecycline, eravacycline, and omadacycline	Photosensitivity	
	Gastrointestinal distress	High incidence of diarrhea, nausea, vomiting
Macrolides	Gastrointestinal distress	Erythromycin is occasionally used as a therapeutic agent for some gastric motility disorders.
	QT_c prolongation	Azithromycin use is associated with an increased risk of death from cardiovascular causes among patients at high baseline risk.
Metronidazole	Peripheral neuropathy	Associated with prolonged use
Clindamycin	Diarrhea and pseudomembranous colitis	
Linezolid, tedizolid	Myelosuppression	Associated with prolonged use
	Optic and peripheral neuropathy	Associated with prolonged use
	Lactic acidosis	
TMP-SMX	Hypersensitivity reactions	Allergy usually associated with sulfonamide moiety
	Nephrotoxicity	Associated with high doses
	Hematologic effects	Associated with prolonged use
Nitrofurantoin	Pneumonitis and other pulmonary reactions	Associated with prolonged use
	Peripheral neuropathy	Associated with accumulation of nitrofurantoin in renal failure. Avoid use in renal impairment.
Fosfomycin	Gastrointestinal effects	
Polymyxins	Nephrotoxicity	Associated with high dose
	Neurotoxicity	Neuromuscular blockade and muscle weakness are well described and usually reversible.
Quinupristin-dalfopristin	Arthralgias and myalgias	
Chloramphenicol	Bone marrow suppression	Aplastic anemia or hematopoietic toxicity
Pleuromutilin	Gastrointestinal	Diarrhea
	QT_c prolongation	When used in conjunction with CYP3A4 substrates

Note: All systemic antibiotics have the potential to alter abdominal flora and induce *Clostridioides difficile* infection.

Abbreviations: aPTT, activated partial thromboplastin time; CPK, creatine phosphokinase; INR, international normalized ratio; LFT, liver function test; PT, prothrombin time; TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 149-3 Important Antibacterial Drug Interactions

ANTIBACTERIAL(S)	INTERACTING AGENT(S)	POTENTIAL EFFECT AND MANAGEMENT
Nafcillin	Warfarin, cyclosporine, tacrolimus	Decreased effects of interacting drug via CYP3A4 induction. Monitor levels of affected drug closely if drugs are given concomitantly.
Ceftriaxone	Calcium-containing IV solutions	Concomitant use is contraindicated in neonates (<28 days); the combination can lead to precipitation of ceftriaxone-calcium particulate. Ceftriaxone and calcium-containing solutions can be given to infants >28 days of age provided they are given sequentially and the lines are thoroughly flushed between infusions, or infused via separate lines.
Carbapenems	Valproic acid	Diminished levels of valproic acid. Monitor valproic acid levels closely if drugs are given concomitantly and consider alternative therapies.
Linezolid, tedizolid	Serotonergic and adrenergic agents (e.g., SSRIs, vasopressors)	Increased levels of serotonergic and adrenergic agents. Monitor for serotonin syndrome. Tedizolid may have less potential than linezolid to cause this drug interaction.
Quinupristin-dalfopristin	Substrates of CYP3A4 (e.g., warfarin, ritonavir, cyclosporine, diazepam, verapamil)	Can result in increased levels of interacting drug
Fluoroquinolones	Theophylline[a]	Can result in theophylline toxicity
	Sucralfate; antacids containing aluminum, calcium, or magnesium; ferrous sulfate– and zinc-containing multivitamins	Can result in decreased oral absorption of fluoroquinolones. Administer fluoroquinolone 2 h before or 6 h after interacting drug.
	Tizanidine[a]	Can result in increased levels of tizanidine and hypotensive, sedative effects. Monitor for side effects if drugs are given concomitantly.
	QT_c-prolonging drugs (e.g. azoles, sotalol, amiodarone, dofetilide, fluoxetine)	Increased risk of cardiotoxicity and arrhythmias. Monitor QT_c.
Rifampin	Substrates of CYP3A4 (e.g., warfarin, ritonavir, cyclosporine, diazepam, verapamil, protease inhibitors, voriconazole)	Can result in decreased levels of interacting drug. Avoid concomitant use if possible. If giving drugs concomitantly, monitor drug levels if possible.
	Substrates of CYP2C19 (e.g., omeprazole, lansoprazole)	
	Substrates of CYP2C9 (e.g., warfarin, tolbutamide)	
	Substrates of CYP2C8 (e.g., repaglinide, rosiglitazone)	
	Substrates of CYP2B6 (e.g., efavirenz)	
	Hormone therapy (e.g., norethindrone)	Can result in decreased levels of hormone. If oral contraceptive and rifampin are given concomitantly, use alternative or additional forms of birth control.
Tetracyclines	Antacids or drugs containing calcium, magnesium, iron, or aluminum	Can result in decreased oral absorption of tetracyclines. Administer tetracycline 2 h before or 6 h after interacting drug.
	Warfarin	Increased effect of warfarin. Monitor levels closely if drugs are given concomitantly.
	Eravacycline: Strong CYP3A4 inducers (e.g., rifampin)	Reduced eravacycline efficacy
Macrolides[b]	Substrates of CYP3A4 (e.g., warfarin, ritonavir, cyclosporine, diazepam, verapamil, amiodarone)	Avoid concomitant administration if possible.
	QT_c-prolonging agents (e.g., fluoroquinolones, sotalol)	Increased risk of cardiotoxicity and arrhythmias. Monitor QT_c.
	Protease inhibitors (e.g., ritonavir)	Can result in increased levels of both macrolides and protease inhibitors. Avoid concomitant use if possible.
	Cimetidine	Cimetidine can increase levels of macrolides.
Metronidazole	Ethanol	Can result in disulfiram-like reaction. Ethanol may be present in some formulations of oral drug suspensions (e.g., ritonavir).
	Warfarin	Can increase warfarin effects. Monitor INR closely if drugs are given concomitantly.
TMP-SMX	Warfarin	Increased effect of warfarin. Monitor levels closely if drugs are given concomitantly.
	Phenytoin	Increased levels of phenytoin. Monitor levels closely if drugs are given concomitantly.
	Methotrexate	Increased levels of methotrexate and prolonged exposure. Monitor levels closely if drugs are given concomitantly.
Oritavancin	Substrates of CYP3A4 (e.g., cyclosporine, warfarin) and CYP2D6 (e.g., aripiprazole) Substrates of CYP2C19 (e.g., omeprazole) and CYP2C9 (e.g., warfarin)	Can result in decreased levels of interacting drug. Avoid concomitant use if possible. If giving drugs concomitantly, monitor drug levels if possible.
Lefamulin	QT_c-prolonging drugs (e.g., azoles, sotalol, amiodarone, dofetilide, fluoxetine)	Increased risk of cardiotoxicity and arrhythmias. Monitor QT_c.
	Strong CYP3A4 inducers (e.g., rifampin)	Reduced lefamulin efficacy
	Strong CYP3A4 strong inhibitors (e.g., ritonavir)	Increased lefamulin exposure

[a]Drug reaction described with ciprofloxacin only. [b]Clarithromycin and erythromycin are potent CYP3A4 inhibitors; the probability of a drug interaction with azithromycin is lower.

Abbreviations: INR, international normalized ratio; SSRI, selective serotonin-reuptake inhibitor; TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 149-4 Drug Indications for Specific Infections, Associated Pathogens, and Sample Susceptibility Rates

ANTIMICROBIAL(S)	INFECTIONS	COMMON PATHOGENS (% SUSCEPTIBLE); RESISTANCE AS NOTED[a]
Penicillin G	Syphilis; yaws; leptospirosis; streptococcal infections; pneumococcal infections; actinomycosis; oral and periodontal infections; meningococcal meningitis and meningococcemia; viridans streptococcal endocarditis; clostridial myonecrosis; tetanus; rat-bite fever; *Pasteurella multocida* infections; erysipeloid (*Erysipelothrix rhusiopathiae*)	*Neisseria meningitidis*; viridans streptococci (60%); *Streptococcus pneumoniae* (97% nonmeningitis; 74% meningitis)
Ampicillin, amoxicillin	Salmonellosis; acute otitis media; *Haemophilus influenzae* meningitis and epiglottitis; *Listeria monocytogenes* meningitis; *Enterococcus faecalis* UTI	*Escherichia coli* (52%); *H. influenzae* (72%); *Salmonella* spp. (89%)
Nafcillin, oxacillin	MSSA bacteremia and endocarditis	*Staphylococcus aureus* (72%); coagulase-negative staphylococci (49%)
Piperacillin-tazobactam	Intraabdominal infections (facultative enteric gram-negative bacilli and obligate anaerobes); infections caused by mixed flora (aspiration pneumonia, diabetic foot ulcers); infections caused by *Pseudomonas aeruginosa*	*P. aeruginosa* (78%)
Cefazolin	*E. coli* UTI; surgical prophylaxis; MSSA bacteremia and endocarditis	*E. coli* (80%)
Cefoxitin, cefotetan	Intraabdominal infections and pelvic inflammatory disease	*Bacteroides fragilis* (60%)[b]
Ceftriaxone	Gonococcal infections; pneumococcal meningitis; viridans streptococcal endocarditis; salmonellosis and typhoid fever; health care–associated infections caused by nonpseudomonal facultative gram-negative enteric bacilli	*S. pneumoniae* (87% meningitis; 99% nonmeningitis); *E. coli* (88%); *Klebsiella pneumoniae* (85%)
Ceftazidime, cefepime	Health care–associated infections caused by facultative gram-negative bacilli and *Pseudomonas* spp.	*P. aeruginosa* (82% for ceftazidime, 85% for cefepime)
Ceftaroline	CAP caused by *S. pneumoniae*, MSSA, *H. influenzae, K. pneumoniae, Klebsiella oxytoca*, and *E. coli*; acute bacterial skin and skin-structure infections caused by MSSA, MRSA, *Streptococcus pyogenes, Streptococcus agalactiae, E. coli, K. pneumoniae*, and *K. oxytoca*	Mostly susceptible; four strains of MRSA with ceftaroline MICs >4 μg/mL reported in isolates from a single Greek hospital[c]; additional case reports, including in patients without prior exposure to ceftaroline[d,e]
Ceftazidime-avibactam, meropenem-vaborbactam	Complicated UTIs (ceftazidime-avibactam and meropenem-vaborbactam) and complicated intraabdominal infections (ceftazidime-avibactam in combination with metronidazole) caused by resistant gram-negative organisms, including *Pseudomonas*, and some anaerobes	*P. aeruginosa* (84–97%)[f] MDR Enterobacterales, including carbapenem-resistant Enterobacterales that produce KPCs No activity against metallo-β-lactamases (e.g., NDM)
Ceftolozane-tazobactam	Complicated UTIs and complicated intraabdominal infections (in combination with metronidazole) caused by resistant gram-negative organisms, including *Pseudomonas*, and some anaerobes	*P. aeruginosa* (>86% overall; 60–80% of ceftazidime- and meropenem-resistant strains)[f] MDR Enterobacterales No activity against KPC-producing organisms
Imipenem, meropenem	Intraabdominal infections, infections caused by *Enterobacter* spp. and ESBL-producing gram-negative bacilli	*P. aeruginosa* (84%); *Acinetobacter calcoaceticus-baumannii* complex (84%) (meropenem susceptibilities reported)
Ertapenem	CAP; complicated UTIs, including pyelonephritis; acute pelvic infections; complicated intraabdominal infections; complicated skin and skin-structure infections, excluding diabetic foot infections accompanied by osteomyelitis or caused by *P. aeruginosa*	*Enterobacter cloacae* (88%); *K. pneumoniae* (98%)
Aztreonam	Infections caused by facultative gram-negative bacilli and *Pseudomonas* in penicillin-allergic patients	
Vancomycin	Bacteremia, endocarditis, and other invasive disease caused by MRSA; pneumococcal meningitis; oral formulation for CDAD	*S. aureus* (100%); *E. faecalis* (93%); *E. faecium* (41%)
Telavancin	Health care– and ventilator-associated pneumonia or skin and soft tissue infections caused by MRSA	*S. aureus*: none reported
Dalbavancin, oritavancin	Complicated skin and soft tissue infections	*S. aureus*: rarely reported for dalbavancin.[g] Rarely reported for oritavancin.[h]
Daptomycin	VRE infections; MRSA bacteremia	*E. faecalis* (99.9%);[i] *E. faecium* (99.7%);[i] *S. aureus* (99.9%)[g]
Gentamicin, tobramycin, amikacin	Combined with penicillin for staphylococcal, enterococcal, or streptococcal endocarditis; combined with β-lactam for gram-negative bacteremia; pyelonephritis	*E. coli* (gentamicin, 90%); *P. aeruginosa* (amikacin, 93%; gentamicin, 89%); *A. calcoaceticus-baumannii* complex (gentamicin, 83%)
Azithromycin, clarithromycin, erythromycin	*Legionella, Campylobacter*, and *Mycoplasma* infections; CAP; GAS pharyngitis in penicillin-allergic patients; bacillary angiomatosis; gastric infections due to *Helicobacter pylori*; MAI infections	*S. pneumoniae* (60%); group A streptococci (82%); *H. pylori* (75%)[j]
Clindamycin	Severe, invasive GAS infections (with a β-lactam); infections caused by obligate anaerobes; infections caused by susceptible staphylococci	*S. aureus* (73%)
Doxycycline, minocycline	Acute bacterial exacerbations of chronic bronchitis; granuloma inguinale; brucellosis (with streptomycin); tularemia; glanders; melioidosis; spirochetal infections caused by *Borrelia* (Lyme disease and relapsing fever; doxycycline); infections caused by *Vibrio vulnificus*; some *Aeromonas* infections; infections due to *Stenotrophomonas* (minocycline); plague; ehrlichiosis; chlamydial infections (doxycycline); granulomatous infections due to *Mycobacterium marinum* (minocycline); rickettsial infections; mild CAP; skin and soft tissue infections caused by gram-positive cocci (e.g., CA-MRSA infections); leptospirosis; syphilis; and actinomycosis in the penicillin-allergic patient	*S. pneumoniae* (54%); *S. aureus* (97%)

(*Continued*)

TABLE 149-4 Drug Indications for Specific Infections, Associated Pathogens, and Sample Susceptibility Rates (Continued)

ANTIMICROBIAL(S)	INFECTIONS	COMMON PATHOGENS (% SUSCEPTIBLE); RESISTANCE AS NOTED[a]
Tigecycline	CAP caused by *S. pneumoniae, H. influenzae*, or *Legionella pneumophila*; complicated skin infections caused by *E. coli*, MRSA, MSSA, *S. pyogenes, Streptococcus anginosus, S. agalactiae, B. fragilis*; complicated intraabdominal infections caused by *E. coli*, vancomycin-susceptible *E. faecalis, Citrobacter freundii, E. cloacae, K. pneumoniae, K. oxytoca, Bacteroides* spp., *Clostridium perfringens*, and *Peptostreptococcus* spp.	Mostly susceptible, although case reports of resistance in *A. baumannii* and *K. pneumoniae*
TMP-SMX	Community-acquired UTI; CA-MRSA skin and soft tissue infections	*E. coli* (73%); *S. aureus* (94%)
Sulfonamides	Nocardial infections; leprosy (dapsone); toxoplasmosis (sulfadiazine)	Unknown
Ciprofloxacin, levofloxacin, moxifloxacin, delafloxacin	CAP (levofloxacin and moxifloxacin); UTI; bacterial gastroenteritis; health care–associated gram-negative enteric infections; *Pseudomonas* infections (ciprofloxacin and levofloxacin); skin and skin-structure infections (delafloxacin)	*S. pneumoniae* (100% levofloxacin); *E. coli* (75% for ciprofloxacin and 70% for levofloxacin); *P. aeruginosa* (78% for ciprofloxacin and 70% for levofloxacin); *Salmonella* spp. (79% for ciprofloxacin and 77% for levofloxacin)
Rifampin	Staphylococcal foreign body infections (in combination with other antistaphylococcal agents); *Legionella* pneumonia; *Mycobacterium tuberculosis*; atypical nontuberculous mycobacterial infection; pneumococcal meningitis when organisms are susceptible or response is delayed	*S. aureus* (99%), although staphylococci rapidly develop resistance with monotherapy
Metronidazole	Obligate anaerobic gram-negative bacteria (e.g., *Bacteroides* spp.); abscess in lung, brain, or abdomen; bacterial vaginosis; CDAD	Mostly susceptible; resistance very rare
Linezolid, tedizolid	VRE; uncomplicated and complicated skin and soft tissue infections caused by MSSA and MRSA; CAP with concurrent bacteremia; health care–associated pneumonia	Mostly susceptible; resistance occasionally seen in VRE
Chloramphenicol	Infections due to gram-positive and gram-negative organisms resistant to standard alternatives (e.g., *Burkholderia*)	Unknown
Colistin	Infections due to gram-negative bacilli resistant to all other chemotherapy (e.g., *P. aeruginosa, Acinetobacter* spp., and *Stenotrophomonas maltophilia*)	*P. aeruginosa* (case reports, outbreaks)
Quinupristin-dalfopristin	VRE; complicated skin and skin-structure infections due to MSSA and *S. pyogenes*	*E. faecalis* (<20%);[k] *E. faecium* (>90%)[k]
Mupirocin	Topical application to nares for *S. aureus* decolonization	*S. aureus* (74–100%)[l]
Nitrofurantoin	UTI caused by most gram-negative bacilli and some gram-positive organisms; prophylaxis in recurrent cystitis	*E. coli* (97%); *E. faecalis* (99%)
Fosfomycin	UTI caused by most gram-negative bacilli and some gram-positive organisms; prophylaxis in recurrent cystitis	Considered low prevalence[m]
Cefiderocol	Complicated UTIs and/or pyelonephritis caused by multidrug-resistant gram-negative bacteria, including extended-spectrum β-lactamase- or carbapenemase-producing organisms and multidrug-resistant *P. aeruginosa, A. baumannii, Stenotrophomonas maltophilia*, and *Burkholderia cepacia*	Very low resistance rates in initial studies
Eravacycline	Complicated intraabdominal infections caused by *E. coli, K. pneumoniae, C. freundii, E. cloacae, K. oxytoca, E. faecalis, E. faecium, S. aureus, S. anginosus* group, *C. perfringens, Bacteroides* spp., and *Parabacteroides distasonis*	Resistance noted in both gram-negative and gram-positive bacteria[n]
Imipenem-cilastatin-relebactam	Complicated intraabdominal infections, pneumonia, and complicated UTI including pyelonephritis caused by multidrug-resistant organisms including Enterobacterales and against some imipenem-nonsusceptible *P. aeruginosa*	Low resistance rates in initial studies
Lefamulin[e]	Community acquired pneumonia caused by MRSA, *S. pneumoniae*, and atypical CAP pathogens	Low resistance rates in target pathogens in initial studies
Meropenem-vaborbactam	Complicated UTI caused by KPC-producing *Enterobacterales*	Identified in KPC-producing strains of *K. pneumoniae*[o]
Omadacycline	Community-acquired bacterial pneumonia caused by *S. pneumoniae, S. aureus* (methicillin-susceptible isolates), *H. influenzae, Haemophilus parainfluenzae, K. pneumoniae, L. pneumophila, M. pneumoniae*, and *Chlamydophila pneumoniae*	Broad spectrum overall, but resistance can occur in gram-negative isolates; not active against *Pseudomonas*
Plazomicin	Complicated UTIs caused by carbapenemase-producing Enterobacteriaceae	Resistance uncommon except in infrequent isolates with plasmid-encoded ribosome modifying methylases

[a]Unless otherwise noted, susceptibility rates are based on isolates from the Massachusetts General Hospital Clinical Microbiology Laboratory collected between January and December 2022. Local rates will vary. [b]JA Karlowsky et al: Antimicrob Agents Chemother 56:1247, 2012. [c]RE Mendes et al: J Antimicrob Chemother 67:1321, 2012. Abbreviations: CA-MRSA, community-acquired MRSA; CAP, community-acquired pneumonia; CA-UTI, community-acquired UTI; CDAD, *Clostridioides difficile*–associated diarrhea; ESBL, extended-spectrum β-lactamase; GAS, group A streptococcal; KPCs, *Klebsiella pneumoniae* carbapenemases; MAI, *Mycobacterium avium-intracellulare*; MDR, multidrug-resistant; MIC, minimal inhibitory concentration; MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-susceptible *S. aureus*; NDM, New Delhi metallo-β-lactamase; TMP-SMX, trimethoprim-sulfamethoxazole; UTI, urinary tract infection; VRE, vancomycin-resistant *Enterococcus*.

the drugs' four-membered lactam ring, which is their core structure. The differing side groups among the agents of this family determine the spectrum of activity. All β-lactams exert a bactericidal effect by inhibiting bacterial cell-wall synthesis. The β-lactams are classified as time-dependent killing agents; therefore, their clinical efficacy is best correlated with the proportion of the dosing interval during which drug levels remain above the MIC for the targeted pathogen.

Penicillins and β-Lactamase Inhibitors Penicillin, the first β-lactam, was discovered in 1928 by Alexander Fleming. Natural

penicillins, such as penicillin G, are active against non-β-lactamase-producing gram-positive and gram-negative bacteria, anaerobes, and some gram-negative cocci. Penicillin G is used for penicillin-susceptible streptococcal infections, pneumococcal and meningococcal meningitis, enterococcal endocarditis, and syphilis. The antistaphylococcal penicillins, which have potent activity against methicillin-susceptible *Staphylococcus aureus* (MSSA), include nafcillin, oxacillin, dicloxacillin, and flucloxacillin. Aminopenicillins, such as ampicillin and amoxicillin, provide added coverage beyond penicillin against gram-negative cocci, such as *Haemophilus influenzae*, and some Enterobacterales, including *Escherichia coli*, *Proteus mirabilis*, *Salmonella*, and *Shigella*. The aminopenicillins are hydrolyzed by many common β-lactamases. These drugs are commonly used for infections caused by susceptible enterococcal and streptococcal species. IV ampicillin is commonly used in meningitis and endocarditis. Oral amoxicillin may be an option for otitis media, respiratory tract infections, and urinary tract infections. The antipseudomonal penicillins include ticarcillin and piperacillin. These penicillin groups generally offer adequate anaerobic coverage; the exceptions are *Bacteroides* species (such as *Bacteroides fragilis*), which produce β-lactamases and are generally resistant. The rising prevalence of β-lactamase-producing bacteria has led to the increased use of β-lactam–β-lactamase inhibitor combinations, such as ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin-clavulanate, piperacillin-tazobactam, ceftolozane-tazobactam, ceftazidime-avibactam, meropenem-vaborbactam, and imipenem-relebactam. The β-lactamase inhibitors themselves do not have antibacterial activity (with the exception of sulbactam, which has activity against *Acinetobacter baumannii*) but typically inhibit the *S. aureus* class A β-lactamase, β-lactamases of *H. influenzae* and *Bacteroides* species, and a number of plasmid-encoded β-lactamases. These combination agents are typically used when broader-spectrum coverage is needed—e.g., in pneumonia and intraabdominal infections. Piperacillin-tazobactam is a useful agent for febrile neutropenia, when local *P. aeruginosa* susceptibility rates are high. Avibactam, vaborbactam, and relebactam inhibit a broader spectrum of β-lactamases than the other inhibitors, including extended-spectrum β-lactamases (ESBLs), AmpC β-lactamases, and some carbapenemases **(see Chap. 150)**. Sulbactam combined with the inhibitor durlobactam is limited to treatment for *Acinetobacter* infections.

Cephalosporins The cephalosporin drug class encompasses several generations distinguished by spectrum of antibacterial activity. The first generation (cefazolin, cefadroxil, and cephalexin) largely has activity against gram-positive bacteria, with some additional activity against *E. coli*, *P. mirabilis*, and *Klebsiella pneumoniae*. First-generation cephalosporins are commonly used for infections caused by MSSA and streptococci (e.g., skin and soft tissue infections). Cefazolin is recommended for surgical prophylaxis against skin organisms. The second generation (cefamandole, cefuroxime, cefaclor, cefprozil, cefuroxime axetil, cefoxitin, and cefotetan) has additional activity against *H. influenzae* and *Moraxella catarrhalis*. Cefoxitin and cefotetan have potent activity against anaerobes as well, although there is some increased resistance seen for *B. fragilis*. Second-generation cephalosporins have been used to treat community-acquired pneumonia because of their activity against *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. They are also used for other mild or moderate infections, such as acute otitis media and sinusitis. The third-generation cephalosporins are characterized by greater potency against gram-negative bacilli and reduced potency against gram-positive cocci. These cephalosporins, which include cefoperazone, cefotaxime, ceftazidime, ceftriaxone, cefdinir, cefixime, and cefpodoxime, are used for infections caused by Enterobacterales, although resistance is an increasing concern. Ceftriaxone penetrates the CSF and can be used to treat meningitis caused by *H. influenzae*, *N. meningitidis*, and susceptible strains of *S. pneumoniae*. It is also used for the treatment of later-stage Lyme disease, gonococcal infections, and streptococcal endocarditis. It is noteworthy that ceftazidime is the only third-generation cephalosporin with activity against *Pseudomonas aeruginosa*, but it lacks activity against gram-positive bacteria. This drug is frequently used for pulmonary infections in cystic fibrosis, postneurosurgical meningitis, and febrile neutropenia. The fourth generation of cephalosporins includes cefepime and cefpirome, broad-coverage agents with potent activity against both gram-negative bacilli, including *P. aeruginosa*, and gram-positive cocci. The fourth generation has clinical applications similar to those of the third generation and may offer additional activity over the first, second, and third generations in the presence of certain β-lactamases. These agents can be used in bacteremia, febrile neutropenia, and intraabdominal and urinary tract infections. Ceftaroline, a fifth-generation cephalosporin, differs from the other cephalosporins in its added activity against methicillin-resistant *S. aureus* (MRSA), which is resistant to all other β-lactams. Ceftaroline's gram-negative activity is similar to that of the third-generation cephalosporins but does not include *P. aeruginosa*. Ceftaroline may be used in community-acquired pneumonia and skin infections, and emerging data support its use in more severe infections such as bacteremia. Adverse reactions to ceftaroline have included hypersensitivity reactions and neutropenia. Ceftolozane-tazobactam and ceftazidime-avibactam are novel cephalosporin–β-lactamase inhibitor combinations with activity against gram-negative bacteria, including *Pseudomonas*, and some anaerobes. Both agents have been studied in complicated intraabdominal infections and complicated urinary tract infections. Ceftolozane-tazobactam is thought to be stable against many ESBL-producing organisms because of the tazobactam component. The addition of avibactam to ceftazidime yields a combination agent with activity against AmpC-, ESBL-, and *K. pneumoniae* carbapenemase (KPC)–producing organisms. These cephalosporin–β-lactamase inhibitor combinations may be of clinical benefit in multidrug-resistant gram-negative infections. Cefiderocol is a novel cephalosporin with enhanced uptake through bacterial iron uptake pathways and stability to a broad range of β-lactamases. It has been studied in complicated urinary tract infections and hospital-acquired and ventilator-associated pneumonia and may provide most benefit for multidrug-resistant gram-negative bacterial infections.

Carbapenems Carbapenems, including doripenem, imipenem, meropenem, and ertapenem, offer the most reliable coverage for strains containing ESBLs. All carbapenems have broad activity against gram-positive cocci, gram-negative bacilli, and anaerobes. None is active against MRSA, but all are active against MSSA, *Streptococcus* species, and Enterobacterales. Ertapenem is the only carbapenem that has poor activity against *P. aeruginosa* and *Acinetobacter*. Imipenem is active against penicillin-susceptible *Enterococcus faecalis* but not *Enterococcus faecium*. Carbapenems are not active against Enterobacterales containing carbapenemases. *Stenotrophomonas maltophilia* and some *Bacillus* species are intrinsically resistant to carbapenems because of a zinc-dependent carbapenemase. Addition of vaborbactam to meropenem and relebactam to imipenem results in inhibition of AmpC β-lactamases, ESBLs, and KPCs but not metallo-carbapenemases, such as NDM (New Delhi metallo-β-lactamases). Carbapenems may decrease the concentration of valproate products, and caution should be used in patients on this combination of therapy.

Monobactams Aztreonam is the sole monobactam in clinical use. Its activity is limited to gram-negative bacteria and includes *P. aeruginosa* and most other Enterobacterales. It is inactivated by ESBLs and carbapenemases. The principal use for aztreonam is as an alternative to penicillins, cephalosporins, or carbapenems in patients with a serious β-lactam allergy. Aztreonam is structurally related to ceftazidime and should be used cautiously in individuals with a serious ceftazidime allergy. It is used in febrile neutropenia and intraabdominal infections when other β-lactams cannot be used. Aztreonam is sometimes used in combination with avibactam for the treatment of NDM carbapenemase gram-negative bacterial infections.

Adverse Reactions to β-Lactam Drugs Agents within the β-lactam class are known for several adverse effects. Gastrointestinal side effects, mainly diarrhea, are common, but hypersensitivity

reactions constitute the most common adverse effect of β-lactams. The reactions' severity can range from rash to anaphylaxis, but the rate of true anaphylactic reactions is only 0.05%. An individual with an accelerated IgE-mediated reaction to one β-lactam agent may still receive another agent within the class, but caution should be used and a β-lactam that has a dissimilar side chain and a low level of cross-reactivity would be the preferred choice. For example, the second-, third-, and fourth-generation cephalosporins and the carbapenems display very low cross-reactivity in patients with penicillin allergy. Aztreonam is the only β-lactam that has no cross-reactivity with the penicillin group. In cases of severe allergy, desensitization (a graded challenge) to the indicated β-lactam, with close monitoring, may be warranted if other antibacterial options are not suitable.

β-Lactams can rarely cause serum sickness, Stevens-Johnson syndrome, nephropathy, hematologic reactions, and neurotoxicity. Neutropenia appears to be related to high doses or prolonged use. Neutropenia and interstitial nephritis caused by β-lactams generally resolve upon discontinuation of the agent. Imipenem and cefepime are associated with an increased risk of seizure, but this risk is likely a class effect and related to high doses or doses that are not adjusted in renal impairment.

SULBACTAM-DURLOBACTAM

Durlobactam is a novel diazabicyclooctane non-β-lactam β-lactamase inhibitor combined with the β-lactamase inhibitor sulbactam for treatment of multidrug-resistant *Acinetobacter* infections. It was approved in the United States in 2023 for treatment of hospital-acquired and ventilator-associated pneumonia caused by *Acinetobacter baumannii-calcoaceticus* complex. Adverse reactions include abnormal liver function tests, diarrhea, anemia, and hypokalemia.

GLYCOPEPTIDES AND LIPOGLYCOPEPTIDES

Vancomycin is a glycopeptide antibiotic with activity against staphylococci (including MRSA and coagulase-negative staphylococci), streptococci (including *S. pneumoniae*), and enterococci. It is not active against gram-negative organisms. Vancomycin also displays activity against *Bacillus* species, *Corynebacterium jeikeium*, and gram-positive anaerobes such as *Peptostreptococcus*, *Actinomyces*, *Clostridium*, and *Propionibacterium* species. Vancomycin has several important clinical uses. It is used for serious infections caused by MRSA, including health care–associated pneumonia, bacteremia, osteomyelitis, and endocarditis. It is also commonly used for skin and soft tissue infections. Oral vancomycin is not absorbed systemically and is reserved for the treatment of *C. difficile* infection. Vancomycin is also an alternative for the treatment of infections caused by MSSA in patients who cannot tolerate β-lactams. Resistance to vancomycin is a rising concern. Strains of vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant enterococci (VRE) are not uncommon. Vancomycin appears to be a concentration-dependent killer, with the AUC/MIC ratio being the best predictor of efficacy (Fig. 149-1). Guidelines recommend targeting a vancomycin trough level of 15–20 μg/mL in MRSA infections in order to maintain an AUC/MIC ratio >400. When using vancomycin, clinicians should monitor for nephrotoxicity. The risk of nephrotoxicity increases when trough levels are >20 μg/mL. Concomitant therapy with other nephrotoxic agents, such as aminoglycosides, also increases the risk. Ototoxicity was reported with early formulations of vancomycin but is currently uncommon because purer formulations are available. Both of these adverse effects are reversible upon discontinuation of vancomycin. Clinicians should be aware of vancomycin infusion reaction (formerly known as "red man syndrome"), a common reaction that presents as a rapid onset of erythematous rash or pruritus on the head, face, neck, and upper trunk. This reaction is caused by histamine release from basophils and mast cells and can be treated with diphenhydramine and slowing of the vancomycin infusion.

Telavancin, dalbavancin, and oritavancin are structurally similar to vancomycin and are referred to as *lipoglycopeptides*. They have antibacterial activity against *S. aureus* (including MRSA and some strains of VISA and vancomycin-resistant *S. aureus* [VRSA]), streptococci, and enterococci. Oritavancin may have activity against some strains of VRE. These lipoglycopeptide agents also provide coverage against anaerobic gram-positive organisms except for *Lactobacillus* and some *Clostridium* species. The clinical efficacy of telavancin has been demonstrated in both skin and soft tissue infections and nosocomial pneumonia, and the efficacy of dalbavancin and oritavancin has been shown in skin and soft tissue infections. The vancomycin resistance phenotype may reduce the potency of all three lipoglycopeptides, but the rate of resistance to these drugs among *S. aureus* and enterococcal isolates has been low. Adverse effects of telavancin include nephrotoxicity, metallic taste, and gastrointestinal side effects. Clinicians should be aware of the potential for electrocardiographic QT_c prolongation that can increase the risk of cardiac arrhythmias when telavancin is used concomitantly with other QT_c-prolonging agents. Telavancin may interfere with certain coagulation tests (e.g., causing false elevations in prothrombin time). Dalbavancin and oritavancin have safety profiles similar to that of vancomycin, with common effects reported as headache and gastrointestinal side effects. These glycolipopeptides should be used cautiously in patients with hypersensitivity reactions to vancomycin, as cross-allergy may be possible.

LIPOPEPTIDES

Daptomycin is a lipopeptide antibiotic with activity against a broad range of gram-positive organisms. It is active against staphylococci (including MRSA and coagulase-negative staphylococci), streptococci, and enterococci. Daptomycin remains active against enterococci that are resistant to vancomycin. In addition, it exhibits activity against *Bacillus*, *Corynebacterium*, *Peptostreptococcus*, and *Clostridium* species. Daptomycin's pharmacodynamic parameter for efficacy is concentration-dependent killing. Resistance to daptomycin is rare, but MICs may be higher for some VISA strains. Daptomycin can be used in skin and soft tissue infections, bacteremia, endocarditis, and osteomyelitis. It is an important alternative for MRSA and other gram-positive infections when bactericidal therapy is needed and vancomycin cannot be used. Daptomycin is generally well tolerated, and its main toxicity consists of elevation of creatine phosphokinase (CPK) levels and myopathy. CPK should be monitored during daptomycin treatment, and the drug should be discontinued if muscular toxicities occur. There have also been case reports of reversible eosinophilic pneumonia associated with daptomycin use.

AMINOGLYCOSIDES

The aminoglycosides are a class of antibacterial agents with concentration-dependent activity against most gram-negative organisms. The most commonly used aminoglycosides are gentamicin, tobramycin, and amikacin, although others, such as streptomycin, kanamycin, neomycin, and paromomycin, may be used in special circumstances. Plazomicin is a new aminoglycoside that is less affected by common resistance mechanisms and is approved for treatment of complicated urinary tract infections and acute pyelonephritis. Aminoglycosides have a significant dose-dependent postantibiotic effect; i.e., they have an antibacterial effect even after serum drug levels fall below inhibitory concentrations. The postantibiotic effect and concentration-dependent killing form the rationale behind extended-interval aminoglycoside dosing, in which a larger dose is given once daily rather than smaller doses multiple times daily. Aminoglycosides are active against gram-negative bacilli, such as Enterobacterales, *P. aeruginosa*, and *Acinetobacter*. They also enhance the activity of cell wall–active agents such as β-lactams or vancomycin against some gram-positive bacteria, including staphylococci and enterococci. This combination therapy is termed *synergistic* because the effect of both agents provides a killing effect greater than would be predicted from the effects of either agent alone. Amikacin and streptomycin have activity against *Mycobacterium tuberculosis*, and amikacin has activity against nontuberculous mycobacteria, including *Mycobacterium avium* complex and *Mycobacterium abscessus*. The aminoglycosides do not have activity against anaerobes, *S. maltophilia*, or *Burkholderia cepacia* complex. Aminoglycosides are used in clinical practice in a variety of infections caused by gram-negative organisms, including bacteremia and urinary tract

infections. They are frequently used in combination for the treatment of *P. aeruginosa* infection. When used in combination with a cell wall–active agent, gentamicin and streptomycin are also important for the treatment of gram-positive bacterial endocarditis. All aminoglycosides can cause nephrotoxicity and ototoxicity. The risk of nephrotoxicity is not well defined; however, some studies have indicated that the effect may be related to the duration of therapy as well as to the concomitant use of other nephrotoxic agents. Nephrotoxicity is usually reversible, but ototoxicity can be irreversible.

MACROLIDES AND KETOLIDES

The macrolides (azithromycin, clarithromycin, and erythromycin) and ketolides (telithromycin) are classes of antibiotics that inhibit protein synthesis. Compared with erythromycin (the older antibiotic), azithromycin and clarithromycin have better oral absorption and tolerability. Azithromycin, clarithromycin, and telithromycin all have broader spectra of activity than erythromycin, which is less frequently used. These agents are commonly used in the treatment of upper and lower respiratory tract infections caused by *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and atypical organisms (e.g., *Chlamydophila pneumoniae*, *Legionella pneumophila*, and *Mycoplasma pneumoniae*); group A streptococcal pharyngitis in penicillin-allergic patients; and nontuberculous mycobacterial infections (e.g., caused by *Mycobacterium marinum* and *Mycobacterium chelonae*) as well as in the prophylaxis and treatment of *M. avium* complex infection in patients with HIV/AIDS and in combination therapy for *Helicobacter pylori* infection and bartonellosis. Enterobacterales, *Pseudomonas* species, and *Acinetobacter* species are intrinsically resistant to macrolides as a result of decreased membrane permeability, although azithromycin is active against gram-negative diarrheal pathogens. The major adverse effects of this drug class include nausea, vomiting, diarrhea and abdominal pain, prolongation of QT_c interval, exacerbation of myasthenia gravis, and tinnitus and reversible deafness, especially in the elderly. Azithromycin specifically has been associated with an increased risk of death, especially among patients with underlying heart disease, because of the risk of QT_c interval prolongation and torsades de pointes arrhythmia. Erythromycin, clarithromycin, and telithromycin inhibit the CYP3A4 hepatic drug-metabolizing enzyme and can result in increased levels of coadministered drugs, including benzodiazepines, statins, warfarin, cyclosporine, and tacrolimus. Azithromycin does not inhibit CYP3A4 and therefore does not interact with these drugs.

CLINDAMYCIN

Clindamycin is a lincosamide antibiotic and is bacteriostatic against some organisms and bactericidal against others. It is used most often to treat bacterial infections caused by anaerobes (e.g., *B. fragilis*, *Clostridium perfringens*, *Fusobacterium* species, *Prevotella melaninogenicus*, and *Peptostreptococcus* species) and susceptible staphylococci and streptococci. Clindamycin is used for treatment of dental infections, anaerobic lung abscess, and skin and soft tissue infections. It is used together with bactericidal agents (penicillins or vancomycin) to inhibit new toxin synthesis in the treatment of streptococcal or staphylococcal toxic shock syndrome. Other uses include treatment of infections caused by *Capnocytophaga canimorsus*, combination therapy for babesiosis and occasionally malaria, and therapy for toxoplasmosis. Clindamycin has excellent oral bioavailability. Adverse effects include nausea, vomiting, diarrhea, *C. difficile*–associated diarrhea and pseudomembranous colitis, maculopapular rash, and rarely Stevens-Johnson syndrome.

TETRACYCLINES

The older (doxycycline, minocycline, and tetracycline) and newer (tigecycline, eravacycline, and omadacycline) tetracyclines inhibit protein synthesis and are bacteriostatic. These drugs have wide clinical uses. They are used in the treatment of skin and soft tissue infections caused by gram-positive cocci (including MRSA), spirochetal infections (e.g., Lyme disease, syphilis, leptospirosis, and relapsing fever), rickettsial infections (e.g., Rocky Mountain spotted fever, scrub typhus), atypical pneumonia, sexually transmitted infections (e.g., *Chlamydia trachomatis* infection, lymphogranuloma venereum, and granuloma inguinale), infections with *Nocardia* and *Actinomyces*, brucellosis, tularemia, Whipple's disease, and malaria. Tigecycline, eravacycline, and omadacycline are also used in combination with other agents for treatment of *M. abscessus*. Tigecycline is a glycylcycline derived from minocycline and is available only in IV formulation. It is indicated in the treatment of complicated skin and soft tissue infections, complicated intraabdominal infections, and community-acquired bacterial pneumonia in adults. Tigecycline has activity against MRSA, vancomycin-sensitive enterococci, many Enterobacterales, and *Bacteroides* species; it has no activity against *P. aeruginosa*. This drug has been used in combination with colistin for the treatment of serious infections with multidrug-resistant gram-negative organisms. A pooled analysis of 13 clinical trials found an increased risk of death and treatment failure among patients given tigecycline alone; as a result, the FDA mandated a black box warning. Eravacycline is a fluorocycline derivative available in IV formulation with a similar spectrum but more potent than tigecycline in vitro. It has been approved for complicated intraabdominal infections. Omadacycline is an aminomethylcycline derivative available in both IV and oral formulations. It has activity similar to that of tigecycline against gram-positive pathogens but is less active against gram-negative pathogens. Omadacycline has been approved for treatment of bacterial skin and skin structure infections and community-acquired bacterial pneumonia. Tetracyclines have reduced absorption when orally coadministered with calcium- and iron-containing compounds, including milk, and doses should be spaced at least 2 h apart. The major adverse reactions to old and new tetracyclines are nausea, vomiting, diarrhea, and photosensitivity. Tetracyclines have been associated with fetal bone-growth abnormalities and should be avoided during pregnancy and in the treatment of children <8 years old.

TRIMETHOPRIM-SULFAMETHOXAZOLE

Trimethoprim-sulfamethoxazole (TMP-SMX) is an antibiotic with two components that each inhibit a separate step in folate synthesis and produce antibacterial activity. TMP-SMX is active against gram-positive bacteria such as staphylococci and streptococci; however, its use against MRSA is usually limited to community-acquired infections, and its activity against *Streptococcus pyogenes* may not be reliable. This drug is also active against many gram-negative bacteria, including *H. influenzae*, *E. coli*, *P. mirabilis*, *Neisseria gonorrhoeae*, and *S. maltophilia*. TMP-SMX is not active against anaerobes or *P. aeruginosa*. It has many uses because of its wide spectrum of activity and high oral bioavailability. Urinary tract infections, skin and soft tissue infections, and respiratory tract infections are among the common uses. Another important indication is for both prophylaxis and treatment of *Pneumocystis jirovecii* infections in immunocompromised patients. Resistance to TMP-SMX has limited its use against many Enterobacterales. Resistance rates among urinary isolates of *E. coli* are almost 25% in the United States. The most common adverse reactions associated with TMP-SMX are gastrointestinal effects such as nausea, vomiting, and diarrhea. In addition, rash is a common allergic reaction and may preclude the subsequent use of other sulfonamides. With prolonged use, leukopenia, thrombocytopenia, and granulocytopenia can develop. TMP-SMX can also cause nephrotoxicity, hyperkalemia, and hyponatremia, which are more common at high doses. TMP-SMX has several important interactions with other drugs (Table 149-3), including warfarin, phenytoin, and methotrexate.

FLUOROQUINOLONES

The fluoroquinolones include norfloxacin, ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, gemifloxacin, and delafloxacin. Ciprofloxacin and levofloxacin have the broadest spectrum of activity against gram-negative bacteria, including *P. aeruginosa* (similar to that of third-generation cephalosporins). Because of the risk of selection of resistance during fluoroquinolone treatment of serious pseudomonal infections, these agents are usually used in combination with an

antipseudomonal β-lactam. Levofloxacin, moxifloxacin, gemifloxacin, and delafloxacin have additional gram-positive activity, including that against *S. pneumoniae* and some strains of MSSA, and with the exception of delafloxacin, these agents are used for treatment of community-acquired pneumonia. Strains of MRSA are commonly resistant to all fluoroquinolones except delafloxacin. Moxifloxacin is used as one component of second-line regimens for multidrug-resistant tuberculosis. Fluoroquinolones are no longer used for treatment of gonorrhea because of common resistance in *N. gonorrhoeae.* Fluoroquinolones exhibit concentration-dependent killing, are well absorbed orally, and have elimination half-lives that usually support once- or twice-daily dosing. Oral coadministration with compounds containing high concentrations of aluminum, magnesium, or calcium can reduce fluoroquinolone absorption. The penetration of fluoroquinolones into prostate tissue supports their use for bacterial prostatitis. Fluoroquinolones are generally well tolerated but can cause central nervous system (CNS) stimulatory effects, including seizures; peripheral neuropathy; glucose dysregulation; and tendinopathy associated with Achilles tendon rupture, particularly in older patients, organ transplant recipients, and patients taking glucocorticoids. Other potential effects on connective tissues include an association with increased risk of aortic aneurysm. Worsening of myasthenia gravis also has been associated with quinolone use. Moxifloxacin causes modest prolongation of the QT_c interval and should be used with caution in patients receiving other QT_c-prolonging drugs.

RIFAMYCINS

The rifamycins include rifampin, rifabutin, and rifapentine. Rifampin is the most commonly used rifamycin. For almost all therapeutic indications, it is used in combination with other agents to reduce the likelihood of selection of high-level rifampin resistance. Rifampin is used foremost in the treatment of mycobacterial infections—specifically, as a mainstay of combination therapy for *M. tuberculosis* infection or as a single agent in the treatment of latent *M. tuberculosis* infection. In addition, it is often used in the treatment of some nontuberculous mycobacterial infections. Rifampin is used in combination regimens for the treatment of staphylococcal infections, particularly prosthetic-valve endocarditis and bone infections with retained hardware. It is a component of combination therapy for brucellosis (with doxycycline) and leprosy (with dapsone for tuberculoid leprosy and with dapsone and clofazimine for lepromatous disease). Rifampin can be used alone for prophylaxis in close contacts of patients with *H. influenzae* or *N. meningitidis* meningitis. The drug has high oral bioavailability, which is further enhanced when it is taken on an empty stomach. Rifampin has several adverse effects, including elevated aminotransferase levels (14%), rash (1–5%), and gastrointestinal events such as nausea, vomiting, and diarrhea (1–2%). Its many clinically relevant interactions with other drugs (Table 149-3) mandate the clinician's careful review of the patient's medications before rifampin initiation to assess safety and the need for additional monitoring, including monitoring of drug levels.

METRONIDAZOLE

Metronidazole is used in the treatment of anaerobic bacterial infections as well as infections caused by protozoa (e.g., amebiasis, giardiasis, trichomoniasis). It is the agent of choice as a component of combination therapy for polymicrobial abscesses in the lung, brain, or abdomen, the etiology of which often includes anaerobic bacteria, and for bacterial vaginosis, pelvic inflammatory disease, and anaerobic infections, such as those due to *Bacteroides*, *Fusobacterium*, and *Prevotella* species. This drug is an alternative agent for treatment of mild to moderate *C. difficile*–associated diarrhea. Metronidazole is bactericidal against anaerobic bacteria and exhibits concentration-dependent killing. It has high oral bioavailability and tissue penetration, including penetration of the blood-brain barrier. The majority of *Actinomyces*, *Propionibacterium*, and *Lactobacillus* species are intrinsically resistant to metronidazole. The major adverse effects include nausea, diarrhea, and a metallic taste. Concomitant ingestion of alcohol may result in a disulfiram-like reaction, and patients are usually instructed to avoid alcohol during treatment. Long-term treatment carries the risk of leukopenia, neutropenia, peripheral neuropathy, and CNS toxicity manifesting as confusion, dysarthria, ataxia, nystagmus, and ophthalmoparesis. Through metronidazole's effect on the CYP2C9 drug-metabolizing enzyme, its coadministration with warfarin can result in decreased metabolism and enhanced anticoagulant effects that require close monitoring. Concomitant administration of metronidazole with lithium can result in increased serum levels of lithium and associated toxicity; coadministration with phenytoin can result in phenytoin toxicity and possibly decreased levels of metronidazole.

OXAZOLIDINONES

Linezolid is a bacteriostatic agent and is indicated for serious infections due to resistant gram-positive bacteria, such as MRSA and VRE. The intrinsic resistance of gram-negative bacteria is mediated primarily by endogenous efflux pumps. Linezolid has excellent oral bioavailability. Adverse effects include myelosuppression and ocular and peripheral neuropathy with prolonged therapy. Peripheral neuropathy may be irreversible. Linezolid is a weak, reversible monoamine oxidase inhibitor, and coadministration with sympathomimetics and foods rich in tyramine should be avoided. Linezolid has been associated with serotonin syndrome when coadministered with selective serotonin reuptake inhibitors. Tedizolid has properties similar to those of linezolid, but with lower dosing due to greater potency, it may be less likely to cause adverse hematologic and neuropathic effects.

PLEUROMUTILINS

Lefamulin is the only member of the pleuromutilin class approved for systemic use; it is available in IV and oral formulations. Lefamulin has in vitro activity against *S. aureus* (including MRSA), *S. pneumoniae*, *H. influenzae*, and atypical respiratory pathogens, including *L. pneumophila*, *M. pneumoniae*, and *C. pneumoniae*, and has been approved for treatment of community-acquired bacterial pneumonia. Adverse effects are most commonly gastrointestinal, including diarrhea (12%), nausea (5%), and vomiting (3%). Prolongation of QT_c interval and hepatic transaminase elevations occur in some patients. There can be interactions with drugs that are either inducers or inhibitors of CYP3A4 or P-glycoprotein transporter.

NITROFURANTOIN

Nitrofurantoin's antibacterial activity results from the drug's conversion to highly reactive intermediates that can damage bacterial DNA and other macromolecules. Nitrofurantoin is bactericidal, and its action is concentration dependent. It displays activity against a range of gram-positive bacteria, including *S. aureus*, *Staphylococcus epidermidis*, *Staphylococcus saprophyticus*, *E. faecalis*, *Streptococcus agalactiae*, group D streptococci, viridans streptococci, and corynebacteria, as well as gram-negative organisms, including *E. coli, Enterobacter*, *Salmonella*, and *Shigella* species. Nitrofurantoin is used primarily in the treatment of urinary tract infections and is preferred in the treatment of such infections in pregnancy. It may be used for the prevention of recurrent cystitis. Recently, there has been interest in the use of nitrofurantoin for treatment of urinary tract infections caused by ESBL-producing Enterobacterales such as *E. coli*, although resistance has been growing in Latin America and parts of Europe. Coadministration with magnesium should be avoided because of decreased absorption, and patients should be encouraged to take the drug with food to increase its bioavailability and decrease the risk of adverse effects, which include nausea, vomiting, and diarrhea. Nitrofurantoin may also cause pulmonary fibrosis and drug-induced hepatitis. Because the risk of adverse reactions increases with age, the use of nitrofurantoin in elderly patients is not recommended. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency are at elevated risk for nitrofurantoin-associated hemolytic anemia.

POLYMYXINS

Colistin and polymyxin B act by disrupting bacterial cell membrane integrity and are active against the nonenteric pathogens *P. aeruginosa* and *A. baumannii* but not against *Burkholderia*. These drugs also

exhibit activity against many Enterobacterales, with the exceptions of *Proteus*, *Providencia*, and *Serratia* species. They lack activity against gram-positive bacteria. Polymyxins are bactericidal and are available in IV formulations. Colistimethate is converted to the active form (colistin) in plasma. Polymyxins are most often used for infections due to pathogens resistant to multiple other antibacterial agents, including urinary tract infections, hospital-acquired pneumonia, and bloodstream infections. Nebulized formulations have been used for adjunctive treatment of refractory ventilator-associated pneumonia as well as a prevention strategy for patients with bronchiectasis and/or cystic fibrosis. The most important adverse effect is dose-dependent reversible nephrotoxicity. Neurotoxicity, including paresthesias, muscle weakness, and confusion, is reversible and less common than nephrotoxicity.

QUINUPRISTIN-DALFOPRISTIN

Quinupristin-dalfopristin contains two members of the streptogramin class of antibiotics and kills bacteria by inhibiting protein synthesis. The antibacterial spectrum of quinupristin-dalfopristin includes staphylococci (including MRSA), streptococci, and *E. faecium* (but not *E. faecalis*). This drug combination is also active against *Corynebacterium* species and *L. monocytogenes*. Quinupristin-dalfopristin is not reliably active against gram-negative organisms. It exhibits concentration-dependent killing, with an AUC/MIC ratio predicting efficacy. The clinical use of quinupristin-dalfopristin is largely for infections due to vancomycin-resistant *E. faecium* and other gram-positive bacterial infections. The drug has demonstrated efficacy in a variety of infections, including urinary tract infections, bone and joint infections, and bacteremia. Adverse effects associated with quinupristin-dalfopristin include infusion-related reactions, arthralgias, and myalgias. The arthralgias and myalgias may be severe enough to warrant drug discontinuation. Quinupristin-dalfopristin inhibits the CYP3A4 drug-metabolizing enzyme, with consequent drug interactions (Table 149-3).

FOSFOMYCIN

Fosfomycin is a phosphonic acid antibiotic that has greater activity in acidic environments and is excreted in its active form in the urine. The oral formulation is primarily for prophylaxis and treatment of uncomplicated cystitis and should be avoided if there is concern about pyelonephritis. The drug is administered as a single 3-g dose that results in high urine concentrations for up to 48 h. Fosfomycin is active against *S. aureus*, vancomycin-susceptible enterococci and VRE, and a wide range of gram-negative organisms, including *E. coli*, *Enterobacter* species, *Serratia marcescens*, *P. aeruginosa*, and *K. pneumoniae*. Notably, the vast majority of ESBL-producing Enterobacterales are susceptible to fosfomycin. *A. baumannii* and *Burkholderia* species are resistant. The emergence of resistance to fosfomycin has not been observed during treatment of cystitis but has been documented during IV treatment of respiratory tract infections and osteomyelitis. The few adverse effects that have been reported include nausea and diarrhea.

CHLORAMPHENICOL

The use of chloramphenicol is limited by its potentially serious toxicities. When other agents are contraindicated or ineffective, chloramphenicol represents an alternative treatment for infections, including meningitis caused by susceptible bacteria such as *N. meningitidis*, *H. influenzae*, and *S. pneumoniae*. It has also been used for the treatment of anthrax, brucellosis, *Burkholderia* infections, chlamydial infections, clostridial infections, ehrlichiosis, rickettsial infections, and typhoid fever. Adverse reactions include aplastic anemia, myelosuppression, and gray baby syndrome. Chloramphenicol inhibits the CYP2C19 and CYP3A4 drug-metabolizing enzymes and consequently increases levels of many classes of drugs.

APPROACH TO PROPHYLAXIS OF INFECTION

Antibacterial prophylaxis is indicated only in selected circumstances **(Table 149-5)** and should be supported by well-designed studies or expert panel recommendations. In all cases, the risk or severity of the infection to be prevented should be greater than the adverse consequences of antibacterial therapy, including the potential for selection of resistance. In addition, the timing and duration of antibacterial treatment should be targeted for maximal effect and minimal required exposure. Prophylaxis of surgical infections targets bacteria that may contaminate the wound during the surgical procedure, including the skin flora of the patient or operating team and the air in the operating room. Delivery of the antibacterial drug within 1 h before the surgical incision is most effective because it maximizes tissue concentrations. For prolonged procedures, redosing may be necessary to maintain effective blood and tissue levels until the wound is closed. Additional dosing is not recommended after the incision is closed, and antimicrobials should be discontinued after incisional closure in the operating room. In patients with nasal carriage of *S. aureus*, preoperative decolonization with nasal mupirocin reduces the rate of *S. aureus* surgical-site infections and is generally recommended for high-risk procedures such as cardiac surgery and orthopedic implantation of prosthetic devices. For dental procedures, preprocedure antibacterial drugs are recommended for select patient populations to prevent transient bacteremia during the procedure and the seeding of certain high-risk cardiac lesions. Prophylaxis is also used in nonprocedural settings in certain patients who have recurrent infections or who are at risk of serious infection from a specific exposure (e.g., close contact with a patient with meningococcal meningitis). Extension of prophylaxis beyond the period of infection risk does not add further benefit and may increase the risk of resistance selection or *C. difficile* disease.

ANTIMICROBIAL STEWARDSHIP

In an era of increasing prevalence of multidrug-resistant bacteria and with a substantial amount of inappropriate antimicrobial use, the need for rational antimicrobial prescribing has never been greater **(Chap. 150)**. *Antimicrobial stewardship* describes the practice of promoting the selection of the appropriate drug, dosage, route, and duration of therapy. Antimicrobial stewardship programs implement a variety of strategies to (1) improve patient care through appropriate antimicrobial use; (2) preserve a vital health care resource by curbing the development of resistance within patient populations; (3) reduce the incidence of adverse effects; and (4) control costs. The Centers for Disease Control and Prevention (CDC) guidelines, The Joint Commission (TJC) Medication Management Standards, and the Centers for Medicare and Medicaid Services (CMS) Conditions of Participation, as well as the 2015 National Action Plan for Combating Antibiotic-Resistant Bacteria, have all supported *antimicrobial stewardship* in various health care settings. Antimicrobial stewardship programs are typically multidisciplinary and often include infectious disease physicians, clinical pharmacists (usually with special training in infectious disease), clinical microbiologists, information systems specialists, infection prevention and control practitioners, and epidemiologists. These teams employ a variety of approaches to achieve the program's goals.

Established strategies of antimicrobial stewardship programs include (1) prospective audit of antimicrobial use, with intervention and feedback; (2) formulary restriction; and (3) preauthorization. *Prospective audit and feedback* are usually undertaken by an infectious disease physician or a pharmacist. In this process, orders for broad-spectrum antimicrobials (e.g., carbapenems) or agents for which more cost-effective alternatives may exist (e.g., daptomycin, ceftazidime-avibactam) are reviewed on a regular basis for appropriateness. In circumstances when antimicrobial use can be further optimized, the stewardship program team can intervene to recommend an alternative. This process has been successful in several quasi-experimental studies, resulting in declines in use of broad-spectrum drugs when unnecessary and decreases in adverse events, such as *C. difficile* infection. *Formulary restriction* is the inclusion of a limited set of antimicrobial agents in a hospital formulary for the purpose of limiting indiscriminate use of antimicrobials in the absence of demonstrated benefit. Such restriction also serves to avoid unnecessary drug expenditure. *Preauthorization* is the practice of requiring clinicians to obtain approval before using

TABLE 149-5 Prophylaxis of Bacterial Infections in Adults

CONDITION	ANTIBACTERIAL AGENTS[a]	TIMING OR DURATION OF PROPHYLAXIS
Surgical		
Clean (cardiac, thoracic, neurologic, orthopedic, vascular, plastic)	Cefazolin (vancomycin,[b] clindamycin)	1 h before incision; re-dose with long procedures
Clean (ophthalmic)	Topical neomycin–polymyxin B–gramicidin, topical moxifloxacin	Every 5–15 min for 5 doses immediately prior to procedure
Clean-contaminated (head and neck)	Cefazolin + metronidazole, ampicillin-sulbactam[c] (clindamycin)	1 h before incision; re-dose with long procedures
Clean-contaminated (hysterectomy, gastroduodenal, biliary, unobstructed small intestine, urologic)	Cefazolin, ampicillin-sulbactam[c] (clindamycin + aminoglycoside, aztreonam, or fluoroquinolone)	1 h before incision; re-dose with long procedures
Clean-contaminated (colorectal, appendectomy)	Cefazolin + metronidazole, ampicillin-sulbactam,[c] ertapenem (clindamycin + aminoglycoside, aztreonam, or fluoroquinolone)	1 h before incision; re-dose with long procedures
Dirty (ruptured viscus)	Therapeutic regimen directed at anaerobes and gram-negative bacteria (e.g., ceftriaxone + metronidazole)	1 h before incision; re-dose with long procedures; continue for 3–5 days after procedure
Dirty (traumatic wound)	Therapeutic regimen: cefazolin (clindamycin ± aminoglycoside, aztreonam, or fluoroquinolone)	1 h before incision; re-dose with long procedures; continue for 3–5 days after procedure
Nonsurgical		
Dental, oral, or upper respiratory procedures in patients with high-risk cardiac lesions (prosthetic valves, congenital heart defects, prior endocarditis)	Amoxicillin PO, ampicillin IM (clindamycin PO, IV)	Oral agents 1 h before procedure; injection 30 min before procedure
Recurrent *S. aureus* skin infections[d]	Mupirocin[e]	Intranasal application for 5 days
Recurrent cellulitis associated with lymphatic disruption[d]	Benzathine penicillin IM monthly, oral penicillin or erythromycin twice daily	Undefined
Recurrent cystitis in women[d]	Nitrofurantoin, TMP-SMX, fluoroquinolone	After sexual intercourse *or* 3 times weekly for up to 1 year
Bite wounds	Amoxicillin-clavulanate (doxycycline, moxifloxacin)	3–5 days
Recurrent spontaneous bacterial peritonitis in cirrhotic patients[d]	Fluoroquinolone[f]	Undefined
Recurrent pneumococcal meningitis in patient with CSF leak or humoral immune defect[d]	Penicillin	Undefined
Exposure to patient with meningococcal meningitis	Rifampin, ciprofloxacin	2 days (rifampin), single dose (ciprofloxacin)
High-risk neutropenia (ANC, ≤100/μL for >7 days)[d]	Levofloxacin or ciprofloxacin[f]	Until neutropenia resolves or fever dictates use of other antibacterials

[a]Regimens in parentheses are alternatives for patients allergic to β-lactams. [b]Vancomycin may be given together with cefazolin to patients known to be colonized with methicillin-resistant *Staphylococcus aureus*. [c]Cefoxitin or cefotetan may also be considered. [d]Not considered routine for all patients, but an acceptable consideration among alternative approaches. [e]Usually coupled with bathing with chlorhexidine-containing skin antiseptic. [f]Choice of fluoroquinolone prophylaxis must be balanced against the risk of selection of resistance.

Abbreviations: ANC, absolute neutrophil count; CSF, cerebrospinal fluid; TMP-SMX, trimethoprim-sulfamethoxazole.

selected antimicrobials. Approval may be provided electronically with sophisticated Computerized Provider Order Entry (CPOE) software, after specific criteria for use are met, or after communication with an infectious disease specialist as designated by the stewardship program. These strategies have led to a decrease in *C. difficile* infections and to improvements in drug susceptibility patterns.

Additional strategies used in specific health care settings are guidelines and pathways, dose optimization, parenteral-to-oral conversion, antibiotic time-out, and de-escalation of therapy. Documentation of the indication for which each antimicrobial is prescribed is also encouraged. Finally, antimicrobial stewardship teams provide ongoing education of best practices. An evolving and increasingly active area of clinical research to identify best practices, antimicrobial stewardship continues to grow as an essential service in various health care settings. The IDSA, in collaboration with several other professional organizations, has published guidelines for developing institutional antimicrobial stewardship programs (*www.idsociety.org/Antimicrobial_Agents/*).

150 Bacterial Resistance to Antimicrobial Agents

David C. Hooper

DEFINITION OF RESISTANCE

The action of antimicrobial agents on a range of targets within the bacterial cell can result in inhibition of bacterial growth or in killing of the bacterial cell (Chap. 149). Reduction in or loss of an agent's antibacterial effect is referred to as *resistance*, and the properties of or alterations in the bacterium that result in reduced antimicrobial activity are termed *resistance mechanisms*. Bacteria can be resistant to single or multiple antimicrobials, as detailed in the sections that follow. The occurrence and magnitude of resistance are often assessed in clinical microbiology laboratories by measurement of the lowest drug concentration that inhibits growth of a bacterium (minimal inhibitory concentration, or MIC) with a standardized inoculum and growth conditions. MIC values are generally interpreted as representing bacterial susceptibility, intermediate susceptibility, or resistance; the interpretation is based on correlations of the MIC values with the pharmacokinetics and delivery of a drug to the site of infection in the body as well as with data from clinical trials. Thus, a clinical laboratory result of "susceptible" for a bacterium predicts a likely clinical response to an appropriately dosed antimicrobial drug by a patient infected with that organism, whereas a result of "resistant" predicts poor or no clinical response to that drug. Breakpoint MIC values for categorization of bacteria as susceptible, intermediate, or resistant are generally developed by regulatory and advisory groups and are often based on the distribution of MIC values from a large collection of recent clinical bacterial isolates. Research studies on the mechanisms and epidemiology of resistance may in some cases use different and less rigid definitions of resistance based on determination of a reproducible increase in an MIC value relative to a baseline reference MIC, independent of clinical breakpoints.

MECHANISMS OF RESISTANCE

Bacteria use a wide variety of mechanisms to interrupt or circumvent the activity of antibacterial agents (Table 150-1 and Fig. 150-1). Although myriad, these mechanisms can generally be grouped into three categories: (1) alteration or bypassing of targets that exhibit reduced binding of the drug, (2) altered access of the drug to its target by reductions in uptake or increases in active efflux, and (3) a modification of the drug that reduces its activity. These mechanisms result from either mutations in bacterial chromosomal genes occurring spontaneously during bacterial DNA replication or the acquisition of new genes by DNA transfer from other bacteria or uptake of exogenous DNA. New genes are most often acquired on self-replicating plasmids or other DNA elements transferred from other bacteria. However, some bacteria, such as *Streptococcus pneumoniae* and *Neisseria gonorrhoeae*, can also take up fragments of environmental DNA from related bacterial species and recombine that DNA directly into their own chromosomes, a process called *transformation*. Not uncommonly, resistant bacteria have combinations of resistance mechanisms either within one category or among categories; many plasmids contain more than one resistance gene; and bacteria can acquire multiple plasmids. Thus, plasmid acquisition itself can in many cases confer resistance to multiple antibacterial agents. Resistance to multiple, structurally unrelated antibiotics can also occur by mutations that cause increased expression or, less often, expanded substrate profiles of certain bacterial efflux pumps, some of which are able to transport multiple antibacterial agents as well as other compounds out of the cell.

Many antibacterial drugs are derived from natural products of environmental microbial species. Some genes encoding resistance to these drugs originate in the drug-producer organism to protect it from its own product and have then been mobilized onto plasmids that spread to other organisms. Surviving nonproducer bacteria in the exposed natural environment may also have evolved resistance under selection pressure that adds to the reservoir of resistance mechanisms. Exposure to antibacterial agents either in nature or during human, animal, or other use then results in the selection of resistant strains within an otherwise susceptible bacterial population. In some cases, resistance mechanisms may confer disadvantages that render bacterial growth or survival fitness inferior to that of susceptible strains. In a number of examples, however, fitness defects are often mitigated over time by compensatory mutational mechanisms that make the bacteria both resistant and fit and thereby more likely to persist in a reservoir even in the absence of continued antimicrobial selection pressures. Discussed below are the major classes of antimicrobial agents currently in clinical use and the most important mechanisms of resistance encountered in clinical infections.

β-Lactams β-lactams, the largest class of antibiotics, inhibit bacterial cell-wall synthesis by binding to cell-wall transpeptidases, cross-linking enzymes that are also called penicillin-binding proteins (PBPs); PBPs are targets that are unique to bacteria and have no mammalian counterpart. The most common mechanism of resistance to β-lactams, particularly in gram-negative bacteria, is their degradation by β-lactamases, enzymes that break down the core β-lactam ring and destroy drug activity. β-Lactamases differ in the spectrum of β-lactams they can degrade. Some β-lactamases are encoded on the bacterial chromosome, and their activity contributes to the intrinsic susceptibility profile of a particular species. Chromosomally encoded β-lactamases can be produced in varying amounts that affect the degree of resistance. In some cases, enzyme expression is physiologically induced by exposure to certain β-lactams; in other cases, enzyme expression can become constant or constitutive through mutations in genes that encode the regulators of expression of a β-lactamase gene. Other β-lactamases are encoded by genes on acquired plasmids and are usually constitutively expressed. The resistance profiles due to plasmids may be present in some strains of a species but not others, depending on which plasmids the strain has acquired. In gram-positive bacteria, β-lactamases are secreted into the extracellular environment, whereas in gram-negative bacteria these enzymes are secreted into the periplasmic space between the cytoplasmic and outer membranes—a limited space that enables the presence of high concentrations of β-lactamase. In gram-negative bacteria, access of β-lactams both to their target PBPs and to β-lactamases requires diffusion across the outer membrane, generally through the porin diffusion channels. Reductions in outer-membrane diffusion channels due to mutation can further augment the efficiency of β-lactamase degradation of β-lactams: slow diffusion acts together with the high enzyme concentrations in the periplasmic space to enhance drug degradation and resistance.

Most strains of *Staphylococcus aureus* produce a plasmid-encoded β-lactamase that degrades penicillin but not semisynthetic penicillins, such as oxacillin and nafcillin. The greatest diversity among β-lactamases, however, is found in gram-negative bacteria. The most common and earliest identified plasmid-encoded β-lactamases of gram-negative bacteria can inactivate all penicillins and most early-generation cephalosporins. Multiple extended-spectrum β-lactamase (ESBL) variants of these early enzymes have emerged and are now widely disseminated. These ESBLs can degrade later-generation cephalosporins (ceftriaxone, cefotaxime, ceftazidime) as well as the monobactam aztreonam, and some ESBLs also degrade the fourth-generation cephalosporin cefepime. Carbapenems (imipenem, meropenem, ertapenem, doripenem) generally are not degraded by ESBLs, but additional β-lactamases, called *carbapenemases*, which degrade carbapenems and most if not all other β-lactams, have emerged and are increasing in prevalence. In the United States, *Klebsiella pneumoniae* carbapenemases (KPCs), which are usually found in strains of *Escherichia coli* and *K. pneumoniae*, are most widespread, but New Delhi metallo-β-lactamases (NDM carbapenemases), which were found initially on the Indian subcontinent, have now appeared and increased in the United States, as has an OXA group carbapenemase, OXA-48. In some cases, high levels of expression of an ESBL or an AmpC chromosomally encoded enzyme (see below), together

TABLE 150-1 The Most Common Mechanisms of Resistance to Antibacterial Agents

ANTIBACTERIAL AGENT(S)	MAJOR TARGET	MECHANISM(S) OF ACTION	MECHANISM(S) OF RESISTANCE
β-Lactams (penicillins, cephalosporins, monobactams, carbapenems)	Cell-wall synthesis	Bind cell-wall cross-linking enzymes (PBPs, transpeptidases)	Drug inactivation by β-lactamases Altered PBP targets Reduced diffusion through porin channels Altered iron uptake proteins (cefiderocol)
Glycopeptides and lipoglycopeptides (vancomycin, teicoplanin, telavancin, dalbavancin, oritavancin)	Cell-wall synthesis	Block cell wall glycosyltransferases by binding D-Ala-D-Ala stem-peptide terminus Teicoplanin, telavancin, dalbavancin, and oritavancin: affect membrane function	Altered D-Ala-D-Ala target (D-Ala-D-Lac) Increased D-Ala-D-Ala target binding at sites distant from cell wall synthesis enzymes
Bacitracin	Cell-wall synthesis	Blocks lipid carrier of cell wall precursors	Active drug efflux
Fosfomycin	Cell-wall synthesis	Blocks linkage of stem peptide to NAG by enoyltransferase	Target enzyme overexpression Drug-modifying enzymes
Aminoglycosides (gentamicin, tobramycin, amikacin, plazomicin)	Protein synthesis	Bind 30S ribosomal subunit Block translocation of peptide chain Cause misreading of mRNA	Drug-modifying enzymes Methylation at ribosome binding site Decreased permeation to target due to active efflux
Tetracyclines (tetracycline, doxycycline, minocycline)	Protein synthesis	Bind 30S ribosomal subunit Inhibit peptide elongation	Active drug efflux Ribosomal protection proteins
Tigecycline, eravacycline, omadacycline	Protein synthesis	Same as tetracyclines	Active drug efflux (pumps different from those affecting tetracyclines)
Macrolides (erythromycin, clarithromycin, azithromycin) and the ketolide telithromycin	Protein synthesis	Bind 50S ribosomal subunit Block peptide chain exit	Methylation at ribosome binding site Active drug efflux
Lincosamides (clindamycin)	Protein synthesis	Bind 50S ribosomal subunit Block peptide bond formation	Methylation at ribosome binding site
Streptogramins (quinupristin, dalfopristin)	Protein synthesis	Same as macrolides	Same as macrolides Drug-modifying enzymes
Chloramphenicol	Protein synthesis	Binds 50S ribosomal subunit Blocks aminoacyl tRNA positioning	Drug-modifying enzymes
Oxazolidinones (linezolid, tedizolid)	Protein synthesis	Bind 50S ribosomal subunit Inhibit initiation of peptide synthesis	Altered rRNA binding site Methylation of ribosome binding site
Pleuromutilins (lefamulin)	Protein synthesis	Bind 50S ribosomal subunit Blocks peptidyl transferase center	Altered L3 and L4 protein binding site Methylation of ribosome binding site
Mupirocin	Protein synthesis	Blocks isoleucyl tRNA synthetase	Acquired resistant tRNA synthetase (drug bypass) Altered native tRNA synthetase target
Sulfonamides (sulfadiazine, sulfisoxazole, and sulfamethoxazole)	Folate synthesis	Inhibit dihydropteroate synthetase	Acquired resistant dihydropteroate synthetase (drug bypass)
Trimethoprim	Folate synthesis	Inhibits dihydrofolate reductase	Acquired resistant dihydrofolate reductase (drug bypass)
Quinolones (norfloxacin, ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, gemifloxacin, delafloxacin)	DNA synthesis	Inhibit DNA gyrase and DNA topoisomerase IV Enzyme–DNA–drug complex: blocks DNA replication apparatus	Altered target(s) Active efflux Protection of target from drug Drug-modifying enzyme (ciprofloxacin)
Rifamycins (rifampin, rifabutin, rifapentine)	RNA synthesis	Inhibit RNA polymerase	Altered target
Nitrofurantoin	Nucleic acid synthesis	Reduces reactive drug derivatives that damage DNA	Altered drug-activating enzymes
Metronidazole	Nucleic acid synthesis	Reduces reactive drug derivatives that damage DNA	Altered drug-activating enzyme Acquired detoxifying enzymes Active efflux
Polymyxins (polymyxin B and polymyxin E [colistin])	Cell membrane	Bind LPS and disrupt both outer and cytoplasmic membranes	Altered cell-membrane charge with reduced drug binding
Daptomycin	Cell membrane	Produces membrane channel and membrane leakage	Altered cell-membrane charge with reduced drug binding

Abbreviations: LPS, lipopolysaccharide; NAG, *N*-acetylglucosamine; PBP, penicillin-binding protein.

with reduced porin diffusion channels, can also result in resistance to carbapenems. In *Pseudomonas aeruginosa*, resistance to carbapenems can occur by mutations that cause reductions in the OprD diffusion channel for imipenem or increased expression of efflux pumps that can remove meropenem from the bacterial cell.

The chromosomal β-lactamase of *K. pneumoniae* preferentially degrades penicillins over cephalosporins. In contrast, the chromosomal β-lactamase of *Enterobacter* and related genera, AmpC, can degrade almost all cephalosporins but is normally expressed in only small amounts. Mutations in regulatory genes that cause increased

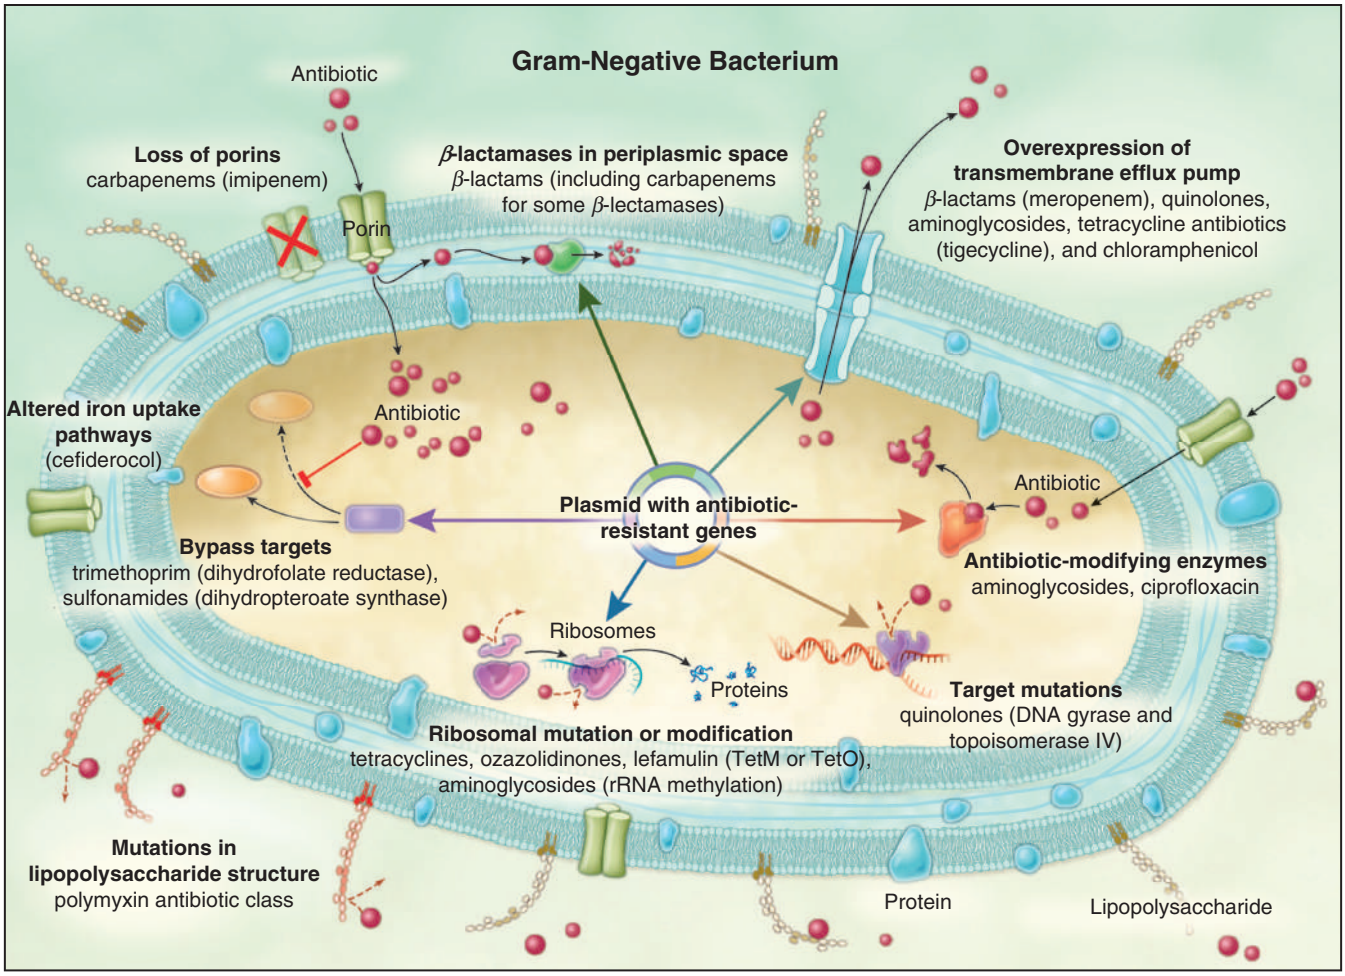

FIGURE 150-1 Antibacterial targets and mechanisms of resistance to antibacterial agents, as illustrated in a gram-negative bacterium. Similar mechanisms are found in gram-positive bacteria, but their lack of an outer membrane causes β-lactamases to be excreted outside the cell, rather than into the periplasmic space between the inner and outer membranes, and reduces the efficiency of efflux pumps because exported drugs can re-enter the cell after crossing a single membrane, rather than the two membranes in gram-negative bacteria. Red spheres indicate antibiotics. *(From AY Peleg, DC Hooper: Hospital-acquired infections due to gram-negative bacteria. N Engl J Med 362:1084, 2010. Copyright © 2010 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

amounts of AmpC to be produced can cause full resistance to penicillins and cephalosporins; the exceptions are cefoxitin and cefepime, which are relatively stable to AmpC. Resistance to cefepime can develop, however, through the combined effects of mutations that cause increased AmpC production and decreased porin diffusion channels. Genes encoding AmpC have also been found on plasmids but are less common than plasmid-encoded ESBLs. A recent novel cephalosporin, cefiderocol, has enhanced stability to β-lactamases and, due to a catechol side group, is actively taken up into the bacterial cell by siderophore iron uptake pathways, rather than diffusing passively through porin channels. It is active against many gram-negative bacteria that are resistant to other β-lactams, including carbapenems. Reduced susceptibility has been reported to occur in strains with mutations in multiple iron transport genes.

Inhibitors of β-lactamases such as clavulanate, sulbactam, tazobactam, avibactam, vaborbactam, relebactam, and durlobactam have been developed and paired with amoxicillin and ticarcillin (clavulanate), ampicillin (sulbactam), piperacillin and ceftolozane (tazobactam), ceftazidime (avibactam), meropenem (vaborbactam), imipenem (relebactam), and sulbactam (durlobactam), which has selective activity against *Acinetobacter*. These inhibitors, with the exception of sulbactam, have little or no antibacterial activity of their own but inhibit plasmid-mediated β-lactamases, including ESBLs. Only avibactam, vaborbactam, and relebactam inhibit AmpC enzymes and some carbapenemases (KPCs but not metallo-carbapenemases, such as NDM).

Resistance to β-lactams also occurs through alterations in the drugs' target transpeptidase enzymes (PBPs) involved in cross-linking of the bacterial cell-wall peptidoglycan structure. In *S. pneumoniae*, *N. gonorrhoeae*, and *Neisseria meningitidis*, resistance to penicillin occurs by recombination of transformed DNA from related species that results in mosaic PBPs with lower affinity for penicillin. A combination of increased expression of an efflux pump and a porin mutation also causes penicillin resistance in *N. gonorrhoeae*. In staphylococci, resistance to methicillin and other β-lactams occurs by acquisition of the *mec* gene, which encodes a PBP2a with reduced drug affinity. PBP2a is a bypass target that can function in cell wall cross-linking in the presence of β-lactams, bypassing their effect on other PBPs. Ceftaroline is the only β-lactam that has affinity for PBP2a and is thus active against methicillin-resistant staphylococcal strains. Resistance to ceftaroline can occur, however, by mutations in the gene encoding PBP2a that reduce its affinity for the drug.

Glycopeptides and Lipoglycopeptides Glycopeptides and lipoglycopeptides inhibit bacterial cell-wall synthesis by binding to the terminal two D-alanine amino acids on the cell-wall peptidoglycan stem peptides, which are involved in peptidoglycan cross-links. In doing so, these drugs block the transpeptidase cross-linking enzymes and glycosyl transferases necessary for cell-wall synthesis. Resistance to vancomycin in enterococci is due to the acquisition of a set of *van* genes that result in (1) the production of D-alanine-D-lactate—instead of the normal D-alanine-D-alanine—at the end of the peptidoglycan stem peptide and (2) the reduction of existing D-alanine-D-alanine–terminated peptides. Vancomycin binds D-alanine-D-lactate with a 1000-fold lower affinity than D-alanine-D-alanine. The *van* genes originated in the organisms that naturally produce vancomycin and have been mobilized and reorganized in transposon mobile genetic elements

and onto plasmids, which can be transferred between enterococci. In rare cases, the *van* gene cassettes have been transferred from enterococci to *S. aureus*, with the consequent generation of full vancomycin resistance. In *S. aureus*, intermediate resistance to vancomycin is more common than full vancomycin resistance and is due to a different mechanism that results from a series of several chromosomal mutations leading to a thickened and poorly cross-linked cell wall. This modified cell wall contains additional D-alanine-D-alanine–terminated stem peptides that bind vancomycin at a site distant from the cell membrane, adjacent to which new peptidoglycan is synthesized and where vancomycin binding blocks transpeptidase and transglycosylase enzymes. Thus, vancomycin's binding to these distant termini impedes its access to the proximal binding sites that result in inhibition of peptidoglycan synthesis. This intermediate-resistance phenotype was first recognized in patients receiving prolonged courses of vancomycin that created an opportunity for selection of the multiple mutations needed to produce the modified cell wall. Because of the energy costs of a thickened cell wall, this intermediate-resistance phenotype may be unstable, with strains returning to susceptibility in the absence of vancomycin selection pressure. Susceptibility to telavancin, dalbavancin, and oritavancin is also reduced in strains that exhibit resistance or intermediate susceptibility to vancomycin, although in some cases, the drugs remain sufficiently active that the strains may still be classified as susceptible based on standard clinical laboratory interpretive criteria.

Aminoglycosides Aminoglycosides are one of several classes of antimicrobials that inhibit protein synthesis by binding to either the 30S or the 50S bacterial ribosomal subunit (both of which differ from eukaryotic ribosomal subunits), with consequent selective antibacterial activity. The aminoglycosides bind to the 30S subunit of the bacterial ribosome. The most common mechanism of resistance to aminoglycosides in gram-negative bacteria is due to acquisition of plasmids with genes encoding transferase enzymes that modify aminoglycosides by the addition of acetyl, adenyl, or phosphate groups; these added groups decrease the drugs' binding affinity to their ribosomal target site. Various transferases differ in which aminoglycosides they modify, and amikacin resistance occurs less often than resistance to gentamicin or tobramycin by these mechanisms. Plazomicin, a recently developed aminoglycoside, is distinctive in that it remains active and is not modified by most transferases. Another mechanism of plasmid-mediated aminoglycoside resistance is due to methylase enzymes that can methylate the site of aminoglycoside binding on the 16S ribosomal RNA of the 30S ribosomal subunit and reduce drug binding to its ribosome target, resulting in resistance to all aminoglycosides, including plazomicin. For streptomycin, a single ribosomal protein mutation may also cause resistance. In *P. aeruginosa*, aminoglycoside resistance can also occur through mutations in regulatory genes causing increased expression of a chromosomally encoded efflux pump, MexXY, which reduces intracellular drug concentrations.

Tetracyclines These antibiotics bind the 16S ribosomal RNA of the 30S ribosomal subunit at a site distinct from the binding site of the aminoglycosides and inhibit bacterial protein synthesis. For tetracyclines, including doxycycline and minocycline, resistance is often plasmid-mediated and due either to active efflux pumps, which in some cases are specific for tetracyclines, or to proteins that protect the ribosome from tetracycline action. Some broad-spectrum, chromosomally encoded efflux pumps may also include tetracyclines among their substrates, and regulatory mutations that cause pump overexpression may confer tetracycline resistance together with resistance to other agents that are pump substrates. There have been recent derivatives of the tetracyclines, including the glycylcycline, tigecycline, the fluorocycline, eravacycline, and the aminomethylcycline, omadacycline, which have modifications on the core tetracycline ring structure rendering them less affected or unaffected by the common tetracycline resistance mechanisms. Resistance to the newer tetracyclines can occur, however, through mutations that cause overexpression of some broad-spectrum efflux pumps, particularly in *Proteus* species. An uncommon plasmid-encoded tetracycline modification mechanism can also cause resistance to the newer agents.

Macrolides, Ketolides, Lincosamides, and Streptogramins These antibiotics are also inhibitors of bacterial protein synthesis, in this case through their binding to the 23S RNA of the 50S ribosomal subunit. They are generally active against gram-positive bacteria. Resistance to macrolides, clindamycin, and quinupristin is most often due to acquired Erm methylases that modify the drug-binding site on the ribosome, reducing drug binding. Resistance to quinupristin by this mechanism renders the quinupristin-dalfopristin combination bacteriostatic rather than bactericidal. Telithromycin, a ketolide structurally related to macrolides, has an additional binding site on the ribosome and remains active in the presence of some methylases. Methylase gene expression can be induced by exposure to most macrolides but generally not ketolides (e.g., telithromycin); however, bacterial strains constitutively expressing methylase genes can display resistance to both macrolides and ketolides. Acquired genes encoding active efflux pumps can also contribute to resistance to macrolides in streptococci and to resistance to macrolides, clindamycin, and dalfopristin in staphylococci. Plasmid-acquired, drug-modifying enzymes in staphylococci can also cause resistance to quinupristin and dalfopristin. Macrolide resistance due to 23S rRNA mutations at the site of drug binding is uncommon in staphylococci and streptococci because of the multiple copies of the rRNA genes on the chromosomes of these species; such resistance mechanisms may occur more frequently, however, in mycobacteria, *Helicobacter pylori*, and *Treponema* species, which have only one or two chromosomal copies of these rRNA genes, thus requiring fewer mutations to generate a resistance phenotype. Among gram-negative bacteria, many of which are not susceptible to current macrolides because of inadequate drug permeation across the outer membrane, some strains with acquired genes for macrolide-modifying enzymes have been described.

Chloramphenicol Chloramphenicol inhibits bacterial protein synthesis by binding to the 23S rRNA of the 50S subunit at a site that overlaps the macrolide-binding site. Chloramphenicol is uncommonly used in human medicine because of infrequent but potentially severe bone marrow toxicity. Resistance to chloramphenicol is most often due to plasmid-encoded, drug-modifying acetyltransferases that have been found in both gram-positive and gram-negative bacteria and whose expression can be induced by drug exposure. Among staphylococci, some resistant strains have been found to have a plasmid-encoded ribosomal methylase that confers resistance to chloramphenicol, clindamycin, and oxazolidinones. As is the case for macrolides, ribosomal mutations causing resistance to chloramphenicol are uncommon because of multiple copies of rRNA genes in the common gram-positive human pathogens. Plasmid-encoded efflux pumps affecting chloramphenicol specifically have been found in gram-negative bacteria, and other pumps affecting chloramphenicol and oxazolidinones have been found in gram-positive bacteria.

Oxazolidinones Linezolid and tedizolid are the only members of the oxazolidinone class of antimicrobials in clinical use, and both are active against gram-positive bacteria only; lack of sufficient activity in gram-negative bacteria results from the ability of native efflux pumps in these bacteria to limit drug access to their cytoplasmic ribosome targets. Oxazolidinones target the bacterial ribosome and inhibit protein synthesis by binding to 23S rRNA of the 50S subunit at a distinct site that overlaps with the chloramphenicol-binding site. Resistance has been seen in enterococci more often than in staphylococci and, in both organisms, is most often due to mutations in multiple copies of the 23S rRNA genes that reduce drug binding to the ribosome. A plasmid-acquired ribosomal methylase gene that enables ribosomal alteration at a site that confers resistance to both linezolid and chloramphenicol has also been found in some strains of both *S. aureus* and coagulase-negative staphylococci but is not yet widespread. A plasmid-encoded active efflux pump conferring resistance to oxazolidinones (both linezolid and tedizolid) and chloramphenicol has been described in animal isolates and a small number of human isolates of *Enterococcus faecalis*.

Pleuromutilins Lefamulin is the only systemic pleuromutilin in clinical use. Retapamulin has been available for topical use in skin infections. Pleuromutilins inhibit bacterial protein synthesis by

binding to the peptidyl transferase center in the 50S ribosomal subunit, and lefamulin is generally active against gram-positive bacteria, *Haemophilus influenzae*, *Moraxella catarrhalis,* and atypical respiratory pathogens, such a *Mycoplasma pneumoniae* and *Legionella* spp. Although there is partial overlap in the site of binding of lefamulin and those of other antibacterials binding the 50S ribosomal subunit, cross-resistance with macrolides, oxazolidinones, lincosamides, and streptogramins is uncommon. Resistance to lefamulin can occur by mutations in L3 and L4 proteins of the 50S subunit that alter the lefamulin binding site. In addition, the plasmid-encoded Cfr methylase, which confers resistance to chloramphenicol and oxazolidinones, can also cause resistance to lefamulin by disrupting its binding site. Vga efflux transporters, which cause resistance to lincosamides and streptogramins, also affect pleuromutilins.

Mupirocin Mupirocin is used only in topical formulations, most often for elimination of nasal carriage of *S. aureus*. It targets bacterial leucyl-tRNA synthetase and inhibits protein synthesis. Resistance to mupirocin occurs by either mutation in the target leucyl-tRNA synthetase (low-level resistance) or the acquisition of a plasmid-encoded resistant tRNA synthetase (high-level resistance), which bypasses drug inhibition of the native, sensitive synthetase.

Sulfonamides and Trimethoprim These agents inhibit the folate biosynthesis pathway at different steps. Sulfonamides are structurally similar to *para*-aminobenzoic acid (PABA) and competitively inhibit dihydropteroate synthetase, which, in an early step in the pathway, uses PABA to synthesize dihydropteroate, a precursor of dihydrofolate. Trimethoprim inhibits dihydrofolate reductase at a later step in the pathway that generates tetrahydrofolate. Clinical use of folate pathway inhibitors most often consists of the combination of sulfamethoxazole and trimethoprim; on occasion, however, trimethoprim or various sulfonamides are used individually. Resistance to both of these antimetabolites can result from mutation in their target enzymes or can be due to plasmid-acquired genes encoding resistant enzymes that bypass the inhibition of the native sensitive enzymes—a resistant dihydropteroate synthetase in the case of sulfonamides and a resistant dihydrofolate reductase in the case of trimethoprim. Resistance to the combination of sulfamethoxazole and trimethoprim requires that the bacterial strain have resistance mechanisms for both agents and yet is relatively common. Resistance due to drug efflux or drug modification has been limited for both sulfonamides and trimethoprim.

Quinolones Quinolones are synthetic inhibitors of bacterial DNA synthesis. They bind to two enzymes required for DNA synthesis: DNA gyrase and DNA topoisomerase IV, which alter DNA conformation and the interlinking of replicated molecules. In addition to inhibiting the enzymes' catalytic functions of altering DNA topology, they stabilize enzyme–DNA complexes that form a barrier to the DNA replication machinery and are a precursor to lethal double-strand DNA breaks. Although related topoisomerase enzymes are involved in mammalian DNA synthesis, the mammalian and bacterial enzymes are sufficiently different from each other for quinolones to have selective activity against bacteria. Resistance to quinolones is most often due either to chromosomal mutations altering the target enzymes DNA gyrase and DNA topoisomerase IV, with consequent reduction in drug binding, or to mutations that increase the expression of native broad-spectrum efflux pumps for which quinolones (among other compounds) are substrates. In addition, three types of acquired genes can confer reduced susceptibility or low-level resistance by protecting the target enzymes, modifying some quinolones (particularly ciprofloxacin and norfloxacin) to reduce their activity, or generating an efflux of quinolones. These genes are usually located on multidrug-resistance plasmids that have spread worldwide. Their presence can promote higher levels of quinolone resistance by enhancing selection of the mutations in chromosomal target genes with exposure to quinolones and can then link quinolone resistance to resistance to other antibacterial drugs that are encoded by the same plasmid.

Rifampin, Rifabutin, and Rifapentine Antimicrobials of the rifamycin class target bacterial RNA polymerase and thereby inhibit transcription of messenger RNA and gene expression. Their activity is generally limited to gram-positive bacteria because native efflux pumps in most gram-negative bacteria reduce drug access to the cytoplasmic enzyme target. Single mutations in the β subunit of RNA polymerase constitute the principal mechanism of acquired rifampin resistance, which is high-level. Thus, rifampin and other rifamycins are used for treatment of infections only in combination with other antibacterial drugs in order to reduce the likelihood of selection of high-level resistance.

Metronidazole Metronidazole is actively taken up by most anaerobic bacteria and then converted to reactive drug derivatives that nonspecifically damage cytoplasmic proteins and nucleic acids. Thus, metronidazole lacks a specific cellular target. Acquired resistance to metronidazole in *Bacteroides* species is rare. Such resistance has been reported in strains that lack the endogenous activating nitroreductase or that have acquired *nim* genes responsible for further reduction of the DNA-damaging nitroso intermediates to an inactive derivative. Active efflux and enhanced DNA repair mechanisms also have been associated with resistance.

Nitrofurantoin Nitrofurantoin is used only for treatment of lower urinary tract infections because adequate drug concentrations are found only in urine. Its mechanism of action is not fully understood but is thought to involve generation of reactive derivative molecules (as occurs with metronidazole) that damage DNA and ribosomes. Resistance to nitrofurantoin in *E. coli* can emerge through a series of mutations that progressively decrease the nitroreductase activity required for generating active nitrofuran metabolites. These mutants are also impaired in growth; this impairment possibly explains the infrequent occurrence of resistance with clinical use of nitrofurantoin.

Polymyxins Because of emerging multidrug resistance in gram-negative bacteria, colistin and polymyxin B have been used for infections due to resistant Enterobacterales, *P. aeruginosa*, and *Acinetobacter* species. Polymyxins are cationic cyclic peptide molecules that bind negatively charged lipopolysaccharides on the gram-negative bacterial outer membrane, with subsequent disruption and permeabilization of both outer-membrane and cytoplasmic-membrane structure. Thus, the polymyxins are bactericidal. Resistance is so far uncommon but can emerge during therapy through mutations that cause reductions in the negative charge of the gram-negative bacterial cell surface, thereby reducing binding of the positively charged colistin. Transferable plasmid-mediated colistin resistance has also been found to be due to *mcr-1* and other *mcr* variants that encode a gene for a phosphoethanolamine transferase that also reduces the negative charge on the cell surface. *mcr*-containing enteric bacteria have now been identified in Asia, Europe, and the United States.

Daptomycin Daptomycin is active against gram-positive bacteria and interacts with and disrupts the cytoplasmic membrane in a calcium-dependent manner, resulting in bactericidal activity. The mechanisms of resistance to daptomycin are complex and involve mutations in several genes that can alter cell membrane charge and structure and reduce daptomycin binding. Resistance to daptomycin is relatively infrequent but has emerged in some *S. aureus* strains with intermediate vancomycin susceptibility from patients treated with vancomycin but not exposed to daptomycin. In some strains of methicillin-resistant *S. aureus*, daptomycin resistance has been linked to acquired susceptibility to β-lactams; combinations of daptomycin with nafcillin or ceftaroline have been successful for treatment of patients infected with resistant strains when daptomycin alone or in combination with other agents has failed. The mechanism of this effect is not yet clear but may involve alteration in surface charge and increased daptomycin binding in the presence of β-lactams. Daptomycin resistance has also been reported in enterococci.

EPIDEMIOLOGY OF RESISTANCE AND REDUCTION OF ITS OCCURRENCE

Multidrug resistance in human bacterial infections has been increasing overall in recent years, substantially limiting the number of antibiotics that can be used to treat some infections. The prevalence of resistance

to various antimicrobials among human pathogens can, however, vary greatly in different geographic areas and even at different institutions in the same area. Thus, specific local data on the occurrence of various types of resistance are an important component of the choice of antimicrobials for empirical treatment of infection until the responsible pathogen is identified and its specific susceptibilities are determined by the clinical microbiology laboratory. Prompt adjustment of the initially chosen antimicrobial on the basis of species and susceptibility data to best target therapy is equally important. These principles emphasize the importance of obtaining appropriate samples for culture or other diagnostic modalities and susceptibility testing—whenever possible, prior to administration of antimicrobials. They also highlight the importance of rapid and sensitive diagnostic methods and the prompt communication of their results to clinicians to inform best choices of antimicrobials.

The overall prevalence of resistance can be affected by a number of factors, including (1) the extent of resistance reservoirs in the patient population; (2) the selection pressures from use of antimicrobials that favor resistant strains over susceptible ones; and (3) the extent by which resistance is amplified by transmission of resistant strains to patients from their environment or other persons, either directly or indirectly via the contaminated hands of health care workers when hand hygiene and other infection control practices are inadequately followed. The likelihood that an individual patient will be infected with a resistant pathogen is likewise affected by his or her history. Studies have shown that prior antibiotic treatment, prior infection with resistant pathogens, and prior hospitalizations all increase this likelihood.

These factors emphasize the importance of the appropriate use of antimicrobials (particularly, the avoidance of their use in clinical conditions in which they are not needed), the use of the shortest courses of therapy sufficient for a successful clinical outcome, and the implementation of antimicrobial stewardship programs **(Chap. 149)** as well as careful and consistent infection control practices in short-term and long-term-care institutions. Antimicrobial agents are distinct among drug classes in human medicine in that—despite their clear clinical value when used appropriately—the extent of their use can compromise their future utility because of resistance. The remarkable ability of pathogens to acquire resistance is inherent in their biology and emphasizes the necessity for clinicians and institutions to pay careful attention to those factors that can be controlled through judicious antimicrobial use and rigorous infection control and prevention practices.

Efforts to address the problems caused by resistance are now being made worldwide. The U.S. Centers for Disease Control and Prevention (CDC) has recently estimated that >2.8 million resistant bacterial infections occur in the United States each year, with 35,900 deaths, and has identified particular resistant pathogens that are of greatest concern because of their overall effects on public health **(Table 150-2)**. Enteric bacteria (such as *E. coli*, *K. pneumoniae*, and *Enterobacter* spp.) and *Acinetobacter* spp. that are resistant to carbapenems are included in the "urgent" category because of their increasing occurrence worldwide and because they are often highly resistant to multiple drugs, with few if any active antimicrobials available for treatment. Resistant *N. gonorrhoeae* is included in this category as well because of the ease with which gonorrhea can be spread from person to person and because limited active agents are now available. Other resistances are common and also affect clinical care, often requiring use of alternatives to first-line agents that can be less effective and less well tolerated. Also affecting clinical care and considered urgent are infections due to *Clostridioides difficile*. Although not directly due to acquired resistance, *C. difficile* disease, like resistant bacterial infections, is linked to antibacterial use (by the disruption of the normal microbiome of the gastrointestinal tract rather than direct resistance selection) and to its ability as a spore-forming bacterium to be spread in health care environments. To address the problems posed by resistance and *C. difficile* disease, the CDC has emphasized a set of five core actions. (1) *Infection prevention and control:* These efforts focus on implementation of evidence-based activities to reduce the risks and incidence of device-related infections overall and on improvement of compliance with infection control practices that prevent transmission of resistant pathogens from one person to another, such as hand hygiene and isolation precautions in health care and long-term care settings. (2) *Tracking and data:* Efforts aim to increase the reporting and sharing of the occurrence of resistance to enhance epidemiologic data and inform targeting of preventive interventions. (3) *Antibiotic use and access:* Antimicrobial stewardship programs with specific components to track usage and educate clinicians on appropriate use have become required in hospitals, and the CDC has implemented efforts to reduce inappropriate use in outpatient settings, with particular attention to upper respiratory illnesses that often do not require antimicrobials because of their common self-limited viral causes. (4) *Vaccines, therapeutics, and diagnostics:* The U.S. Congress and the U.S. Food and Drug Administration, as well as agencies in other countries, have recently developed incentives and enhanced regulatory pathways for drug approval that pharmaceutical companies can use for development of antimicrobials that specifically address particular resistant pathogens. Both small and large companies have undertaken efforts in this area. New technologies for rapid detection of resistance and susceptibility are also being developed by multiple diagnostics companies in order to facilitate the appropriate choice of antimicrobials earlier in the course of illness, providing an important tool for antimicrobial stewardship programs. (5) *Environment and sanitation:* Reservoirs of resistant bacteria and resistance genes on mobile genetic elements can exist in agriculture and food production and domestic animals and have the potential for introduction into humans. Thus, antibiotic use in these environments can amplify resistance reservoirs and increase the chance of human exposure. Therefore, public health interventions addressing these issues in a One Health approach (*https://www.cdc.gov/onehealth/index.html*) are an important component of managing resistance risks.

TABLE 150-2 Antibiotic Resistance Threats in the United States, 2019

THREAT CATEGORY	ORGANISMS
Urgent	Carbapenem-resistant *Acinetobacter*
	Candida auris
	Clostridioides difficile
	Carbapenem-resistant Enterobacterales
	Drug-resistant *Neisseria gonorrhoeae*
Serious	Drug-resistant *Campylobacter*
	Drug-resistant *Candida*
	Extended-spectrum β-lactamase–producing Enterobacterales
	Vancomycin-resistant *Enterococcus*
	Multidrug-resistant *Pseudomonas aeruginosa*
	Drug-resistant nontyphoidal *Salmonella*
	Drug-resistant *Salmonella* serotype Typhi
	Drug-resistant *Shigella*
	Methicillin-resistant *Staphylococcus aureus*
	Drug-resistant *Streptococcus pneumoniae*
	Drug-resistant *Mycobacterium tuberculosis*
Concerning	Erythromycin-resistant group A *Streptococcus*
	Clindamycin-resistant group B *Streptococcus*
Watch List	Azole-resistant *Aspergillus fumagatis*
	Drug-resistant *Mycoplasma genitalium*
	Drug-resistant *Bordetella pertussis*

Section 5 Diseases Caused by Gram-Positive Bacteria

151 Pneumococcal Infections

David Goldblatt, Katherine L. O'Brien

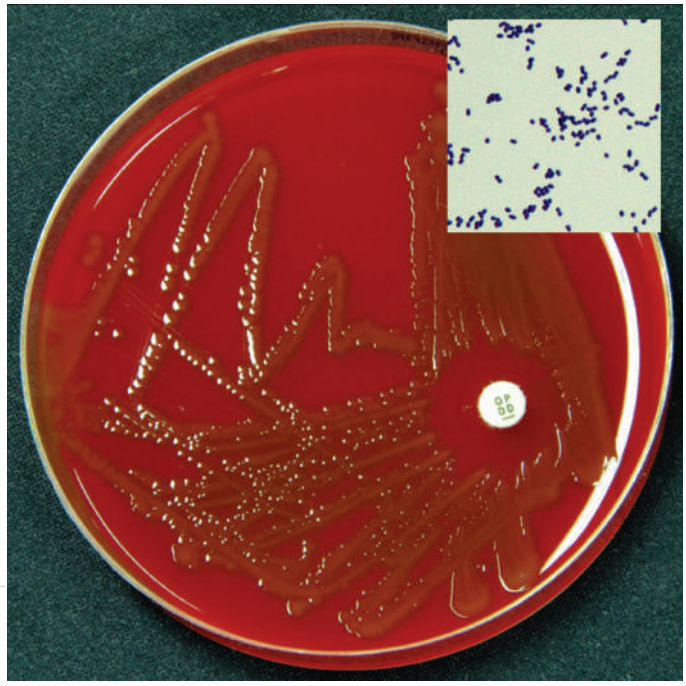

FIGURE 151-1 Pneumococci growing on blood agar, illustrating α hemolysis and optochin sensitivity (zone around optochin disk). *Inset:* Gram's stain, illustrating gram-positive diplococci. *(Photographs courtesy of Paul Turner, University of Oxford, United Kingdom.)*

In the late nineteenth century, pairs of micrococci were first recognized in the blood of rabbits injected with human saliva by both Louis Pasteur, working in France, and George Sternberg, an American army physician. The important role of these micrococci in human disease was not appreciated at that time. By 1886, when the organism was designated "pneumokokkus" and *Diplococcus pneumoniae*, it had been isolated by many independent investigators, and its role in the etiology of pneumonia was well known. In the 1930s, pneumonia was the third leading cause of death in the United States (after heart disease and cancer) and was responsible for ~7% of all deaths both in the United States and in Europe. While pneumonia was caused by a host of pathogens, lobar pneumonia—a pattern more likely to be caused by the pneumococcus—accounted for approximately one-half of all pneumonia deaths in the United States in 1929. In 1974, the organism was reclassified as *Streptococcus pneumoniae*.

MICROBIOLOGY

Etiologic Agent Pneumococci are spherical gram-positive bacteria of the genus *Streptococcus*. Within this genus, cell division occurs along a single axis, and bacteria grow in chains or pairs—hence the name *Streptococcus*, from the Greek *streptos*, meaning "twisted," and *kokkos*, meaning "berry." At least 22 streptococcal species are recognized and are divided further into groups based on their hemolytic properties. *S. pneumoniae* belongs to the α-hemolytic group that characteristically produces a greenish color on blood agar because of the reduction of iron in hemoglobin **(Fig. 151-1)**. The bacteria are fastidious and grow best in 5% CO_2 but require a source of catalase (e.g., blood) for growth on agar plates, where they develop mucoid (smooth/shiny) colonies. Pneumococci without a capsule produce colonies with a rough surface. Unlike that of other α-hemolytic streptococci, their growth is inhibited in the presence of optochin (ethylhydrocupreine hydrochloride), and they are bile soluble.

In common with other gram-positive bacteria, pneumococci have a cell membrane beneath a cell wall, which in turn is covered by a polysaccharide capsule. Pneumococci are divided into serogroups or serotypes based on capsular polysaccharide structure, as distinguished with rabbit polyclonal antisera; capsules swell in the presence of specific antiserum (the Quellung reaction). The most recently discovered serotypes—6C, 6D, 6F, 6G, 6H, 10D, 11E, 20A, 20B, and 35D—have been identified with monoclonal antibodies and by serologic, genetic, and biochemical means. The currently recognized 100 serotypes fall into 21 serogroups, and each serogroup contains two to eight serotypes with closely related capsules. Detailed genetic analysis of the locus coding for the polysaccharide capsule, the *cps* locus, continues to reveal putative novel capsular polysaccharides, variants within existing serogroups that are designated with an "X." In the absence of type-specific antibody, the capsule protects the bacteria from phagocytosis by host cells and is arguably the most important determinant of pneumococcal virulence. Unencapsulated variants are occasionally identified in cases of invasive pneumococcal disease; however, when their genotype is assessed, they often contain capsular genes. Thus it is likely that they were encapsulated in vivo and have stopped producing capsule during the laboratory steps of pathogen isolation.

Virulence Factors Within the cytoplasm, cell membrane, and cell wall, many molecules that may play a role in pneumococcal pathogenesis and virulence have been identified **(Fig. 151-2)**. These proteins are often involved in direct interactions with host tissues or in concealment of the bacterial surface from host defense mechanisms. Pneumolysin (PLY) is a secreted cytotoxin thought to result in cytolysis of cells and tissues, and LytA enhances pathogenesis. A number of cell wall proteins interfere with the complement pathway, thus inhibiting complement deposition and preventing lysis and/or opsonophagocytosis. The pneumococcal H inhibitor (Hic) impedes the formation of C3 convertase, while pneumococcal surface protein C (PspC), also known as choline-binding protein A (CbpA), binds factor H and is thought to accelerate the breakdown of C3. PspA and CbpA inhibit the deposition of or degrade C3b. To avoid clearance by the mucus, pneumococci utilize the matrix metalloprotease ZmpA, which cleaves mucosal IgA to evade complement activation, preventing agglutination and thus clearance by the mucociliary flow.

The numerous pneumococcal proteins thought to be involved in adhesion include pneumococcal surface adhesin A (PsaA) and the exoglycosidases such as neuraminidase (NanA), β-galactosidase (BgaA), and β-N-Acetylglucosaminidase (StrH), which deglycosylate host glycoproteins releasing sugars as a nutrient source and exposing hidden receptors for adhesion. Once through the epithelial barrier, pneumococci utilize PLY and mannose receptor C type lectin 1 (MRC-1/CD206) on the surface of dendritic cells and macrophages to enter cells, where they may survive intracellularly in vacuoles thus

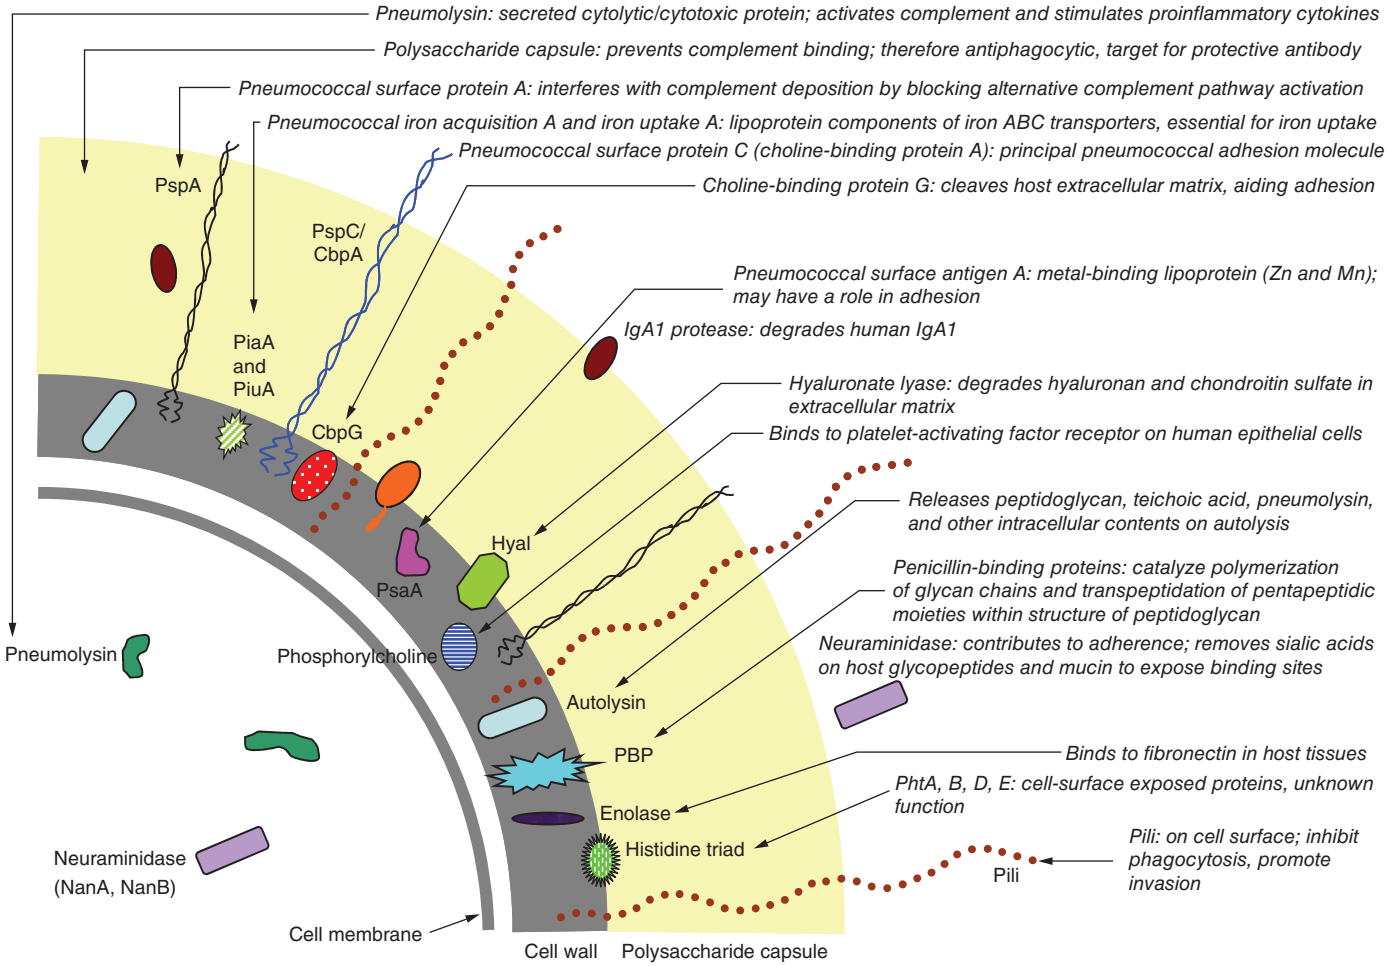

FIGURE 151-2 Schematic diagram of the pneumococcal cell surface, with key antigens and their roles highlighted.

facilitating spread. To outcompete the other co-colonizing bacteria, the pneumococcus produces bacteriocins called pneumocins that mediate intraspecific competition. Some of the antigens mentioned above are potential vaccine candidates (see "Prevention," below). Biofilm production by pneumococci is now well recognized and is likely to be an important mechanism aiding survival of pneumococci in the upper respiratory tract and contributing to local disease manifestations such as otitis media.

Although the capsule surrounding the cell wall of *S. pneumoniae* is the basis for categorization by serotype, the disease potential of a serotype is also related to the genetic composition of the strain. Molecular genotyping and epidemiology are therefore essential. Conventionally, multilocus sequence typing (MLST) was the gold-standard technique for epidemiologic analyses due to its simplicity and effectiveness. Alleles at seven loci are sequenced, compared with all of the known alleles at that locus and a unique sequence type (ST) assigned using the pneumococcal MLST website (*pubmlst.org/organisms/streptococcus-pneumoniae/*). With the advent of high-throughput and relatively inexpensive sequencing techniques, whole-genome sequencing has facilitated even more precise molecular epidemiology: enhanced genomic epidemiology can be performed using ribosomal MLST (rMLST; >50 ribosomal genes) or core genome MLST (cgMLST; >1300 core genes) with assignment via the PubMLST website, while *k*-mer–based methods fully exploit core and accessory genomic variation (PopPUNK, *github.com/bacpop/PopPUNK*) to assign Global Pneumococcal Sequence Clusters (GPSCs) via the Global Pneumococcal Sequencing project website (*pneumogen.net*).

Twenty-three years after the first pneumococcal genome was sequenced, >50,000 pneumococcal genomes are now available on public nucleotide sequence databases. There are two curated pneumococcal genome databases: the PubMLST Pneumococcal Genome Library contains ~33,000 curated, published, assembled genomes and isolate provenance data (*pubmlst.org/organisms/streptococcus-pneumoniae/pgl/*), and the GPS Database Monocle Dataviewer, which contains ~21,000 high-quality genomes with epidemiologic data (*www.pneumogen.net/gps/gps-database-overview/*). These databases are publicly available and free to access. Over the past decade, web applications such as Pathogenwatch (*pathogen.watch/*) have provided a user-friendly platform to enable fast and reliable analysis of pneumococcal genome data without the requirement for bioinformatic expertise. Users can simply drag and drop genome data into a browser to obtain details such as serotype, genotype (including GPSC and MLST), and antimicrobial resistance profiles. In recent years, genome sequence analyses have made major contributions to the understanding of pneumococcal molecular epidemiology, biology, diversity, pathogenicity, and vaccine impact.

EPIDEMIOLOGY

(See also "Global Health," below.) Pneumococcal infections remain a significant global cause of morbidity and death, particularly among children and the elderly. Rapid and dramatic changes in the epidemiology of this disease during the past 20 years in several developed countries followed the licensure and routine childhood administration of pneumococcal polysaccharide–protein conjugate vaccine (PCV). With PCV introduction in low- and middle-income countries (LMIC), additional profound changes in pneumococcal ecology and disease epidemiology are occurring. The disease burden and serotype distribution in the PCV era are influenced not only by the reduction in disease caused by serotypes included in PCV but also by serotype replacement as a result of reductions in vaccine serotypes, concomitant secular trends in pneumococcal strains unrelated to vaccine use, the impact of antibiotic use on pneumococcal strain ecology, and surveillance system attributes that can themselves affect analysis of epidemiologic features of pneumococcal strains and disease.

Serotype Distribution Not all pneumococcal serotypes are equally likely to cause disease; observed serotype distributions vary by age category, disease syndrome, and geography. Geographic differences may be driven by variations in the relative prevalence of syndromes causing disease rather than by true serotype distribution differences, as certain serotypes are more common causes of some syndromes than others (e.g., pneumonia and meningitis). Most data on serotype distribution come from pediatric invasive pneumococcal disease (IPD, defined as infection of a normally sterile site); much less information on global or regional serotype distributions is available for disease in adults. In the era before PCV use, five to seven serotypes caused >60% of IPD cases among children <5 years of age in most parts of the world; seven serotypes (1, 5, 6A, 6B, 14, 19F, and 23F) accounted for ~60% of such cases in all areas of the world, but in any given region these seven serotypes may not all rank as the most common disease strains. Some serotypes (e.g., types 1 and 5) not only tend to cause disease in areas with a high disease burden but also cause waves of disease in lower-burden areas (e.g., Europe) or outbreaks (e.g., in military barracks; meningitis in sub-Saharan Africa). The widespread use of pneumococcal conjugate vaccines has significantly altered serotype-specific epidemiology, with some of the serotypes identified above now causing little invasive disease in countries with mature vaccine programs and emerging serotypes, not prominent in the pre–conjugate vaccine era, appearing as important causes of invasive disease. These include serotypes such as 15BC, 22F, 10A, 23B, 12F, 15A, and 8 while some serotypes included in PCVs such as 3 and 19A continue to cause IPD.

Nasopharyngeal Carriage Pneumococci are intermittent inhabitants of the healthy human nasopharynx and are transmitted by respiratory droplets. In children, pneumococcal nasopharyngeal ecology varies by geographic region, socioeconomic status, climate, degree of crowding, and particularly intensity of exposure to other children, with children in day-care settings having higher rates of colonization. In developed-world settings, children serve as the major vectors of pneumococcal transmission. By 1 year of age, ~50% of children have had at least one episode of pneumococcal colonization. Cross-sectional prevalence data show rates of pneumococcal carriage ranging from 20% to 50% among children <5 years of age and from 5% to 15% among young and middle-aged adults; **Fig. 151-3** shows relevant data from the United Kingdom. Data on colonization rates among healthy elderly individuals are limited. In LMICs, pneumococcal acquisition occurs much earlier, sometimes within the first few days after birth, and nearly all infants have had at least one episode of colonization by 2 months of age. Cross-sectional studies show that up to the age of 5 years, 70–90% of children carry *S. pneumoniae* in the nasopharynx, and a significant proportion of adults (sometimes >40%) also are colonized. Their high rates of colonization make adults an important source of transmission and may affect community transmission dynamics.

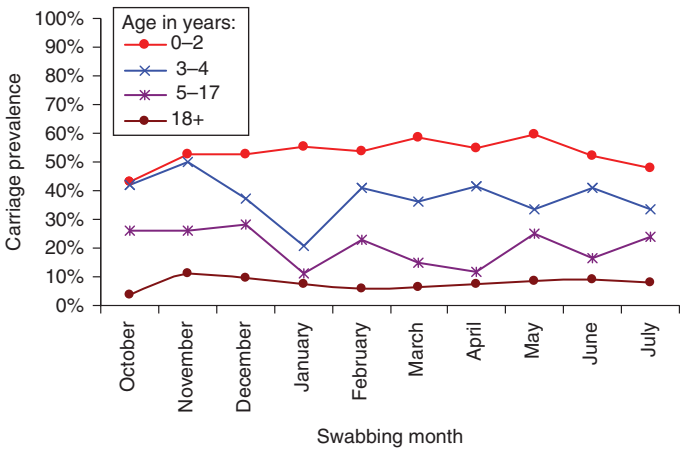

FIGURE 151-3 Prevalence of pneumococcal carriage in adults and children resident in the United Kingdom who had nasopharyngeal swabs collected monthly for 10 months (no seasonal trend; *t* test trend, >.05). *(Data adapted from D Goldblatt et al: J Infect Dis 192:387, 2005.)*

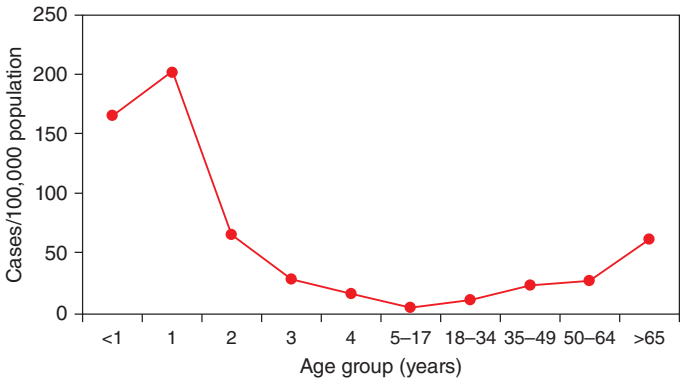

FIGURE 151-4 Rates of invasive pneumococcal disease before the introduction of pneumococcal conjugate vaccine, by age group: United States, 1998. *(Source: CDC, Active Bacterial Core Surveillance/Emerging Infectious Program Network, 2000. Data adapted from MMWR 49[RR-9], 2000.)*

Invasive Disease and Pneumonia IPD develops when *S. pneumoniae* invades the bloodstream and seeds other organs or directly reaches the cerebrospinal fluid (CSF) by local extension. Pneumonia may follow aspiration of pneumococci, although only 10–30% of pneumococcal pneumonia cases are associated with a positive blood culture (and thus contribute to the measured burden of IPD). The substantial variation of IPD rates with age is illustrated by data from the United States for 1998–1999, a period prior to PCV introduction. Rates of IPD were highest among children <2 years of age and among adults ≥65 years of age (188 and 60 cases/100,000, respectively; **Fig. 151-4**). Since the introduction of PCV, IPD rates among infants and children in the United States have fallen by >75%, a decrease driven by the near elimination of vaccine-serotype IPD. A similar impact of PCV on vaccine-serotype IPD rates has been consistently observed in countries where PCV has been introduced into the routine pediatric vaccination schedule. However, the magnitudes of change in the non-vaccine-serotype IPD rate in various countries have been heterogeneous; the interpretation of this heterogeneity is a complex issue. In the United States, Canada, and Australia, rates of non-vaccine-serotype IPD have increased but the magnitude of the increase is generally small relative to the substantial reductions in vaccine-serotype IPD. In contrast, in other settings (e.g., Alaska Native communities and adults in the United Kingdom), the reduction in vaccine-serotype IPD has been offset by notable increases in rates of disease caused by non-vaccine serotypes. Explanations for the heterogeneity of findings include replacement disease resulting from vaccine pressure, changes in clinical case investigation, secular trends unrelated to PCV use, antibiotic pressure selecting for resistant organisms, changes in surveillance or reporting systems, rapidity of PCV introduction, and inclusion of a catch-up campaign. Serotype replacement in IPD follows the use of PCV7, PCV10, and PCV13, but the magnitude of this phenomenon may be small relative to the reduction in disease from vaccine serotypes in vaccinated populations. In adults in the UK, however, where rates of IPD due to vaccine serotypes fell following PCV introduction, the increase in IPD secondary to non- vaccine serotypes is eroding the original impact of PCV. Furthermore, not all vaccine serotypes have declined and persistent disease due to serotypes 3 and 19A in particular has been noted in many settings.

Pneumonia is the most common of the serious pneumococcal disease syndromes and poses special challenges from a clinical and public health perspective. Most cases of pneumococcal pneumonia are not associated with bacteremia, and in these cases a definitive etiologic diagnosis is difficult or impossible. As a result, estimates of disease burden focus primarily on IPD rates and fail to include the major portion of the burden of serious pneumococcal disease. Among children, PCV trials designed to collect efficacy data on syndrome-based outcomes (e.g., radiographically confirmed pneumonia, clinically diagnosed pneumonia) have revealed the burden of culture-negative pneumococcal pneumonia. These trials have provided the means to infer that only ~5–20% of pneumococcal pneumonia cases result in bacteremia. An important randomized controlled trial of PCV among the elderly in

the Netherlands (the CAPiTA trial) has revealed the small fraction of adult pneumococcal pneumonia patients who also have bacteremia. Use of high-quality sputum specimens and, in the case of adults with a low likelihood of colonization absent disease, urine antigen detection both contribute to the diagnosis of nonbacteremic pneumococcal pneumonia. Furthermore, accruing evidence continues to indicate that pneumococcal pneumonia events are often the result of co-infection with viral or other bacterial pathogens. Thus a pneumonia case resulting from a pulmonary infection with a single pathogen is probably an uncommon event; rather, most cases of pneumonia likely result from the sequential or contemporaneous co-infection of a host with multiple pathogens, often both viruses and bacteria.

The case–fatality ratios (CFRs) for pneumococcal pneumonia and IPD vary by age, underlying medical condition, and access to care. In addition, the CFR for pneumococcal pneumonia varies with the severity of disease at presentation (rather than according to whether the pneumonia episode is associated with bacteremia) and with the patient's age (from <5% among hospitalized patients 18–44 years old to >12% among those >65 years old, even when appropriate and timely management is available). Notably, the likelihood of death in the first 24 h of hospitalization did not change substantially with the introduction of antibiotics; this surprising observation highlights the fact that the pathophysiology of severe pneumococcal pneumonia among adults reflects a rapidly progressive cascade of events that often unfolds irrespective of antibiotic administration. Management in an intensive care unit can provide critical support for the patient through the acute period, with lower CFRs, while antibiotics address the underlying infection.

Rates of pneumococcal disease vary by season, with higher rates in colder than in warmer months in temperate climates; by sex, with males more often affected than females; and by risk group, with risk factors including underlying medical conditions, behavioral issues (e.g., smoking), and ethnic group. In the United States, some Native American populations (including Alaska Natives) and African Americans have higher rates of disease than the general population; the increased risk is probably attributable to socioeconomic conditions and the prevalence of underlying risk factors for pneumococcal disease. Medical conditions that increase the risk of pneumococcal infection are listed in Table 151-1. Outbreaks of disease are well recognized in crowded settings with susceptible individuals, such as infant day-care facilities, military barracks, and nursing homes. Furthermore, there is a clear association between preceding viral respiratory disease (especially but not exclusively influenza) and risk of secondary pneumococcal infections. The significant role of pneumococcal pneumonia in the morbidity and mortality associated with seasonal and pandemic influenza is increasingly well recognized.

Antibiotic Resistance Reduced pneumococcal susceptibility to penicillin was first noted in 1967, but not until the 1990s did reduced antibiotic susceptibility emerge as a significant clinical and public health issue, with an increasing prevalence of pneumococcal isolates resistant to single or multiple classes of antibiotics and a rising absolute magnitude of minimal inhibitory concentrations (MICs). Strains with reduced susceptibility to penicillin G, cefotaxime, ceftriaxone, macrolides, and other antibiotics are now found worldwide and account for a significant proportion of disease-causing strains in many locations, especially among children. Vancomycin resistance has not yet been observed in clinical pneumococcal strains. Lack of antimicrobial susceptibility is clearly related to a subset of serotypes, many of which disproportionately cause disease among children. Resistance phenotypes are based on a diverse array of mutational events and inter- and intraspecies gene-transfer phenomena carried out by several types of mobile genetic elements, with consequent dissemination of successful resistant clones. The vicious cycle of antibiotic exposure, selection of resistant organisms in the nasopharynx, and transmission of these organisms within the community, leading to difficult-to-treat infections and increased antibiotic exposure, has been interrupted to some extent by the introduction and routine use of PCV. The clinical implications of pneumococcal antimicrobial nonsusceptibility are addressed in "Treatment," below.

TABLE 151-1 Clinical Risk Groups for Pneumococcal Infection

CLINICAL RISK GROUP	EXAMPLES
Asplenia or splenic dysfunction	Sickle cell disease and other hemoglobinopathies, celiac disease
Chronic respiratory disease	Chronic obstructive pulmonary disease, bronchiectasis, cystic fibrosis, interstitial lung fibrosis, pneumoconiosis, bronchopulmonary dysplasia, aspiration risk, neuromuscular disease (e.g., cerebral palsy), severe asthma
Chronic heart disease	Ischemic heart disease, congenital heart disease, hypertension with cardiac complications, chronic heart failure
Chronic kidney disease	Nephrotic syndrome, chronic renal failure, renal transplantation
Chronic liver disease	Cirrhosis, biliary atresia, chronic hepatitis
Diabetes mellitus	Diabetes mellitus requiring insulin or oral hypoglycemic drugs
Immunocompromise/ immunosuppression	HIV infection, primary immunodeficiency (including B cell, T cell, complement, and some phagocytic disorders), leukemia, lymphoma, Hodgkin's disease, multiple myeloma, generalized malignancy, chemotherapy, organ or bone marrow transplantation, systemic glucocorticoid treatment for >1 month at a dose equivalent to ≥20 mg/d (children, ≥1 mg/kg per day)
Cochlear implants	…
Cerebrospinal fluid leaks	…
Miscellaneous	Infancy and old age; prior hospitalization; alcoholism; malnutrition; cigarette smoking; day-care center attendance; residence in military training camps, prisons, homeless shelters

Note: Groups for whom pneumococcal vaccines are recommended by the Advisory Committee on Immunization Practices can be found at *www.cdc.gov/vaccines/schedules/*.

PATHOGENESIS

Pneumococci colonize the human nasopharynx from an early age; colonization acquisition events are generally described as asymptomatic, but evidence exists to associate acquisition with mild respiratory symptoms, especially in the very young. Bacteria survive in the nasopharynx protected by a variety of factors, including their bacterial capsule and the formation of a biofilm. From the nasopharynx, the bacteria spread either via the bloodstream to distant sites (e.g., brain, joint, bones, peritoneal cavity) or locally to mucosal surfaces where they can cause otitis media or pneumonia. Direct spread from the nasopharynx to the central nervous system (CNS) can occur in rare cases of skull-base fracture, although most cases of pneumococcal meningitis are secondary to hematogenous spread. The pneumococcus is not a static bacterium; rather, it modifies its expression of capsule in adaptation to the external environment. In the nasopharynx, the pneumococcus downregulates capsular expression, averting protective immunologic mechanisms that recognize capsule; rough colonies are the phenotype on culture. Upon invasion by traversal of the epithelium, the pneumococcus upregulates its capsular expression, transforming its appearance on culture to smooth colonies—a change illustrating the dynamic nature of the organism in response to the local environment. Pneumococci can cause disease in almost any organ or part of the body; however, otitis media, pneumonia, bacteremia, and meningitis are most common. Colonization is a relatively frequent event, yet disease is rare. In the nasopharynx, pneumococci survive in mucus secreted by epithelial cells and in a biofilm they create, where they can avoid local immune factors such as leukocytes and complement. The mucus itself is a component of local defense mechanisms, and the flow of mucus (driven in part by cilia in what is known as the *mucociliary escalator*) effects mechanical clearance of pneumococci. While many colonization episodes are of short duration, longitudinal studies in adults and children have revealed persistent colonization with a specific serotype over many months. Colonization eventually results in

the development of capsule- and protein-specific serum IgG antibodies, which are thought to play a role in mediating clearance of bacteria from the nasopharynx. IgG antibodies to surface-exposed cell-wall or secreted proteins also appear in the circulation in an age-dependent fashion or after colonization; these antibodies are likely to have a disease-modifying and/or protective role. Recent acquisition of a new colonizing serotype is more likely to be associated with subsequent invasion, presumably as a result of the absence of type-specific immunity. Intercurrent viral infections make the host more susceptible to pneumococcal colonization, and pneumococcal disease in a colonized individual often follows perturbation of the nasopharyngeal mucosa by such infections. Local cytokine production after a viral infection is thought to upregulate adhesion factors in the respiratory epithelium, allowing pneumococci to adhere via a variety of surface adhesin molecules, including PsaA, PspA, CbpA, PspC, Hyl, pneumolysin, and the neuraminidases (Fig. 151-2). Adhesion coupled with inflammation induced by pneumococcal factors such as peptidoglycans and teichoic acids results in invasion. It is the inflammation induced by various bacterium-derived factors that is responsible for the pathology associated with pneumococcal infection. Pneumococcal cell wall–derived teichoic acids and peptidoglycans induce a variety of cytokines, including the proinflammatory cytokines interleukin (IL) 1, IL-6, and tumor necrosis factor, and activate complement via the alternative pathway. Polymorphonuclear leukocytes are thus attracted, and an intense inflammatory response is initiated. Pneumolysin also is important in local pathology, inducing proinflammatory cytokine production by local monocytes.

The pneumococcal capsule, consisting of polysaccharides with antiphagocytic properties (i.e., the capacity to resist complement deposition in the absence of type-specific antibody), plays an important role in pathogenesis. While most capsular types can cause human disease, certain capsular types are more commonly isolated from sites of infection. The reason for the dominance of some serotypes over others in IPD is unclear.

HOST DEFENSE MECHANISMS

Innate Immunity As described above, intact respiratory epithelium and a host of nonspecific or innate immune factors (e.g., mucus, splenic function, complement, neutrophils, and macrophages) constitute the first line of defense against pneumococci. Physical factors such as the cough reflex and the mucociliary escalator are important in clearing bacteria from the lungs. Immunologic factors are critical as well: C-reactive protein (CRP) binds phosphorylcholine in the pneumococcal cell wall, inducing complement activation and leading to bacterial clearance; Toll-like receptor 2 (TLR2) recognizes pneumococcal-derived lipoproteins. In animal models, the absence of host TLR2 leads to more severe infection and impaired clearance of nasopharyngeal colonization. TLR4 appears to be necessary for the proinflammatory effect of pneumolysin on macrophages. The importance of TLR recognition is underlined by descriptions of an inherited deficiency of human IL-1 receptor–associated kinase 4 (IRAK-4) that manifests as an unusual susceptibility to infection with bacteria, including *S. pneumoniae*. IRAK-4 is essential for the normal functioning of several TLRs. Other factors that interfere with these nonspecific mechanisms (e.g., viral infections, cystic fibrosis, bronchiectasis, complement deficiency, chronic obstructive pulmonary disease) all predispose to the development of pneumococcal pneumonia. Patients who lack a spleen or have abnormal splenic function (e.g., persons with sickle cell disease) are at high risk of developing overwhelming pneumococcal disease.

Acquired Immunity Acquired immunity induced following colonization or through exposure to cross-reactive antigens rests largely on the development of serum IgG antibody specific for the pneumococcal capsular polysaccharide. Nearly all polysaccharides are T cell–independent antigens; B cells can make antibodies to such antigens without T cell help. However, in children <1–2 years old, such B cell responses are poorly developed. This delayed ontogeny of capsule-specific IgG in young children is associated with susceptibility to pneumococcal infection (Fig. 151-4). The extremely high risk of pneumococcal infection in the absence of serum immunoglobulin (i.e., in conditions such as agammaglobulinemia) highlights the important role of capsular antibody in protection against disease. Each serotype's capsule is chemically distinct, even though for some serotypes the chemical distinction from another type may be a minor one; thus immunity tends to be serotype specific, although some cross-immunity exists. For example, conjugate vaccine–induced antibodies to serotype 6B prevent infection due to serotype 6A but not 6C; cross-protection against serotype 6C requires the administration of vaccines containing 6A. Antibodies to surface-exposed or secreted pneumococcal proteins (such as pneumolysin, PsaA, and PspA) also appear in the circulation with increasing age of the host and are likely to contribute to protection. Data from murine models suggest that CD4+ T cells may play a role in preventing pneumococcal colonization and disease, and experimental data derived from humans suggest that IL-17-secreting CD4+ T cells may be relevant.

APPROACH TO THE PATIENT

Pneumococcal Infections

There is no pathognomonic presentation of pneumococcal disease; patients may present with one or more clinical syndromes (e.g., pneumonia, meningitis, sepsis). *S. pneumoniae* can infect nearly any body tissue, manifesting as disease ranging in severity from mild and self-limited to life-threatening. The differential diagnosis of common clinical syndromes such as pneumonia, otitis media, fever of unknown origin, and meningitis should always include pneumococcal infection. A microbiologically confirmed diagnosis is made in only a minority of pneumococcal cases since, in most circumstances (and especially in pneumonia and otitis media), fluid from the site of infection is not available for etiologic determination, and infection of body fluids distant from the site of infection (e.g., blood in the case of pneumonia) occurs in only a minority of true pneumococcal cases. Empirical therapy that includes appropriate treatment for *S. pneumoniae* is often indicated.

Algorithms for assessment and management of ill children (Integrated Management of Childhood Illness; IMCI) have been developed for use in the developing world or in other settings where evaluation by a trained physician may not be feasible. No such algorithms for the management of adults with suspected disease exist. Children who present with signs associated with increased risk of serious disease, such as an inability to drink, convulsions, lethargy, and severe malnutrition, are categorized as having very severe disease without further evaluation by the community health care worker; are given antibiotics; and are immediately referred to a hospital for diagnosis and management. Children who present with cough and tachypnea (the latter defined according to specific age strata) are further stratified into severity categories based on the presence or absence of lower chest wall indrawing and are managed accordingly either with antibiotics alone or with antibiotics and referral to a hospital facility. Children with cough but no tachypnea are categorized as having a nonpneumonia respiratory illness.

CLINICAL MANIFESTATIONS

The clinical manifestations of pneumococcal disease depend on the site of infection and the duration of illness. Clinical syndromes are classified as noninvasive (e.g., otitis media) or invasive (e.g., bacteremic pneumonia, meningitis) according to whether a normally sterile site is infected. The pathogenesis of noninvasive illness involves contiguous spread from the nasopharynx or skin; invasive disease involves infection of a normally sterile body fluid or follows bacteremia. Regardless of the mechanism, all pneumococcal infections result from nasopharyngeal acquisition of the organism.

Pneumonia Pneumonia is the most common serious pneumococcal syndrome and is considered invasive when associated with a positive blood culture. Whether to categorize nonbacteremic pneumococcal pneumonia as invasive or noninvasive remains debatable.

Pneumococcal pneumonia can present as a mild community-acquired infection at one extreme and as a life-threatening disease requiring intubation and intensive support at the other.

PRESENTING MANIFESTATIONS The presentation of pneumococcal pneumonia does not reliably distinguish it from pneumonia of other etiologies. In a subset of cases, pneumococcal pneumonia is recognized at the outset as associated with a viral upper respiratory infection and is characterized by the abrupt onset of cough and dyspnea accompanied by fever, shaking chills, and myalgias. The cough evolves from nonpurulent to productive of sputum that is purulent and sometimes tinged with blood. Patients may describe stabbing pleuritic chest pain and significant dyspnea indicating involvement of the parietal pleura. Among the elderly, the presenting clinical symptoms may be less specific, with confusion or malaise but without fever or cough. In such cases, a high index of suspicion is required because failure to treat pneumococcal pneumonia promptly in an elderly patient is likely to result in rapid evolution of the infection, with increased severity, morbidity, and risk of death.

FINDINGS ON PHYSICAL EXAMINATION The clinical signs associated with pneumococcal pneumonia among adults include tachypnea (defined as >20 breaths/min) and tachycardia, hypotension in severe cases, and fever in most cases (although not in all elderly patients). Respiratory signs are varied, including dullness to percussion in areas of the chest with significant consolidation, crackles on auscultation, reduced expansion of the chest in some cases as a result of splinting to reduce pain, bronchial breathing in a minority of cases, pleural rub in occasional cases, and cyanosis in cases with significant hypoxemia. Among infants with severe pneumonia, chest wall indrawing and nasal flaring are common. Nonrespiratory findings can include upper abdominal pain if the diaphragmatic pleura is involved as well as mental status changes, particularly confusion in elderly patients.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of pneumococcal pneumonia includes cardiac conditions such as myocardial infarction and heart failure with atypical pulmonary edema; pulmonary conditions such as atelectasis; and pneumonia caused by viral pathogens, mycoplasmas, *Haemophilus influenzae*, *Klebsiella pneumoniae*, *Staphylococcus aureus*, *Legionella*, or (in HIV-infected and otherwise immunocompromised hosts) *Pneumocystis jirovecii*. In cases with abdominal symptoms, the differential diagnosis includes cholecystitis, appendicitis, perforated peptic ulcer disease, and subphrenic abscesses. The challenge in cases with abdominal symptoms is to remember to include pneumococcal pneumonia—a nonabdominal process—in the differential diagnosis.

DIAGNOSIS Some authorities advocate treating uncomplicated, nonsevere, community-acquired pneumonia without determining the microbiologic etiology, given that this information is unlikely to alter clinical management. However, efforts to identify the cause of pneumonia are important when the disease is more severe and when the diagnosis of pneumonia is not clearly established. The gold standard for etiologic diagnosis of pneumococcal pneumonia is pathologic examination of lung tissue. In lieu of that procedure, evidence of an infiltrate on chest radiography warrants a diagnosis of pneumonia. However, cases of pneumonia without radiographic evidence do occur. An infiltrate can be absent either early in the course of the illness or with dehydration; upon rehydration, an infiltrate usually appears. The radiographic appearance of pneumococcal pneumonia is varied; it classically consists of lobar or segmental consolidation **(Fig. 151-5)** but in some cases is patchy. More than one lobe is involved in ~30% of cases. Consolidation may be associated with a small pleural effusion or empyema in complicated cases. In children, "round pneumonia," a distinctly spherical consolidation on chest radiography, is associated with a pneumococcal etiology. Round pneumonia is uncommon in adults. *S. pneumoniae* is not the only cause of such lesions; other causes, especially cancer, should be considered.

Blood drawn from patients with suspected pneumococcal pneumonia can be used for supportive or definitive diagnostic tests. Blood cultures are positive for pneumococci in a minority (<30%) of cases of pneumococcal pneumonia, as evidenced especially by vaccine clinical trials, which provide an independent method to reveal the contribution of the pneumococcus to pneumonia cases. Nonspecific findings include an elevated polymorphonuclear leukocyte count (>15,000/μL in most cases and upward of 40,000/μL in some), leukopenia in <10% of cases (a poor prognostic sign associated with a fatal outcome), and elevated values in liver function tests (e.g., both conjugated and unconjugated hyperbilirubinemia). Anemia, low serum albumin levels, hyponatremia, and elevated serum creatinine levels are all found in ~20–30% of patients.

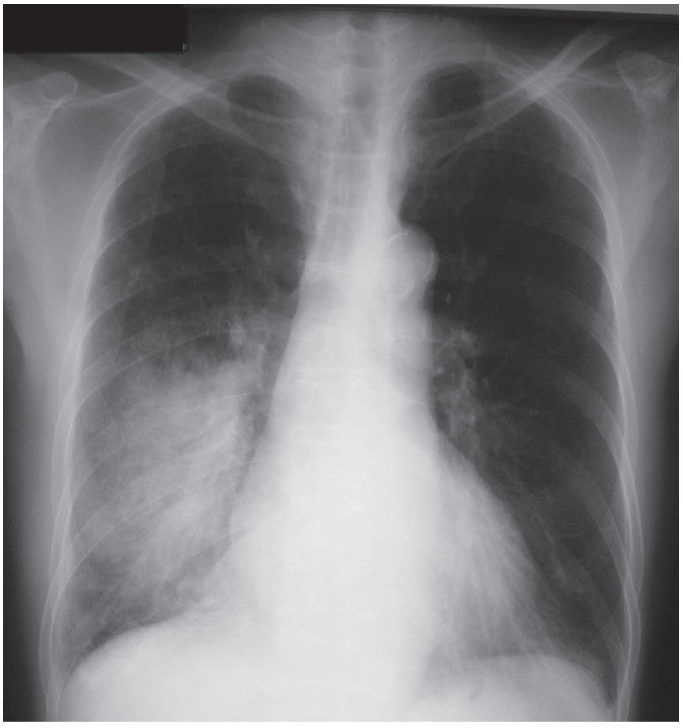

FIGURE 151-5 Chest radiograph depicting classic lobar pneumococcal pneumonia in the right lower lobe of an elderly patient's lung.

Urinary pneumococcal antigen assays, based on identifying a ubiquitous common cell wall polysaccharide, have facilitated etiologic diagnosis, but the application of the results is confounded by the fact that nasopharyngeal colonization with the pneumococcus, in the absence of disease, also results in a positive test. In adults, therefore, a positive pneumococcal urinary antigen test has a predictive value for etiologic attribution of pneumonia because the prevalence of pneumococcal nasopharyngeal colonization is relatively low, although the sensitivity of the assay is modest. In communities, particularly those in low-income countries, where colonization rates among adults are high, urine antigen assays may be less useful. The same issue holds for children, in whom a positive urinary antigen test is usually uninformative for etiologic attribution of their pneumonia illness because colonization rates are generally high. A recent advance is the development of quantitative serotype-specific urinary antigen detection assays for up to 24 pneumococcal antigens; their application for adults and children holds promise, especially in detecting serotypes that are rarely identified in asymptomatic carriage (e.g., serotype 1), even among children.

Most cases of pneumococcal pneumonia in adults are diagnosed by Gram's staining and culture of sputum. The utility of a sputum specimen is directly related to its quality and the patient's antibiotic treatment status.

COMPLICATIONS Empyema is the most common focal complication of pneumococcal pneumonia, occurring in <5% of cases. When fluid in the pleural space is accompanied by fever and leukocytosis (even low-grade) after 4–5 days of appropriate antibiotic treatment for pneumococcal pneumonia, empyema should be considered. Parapneumonic effusions are more common than empyema, representing a self-limited inflammatory response to pneumonia. Pleural fluid with frank pus, bacteria (detected by microscopic examination), or a pH of ≤7.1 indicates empyema and demands aggressive and complete drainage, usually through chest tube insertion.

Meningitis Pneumococcal meningitis usually presents as a pyogenic condition that is clinically indistinguishable from meningitis of other bacterial etiologies. Meningitis can be the primary presenting pneumococcal syndrome or a complication of other conditions such as skull fracture, otitis media, bacteremia, or mastoiditis. Now that *H. influenzae* type b vaccine is routinely used in children, *S. pneumoniae* and *Neisseria meningitidis* are the most common bacterial causes of meningitis in both adults and children. Pyogenic meningitis, including that due to *S. pneumoniae*, is associated clinically with findings that include severe, generalized, gradual-onset headache, fever, and nausea as well as specific CNS manifestations such as stiff neck, photophobia, seizures, and confusion. Clinical signs include a toxic appearance, altered consciousness, bradycardia, and hypertension indicative of increased intracranial pressure. A small proportion of adult patients have Kernig's or Brudzinski's sign or cranial nerve palsies (particularly of the third and sixth cranial nerves).

A definitive diagnosis of pneumococcal meningitis rests on the examination of CSF for (1) evidence of turbidity (visual inspection); (2) elevated protein level, elevated white blood cell count, and reduced glucose concentration (quantitative measurement); and (3) specific identification of the etiologic agent (culture, Gram's staining, antigen testing, or polymerase chain reaction [PCR]). A blood culture positive for *S. pneumoniae* in conjunction with clinical manifestations of meningitis also is considered confirmatory. As discussed in "Pneumonia," above, detection of pneumococcal antigen in urine is considered highly specific among adults because of the low prevalence of nasopharyngeal colonization in this age group.

The mortality rate for pneumococcal meningitis is ~20%. In addition, up to 50% of survivors experience acute or chronic complications, including deafness, hydrocephalus, and mental retardation in children and diffuse brain swelling, subarachnoid bleeding, hydrocephalus, cerebrovascular complications, and hearing loss in adults.

Other Invasive Syndromes *S. pneumoniae* can cause other invasive syndromes involving virtually any body site. These syndromes include primary bacteremia without other sites of infection (bacteremia without a source; occult bacteremia), osteomyelitis, septic arthritis, endocarditis, pericarditis, and peritonitis. The essential diagnostic approach is collection of fluid from the site of infection by sterile technique and examination by Gram's staining, culture, and—when relevant—capsular antigen assay or PCR. Hemolytic-uremic syndrome can complicate invasive pneumococcal disease.

Noninvasive Syndromes The major noninvasive syndromes caused by *S. pneumoniae* are sinusitis, bacterial bronchitis, and otitis media; the latter is the most common pneumococcal syndrome and most often affects young children. The manifestations of otitis media include the acute onset of severe pain, fever, deafness, and tinnitus, most frequently in the setting of a recent upper respiratory tract infection. Clinical signs include a red, swollen, often bulging tympanic membrane with reduced movement on insufflation or tympanography. Redness of the tympanic membrane is not sufficient for the diagnosis of otitis media.

Pneumococcal sinusitis is also a complication of upper respiratory tract infections and presents with facial pain, congestion, fever, and—in many cases—persistent nighttime cough. A definitive diagnosis is made by aspiration and culture of sinus material; however, presumptive treatment is most commonly initiated after application of a strict set of clinical diagnostic criteria. Pneumococcal bronchitis is usually seen in the context of pre-existing lung conditions such as bronchiectasis or chronic obstructive pulmonary disease (COPD) and may be caused by nontypeable strains.

TREATMENT

Pneumococcal Infections

Historically, the activity of penicillin against pneumococci made parenteral penicillin G the drug of choice for disease caused by susceptible organisms, including community-acquired pneumonia. Today, parenteral β-lactam drugs such as ampicillin, cefotaxime, ceftriaxone, and cefuroxime are often used as first-line agents for community-acquired infections. Macrolides and cephalosporins are alternatives for penicillin-allergic patients. While agents such as clindamycin, tetracycline, and trimethoprim-sulfamethoxazole exhibit some activity against pneumococci, resistance to these agents is frequently encountered in different parts of the world.

Penicillin-resistant pneumococci were first described in the mid-1960s, at which point tetracycline- and macrolide-resistant strains had already been reported. Multidrug-resistant strains were first described in the 1970s, but it was during the 1990s that pneumococcal drug resistance reached pandemic proportions. The use of antibiotics selects for resistant pneumococci, and strains resistant to β-lactam agents and to multiple drugs are now found all over the world. The emergence of high rates of macrolide and fluoroquinolone resistance also has been described. Drug-resistant pneumococci are considered a serious threat by the Centers for Disease Control and Prevention.

The molecular basis of penicillin resistance in *S. pneumoniae* is the alteration of penicillin-binding protein (PBP) genes by transformation and horizontal transfer of DNA from related streptococcal species. Such alteration of PBPs results in lower affinity for penicillins. Depending on the specific PBP(s) and the number of PBPs altered, the level of resistance ranges from intermediate to high. For many years, penicillin susceptibility breakpoints have been defined by MICs as follows: susceptible, ≤0.06 μg/mL and resistant, ≥2.0 μg/mL. However, in vitro results often were not predictive of the response of a patient to treatment for pneumococcal diseases other than meningitis. Revised recommendations have been based on the penicillin G breakpoints established in 2008 by the Clinical and Laboratory Standards Institute. For IV treatment of meningitis with at least 24 million units per day in 8 divided doses, the susceptibility breakpoint remains ≤0.06 μg/mL, and MICs of ≥0.12 μg/mL indicate resistance. For IV treatment of nonmeningeal infections with 12 million units per day in 6 divided doses, the breakpoints are ≤2 μg/mL for susceptible organisms and ≥8 μg/mL for resistant organisms; a dosage of 18–24 million units per day is recommended for strains with MICs in the intermediate category.

Although guidelines for antibiotic therapy should be driven in part by local patterns of resistance, guidelines from national organizations in many countries (e.g., the Infectious Diseases Society of America/American Thoracic Society, the British Thoracic Society, the European Respiratory Society) lay out evidence-based approaches. The following guidelines for the treatment of individual sepsis syndromes are based on those advocated by the American Academy of Pediatrics Red Book and updated in 2023.

MENINGITIS LIKELY OR PROVEN TO BE DUE TO *S. PNEUMONIAE*

In areas of the world with an increased prevalence of resistant pneumococci, first-line therapy for persons ≥1 month of age is a combination of vancomycin (adults, 30–60 mg/kg per day; infants and children, 60 mg/kg per day) and cefotaxime (adults, 8–12 g/d in 4–6 divided doses; children, 225–300 mg/kg per day in 1 dose or 2 divided doses) or ceftriaxone (adults, 4 g/d in 1 dose or 2 divided doses; children, 100 mg/kg per day in 1 dose or 2 divided doses). In low-prevalence areas and where the patient has not recently traveled, vancomycin is not included in first-line therapy. If children are hypersensitive to β-lactam agents (penicillins and cephalosporins), rifampin (adults, 600 mg/d; children, 20 mg/d in 1 dose or 2 divided doses) can be substituted for cefotaxime or ceftriaxone and added as a second agent. A repeat lumbar puncture should be considered after 48 h if the organism is not susceptible to penicillin and information on cephalosporin sensitivity is not yet available, if the patient's clinical condition does not improve or deteriorates, or if dexamethasone has been administered interfering with the ability to interpret clinical responses in the deteriorating patient. When antibiotic sensitivity data become available, treatment should be modified accordingly. If the isolate is sensitive

to penicillin, vancomycin can be discontinued and penicillin can replace the cephalosporin, or cefotaxime or ceftriaxone can be continued alone. If the isolate displays any resistance to penicillin but is susceptible to the cephalosporins, vancomycin can be discontinued and cefotaxime or ceftriaxone continued. If the isolate exhibits any resistance to penicillin and is not susceptible to cefotaxime and ceftriaxone, vancomycin and high-dose cefotaxime or ceftriaxone can be continued and rifampin may be added. Data support the use of corticosteroids in high-income countries but do not appear to have a beneficial effect in low-income countries. This discrepancy in the efficacy of corticosteroids may be related to differences in availability of appropriate and timely medical care. Glucocorticoids significantly reduce rates of mortality, severe hearing loss, and neurologic sequelae in adults and should be administered to those with community-acquired bacterial meningitis. If dexamethasone is given to either adults or children, it should be administered before or in conjunction with the first antibiotic dose.

SEPSIS (EXCLUDING MENINGITIS)

In previously well children with noncritical illness, therapy with a recommended antibiotic should be instigated at the usually recommended dosages: ampicillin 200 mg/kg/day (doses 6 h apart), cefotaxime, 75–225 mg/kg/day (doses 8 h apart), ceftriaxone, 50–75 mg/kg/day (doses 12–24 h apart) or penicillin G, 250,000–400,000 units/kg per day (in divided doses 4–6 h apart). For critically ill children, including those who have myocarditis or multilobular pneumonia with hypoxia or hypotension, vancomycin may be added if the isolate may possibly be resistant to β-lactam drugs, with its use reviewed once susceptibility data become available. If the organism is resistant to β-lactam agents, therapy should be modified on the basis of clinical response and susceptibility to other antibiotics. Clindamycin or vancomycin can be used as a first-line agent for children with severe β-lactam hypersensitivity, but vancomycin should not be continued if the organism is shown to be sensitive to other non-β-lactam antibiotics.

For outpatient management, oral amoxicillin (45–90 mg/kg/day, doses 8 h apart) provides effective treatment for virtually all cases of pneumococcal pneumonia. Cephalosporins, which are far more expensive, offer no advantages over amoxicillin. Levofloxacin (500–750 mg/d as a single dose) and moxifloxacin (400 mg/d as a single dose) also are highly likely to be effective in the United States except in patients who come from closed populations where these drugs are used widely or who have themselves been treated recently with a quinolone. Clindamycin (600–1200 mg/d every 6 h) is effective in 90% of cases and azithromycin (500 mg on day 1 followed by 250–500 mg/d) or clarithromycin (500–750 mg/d as a single dose) in 80% of cases. Treatment failure resulting in bacteremic disease due to macrolide-resistant isolates has been amply documented in patients given azithromycin empirically. As noted above, rates of resistance to all these antibiotics are relatively low in some countries and much higher in others; high-dose amoxicillin remains the best option worldwide.

The optimal duration of treatment for pneumococcal pneumonia is uncertain, but its continuation for at least 5 days once the patient becomes afebrile appears to be a prudent approach—although in adults, 5 days in total will usually suffice. Cases with a second focus of infection (e.g., empyema or septic arthritis) require longer therapy.

ACUTE OTITIS MEDIA

Amoxicillin (80–90 mg/kg per day) is recommended for infants <6 months of age and those 6–23 months of age with bilateral disease. Observation and symptom-based treatment without antibiotics are advocated for nonsevere illness and an uncertain diagnosis in children 6 months to 2 years of age and nonsevere illness (even if the diagnosis seems certain) in children >2 years of age. Although the optimal duration of therapy has not been conclusively established, a 10-day course is recommended for younger children and for children with severe disease at any age. For children >6 years old who have mild or moderate disease, a course of 5–7 days is considered adequate. Patients whose illness fails to respond should be reassessed at 48–72 h. If acute otitis media is confirmed and antibiotic treatment has not been started, administration of amoxicillin should be commenced. If antibiotic therapy fails, a change is indicated. Failure to respond to second-line antibiotics (such as high-dose amoxicillin-clavulanate) as well indicates that myringotomy or tympanocentesis may need to be undertaken in order to obtain samples for culture.

The above recommendations can also be followed for the treatment of sinusitis. Detailed information on the further management of these conditions in children has been published by the American Academy of Pediatrics, the American Academy of Family Physicians, the Pediatric Infectious Diseases Society, and the Infectious Diseases Society of America.

PREVENTION

Measures to prevent pneumococcal disease include vaccination against *S. pneumoniae* and influenza viruses, reduction of comorbidities that increase the risk of pneumococcal disease, and prevention of antibiotic overuse, which fuels pneumococcal resistance.

Capsular Polysaccharide Vaccines The 23-valent pneumococcal polysaccharide vaccine (PPSV23), containing 25 μg of each capsular polysaccharide, has been licensed for use since 1983. Recommendations for its use vary by country with an age-based recommendation for those ≥65 years of age most commonly found. However, the utility of PPSV23 is likely to be limited in the future as more countries introduce the newly licensed (2021) extended-valency pneumococcal conjugate vaccines (see "Polysaccharide–Protein Conjugate Vaccines," below).

The effectiveness of PPSV23 against IPD, pneumococcal pneumonia, all-cause pneumonia, and death is controversial, with wide variation in observations. The many published meta-analyses of PPSV efficacy have often reached opposing conclusions with regard to a given clinical entity. Generally, observational studies cite greater effectiveness than do controlled clinical trials. The consensus is that PPSV is effective against IPD but is less effective against nonbacteremic pneumococcal pneumonia. However, the results of some published trials, observational studies, and meta-analyses contradict this view. Effectiveness is often lower in the elderly and in immunodeficient patients whose condition is associated with reduced antibody responses to vaccines than in younger, healthier populations. When PPSV is effective, the duration of protection following a single dose of vaccine is estimated to be ~5 years.

Even in the setting of routine pneumococcal conjugate vaccination of infants (which indirectly protects adults from vaccine-serotype strains), disease caused by serotypes not represented in the conjugate vaccine continues to be a significant burden among adults.

Polysaccharide–Protein Conjugate Vaccines Infants and young children respond poorly to PPSV, which contains T cell–independent antigens. Consequently, another class of pneumococcal vaccines, the PCVs, were developed specifically for infants and young children. The first product, a 7-valent PCV, was licensed in 2000 in the United States and two PCV products—containing 10 and 13 serotypes, respectively—were licensed in 2009 and 2010, respectively. The serotypes included in these original PCV formulations were important causes of IPD and antibiotic resistance among young children. Randomized controlled trials and real-world evidence accumulated following their widespread use have demonstrated a high degree of efficacy of PCVs against vaccine-serotype IPD as well as efficacy against pneumonia, otitis media, nasopharyngeal colonization, and all-cause mortality. PCVs are recommended by the World Health Organization for inclusion in routine childhood immunization schedules worldwide, especially in countries with high infant mortality rates. To date 146 countries (75%) have PCV in their National Immunization program, 15 are planning introduction, and 33 have no national decision.

In 2021, two new PCVs were licensed for adults: a 15-valent pneumococcal conjugate vaccine, VAXNEUVANCE (Merck), and a

20-valent pneumococcal conjugate vaccine, PREVNAR 20 (Pfizer). Both vaccines are now also licensed for infant immunization and are likely to gradually replace PCV10 and PCV13. The additional serotypes in the new vaccines account for a variable fraction of the residual IPD in children (additional 15–45%) and adults (additional 11–33%) for PCV15 and PCV20, respectively, in countries where PCV13 coverage is high. For adults the United States Advisory Committee on Immunization Practices (ACIP) now recommends PCV20 instead of PPSV23 for all persons ≥65 years of age and for those 2–64 years of age who have underlying medical conditions that put them at increased risk for pneumococcal disease or, if infected, disease of increased severity (Table 151-1; see also *www.cdc.gov/vaccines/schedules*). United States recommendations for PPSV23 are now limited to sequential use in the above age groups receiving the PCV15 vaccine.

The introduction of PCV in high-income settings has resulted in a >90% reduction in vaccine-serotype IPD among the whole population. This decline has been noted not only in those age groups immunized but also in adults and is attributable to the near elimination of vaccine-serotype nasopharyngeal colonization in immunized infants, which reduces spread to adults. This protection of unimmunized community members through vaccination of a subset of the community is termed *the indirect effect*. Increases in colonization with—and concomitantly in disease due to—non-vaccine-serotype strains (i.e., replacement colonization and disease) have been seen. The scale of replacement disease has varied geographically with the impact eroding vaccine impact significantly in the elderly in the United Kingdom while having relatively little impact in the United States (see "Epidemiology," above). Since vaccine-serotype strains are more commonly resistant to antibiotics than are non-vaccine serotypes, use of PCV has also resulted in substantial declines in the proportion and absolute rates of drug-resistant pneumococcal disease. The ACIP recommendations for the use of conjugate vaccines can be found at *www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/pneumo.html*. PCV has been shown to prevent pneumococcal infection in HIV-infected adults.

Other Prevention Strategies Pneumococcal disease can be averted through the prevention of illnesses that predispose individuals to pneumococcal infections. Relevant measures include smoking cessation and influenza vaccination, as well as improved management and control of diabetes, HIV infection, heart disease, and lung disease. Finally, the reduction of antibiotic misuse is a strategy for the prevention of pneumococcal disease in that antimicrobial resistance directly and indirectly perpetuates organism transmission and disease in the community.

GLOBAL HEALTH

In 2015, pneumococcal infections were estimated to have caused ~317,000 annual deaths worldwide among children 1–59 months of age, accounting for 9.7% of the 3.2 million all-cause deaths and 38% of all pneumonia deaths in this age group. Updated estimates of residual pneumococcal disease burden since the widespread introduction of PCV have not been published. Reliable estimates of adult cases and deaths globally are more difficult to establish because of limited data from parts of the world where most disease occurs. Rates of pneumococcal disease and mortality vary substantially across geographic settings, with the highest rates in selected countries of sub-Saharan Africa and southern Asia, where risk factors for pneumococcal disease—including HIV infection, lack of breast feeding of infants and children, malnutrition, sickle cell disease, and limited access to medical care—are prevalent. Serotypes causing disease exhibit some heterogeneity across geographic settings, but a small number of serotypes universally account for the preponderance of disease in the absence of vaccination; accordingly, vaccine development and vaccination programs are globally relevant. Reductions in disease from pneumococcal infections are anchored in prevention through the inclusion of pneumococcal vaccines in infant immunization programs, timely assessment and appropriate treatment of persons with pneumococcal infections, and reduction of risk factors for pneumococcal disease. The use of vaccines for the prevention of adult pneumococcal disease, particularly among the elderly, is currently implemented in high-income countries, with virtually no use in low-income countries where most cases of disease exist.

152 Staphylococcal Infections

Franklin D. Lowy, Anne-Catrin Uhlemann

Staphylococcus aureus, the most virulent of the many (≥40) staphylococcal species, has demonstrated its versatility by remaining a major cause of morbidity and mortality worldwide despite the availability of numerous effective antistaphylococcal antibiotics. *S. aureus* is a pluripotent pathogen, causing disease through both toxin- and non-toxin-mediated mechanisms. It is responsible for numerous nosocomial and community-based infections that range from relatively minor skin and soft tissue infections (SSTIs) to life-threatening systemic infections.

The "other" staphylococci, coagulase-negative staphylococci, are less virulent than *S. aureus* but remain important pathogens in select settings, such as infections involving prosthetic devices.

MICROBIOLOGY AND TAXONOMY

Staphylococci, gram-positive cocci in the family Micrococcaceae, form grapelike clusters on Gram's stain **(Fig. 152-1)**. These organisms (~1 μm in diameter) are catalase-positive (unlike streptococcal species), nonmotile, aerobic, and facultatively anaerobic. They are capable of prolonged survival on environmental surfaces under varying conditions. Some species have a relatively broad host range, including mammals and birds, whereas the host range for others is quite narrow—i.e., limited to one or two closely related animals.

S. aureus is generally distinguished from other staphylococcal species by coagulase production, a surface enzyme that converts fibrinogen to fibrin. However, several of the "coagulase-negative staphylococci,"

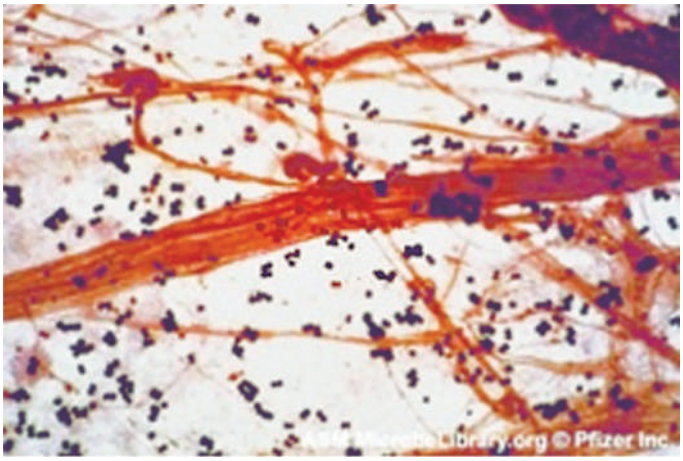

FIGURE 152-1 Gram's stain of *S. aureus* in a sputum sample, illustrating staphylococcal clusters. *(From ASM MicrobeLibrary.org. © Pfizer, Inc.)*

including *S. pseudintermedius* and *S. argenteus*, are coagulase-positive. As a result, description of these other staphylococci as non–*S. aureus* staphylococci (NSaS) is more accurate.

S. aureus ferments mannitol, is positive for protein A, and produces DNAse. On blood agar plates, *S. aureus* forms golden β-hemolytic colonies; in contrast, most NSaS form small, white nonhemolytic colonies. Latex kits that detect both protein A and clumping factor can distinguish *S. aureus* from most other staphylococcal species. Point-of-care tests targeting these two proteins also are used for the rapid detection of staphylococcal colonization. Newer methods such as matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF) are increasingly being used for staphylococcal speciation.

Determining whether multiple staphylococcal isolates from different patients are the same or different is often relevant when there is concern that a nosocomial outbreak of staphylococcal infections is due to a common point source (e.g., a contaminated medical instrument). Molecular typing methods, such as pulsed-field gel electrophoresis and sequence-based techniques (e.g., staphylococcal protein A [SpA] typing), have been used for this purpose. More recently, whole-genome sequencing has emerged as the gold standard for discrimination among different isolates.

S. AUREUS INFECTIONS

EPIDEMIOLOGY

S. aureus is both a commensal and an opportunistic pathogen. Approximately 20–40% of healthy persons are colonized with *S. aureus*, with a smaller percentage (~10%) persistently colonized with the same strain. The rate of colonization is elevated among type 1 diabetics, HIV-infected patients, patients undergoing hemodialysis, injection drug users, and individuals with damaged skin. The anterior nares and oropharynx are frequent sites of human colonization, although the skin (especially when damaged), axilla, vagina, and perineum also are often colonized. These colonization sites serve as potential reservoirs for future infections.

Most individuals who develop *S. aureus* infections become infected with a strain that is already a part of their own commensal flora. Breaches of the skin or mucosal membrane allow *S. aureus* to initiate infection. Person-to-person transmission of *S. aureus* also occurs, most frequently from direct personal contact with an infected body site. Spread of staphylococci in aerosols of respiratory or nasal secretions from heavily colonized individuals, although rare, has been reported.

Some diseases increase the risk of *S. aureus* infection. Diabetes, for example, combines an increased rate of *S. aureus* colonization and the use of injectable insulin with the possibility of impaired leukocyte function. Individuals with congenital or acquired qualitative or quantitative defects of polymorphonuclear leukocytes (PMNs) are at increased risk of *S. aureus* infections; this group includes neutropenic patients (e.g., those receiving chemotherapeutic agents), those with chronic granulomatous disease, and those with autosomal dominant hyperimmunoglobulin E (Job syndrome) or Chédiak-Higashi syndrome. Other groups at risk include individuals with end-stage renal disease, HIV infection, skin abnormalities, or prosthetic devices.

S. aureus is a leading cause of health care–associated infections **(Chap. 147)**. It is the most common cause of surgical wound infections and is second only to NSaS as a cause of primary bacteremia. These isolates are often resistant to multiple antibiotics; thus, available therapeutic options may be limited. In the community, *S. aureus* remains an important cause of SSTIs, respiratory infections, and, especially among injection drug users, infective endocarditis. The increasing use of home infusion therapy also poses a risk of community-acquired staphylococcal infections.

In the past three decades, there has been a dramatic change in the epidemiology of infections due to methicillin-resistant *S. aureus* (MRSA). In addition to its major role as a nosocomial pathogen, MRSA has become an established community-based pathogen. Numerous outbreaks of community-associated MRSA (CA-MRSA) infections have been reported in both rural and urban settings in widely separated regions throughout the world.

This trend appears to be due in part to the dramatic increase in MRSA colonization found in the community in different parts of the world. Outbreaks of CA-MRSA infections have occurred among such diverse groups as children, prisoners, athletes, Native Americans, and drug users. Risk factors common to these outbreaks include poor hygienic conditions, close contact, contaminated material, and damaged skin. In some geographic regions of the world, the infections have been caused by a single CA-MRSA strain, while in others, a variety of CA-MRSA strains have been responsible. In the United States, strain sequence type 8 (PFGE type USA300) has been the predominant clone **(Fig. 152-2)**. Although most infections caused by these strains have involved the skin and soft tissue, 5–10% have been invasive and potentially life-threatening. CA-MRSA strains have also been responsible for an increasing number of nosocomial infections. Of concern has been the enhanced capacity of CA-MRSA to cause disease in immunocompetent individuals.

PATHOGENESIS

General Concepts *S. aureus* is a pyogenic pathogen known for its capacity to induce abscess formation at both local and distant sites (i.e., metastatic infections). This classic pathologic response to *S. aureus* defines the framework within which infections will progress. The bacteria elicit an inflammatory response characterized by an initial intense infiltration of PMNs and a subsequent infiltration of macrophages and fibroblasts. Either the host cellular response (including the deposition of fibrin and collagen) contains the infection with the formation of a fibrinous capsule, or infection spreads to the adjoining tissue or into the bloodstream.

In toxin-mediated staphylococcal disease, infection is not invariably present. For example, in staphylococcal food poisoning, once the heat-stable enterotoxin has been released into food, symptoms can develop in the absence of viable bacteria. In staphylococcal toxic shock syndrome (TSS), conditions allowing toxin elaboration at colonization sites (e.g., the presence of a superabsorbent tampon) suffice for initiation of clinical illness.

The *S. aureus* Genome The complete genomes of *S. aureus* strains are now readily available. Among the interesting revelations are (1) the high degree of nucleotide sequence similarity of the core genomes of different strains; (2) the acquisition of a relatively large amount of genetic information by horizontal transfer from other bacterial species; and (3) the presence of unique "pathogenicity" or "genomic" islands—mobile genetic elements that contain clusters of enterotoxin and exotoxin genes and/or antimicrobial resistance determinants. Among the genes in these islands is *mecA*, the gene responsible for methicillin resistance. Methicillin resistance–containing islands have been designated staphylococcal cassette chromosome *mec* (SCC*mec*). There are different SCC*mec* types that range in size from ~20 to 60 kb. Among the more common SCC*mec* types, types 1–3 are

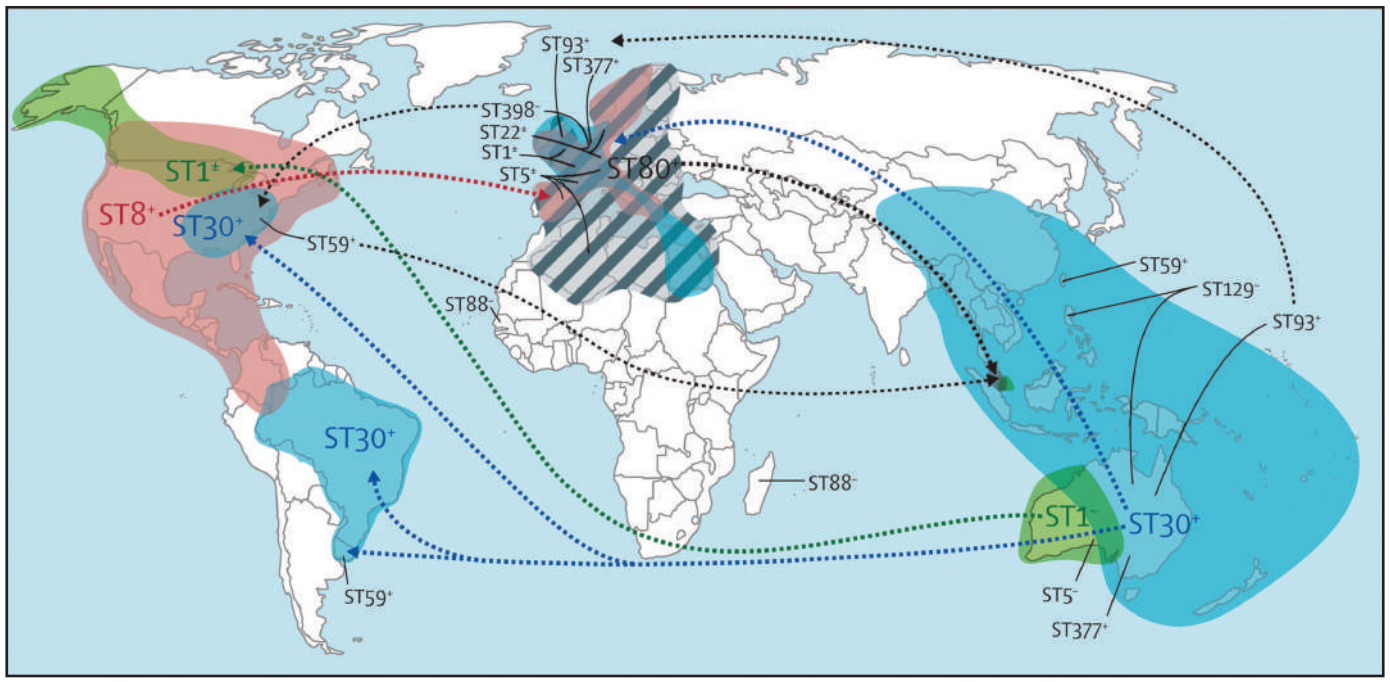

FIGURE 152-2 Global distribution of community-associated MRSA. Dotted lines indicate possible route of dissemination. Estimates of the areas are shown where infection with the main strains—i.e., ST1 *(green)*, ST8 *(red)*, ST30 *(blue)*, and ST80 *(gray hatched)*—have been reported. +, Panton-Valentine leukocidin (PVL)-positive strains; –, PVL-negative strains; ±, PVL-positive and -negative strains. *(Reproduced with permission from FR DeLeo, M Otto, BN Kreiswirth, HF Chambers: Community-associated methicillin-resistant Staphylococcus aureus. Lancet 375:1557, 2010.)*

traditionally associated with nosocomial MRSA isolates, whereas types 4–6 have been associated with epidemic CA-MRSA strains.

A relatively limited number of MRSA clones have been responsible for most community- and hospital-associated infections worldwide. A comparison of these strains with those from earlier outbreaks (e.g., the phage 80/81 strains from the 1950s) has revealed preservation of much of the nucleotide sequence over time. This observation suggests that these strains possess determinants that facilitate survival and spread.

Regulation of Virulence Gene Expression In both toxin-mediated and non-toxin-mediated diseases due to *S. aureus*, the expression of virulence determinants associated with infection depends on a series of regulatory genes (e.g., accessory gene regulator [*agr*] and staphylococcal accessory regulator [*sar*]) that coordinately control the expression of many virulence genes. The regulatory gene *agr* is part of a quorum-sensing signal transduction pathway that senses and responds to bacterial density. Staphylococcal surface proteins are synthesized during the bacterial exponential growth phase in vitro. In contrast, many secreted proteins, such as α toxin, the enterotoxins, and assorted enzymes, are released during the post–exponential growth phase in response to transcription of the effector molecule of *agr*, RNAIII.

These regulatory genes appear to serve a similar function in vivo. Successful invasion requires the sequential expression of these different bacterial elements. Bacterial adhesins are needed to initiate colonization of host tissue surfaces. The subsequent release of various enzymes enables the colony to obtain nutritional support and permits bacteria to spread to adjacent tissues. Studies with strains in which these regulatory genes are inactivated show reduced virulence in several animal models of *S. aureus* infection.

Pathogenesis of Invasive *S. aureus* Infection Staphylococci are opportunists. For these organisms to invade the host and cause infection, some or all of the following steps are necessary: contamination and colonization of host tissue surfaces, breach of cutaneous or mucosal barriers, establishment of a localized infection, invasion, evasion of the host response, and metastatic spread. Colonizing strains or strains transferred from other exposures are introduced into damaged skin, a wound, or the bloodstream. Recurrences of *S. aureus* infections are common, apparently because of the capacity of these pathogens to persist in a quiescent state in various tissues, and then to cause recrudescent infections when suitable conditions arise.

***S. AUREUS* COLONIZATION OF BODY SURFACES** The anterior nares and oropharynx are primary sites of staphylococcal colonization. In the nares, colonization appears to involve the attachment of *S. aureus* to keratinized epithelial cells. Other factors that contribute to colonization include the influence of other resident nasal flora and their bacterial density, host factors, and nasal mucosal damage (e.g., that resulting from inhalational drug use). Other colonized body sites, such as damaged skin, the groin, and the oropharynx, may be particularly important reservoirs for CA-MRSA strains.

INOCULATION AND COLONIZATION OF TISSUE SURFACES Staphylococci may be introduced into tissue as a result of minor abrasions (e.g., mosquito bites), administration of medications such as insulin, or establishment of IV access with catheters. After introduction into a tissue site, bacteria replicate and colonize the host tissue surface. A family of structurally related *S. aureus* surface proteins referred to as MSCRAMMs (microbial surface components recognizing adhesive matrix molecules) play an important role as mediators of adherence to these different sites. By adhering to exposed matrix molecules (e.g., fibrinogen, collagen, fibronectin), MSCRAMMs, such as clumping factor and collagen-binding protein, enable the bacteria to colonize different host tissue surfaces; these proteins contribute to the pathogenesis of invasive infections such as endocarditis and septic arthritis by facilitating the adherence of *S. aureus* to surfaces with exposed fibrinogen or collagen.

Although NSaS are classically known for their ability to elaborate biofilms and to colonize prosthetic devices, *S. aureus* also possesses the genes responsible for biofilm formation, such as the intercellular adhesion (*ica*) locus. Binding to these devices occurs in a stepwise fashion, involving staphylococcal adherence to serum constituents that have coated the device surface and subsequent biofilm elaboration. *S. aureus* is thus a frequent cause of biomedical device–related infections.

INVASION After colonization, staphylococci replicate at the initial site of infection, elaborating enzymes that include serine proteases, hyaluronidases, thermonucleases, and lipases. These enzymes facilitate bacterial survival and local spread across tissue surfaces. The lipases may facilitate survival in lipid-rich areas such as the hair follicles, where *S. aureus* infections are often initiated.

Constitutional findings may result from either localized or systemic infections. The staphylococcal cell wall—consisting of alternating *N*-acetyl muramic acid and *N*-acetyl glucosamine units in combination with an additional cell wall component, lipoteichoic acid—can initiate an inflammatory response that includes the sepsis syndrome. Staphylococcal alpha (α) toxin is a critical staphylococcal toxin. It causes pore formation in various eukaryotic cells and can also initiate an inflammatory response with findings suggestive of sepsis. The *S. aureus* toxin Panton-Valentine leukocidin is cytolytic to PMNs, macrophages, and monocytes. Strains elaborating this toxin have been epidemiologically linked with cutaneous and more serious infections (i.e., pneumonia) caused by strains of CA-MRSA.

EVASION OF HOST DEFENSE MECHANISMS Staphylococci have many host immune evasion strategies that are crucial to their survival. They possess an antiphagocytic polysaccharide microcapsule. Most human *S. aureus* infections are due to strains with capsular types 5 and 8. The zwitterionic (both negatively and positively charged) *S. aureus* capsule also plays a critical role in the induction of abscess formation. Protein A, an MSCRAMM unique to *S. aureus*, acts as an Fc receptor, binding the Fc portion of IgG subclasses 1, 2, and 4 and preventing opsonophagocytosis by PMNs. Both chemotaxis inhibitory protein of staphylococci (CHIPS, a secreted protein) and extracellular adherence protein (EAP, a surface protein) interfere with PMN migration to sites of infection. There are several cytolytic toxins, including α toxin and Panton-Valentine toxin, that are secreted by staphylococci that cause lysis of different host cells and contribute to host tissue damage.

An additional potential mechanism of *S. aureus* evasion is its capacity for intracellular survival. Both professional and nonprofessional phagocytes internalize staphylococci. Internalization by these cells may provide a sanctuary that protects bacteria against the host's defenses. This phenomenon appears to be especially relevant for hepatic Kupffer cells during staphylococcal bacteremias. The intracellular environment favors the phenotypic expression of *S. aureus* small-colony variants, which are found in patients receiving antimicrobial therapy (e.g., with aminoglycosides) and in those with cystic fibrosis or osteomyelitis. These variants, whether intra- or extracellular, may facilitate prolonged staphylococcal survival in different tissue sites and enhance the likelihood of recurrences. Finally, *S. aureus* can survive within PMNs and may use these cells to spread and seed other tissue sites.

PATHOGENESIS OF COMMUNITY-ACQUIRED MRSA INFECTIONS A number of specific virulence determinants contribute to the pathogenesis of CA-MRSA infections. A strong epidemiologic association links the presence of the gene for the Panton-Valentine leukocidin with SSTIs and with necrotizing postinfluenza pneumonia. Other determinants that play a role in the pathogenesis of these infections and contribute to the unique virulence of these clones include the arginine catabolic mobile element (ACME), a cluster of unique genes that may facilitate evasion of host defense mechanisms; phenol-soluble modulins, a family of cytolytic peptides; and α toxin.

Host Response to *S. aureus* Infection The primary host response to *S. aureus* infection is the recruitment of PMNs. These cells are attracted to infection sites by bacterial components such as formylated peptides or peptidoglycan as well as by the cytokines tumor necrosis factor (TNF) and interleukins (ILs) 1 and 6, which are released by activated macrophages and endothelial cells.

Although most individuals have antibodies to staphylococci, it is not clear that antibody levels are qualitatively or quantitatively sufficient to protect against infection. Anticapsular and anti-MSCRAMM antibodies facilitate opsonization in vitro and have been protective against infection in several animal models; however, vaccines with these components have not yet successfully prevented staphylococcal infections in clinical trials.

Pathogenesis of Toxin-Mediated Disease *S. aureus* produces three types of toxins: cytotoxins, pyrogenic toxin superantigens, and exfoliative toxins. Both epidemiologic data and studies in animals suggest that antitoxin antibodies are protective against illness in TSS, staphylococcal food poisoning, and staphylococcal scalded-skin syndrome (SSSS). Illness develops after toxin synthesis and absorption and the subsequent toxin-initiated host response.

ENTEROTOXIN AND TOXIC SHOCK SYNDROME TOXIN 1 (TSST-1) The pyrogenic toxin superantigens are a family of small-molecular-size, structurally similar proteins that are responsible for two diseases: TSS and food poisoning. TSS results from the ability of TSST-1 and enterotoxins to function as T-cell mitogens. In the normal process of antigen presentation, the antigen is first processed within the cell, and peptides are then presented in the major histocompatibility complex (MHC) class II groove, initiating a measured T-cell response. In contrast, TSST-1 and enterotoxins bind directly to the invariant region of MHC—outside the MHC class II groove. TSST-1 and the enterotoxins can then bind T-cell receptors via the vβ chain; this binding results in a dramatic overexpansion of T-cell clones (up to 20% of the total T-cell population). The consequence of this T-cell expansion is a cytokine storm, with the release of inflammatory mediators that include interferon γ, IL-1, IL-6, TNF-α, and TNF-β. The resulting multisystem disease produces a constellation of findings that mimic those found in endotoxin shock; however, the pathogenic mechanisms differ.

A different region of the enterotoxin molecule is responsible for the symptoms of food poisoning. The enterotoxins are heat stable and can survive conditions that kill the bacteria. Illness results from the ingestion of preformed toxin; as a result, the incubation period is short (1–6 h). The toxin stimulates the vagus nerve and the vomiting center of the brain. It also appears to stimulate intestinal peristaltic activity.

EXFOLIATIVE TOXINS AND SSSS The exfoliative toxins are responsible for SSSS, most commonly seen in newborns. The toxins that produce disease in humans are of two serotypes: ETA and ETB. These toxins are serine proteases that cleave desmosomal cadherins in the superficial layer of the skin, triggering exfoliation. The result is a split in the epidermis at the granular level, which is responsible for the superficial desquamation of the skin that typifies this illness.

DIAGNOSIS

Staphylococcal infections are readily diagnosed by Gram's stain (Fig. 152-1) and microscopic examination of abscess contents or of infected tissue. Routine cultures of infected material usually are positive; blood cultures are sometimes positive even when infections are localized to extravascular sites. *S. aureus* is rarely a blood culture contaminant. Polymerase chain reaction (PCR)–based assays are now often used for the rapid diagnosis of *S. aureus* infection. A number of point-of-care tests are available to screen patients for colonization with MRSA. Determining whether patients with documented *S. aureus* bacteremia also have infective endocarditis or a metastatic focus of infection remains a diagnostic challenge. Uniformly positive cultures of blood collected over time suggest an endovascular infection such as endocarditis (see "Bacteremia, Sepsis, and Infective Endocarditis," below).

CLINICAL SYNDROMES

(Table 152-1)

Skin and Soft Tissue Infections *S. aureus* causes a variety of cutaneous infections. Common factors predisposing to *S. aureus* cutaneous infection include chronic skin conditions (e.g., eczema), skin damage (e.g., insect bites, minor trauma), injections (e.g., in diabetes, injection drug use), and poor personal hygiene. These infections are characterized by the formation of pus-containing blisters, which often begin in hair follicles and spread to adjoining tissues. *Folliculitis* is a superficial infection that involves the hair follicle, with a central area of purulence (pus) surrounded by induration and erythema. *Furuncles* (boils) are more extensive, painful lesions that tend to occur in hairy, moist regions of the body and extend from the hair follicle to become a true abscess with an area of central purulence. *Carbuncles* are most often located in the lower neck and are even more severe and painful, resulting from the coalescence of other lesions that extend to a deeper layer of the subcutaneous tissue. In general, furuncles and carbuncles are readily apparent, with pus often expressible or discharging from the abscess. Other cutaneous *S. aureus* infections include impetigo

TABLE 152-1 Common Illnesses Caused by *Staphylococcus aureus*
Skin and Soft Tissue Infections
Folliculitis
Abscess, furuncle, carbuncle
Cellulitis
Impetigo
Mastitis
Surgical wound infections
Musculoskeletal Infections
Septic arthritis
Osteomyelitis (hematogenous or contiguous spread)
Pyomyositis
Psoas abscess
Respiratory Tract Infections
Ventilator-associated or nosocomial pneumonia
Septic pulmonary emboli
Postviral pneumonia (e.g., influenza)
Empyema
Bacteremia and Its Complications
Sepsis, septic shock
Metastatic foci of infection (kidney, joints, bone, lung)
Infective endocarditis
Infective Endocarditis
Injection drug use–associated
Native-valve
Prosthetic-valve
Nosocomial
Device-Related Infections (e.g., intravascular catheters, prosthetic joints)
Toxin-Mediated Illnesses
Toxic shock syndrome
Food poisoning
Staphylococcal scalded-skin syndrome
Invasive Infections Associated with Community-Acquired Methicillin-Resistant *S. aureus*
Necrotizing fasciitis
Waterhouse-Friderichsen syndrome
Necrotizing pneumonia
Purpura fulminans

and cellulitis. *S. aureus* is one of the most common causes of surgical wound infections.

Mastitis develops in 1–3% of nursing mothers. This infection of the breast, which generally presents within 2–3 weeks after delivery, is characterized by findings that range from cellulitis to abscess formation. Systemic signs, such as fever and chills, are often present in more severe cases.

Musculoskeletal Infections *S. aureus* is a common cause of bone infections—both those resulting from hematogenous dissemination and those arising from contiguous spread from a soft tissue site. *Hematogenous osteomyelitis* in children most often involves the long bones. Infections present with fever and bone pain or with a child's reluctance to bear weight. The white blood cell count and erythrocyte sedimentation rate are often elevated. Blood cultures are positive in ~50% of cases. When necessary, bone biopsies for culture and histopathologic examination are usually diagnostic.

In adults, hematogenous osteomyelitis involving the long bones is less common. However, *vertebral osteomyelitis* is among the more common clinical presentations. Vertebral bone infections are most often seen in patients with endocarditis, those undergoing hemodialysis, diabetics, and injection drug users. These infections may present with intense back pain and fever but may also be clinically occult, presenting as chronic back pain with low-grade fever. *S. aureus* is the most common cause of epidural abscess, a complication that can result in neurologic compromise. Patients report difficulty voiding or walking and radicular pain in addition to the symptoms associated with their osteomyelitis. Surgical intervention in this setting often constitutes a medical emergency.

Magnetic resonance imaging (MRI) is the most reliable imaging modality to help establish the diagnosis of osteomyelitis **(Fig. 152-3)**. Routine x-rays are an appropriate first step, but findings may be normal for up to 14 days after the onset of symptoms. If an MRI is not possible, computed tomography (CT) is an acceptable alternative.

Bone infections that result from contiguous spread tend to develop from soft tissue infections, such as those associated with diabetic or vascular ulcers, surgery, or trauma. Exposure of bone, a draining fistulous tract, failure to heal, or continued drainage suggests involvement of underlying bone. Bone involvement is established by bone culture and histopathologic examination (revealing evidence of PMN infiltration). Contamination of culture material from adjacent tissue can make the diagnosis of osteomyelitis difficult in the absence of pathologic confirmation. Samples obtained during surgery are the most reliable. An MRI is the most reliable radiologic test to distinguish between osteomyelitis and overlying soft tissue infection with underlying osteitis.

In both children and adults, *S. aureus* is the most common cause of *septic arthritis* in native joints. If left untreated, this infection is rapidly progressive and may be associated with extensive joint destruction. It presents with intense pain on motion of the affected joint, swelling, and fever. Aspiration of the joint reveals turbid fluid, with >50,000 PMNs/μL and gram-positive cocci in clusters seen on Gram's stain (Fig. 152-1). In adults, septic arthritis may result from trauma, surgery, or hematogenous dissemination. The most commonly involved joints include the knees, shoulders, hips, and phalanges. Infection frequently develops in joints previously damaged by osteoarthritis or rheumatoid

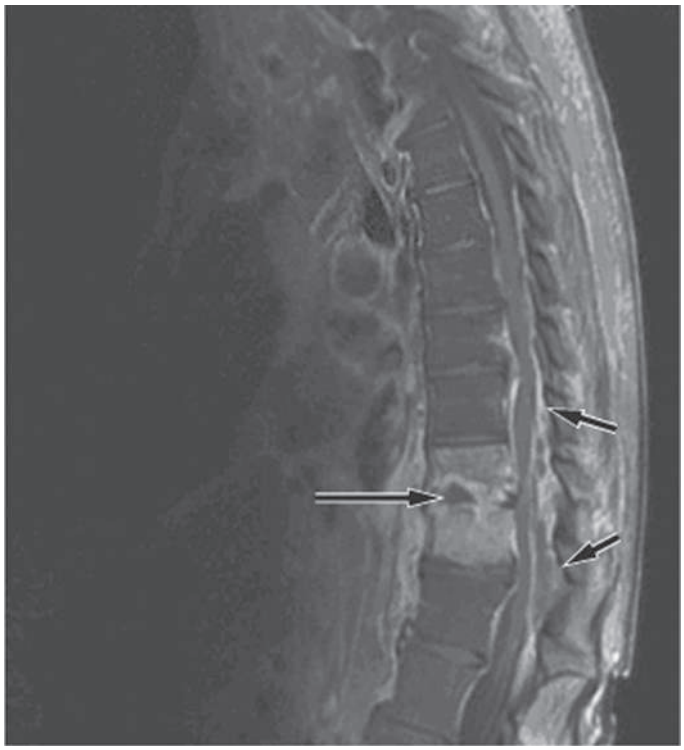

FIGURE 152-3 *S. aureus* vertebral osteomyelitis and epidural abscess involving the thoracic disk between T9 and T10. Sagittal postcontrast magnetic resonance imaging of the spine illustrates destruction of the T9–T10 intervertebral space with enhancement (*long arrow*). There is impingement on the thoracic cord and an epidural collection extending from T9 through T11 (*short arrows*).

arthritis. Iatrogenic infections resulting from aspiration or injection of agents into the joint also occur. In these settings, the patient experiences increased pain and swelling in the involved joint in association with fever.

Pyomyositis is an unusual infection of skeletal muscles that is seen primarily in tropical climates but also occurs in immunocompromised (e.g., HIV-infected) patients. It is believed to arise from occult bacteremia. Pyomyositis presents as fever, swelling, and pain overlying the involved muscle. Aspiration of fluid from the involved tissue yields pus. Although a history of trauma may be associated with the infection, its pathogenesis is poorly understood.

Respiratory Tract Infections Respiratory tract infections caused by *S. aureus* occur in selected clinical settings. *S. aureus* is a cause of serious respiratory tract infections in newborns and infants; these infections present with shortness of breath, fever, and respiratory failure. Chest x-ray may reveal pneumatoceles (shaggy, thin-walled cavities). Pneumothorax and empyema are recognized complications.

In adults, nosocomial *S. aureus* pulmonary infections are common among intubated patients in intensive care units. Nasally colonized patients are at increased risk of these infections. The clinical presentation is no different from pulmonary infections caused by other bacterial pathogens. Patients produce increased volumes of purulent sputum and develop respiratory distress, fever, and new pulmonary infiltrates. Distinguishing bacterial pneumonia from respiratory failure or other causes of new pulmonary infiltrates in critically ill patients is difficult and relies on a constellation of clinical, radiologic, and laboratory findings.

Community-acquired respiratory tract infections due to *S. aureus* often follow viral infections—most commonly influenza. Patients may present with fever, bloody sputum production, and midlung-field pneumatoceles or multiple, patchy pulmonary infiltrates. Diagnosis is made by sputum Gram's stain and culture. Blood cultures, although useful, are usually negative.

Bacteremia, Sepsis, and Infective Endocarditis *S. aureus* bacteremia may be complicated by sepsis, endocarditis, vasculitis, or metastatic seeding (establishment of suppurative collections at other tissue sites). Among the more commonly seeded tissue sites are bones, joints, kidneys, and lungs. The frequency of metastatic seeding during bacteremia has been estimated to be as high as 31%. The incidence of these complications increases with the duration of the bacteremia.

Recognition of these complications by clinical criteria alone is challenging. Comorbid conditions that are frequently seen in association with *S. aureus* bacteremia and that increase the risk of complications include diabetes, HIV infection, and renal insufficiency. Other host factors that increase the risk of complications include presentation with community-acquired *S. aureus* bacteremia, lack of an identifiable primary focus of infection, and the presence of prosthetic devices or material.

Clinically, *S. aureus* sepsis presents in a manner similar to that documented for sepsis due to other bacteria. The well-described progression of hemodynamic changes—beginning with respiratory alkalosis and clinical findings of hypotension and fever—is commonly seen. The microbiologic diagnosis is established by positive blood cultures.

The overall incidence of *S. aureus* endocarditis has increased over the past 20 years. *S. aureus* is now the leading cause of endocarditis worldwide, accounting for 25–35% of cases. This increase is due, at least in part, to the increased use of intravascular devices and, more recently, the upsurge in injection drug use. Studies using transesophageal echocardiography found an endocarditis incidence of ~25% among patients with intravascular catheter–associated *S. aureus* bacteremia. Other factors associated with an increased risk of endocarditis are hemodialysis, the presence of intravascular prosthetic devices at the time of bacteremia, and immunosuppression. Patients with implantable cardiac devices (e.g., permanent pacemakers) are at increased risk of endocarditis or device-related infections. Despite the availability of effective antibiotics, mortality rates from these infections continue to range from 20 to 40%, depending on both the host and the nature of the infection. Complications of *S. aureus* endocarditis include cardiac valvular insufficiency, peripheral emboli, metastatic seeding, vasculitis, and central nervous system (CNS) involvement (e.g., mycotic aneurysms, embolic strokes).

S. aureus endocarditis is encountered in four clinical settings: (1) right-sided endocarditis in association with injection drug use; (2) left-sided native-valve endocarditis; (3) prosthetic-valve endocarditis; and (4) nosocomial endocarditis. In each of these settings, the diagnosis is suspected from the patient's history and the recognition of physical signs suggestive of endocarditis. These findings include cardiac manifestations, such as new or changing cardiac valvular murmurs; cutaneous evidence, such as vasculitic lesions, Osler's nodes, or Janeway lesions; evidence of right- or left-sided embolic disease; and a history suggesting a risk for *S. aureus* bacteremia. In the absence of antecedent antibiotic therapy, blood cultures are almost uniformly positive. Transthoracic echocardiography, while less sensitive than transesophageal echocardiography, is less invasive and often identifies valvular vegetations. The Duke criteria **(Chap. 133)** are commonly used to help establish this diagnosis.

Acute right-sided tricuspid valvular *S. aureus* endocarditis is most often seen in patients who inject drugs. The classic presentation includes a high fever, a toxic clinical appearance, pleuritic chest pain, and the production of purulent, sometimes bloody, sputum. Chest x-rays or CT scans reveal evidence of septic pulmonary emboli (small, peripheral, circular lesions that may cavitate with time) **(Fig. 152-4)**. A high percentage of affected patients have no history of antecedent valvular damage. At the outset of their illness, patients may present with fever alone, without cardiac or other localizing findings. As a result, a high index of clinical suspicion is essential for diagnosis.

Individuals with antecedent cardiac valvular damage more commonly present with left-sided native-valve endocarditis involving the damaged valve. These patients tend to be older than those with right-sided endocarditis, their prognosis is worse, and their incidence of complications (including peripheral emboli, cardiac decompensation, cerebrovascular events, and metastatic seeding) is increased.

S. aureus is one of the more common causes of prosthetic-valve endocarditis. This infection is especially fulminant in the early postoperative period and is associated with increased morbidity and mortality. In most instances, medical therapy alone is not sufficient and urgent valve replacement is necessary. Patients are prone to develop valvular insufficiency or myocardial abscesses originating from the region of valve implantation.

The increased frequency of nosocomial endocarditis (15–30% of cases, depending on the series) reflects in part the increased use of intravascular devices. This form of endocarditis is most commonly caused by *S. aureus*. These patients are often critically ill, are receiving antibiotics for various other indications, and have comorbid conditions. As a result, blood cultures may be negative, and the diagnosis missed.

Prosthetic Device–Related Infections *S. aureus* accounts for a large proportion of prosthetic device–related infections. These infections include intravascular and peritoneal catheters, prosthetic valves, orthopedic devices, pacemakers, left ventricular assist devices, or vascular grafts. In contrast with the more indolent presentation of

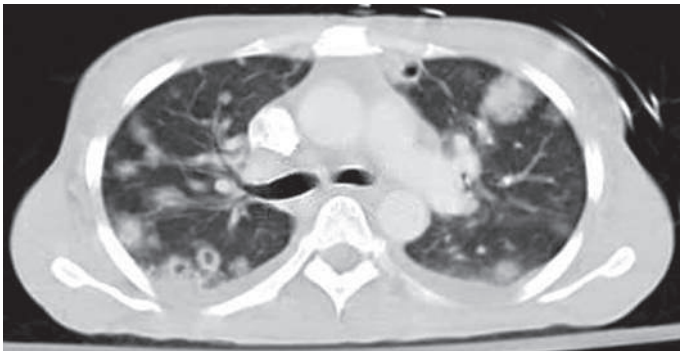

FIGURE 152-4 Computed tomography scan illustrating septic pulmonary emboli in a patient with methicillin-resistant *Staphylococcus aureus* bacteremia.

NSaS infections, *S. aureus* device-related infections are often acute, have both local and systemic manifestations, and tend to progress more rapidly. It is relatively common for a pyogenic collection to be present at the device site. Aspiration of these collections and performance of blood cultures are important components in establishing a diagnosis. *S. aureus* infections tend to occur more commonly soon after implantation unless the device is used for access (e.g., intravascular or hemodialysis catheters). In the latter instance, infections can occur at any time. As in most prosthetic-device infections, successful therapy usually involves removal of the device. Left in place, the device serves as a potential nidus for either persistent or recurrent infections.

Urinary Tract Infections Urinary tract infections (UTIs) are infrequently caused by *S. aureus*. The presence of *S. aureus* in the urine often suggests hematogenous dissemination. Ascending *S. aureus* infections occasionally result from instrumentation of the genitourinary tract.

Infections Associated with Community-Acquired MRSA Although skin and soft tissues are by far the most common sites of infection associated with CA-MRSA, 5–10% of these infections are invasive and can be life-threatening. The latter unique infections, including necrotizing fasciitis, necrotizing pneumonia, and sepsis with Waterhouse-Friderichsen syndrome or purpura fulminans, were rarely associated with *S. aureus* prior to the emergence of CA-MRSA. These life-threatening infections reflect the increased virulence of CA-MRSA strains.

Toxin-Mediated Diseases • **FOOD POISONING** *S. aureus* is among the most common causes of foodborne outbreaks in the United States. Staphylococcal food poisoning results from the inoculation of toxin-producing *S. aureus* into food by colonized food handlers. Toxin is then elaborated in such growth-promoting food as custards, potato salad, or processed meats. Even if the bacteria are killed by warming, the heat-stable toxin is not destroyed. The onset of illness is rapid, occurring within 1–6 h of ingestion; it is characterized by nausea and vomiting, although diarrhea, hypotension, and dehydration may occur. The differential diagnosis includes diarrhea of other etiologies, especially that caused by similar toxins (e.g., the toxins elaborated by *Bacillus cereus*). The rapidity of onset, the absence of fever, and the epidemic nature of the presentation (without secondary spread) should arouse suspicion of staphylococcal food poisoning. Symptoms generally resolve within 8–10 h. The diagnosis can be established by the demonstration of bacteria or the documentation of enterotoxin in the implicated food. Treatment is entirely supportive.

TOXIC SHOCK SYNDROME TSS gained attention in the early 1980s, when a nationwide outbreak occurred among young, otherwise healthy, menstruating women. Epidemiologic investigation demonstrated that these cases were associated with the use of a highly absorbent tampon recently introduced to the market. Subsequent studies established the role of TSST-1 in these illnesses. Withdrawal of the tampon from the market resulted in a rapid decline in the incidence of this disease. However, menstrual and nonmenstrual cases continue to be reported. Nonmenstrual cases are seen in patients with surgical or postpartum wound infections, especially when packing of the wound occurs.

The clinical presentation is similar in menstrual and nonmenstrual TSS. Evidence of clinical *S. aureus* infection is not a prerequisite. TSS results from the elaboration of an enterotoxin or the structurally related enterotoxin-like TSST-1. More than 90% of menstrual cases are caused by TSST-1, whereas a high percentage of nonmenstrual cases are caused by enterotoxins (e.g., enterotoxin B). TSS begins with relatively nonspecific flulike symptoms. In menstrual cases, the onset usually comes 2 or 3 days after the start of menstruation. Patients present with fever, hypotension, and erythroderma of variable intensity. Mucosal involvement is common (e.g., conjunctival hyperemia). The illness can rapidly progress to symptoms that include vomiting, diarrhea, confusion, myalgias, and abdominal pain. These symptoms reflect the multisystemic nature of the disease, with involvement of the liver, kidneys, gastrointestinal tract, and/or CNS. Desquamation of the skin occurs during convalescence, usually 1–2 weeks after the onset of illness. Laboratory findings may include azotemia, leukocytosis, hypoalbuminemia, thrombocytopenia, and liver function abnormalities.

TABLE 152-2 Case Definition of *Staphylococcus aureus* Toxic Shock Syndrome

Clinical Criteria
An illness with the following clinical manifestations:
• Fever: temperature ≥102.0°F (≥38.9°C)
• Rash: diffuse macular erythroderma
• Desquamation: 1–2 weeks after rash onset
• Hypotension: systolic blood pressure ≤90 mmHg for adults or less than the fifth percentile, by age, for children <16 years old
• Multisystem involvement (≥3 of the following organ systems)
– Gastrointestinal: vomiting or diarrhea at illness onset
– Muscular: severe myalgia or creatine phosphokinase level at least twice ULN
– Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia
– Renal: blood urea nitrogen or creatinine level at least twice ULN for laboratory or urinary sediment with pyuria (≥5 leukocytes per high-power field) in the absence of urinary tract infection
– Hepatic: total bilirubin or aminotransferase level at least twice ULN for laboratory
– Hematologic: platelet count <10^5/mL
– Central nervous system: disorientation or alterations in consciousness without focal neurologic signs in the absence of fever and hypotension
Laboratory Criteria
Negative results in the following tests, if obtained:
• Blood or cerebrospinal fluid cultures for another pathogen[a]
• Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles
Case Classification
Probable: a case that meets the laboratory criteria and in which four of the five clinical criteria are fulfilled
Confirmed: a case that meets the laboratory criteria and in which all five of the clinical criteria are fulfilled, including desquamation (unless the patient dies before desquamation occurs)

[a]Blood cultures may be positive for *S. aureus*.

Abbreviation: ULN, upper limit of normal.

Diagnosis of TSS still depends on a constellation of findings rather than one specific finding and on a lack of evidence of other possible infections (Table 152-2). These other diagnoses include drug toxicities, viral exanthems, Rocky Mountain spotted fever, sepsis, and Kawasaki disease. Illness occurs only in persons who lack antibody to TSST-1. Recurrences are possible if antibody fails to develop after the illness.

STAPHYLOCOCCAL SCALDED-SKIN SYNDROME SSSS primarily affects newborns and children. The illness may vary from a localized blister to exfoliation of much of the skin surface. The skin is usually fragile and often tender, with thin-walled, fluid-filled bullae (Fig. 152-5). Gentle pressure results in rupture of the lesions, leaving denuded underlying skin. The mucous membranes are usually spared. In more generalized infection, there are often constitutional symptoms, including fever, lethargy, and irritability with poor feeding. Significant amounts of fluid can be lost in more extensive cases. Illness usually follows localized infection at one of several possible sites. SSSS is much less common among adults but can follow infections caused by exfoliative toxin–producing strains.

NON–*S. AUREUS* STAPHYLOCOCCAL INFECTIONS

Although less virulent than *S. aureus*, NSaS are among the most common causes of prosthetic-device infections, including endocarditis. They also are increasingly a cause of native-valve endocarditis and life-threatening bloodstream infections in neonates and in neutropenic patients. Approximately half of the identified NSaS species have been associated with human infections. Of these species, *Staphylococcus*

FIGURE 152-5 Staphylococcal scalded skin syndrome in a 6-year-old boy. Nikolsky's sign, with separation of the superficial layer of the outer epidermal layer, is visible. *(Adapted from LA Schenfeld: Staphylococcal scalded skin syndrome: N Engl J Med 342:1178, 2000.)*

epidermidis is the most common human pathogen. It is part of the normal human flora and is found on the skin (where it is the most abundant bacterial species) as well as in the oropharynx and vagina. *Staphylococcus saprophyticus*, a novobiocin-resistant species, is a common pathogen in UTIs.

PATHOGENESIS

S. epidermidis is the NSaS species most often associated with prosthetic-device infections. Infection is a two-step process, with initial adhesion to the device followed by colonization. *S. epidermidis* is uniquely adapted to colonize these devices because of its capacity to elaborate the extracellular polysaccharide (glycocalyx or slime) that facilitates formation of a protective biofilm on the device surface.

Implanted prosthetic material is rapidly coated with host matrix molecules such as fibrinogen or fibronectin. These molecules serve as potential bridging ligands, facilitating initial bacterial attachment to the device surface. A number of staphylococcal surface-associated proteins, such as autolysin (AtlE), fibrinogen-binding protein, and accumulation-associated protein (AAP), appear to play a role in attachment to either modified or unmodified prosthetic surfaces. The polysaccharide intercellular adhesin facilitates subsequent staphylococcal colonization, aggregation, and accumulation on the device surface. Intercellular adhesin (*ica*) genes are more commonly found in strains of *S. epidermidis* that are associated with device infections than in strains associated with colonization of mucosal surfaces. Biofilm acts as a barrier, protecting bacteria from host defense mechanisms as well as from antibiotics while providing a suitable environment for bacterial maturation, survival, and potential spread to other tissue sites.

Two additional NSaS species, *Staphylococcus lugdunensis* and *Staphylococcus schleiferi*, produce more serious infections (native-valve endocarditis and osteomyelitis) than do other NSaS. The basis for this enhanced virulence is not known, although both species appear to share more virulence determinants with *S. aureus* (e.g., clumping factor and lipase) than do other NSaS.

The capacity of *S. saprophyticus* to cause UTIs in young women appears related to the presence of adhesins that facilitate adherence to uroepithelial cells. A 160-kDa hemagglutinin/adhesin may contribute to this affinity.

DIAGNOSIS

Although the detection of NSaS at sites of infection or in the bloodstream by standard microbiologic culture methods is not difficult, interpretation of these results is frequently problematic. Because these organisms are present in large numbers on the skin, they often contaminate cultures. It has been estimated that only 10–20% of blood cultures positive for NSaS reflect true bacteremia. Similar problems arise with cultures obtained from other sites. Among the clinical findings suggestive of true bacteremia are fever, evidence of local infection (e.g., erythema or purulent drainage at the IV catheter site), leukocytosis, and systemic signs of sepsis. Laboratory findings suggestive of true bacteremia include repeated isolation of the same strain (i.e., the same species with the same antibiogram or with a closely related DNA fingerprint) from separate cultures, growth of the strain within 48 h, and bacterial growth in both aerobic and anaerobic bottles.

CLINICAL SYNDROMES

NSaS cause a variety of prosthetic device–related infections, including those that involve prosthetic cardiac valves and joints, vascular grafts, intravascular devices, and CNS shunts. In all of these settings, the clinical presentation is similar. The signs of localized infection are often subtle, the rate of disease progression is slow, and the systemic findings are often limited. Signs of infection, such as purulent drainage, pain at the site, or loosening of prosthetic implants, are sometimes evident. Fever is frequently but not always present, and there may be mild leukocytosis. Acute-phase reactant levels, erythrocyte sedimentation rate, and C-reactive protein concentration may be elevated.

Infections that are not associated with prosthetic devices include, as noted, native-valve endocarditis due to NSaS, which accounts for ~5% of cases. Infections in preterm infants and neutropenic patients are often associated with the need for intravascular devices. *S. lugdunensis* appears to be a more aggressive pathogen in this setting, causing greater mortality and rapid valvular destruction with abscess formation than other NSaS.

TREATMENT

Staphylococcal Infections

GENERAL PRINCIPLES OF THERAPY

Source control (e.g., incision and drainage of suppurative collections or removal of infected prosthetic devices), coupled with rapid institution of appropriate antimicrobial therapy, is essential for the management of all staphylococcal infections. The emergence of MRSA as a community-based pathogen has increased the importance of culturing all sites of infection to determine antimicrobial susceptibility and optimize oral treatment regimens.

DURATION OF ANTIMICROBIAL THERAPY

Therapy for *S. aureus* bacteremia is generally prolonged (4–6 weeks) because of the high risk of complications (e.g., endocarditis, metastatic foci of infection). Among the findings associated with complicated bacteremias are (1) persistently positive blood cultures 96 h after institution of therapy, (2) failure to promptly remove or drain an identified focus of infection (i.e., an intravascular catheter), (3) the presence of deep-seated infections, and (4) acquisition of the infection in the community. Patients with uncomplicated bacteremias are defined by a removable focus of infection, prompt response to antimicrobial therapy (i.e., no fever or positive blood cultures after 3–4 days), no evidence of metastatic foci of infection, and no implanted prostheses. In these latter infections, short-course therapy (2 weeks) can be given; however, these findings are not always predictive of an uncomplicated bacteremia. Given these concerns, caution is therefore needed in instituting a short course of therapy. Transesophageal echocardiography to rule out endocarditis is generally necessary because neither clinical nor laboratory findings can reliably detect cardiac involvement. A thorough radiologic investigation to identify potential metastatic collections is also indicated. All symptomatic body sites must be carefully evaluated.

Recent studies have demonstrated that parenteral therapy is not always necessary to complete a course of treatment for invasive staphylococcal infections such as endocarditis or osteomyelitis for carefully selected patients. These include patients with uncomplicated staphylococcal bacteremia.

NSaS treatment is complicated by the possibility that a single isolate may be a contaminant. Therapy for 7–14 days is recommended

for documented infections (i.e., blood cultures of the same strain ≥24 h apart) in the absence of endocarditis or additional sites of infection.

CHOICE OF ANTIMICROBIAL AGENTS

The choice of antimicrobial agents to treat both coagulase-positive and coagulase-negative staphylococcal infections is often difficult because of the prevalence of multidrug-resistant strains and the limited number of clinical trials that have compared the available agents. Staphylococcal resistance to most antibiotic families, including β-lactams, aminoglycosides, fluoroquinolones, and (to a lesser extent) glycopeptides, has increased. This trend is even more apparent with NSaS; >80% of nosocomial isolates are resistant to methicillin, and these methicillin-resistant strains are often resistant to other antibiotics. Because the selection of antimicrobial agents for *S. aureus* infections is similar to that for NSaS infections, treatment options for these pathogens are discussed together and are summarized in **Table 152-3**.

TABLE 152-3 Antimicrobial Therapy for Staphylococcal Infections[a]

SENSITIVITY/ RESISTANCE OF ISOLATE	DRUG OF CHOICE	ALTERNATIVE(S)	COMMENTS
Parenteral Therapy for Serious Infections			
Sensitive to penicillin	Penicillin G (4 mU q4h)	Nafcillin or oxacillin (2 g q4h), cefazolin (2 g q8h), vancomycin (15–20 mg/kg q8h[b])	Fewer than 5% of isolates are sensitive to penicillin. The clinical microbiology laboratory must verify that the strain is not a β-lactamase producer.
Sensitive to methicillin; resistant to penicillin	Nafcillin or oxacillin (2 g q4h), cefazolin (2 g q8h)	Daptomycin (6–10 mg/kg IV q24h[b,d]), vancomycin (15–20 mg/kg q8h[b]), ceftobiprole (500 mg IV q6h[g])	Patients with a penicillin allergy can be treated with a cephalosporin if the allergy does not involve an anaphylactic or accelerated reaction; desensitization to β-lactams may be indicated in selected cases of serious infection when maximal bactericidal activity is needed (e.g., prosthetic-valve endocarditis[c]). Vancomycin is a less effective option than a β -lactam.
Resistant to methicillin	Vancomycin (15–20 mg/kg q8–12h[b]), daptomycin (6–10 mg/kg IV q24h[b,d]) for bacteremia, endocarditis, osteomyelitis, and complicated skin infections	Linezolid (600 mg q12h PO or IV), ceftaroline (600 mg IV q8–12h), telavancin (7.5–10 mg/kg IV q24h)[b], TMP-SMX (5 mg [based on TMP]/kg IV q8–12h)[f] Additional agents include tedizolid (200 mg once daily IV), oritavancin (single dose of 1200 mg), dalbavancin (single dose of 1500 mg), delafloxacin (300 mg q 12 h IV), omadacycline 100 mg OD). Ceftobiprole (500 mg IV q6h[g])	Sensitivity testing is necessary before an alternative drug is selected. The efficacy of adjunctive therapy is not well established in many settings. Linezolid, ceftaroline, and telavancin have in vitro activity against most VISA and VRSA strains. See footnote for treatment of prosthetic-valve endocarditis.[c]
Resistant to methicillin with intermediate or complete resistance to vancomycin[e]	Daptomycin (6–10 mg/kg q24h[b,d]) for bacteremia, endocarditis, osteomyelitis, and complicated skin infections	Same as for methicillin-resistant strains (check antibiotic susceptibilities) *or*	Same as for methicillin-resistant strains; check antibiotic susceptibilities. Ceftaroline is used either alone or in combination with daptomycin.
		Ceftaroline (600 mg IV q8–12h) Newer agents include tedizolid (200 mg once daily IV or PO), oritavancin (single dose of 1200 mg), and dalbavancin (single dose of 1500 mg). These drugs are approved only for the treatment of skin and soft tissue infections.	
Not yet known (i.e., empirical therapy)	Vancomycin (15–20 mg/kg q8–12h[b]), daptomycin (6–10 mg/kg q24h[b,d]) for bacteremia, endocarditis, osteomyelitis, and complicated skin infections	—	Empirical therapy is given when the susceptibility of the isolate is not known. Vancomycin with or without a β-lactam is recommended for suspected community- or hospital-acquired *Staphylococcus aureus* infections because of the increased frequency of methicillin-resistant strains in the community. If isolates with an elevated MIC to vancomycin (≥1.5 μg/mL) are common in the community, daptomycin may be preferable.
Oral Therapy for Skin and Soft Tissue Infections			
Sensitive to methicillin	Dicloxacillin (500 mg qid), cephalexin (500 mg qid), or cefadroxil (1 g q12h)	Minocycline or doxycycline (100 mg q12h[b]), TMP-SMX (1 or 2 DS tablets bid), clindamycin (300–450 mg tid), linezolid (600 mg PO q12h), tedizolid (200 mg PO q24h)	It is important to know the antibiotic susceptibility of isolates in the specific geographic region. All collections should be drained, and drainage should be cultured.
Resistant to methicillin	Clindamycin (300–450 mg tid), TMP-SMX (1 or 2 DS tablets bid), minocycline or doxycycline (100 mg q12h[b]), linezolid (600 mg bid), or tedizolid (200 mg once daily)	Delafloxacin 450 mg q12 h, omadacycline 300 mg once a day	It is important to know the antibiotic susceptibility of isolates in the specific geographic region. All collections should be drained, and drainage should be cultured.

[a]Recommended dosages are for adults with normal renal and hepatic function. [b]The dosage must be adjusted for patients with reduced creatinine clearance. [c]For the treatment of prosthetic-valve endocarditis, the addition of gentamicin (1 mg/kg q8h) and rifampin (300 mg PO q8h) is recommended, with adjustment of the gentamicin dosage if the creatinine clearance rate is reduced. [d]Daptomycin cannot be used for the treatment of pneumonia. [e]Vancomycin-resistant *S. aureus* isolates from clinical infections have been reported. [f]TMP-SMX may be less effective than vancomycin. [g]Additional studies are needed.

Abbreviations: DS, double-strength; TMP-SMX, trimethoprim-sulfamethoxazole; VISA, vancomycin-intermediate *S. aureus;* VRSA, vancomycin-resistant *S. aureus.*

Source: Modified from C Liu et al: Clin Infect Dis 52:285, 2011; DL Stevens et al: Clin Infect Dis 59:148, 2014; DL Stevens et al: Med Lett Drugs Ther 56:39, 2014; and LM Baddour et al: Circulation 132:1435, 2015.

Few strains of staphylococci (≤5%) remain susceptible to penicillin. This is a result of the widespread dissemination of plasmids containing the enzyme penicillinase. Penicillin-resistant isolates are treated with semisynthetic penicillinase-resistant penicillins (SPRPs), such as oxacillin or nafcillin. Methicillin, the first of the SPRPs, is no longer used. Cephalosporins are alternative therapeutic agents for these infections. In patients with a history of serious β-lactam allergies, alternatives to SPRPs for the treatment of invasive infections should be used only after careful consideration. Desensitization to β-lactams remains an option for life-threatening infections. Second- and third-generation cephalosporins offer no therapeutic advantage over first-generation cephalosporins for the treatment of staphylococcal infections, and some third-generation cephalosporins (e.g., ceftazidime, ceftriaxone) have considerably less activity and should be avoided. The carbapenems have excellent activity against methicillin-sensitive *S. aureus* but not against MRSA.

The isolation of MRSA was reported within 1 year of the introduction of methicillin. Since then, the prevalence of MRSA has steadily increased. In many U.S. hospitals and elsewhere, 40–50% of *S. aureus* isolates are resistant to methicillin. Resistance to methicillin indicates resistance to all SPRPs as well as to all cephalosporins (except ceftaroline). Production of a novel penicillin-binding protein (PBP2a) is responsible for methicillin resistance. This protein is synthesized by the *mecA* gene, which (as stated above) is part of a large mobile genetic element—a pathogenicity or genomic island—called SCC*mec*. It is hypothesized that *mecA* was acquired via horizontal transfer from related staphylococcal species. Phenotypic expression of methicillin resistance may be constitutive (i.e., expressed in all cells in a population) or heterogeneous (i.e., displayed by only a proportion of the total cell population). Detection of methicillin resistance is enhanced by growth of cultures at reduced temperatures (≤35°C for 24 h) and with increased concentrations of salt in the medium. Culture techniques are increasingly being replaced by PCR-based or other methods (e.g., latex agglutination) that allow for the rapid detection of methicillin resistance.

Either vancomycin or daptomycin is recommended as the drug of choice for the treatment of invasive MRSA infections. MRSA susceptibility to vancomycin has decreased in many areas of the world. It is important to note that vancomycin is less effective than SPRPs for the treatment of infections due to methicillin-susceptible strains.

Three types of staphylococcal resistance to vancomycin have emerged. (1) Minimal inhibitory concentration (MIC; an in vitro measure of susceptibility) "creep" refers to the incremental increase in vancomycin MICs that has been detected in various geographic areas. Studies suggest that morbidity and mortality may be increased in infections due to *S. aureus* strains with vancomycin MICs of ≥1.5 μg/mL. (2) In 1997, an *S. aureus* strain with reduced susceptibility to vancomycin (vancomycin-intermediate *S. aureus* [VISA]) was reported from Japan. Subsequently, additional VISA clinical isolates were reported. These strains were resistant to methicillin and many other antimicrobial agents. The VISA strains appear to evolve (under vancomycin selective pressure) from strains that are susceptible to vancomycin but are heterogeneous, with a small proportion of the bacterial population expressing the resistance phenotype. The mechanism of VISA resistance is in part due to an abnormally thick cell wall. Vancomycin is trapped by the abnormal peptidoglycan cross-linking and is unable to gain access to its target site. Regulatory genes involved in cell wall metabolism appear to play an important role in this type of resistance. (3) In 2002, the first clinical isolate of fully vancomycin-resistant *S. aureus* (VRSA) was reported. Resistance in this and several additional clinical isolates was due to the presence of *vanA*, the gene responsible for expression of vancomycin resistance in enterococci. This observation suggested that resistance was acquired as a result of horizontal conjugal transfer from a vancomycin-resistant strain of *Enterococcus faecalis*. Several of the patients infected with the VRSA strain had both MRSA and vancomycin-resistant enterococci cultured from infection sites. The *vanA* gene is responsible for the synthesis of the dipeptide D-Ala-D-Lac in place of D-Ala-D-Ala. Vancomycin cannot bind to the altered peptide. While isolates with MICs of ≥1.5 μg/mL have been relatively common in some areas, VISA and VRSA isolates are uncommon.

Daptomycin, a parenteral bactericidal agent with antistaphylococcal activity, is approved for the treatment of bacteremia (including right-sided endocarditis) and complicated skin infections. It is not effective in respiratory infections. This drug has a unique mechanism of action: it disrupts the cytoplasmic membrane. Staphylococcal resistance to daptomycin has been reported. Resistance can emerge during therapy; patients previously treated with vancomycin may have elevated daptomycin MICs. Patients need to be monitored for rhabdomyolysis with creatine phosphokinase measurement and for eosinophilic pneumonia.

Linezolid—the first oxazolidinone—is bacteriostatic against staphylococci; it offers the advantage of comparable bioavailability after oral or parenteral administration. Cross-resistance with other inhibitors of protein synthesis has not been detected. Resistance to linezolid is rare but has been reported. Serious adverse reactions to linezolid include thrombocytopenia, occasional cases of neutropenia, and rare instances of lactic acidosis or peripheral and optic neuropathy. These reactions tend to occur after relatively prolonged courses of therapy.

Tedizolid, a second oxazolidinone, is available as both oral and parenteral preparations. It exhibits enhanced in vitro activity against antibiotic-resistant gram-positive bacteria, including staphylococci. Tedizolid is administered once a day. Data on its efficacy for the treatment of deep-seated infections are limited.

Ceftaroline is a fifth-generation cephalosporin with bactericidal activity against MRSA (including strains with reduced susceptibility to vancomycin and daptomycin). It is generally well tolerated. Ceftaroline is approved for use in nosocomial pneumonias and for SSTIs. It has increasingly been used to treat invasive MRSA infections with or without glycopeptides.

Telavancin is a parenteral lipoglycopeptide derivative of vancomycin that is approved for the treatment of complicated SSTIs and for nosocomial pneumonias. The drug has two targets: the cell wall and the cell membrane. It remains active against VISA strains. Because of its potential nephrotoxicity, telavancin should be avoided in patients with renal disease.

Dalbavancin and oritavancin are long-acting, parenterally administered lipoglycopeptides that have been used to treat complicated SSTIs. Because of their long half-lives, they can be administered on a weekly basis. Both have been used as single-dose regimens for the treatment of SSTIs. Emerging data support their use for the treatment of invasive staphylococcal infections.

Although the quinolones are active against staphylococci in vitro, the frequency of staphylococcal resistance to these agents has increased, especially among methicillin-resistant isolates. Of particular concern in MRSA is the possibility of quinolone resistance emerging during therapy. Therefore, quinolones are not recommended for the treatment of MRSA infections. Resistance to the quinolones is most commonly chromosomal and results from mutations of the topoisomerase IV or DNA gyrase genes, although multidrug efflux pumps also may contribute. Although the newer quinolones exhibit increased in vitro activity against staphylococci, it is uncertain whether this increase translates into enhanced in vivo activity. Delafloxacin, a fluoroquinolone with broad-spectrum activity, has excellent activity against MRSA, retaining activity against some isolates resistant to other fluoroquinolones.

Tigecycline, a broad-spectrum minocycline analogue, has bacteriostatic activity against MRSA and is approved for use in SSTIs as well as intraabdominal infections caused by *S. aureus*. It is not recommended for the treatment of invasive infections.

Other older antibiotics, such as minocycline, doxycycline, clindamycin, and trimethoprim-sulfamethoxazole, continue to be successfully used to treat MRSA infections.

Ceftobiprole is a new antibiotic with excellent activity against both MRSA and methicillin-susceptible *S. aureus* (MSSA). It has

been shown in clinical trials to be effective in treating complicated staphylococcal bacteremias, SSTIs, and pneumonia.

The benefit of antistaphylococcal combinations to enhance bactericidal activity in the treatment of deep-seated infections remains controversial. Clinical studies have not documented a therapeutic benefit from the addition of gentamicin to single-drug regimens; recent reports have raised concern about the potential nephrotoxicity of gentamicin and adverse reactions from, or drug interactions with, rifampin. As a result, the use of gentamicin in combination with β-lactams or other antimicrobial agents is no longer routinely recommended for the treatment of invasive infections such as native-valve endocarditis. Rifampin continues to be used for the treatment of prosthetic device–related infections and for osteomyelitis.

Omadacycline and eravacycline are broad-spectrum semisynthetic tetracycline derivatives with activity against MRSA. They are currently approved for the treatment of SSTIs.

The use of bacteriophages with activity against staphylococci is now being investigated in clinical trials as adjunctive therapy in invasive infections.

ANTIMICROBIAL THERAPY FOR SELECTED SETTINGS

Empirical Therapy Empirical coverage for MRSA is indicated when antibiotic susceptibility is not known. Vancomycin or daptomycin is generally recommended. It remains uncertain whether daptomycin is preferable when elevated vancomycin MICs (>1.5 μg/mL) are common in a specific locale.

Salvage Therapy Salvage therapy for complicated *S. aureus* infections is sometimes needed when the bacteremia persists (i.e., for 3 days) despite appropriate treatment. The risk of a poor outcome (i.e., increased mortality, metastatic infections) is increased with the duration of bacteremia. Prolonged bacteremia can occur with both MRSA and MSSA. There is limited high-quality evidence to serve as a guide to salvage therapy. The combination of daptomycin or vancomycin with a β-lactam antibiotic (e.g., ceftaroline) has been successfully used to treat patients with persistent MRSA bacteremia, even those patients with isolates displaying reduced susceptibility to these antimicrobial agents. This combination appears to enhance the bactericidal activity of daptomycin by reducing the bacterial cell-surface charge and thus allowing enhanced daptomycin binding. For vancomycin, the combination may allow more strategic binding to the target site with reduced cell-wall thickness. Other combinations have included trimethoprim-sulfamethoxazole or rifampin combined with daptomycin. Linezolid and ceftaroline have also been used as single alternative agents.

Endocarditis *S. aureus* endocarditis is usually an acute, life-threatening infection. Thus, prompt collection of blood for cultures should be followed by immediate institution of empirical antimicrobial therapy. For native-valve endocarditis, therapy with a β-lactam is recommended. If a MRSA strain is isolated, vancomycin (15–20 mg/kg every 8–12 h, given in equal doses up to a total of 2 g, with the dose adjusted in the case of renal disease) or daptomycin (6–10 mg/kg every 24 h) is recommended. The vancomycin dose should be adjusted based on area under the curve (AUC)-based dosing, although measurement of trough levels may also be used. Patients are generally treated for 6 weeks. For prosthetic-valve endocarditis, surgery in addition to antibiotic therapy is often necessary. The combination of a β-lactam agent—or, if the isolate is β-lactam-resistant, vancomycin or daptomycin—with an aminoglycoside (gentamicin, 1 mg/kg IV every 8 h) for 2 weeks and rifampin (300 mg orally or IV every 8 h) for ≥6 weeks is recommended. Infectious diseases and, if necessary, surgical consultation should be considered.

Bone and Joint Infections For hematogenous osteomyelitis or septic arthritis in children, a 4-week course of therapy is usually adequate. In adults, treatment is often more prolonged. For chronic forms of osteomyelitis, surgical debridement is necessary in combination with antimicrobial therapy. For joint infections, a critical component of therapy is the repeated aspiration or arthroscopy of the affected joint to prevent damage from leukocytes. The combination of rifampin with ciprofloxacin has been used successfully to treat or suppress prosthetic-joint infections, especially when the device cannot be removed. The efficacy of this combination may reflect enhanced activity against staphylococci in biofilms as well as the attainment of effective intracellular concentrations.

Skin and Soft Tissue Infections The increase in SSTIs caused by CA-MRSA has drawn attention to the need for initiation of appropriate empirical therapy. Even small abscesses appear to benefit from antibiotic therapy in addition to incision and drainage. Antibiotics are selected depending on local antibiotic susceptibility data; several oral agents have been used to treat these infections, including clindamycin, trimethoprim-sulfamethoxazole, doxycycline, linezolid, and tedizolid. Parenteral therapy is reserved for more complicated infections.

Toxic Shock Syndrome Treatment of shock is the mainstay of therapy for TSS. Both fluids and pressors may be necessary. Tampons or other packing material should be promptly removed. Some investigators recommend therapy with a combination of clindamycin and a semisynthetic penicillin or (if the isolate is resistant to methicillin) vancomycin. Clindamycin is advocated because, as a protein synthesis inhibitor, it reduces toxin production. Linezolid also appears to be effective. A semisynthetic penicillin or a glycopeptide is recommended to eliminate any potential focus of infection as well as to eradicate persistent carriage that might increase the possibility of recurrence. Intravenous immunoglobulin to treat TSS is of uncertain benefit. Glucocorticoids are not recommended for the treatment of this disease.

Other Toxin-Mediated Diseases Therapy for staphylococcal food poisoning is entirely supportive. For SSSS, antistaphylococcal therapy targets the primary site of infection.

NONTRADITIONAL APPROACHES TO ANTISTAPHYLOCOCCAL THERAPY

In addition to the development of new antibiotics, new and nontraditional approaches to therapy are currently being investigated. These include the use of phages or phage-derived peptides, as well as probiotics and antivirulence strategies that target selected virulence determinants.

PREVENTION

Primary prevention of *S. aureus* infections in the hospital setting involves hand washing and careful attention to appropriate isolation procedures. Through careful screening for MRSA carriage and strict isolation practices, several Scandinavian countries have been remarkably successful at preventing the introduction and dissemination of MRSA in hospitals.

Decolonization strategies, using both universal and targeted approaches with topical agents (e.g., mupirocin) to eliminate nasal colonization and/or chlorhexidine to eliminate colonization of additional body sites with *S. aureus*, have been successful in some clinical settings where the risk of infection is high (e.g., intensive care units). An analysis of clinical trials suggests that decolonization can reduce the incidence of postsurgical infections among people nasally colonized with *S. aureus*. The risk of recurrent admissions among patients with *S. aureus* bacteremia following discharge is high (~22% within 30 days). Decolonization following discharge with mupirocin and chlorhexidine can lower the incidence of recurrent infections.

"Bundling" (the application of selected medical interventions in a sequence of prescribed steps) has reduced rates of nosocomial infections related to procedures such as the insertion of intravenous catheters, in which staphylococci are among the most common pathogens (see Table 147-1). A number of immunization strategies to prevent *S. aureus* infections—both active (e.g., capsular polysaccharide–protein conjugate vaccine) and passive (e.g., clumping factor antibody)—have been investigated. However, to date, none has been successful for either prophylaxis or therapy in clinical trials.

Strategies to prevent recurrent *S. aureus* infections in the community have had limited success. Decolonization with intranasal mupirocin and chlorhexidine washes of the infected individual and the additional decolonization of household members combined with environmental cleaning of surfaces and personal items have all been studied. For individuals with extensive skin disease and recurrent infections, the use of bleach baths (e.g., one-half cup of household bleach in a half-filled bathtub) for 15 minutes three times weekly may be useful.

153 Streptococcal Infections

Michael R. Wessels

Many varieties of streptococci are found as part of the normal flora colonizing the human respiratory, gastrointestinal, and genitourinary tracts. Several species are important causes of human disease. Group A *Streptococcus* (GAS; *Streptococcus pyogenes*) is responsible for streptococcal pharyngitis, one of the most common bacterial infections of school-age children, and for the postinfectious syndromes of acute rheumatic fever (ARF) and poststreptococcal glomerulonephritis (PSGN). Group B *Streptococcus* (GBS; *Streptococcus agalactiae*) is a leading cause of bacterial sepsis and meningitis in newborns and a major cause of endometritis and fever in parturient women. Viridans streptococci are a common cause of bacterial endocarditis. Enterococci, which are morphologically similar to streptococci, are now considered a separate genus on the basis of DNA homology studies. Thus, the species previously designated as *Streptococcus faecalis* and *Streptococcus faecium* have been renamed *Enterococcus faecalis* and *Enterococcus faecium*, respectively. **The enterococci are discussed in Chap. 154.**

Streptococci are gram-positive, spherical to ovoid bacteria that characteristically form chains when grown in liquid media. Most streptococci that cause human infections are facultative anaerobes, although some are strict anaerobes. Streptococci are relatively fastidious organisms, requiring enriched media for growth in the laboratory. Clinicians and clinical microbiologists identify streptococci by several classification systems, including hemolytic pattern, Lancefield group, species name, and common or trivial name. Many streptococci associated with human infection produce a zone of complete (β) hemolysis around the bacterial colony when cultured on blood agar. The β-hemolytic streptococci that form large (≥0.5-mm) colonies on blood agar can be classified by the Lancefield system, a serologic grouping based on the reaction of specific antisera with bacterial cell-wall carbohydrate antigens. With rare exceptions, organisms belonging to Lancefield groups A, B, C, and G are all β-hemolytic, and each is associated with characteristic patterns of human infection. Other streptococci produce a zone of partial (α) hemolysis, often imparting a greenish appearance to the agar. These α-hemolytic streptococci are further identified by biochemical testing and include *Streptococcus pneumoniae* **(Chap. 151)**, an important cause of pneumonia, meningitis, and other infections, and the several species referred to collectively as the *viridans streptococci*, which are part of the normal oral flora and are important agents of subacute bacterial endocarditis. Finally, some streptococci are nonhemolytic, a pattern sometimes called γ *hemolysis*. Among the organisms classified serologically as group D streptococci, the enterococci are assigned to a distinct genus **(Chap. 154)**. The classification of the major streptococcal groups causing human infections is outlined in **Table 153-1**.

GROUP A STREPTOCOCCI

Lancefield group A consists of a single species, *S. pyogenes*. As its species name implies, this organism is associated with a variety of suppurative infections. In addition, GAS can trigger the postinfectious syndromes of ARF (which is uniquely associated with *S. pyogenes* infection; **Chap. 371**) and PSGN **(Chap. 326)**.

Worldwide, GAS infections and their postinfectious sequelae (primarily ARF and rheumatic heart disease) account for an estimated 500,000 deaths per year. Although data are incomplete, the incidence of all forms of GAS infection and that of rheumatic heart disease are thought to be tenfold higher in resource-limited countries than in

TABLE 153-1 Classification of Streptococci

LANCEFIELD GROUP	REPRESENTATIVE SPECIES	HEMOLYTIC PATTERN	TYPICAL INFECTIONS
A	*S. pyogenes*	β	Pharyngitis, impetigo, cellulitis, scarlet fever
B	*S. agalactiae*	β	Neonatal sepsis and meningitis, puerperal infection, urinary tract infection, diabetic ulcer infection, endocarditis
C, G	*S. dysgalactiae* subsp. *equisimilis*	β	Cellulitis, bacteremia, endocarditis
D	Enterococci[a]: *E. faecalis, E. faecium*	Usually nonhemolytic	Urinary tract infection, nosocomial bacteremia, endocarditis
	Nonenterococci: *S. gallolyticus* (formerly *S. bovis*)	Usually nonhemolytic	Bacteremia, endocarditis
Variable or nongroupable	Viridans streptococci: *S. sanguis, S. mitis*	α	Endocarditis, dental abscess, brain abscess
	Intermedius or *milleri* group: *S. intermedius, S. anginosus, S. constellatus*	Variable	Brain abscess, visceral abscess
	Anaerobic streptococci[b]: *Peptostreptococcus magnus*	Usually nonhemolytic	Sinusitis, pneumonia, empyema, brain abscess, liver abscess

Lancet Infect Dis 5:685, 2005.)*

developed countries **(Fig. 153-1)**. As has been observed with infections due to other pathogens associated with the human respiratory tract, the incidence of streptococcal pharyngitis and of invasive GAS infection fell during 2020–2022 in association with COVID-19-related social distancing restrictions. A rebound in GAS infection has been observed in many countries beginning in the last quarter of 2022. Unusually high rates of invasive GAS infections in both children and adults were reported in 2023 and 2024 from centers in Europe and the United States. Prominent among these cases have been severe pneumonia and empyema, sometimes as a co-infection with influenza or another respiratory virus, as well as necrotizing soft tissue infections and streptococcal toxic shock. A GAS strain designated $M1_{UK}$ first emerged in the United Kingdom in association with an upsurge in scarlet fever and has since been implicated as a dominant strain in invasive GAS infections in the United Kingdom and other European countries. Multiple other lineages of GAS have been identified in invasive infections elsewhere in Europe and around the world.

PATHOGENESIS

GAS elaborates a number of cell-surface components and extracellular products important in both the pathogenesis of infection and the human immune response. The cell wall contains a carbohydrate antigen that may be released by acid treatment. The reaction of such acid extracts with group A–specific antiserum is the basis for definitive identification of a streptococcal strain as *S. pyogenes*. Rarely, the group A antigen may be present on isolates of *S. dysgalactiae ssp. equisimilis*, which usually express the group C or G antigen (see "Streptococci of Groups C and G," below). The major surface protein of GAS is M protein, which is the basis for the serotyping of strains with specific antisera. The M protein molecules are fibrillar structures anchored in the cell wall of the organism that extend as hairlike projections away from the cell surface. The amino acid sequence of the distal or amino-terminal portion of the M protein molecule is variable, accounting for the antigenic variation of the different M types, while more proximal regions of the protein are relatively conserved. Traditional M-typing by serologic methods has been largely supplanted by use of the polymerase chain reaction to amplify the variable region of the *emm* gene, which encodes M protein. DNA sequence analysis of the amplified gene segment can be compared with an extensive database (developed at the Centers for Disease Control and Prevention [CDC]) for assignment of *emm* type. Use of *emm* typing has increased the number of identified *emm* types to more than 200. This method eliminates the need for typing sera, which are available in only a few reference laboratories. The presence of M protein on a GAS isolate correlates with its capacity to resist phagocytic killing in fresh human blood. This phenomenon appears to be due, at least in part, to the binding of plasma fibrinogen to M protein molecules on the streptococcal surface, which interferes with complement activation and deposition of opsonic complement fragments on the bacterial cell. This resistance to phagocytosis may be overcome by M protein–specific antibodies; thus, individuals with antibodies to a given M type acquired as a result of prior infection are protected against subsequent infection with organisms of the same M type but not against infection with different M types.

GAS also elaborates, to varying degrees, a polysaccharide capsule composed of hyaluronic acid. While most clinical isolates of GAS produce a hyaluronic acid capsule, strains of M type 4 or 22 lack a capsule, as do some isolates of M type 89. The fact that acapsular strains have been associated with pharyngitis and invasive infection implies that the capsule is not essential for virulence. The production of large amounts of capsule by certain strains imparts a characteristic mucoid appearance to the colonies. The capsular polysaccharide plays an important role in protecting GAS from ingestion and killing by phagocytes. In contrast to M protein, the hyaluronic acid capsule is a weak immunogen, and antibodies to hyaluronate have not been shown to be important in protective immunity. The presumed explanation is the apparent structural identity between streptococcal hyaluronic acid and the hyaluronic acid of mammalian connective tissues. The capsular polysaccharide may also play a role in GAS colonization of the pharynx by binding to CD44, a hyaluronic acid–binding protein expressed on human pharyngeal epithelial cells.

GAS produces a large number of extracellular products that may be important in local and systemic toxicity and in the spread of infection through tissues. These products include streptolysins S and O, toxins that damage cell membranes and account for the hemolysis produced by the organisms; streptokinase; DNAses; SpyCEP, a serine protease that cleaves and inactivates the chemoattractant cytokine interleukin 8, thereby inhibiting neutrophil recruitment to the site of infection; and several pyrogenic exotoxins. Previously known as erythrogenic toxins, the pyrogenic exotoxins cause the rash of scarlet fever. Since the mid-1980s, pyrogenic exotoxin–producing strains of GAS have been linked to unusually severe invasive infections, including necrotizing fasciitis and the streptococcal toxic shock syndrome (TSS). Several extracellular products stimulate specific antibody responses useful for serodiagnosis of recent streptococcal infection. Tests for antibodies to streptolysin O and DNase B are used most commonly for detection of preceding streptococcal infection in cases of suspected ARF or PSGN.

Pharyngitis Although seen in patients of all ages, GAS pharyngitis is one of the most common bacterial infections of childhood, accounting for 20–40% of all cases of exudative pharyngitis in children; it is rare among those under the age of 3. Younger children may manifest streptococcal infection with a syndrome of fever, malaise, and lymphadenopathy without exudative pharyngitis. Infection is acquired through contact with another individual carrying the organism. Respiratory droplets are the usual mechanism of spread, although other routes, including food-borne outbreaks, have been well described. The incubation period is 1–4 days. Symptoms include sore throat, fever and chills, malaise, and sometimes abdominal complaints and vomiting, particularly in children. Both symptoms and signs are variable, ranging from mild throat discomfort with minimal physical findings to high fever and severe sore throat associated with intense erythema and swelling of the pharyngeal mucosa and the presence of purulent exudate over the posterior pharyngeal wall and tonsillar pillars. Enlarged, tender anterior cervical lymph nodes commonly accompany exudative pharyngitis.

The differential diagnosis of streptococcal pharyngitis includes the many other bacterial and viral etiologies (Table 153-2). Streptococcal infection is an unlikely cause when symptoms and signs suggestive of viral infection are prominent (conjunctivitis, coryza, cough, hoarseness, or discrete ulcerative lesions of the buccal or pharyngeal mucosa). Because of the range of clinical presentations of streptococcal pharyngitis and the large number of other agents that can produce the same clinical picture, diagnosis of streptococcal pharyngitis on clinical grounds alone is not reliable. The throat culture remains the diagnostic gold standard. Culture of a throat specimen that is properly collected (i.e., by vigorous rubbing of a sterile swab over both tonsillar pillars) and properly processed is the most sensitive and specific means of definitive diagnosis. A rapid diagnostic test for latex agglutination or enzyme immunoassay of swab specimens is a useful adjunct to throat culture. Rapid diagnostic tests typically have a specificity of >95%. Thus, a positive result can be relied upon for definitive diagnosis and eliminates the need for throat culture. In settings in which the incidence of rheumatic fever is low, a confirmatory throat culture is not recommended for routine evaluation of most adults with a negative rapid test. However, because rapid diagnostic tests are less sensitive than throat culture (relative sensitivity in comparative studies, 70–90%), a negative result should be confirmed by throat culture for individuals at higher risk such as those with a history of rheumatic fever or immunocompromise or a family member with such a history; patients living in congregate settings of young adults such as dormitories or military facilities where the incidence of GAS pharyngitis may be elevated; individuals with household exposure to someone with proven GAS infection; and those living in an area in which rheumatic fever is endemic. National or professional organization guidelines in some countries with a very low incidence of ARF recommend symptomatic treatment for patients with mild symptoms and restricting diagnostic testing and/or antibiotic treatment to those with suggestive clinical features (e.g., fever, tonsillar swelling or exudate, tender anterior cervical adenopathy, and/or absence of cough) or special risk factors.

TABLE 153-2 Infectious Etiologies of Acute Pharyngitis

ORGANISM	ASSOCIATED CLINICAL SYNDROME(S)
Viruses	
Rhinovirus	Common cold
Coronavirus	Common cold, COVID-19
Adenovirus	Pharyngoconjunctival fever
Influenza virus	Influenza
Parainfluenza virus	Cold, croup
Coxsackievirus	Herpangina, hand-foot-and-mouth disease
Herpes simplex virus	Gingivostomatitis (primary infection)
Epstein-Barr virus	Infectious mononucleosis
Cytomegalovirus	Mononucleosis-like syndrome
HIV	Acute (primary) infection syndrome
Bacteria	
Group A streptococci	Pharyngitis, scarlet fever
Group C or G streptococci	Pharyngitis
Mixed anaerobes	Vincent's angina
Arcanobacterium haemolyticum	Pharyngitis, scarlatiniform rash
Neisseria gonorrhoeae	Pharyngitis
Treponema pallidum	Secondary syphilis
Francisella tularensis	Pharyngeal tularemia
Corynebacterium diphtheriae	Diphtheria
Yersinia enterocolitica	Pharyngitis, enterocolitis
Yersinia pestis	Plague
Chlamydiae	
Chlamydia pneumoniae	Bronchitis, pneumonia
Chlamydia psittaci	Psittacosis
Mycoplasmas	
Mycoplasma pneumoniae	Bronchitis, pneumonia

TREATMENT

GAS Pharyngitis

In the usual course of uncomplicated streptococcal pharyngitis, symptoms resolve after 3–5 days. The course is shortened little by treatment, which is given primarily to prevent suppurative complications and ARF. Prevention of ARF depends on eradication of the organism from the pharynx, not simply on resolution of symptoms, and requires 10 days of penicillin treatment (Table 153-3). A first-generation cephalosporin, such as cephalexin or cefadroxil, may be substituted for penicillin in cases of penicillin allergy if the nature of the allergy is not an immediate hypersensitivity reaction (anaphylaxis or urticaria) or another potentially life-threatening manifestation (e.g., severe rash and fever).

Alternative agents are erythromycin and azithromycin. Azithromycin offers the advantages of better gastrointestinal tolerability, once-daily dosing, and a 5-day treatment course. Resistance to erythromycin and other macrolides is common among isolates from several countries, including Spain, Italy, Finland, Japan, and Korea. Macrolide resistance may be becoming more prevalent

TABLE 153-3 Treatment of Group A Streptococcal Infections

INFECTION	TREATMENT[a]
Pharyngitis	Benzathine penicillin G (1.2 mU IM) *or* penicillin V (250 mg PO tid or 500 mg PO bid) × 10 days
	(Children <27 kg: Benzathine penicillin G [600,000 units IM] *or* penicillin V [250 mg PO bid or tid] × 10 days)
Impetigo	Same as pharyngitis
Erysipelas/cellulitis	Severe: Penicillin G (1–2 mU IV q4h)
	Mild to moderate: Procaine penicillin (1.2 mU IM bid)
Necrotizing fasciitis/myositis	Surgical debridement *plus* penicillin G (2–4 mU IV q4h) *plus* clindamycin[b] (600–900 mg IV q8h)
Pneumonia/empyema	Penicillin G (2–4 mU IV q4h) *plus* drainage of empyema
Streptococcal toxic shock syndrome	Penicillin G (2–4 mU IV q4h) *plus* clindamycin[b] (600–900 mg IV q8h) *plus* IV immunoglobulin (2 g/kg as a single dose)

[a]Penicillin allergy: A first-generation cephalosporin, such as cephalexin or cefadroxil, may be substituted for penicillin in cases of penicillin allergy if the nature of the allergy is not an immediate hypersensitivity reaction (anaphylaxis or urticaria) or another potentially life-threatening manifestation (e.g., severe rash and fever). Alternative agents for oral therapy are erythromycin (10 mg/kg PO qid, up to a maximum of 250 mg per dose) and azithromycin (a 5-day course at a dose of 12 mg/kg once daily, up to a maximum of 500 mg/d). Vancomycin is an alternative for parenteral therapy. [b]Linezolid (600 mg IV q12h) may be substituted for isolates resistant to clindamycin. See text for discussion.

elsewhere with the increasing use of this class of antibiotics. Data from the CDC and the Active Bacterial Core surveillance program indicate a rise in macrolide resistance among invasive GAS isolates in the United States to >30% since 2021. In areas with resistance rates exceeding 5–10%, macrolides should be avoided unless results of susceptibility testing are known.

Follow-up culture after treatment is not routinely recommended but may be warranted in selected cases, such as those involving patients or families with frequent streptococcal infections or those occurring in situations in which the risk of ARF is thought to be high (e.g., when cases of ARF have recently been reported in the community).

Complications Suppurative complications of streptococcal pharyngitis have become uncommon with the widespread use of antibiotics for most symptomatic cases. These complications result from the spread of infection from the pharyngeal mucosa to deeper tissues by direct extension or by the hematogenous or lymphatic route and may include cervical lymphadenitis, peritonsillar or retropharyngeal abscess, sinusitis, otitis media, meningitis, bacteremia, endocarditis, and pneumonia. Local complications, such as peritonsillar or parapharyngeal abscess formation, should be considered in a patient with unusually severe or prolonged symptoms or localized pain associated with high fever and a toxic appearance. Nonsuppurative complications include ARF **(Chap. 370)** and PSGN **(Chap. 326)**, both of which are thought to result from immune responses to streptococcal infection. Penicillin treatment of streptococcal pharyngitis reduces the likelihood of ARF but not that of PSGN.

BACTERIOLOGIC TREATMENT FAILURE AND THE ASYMPTOMATIC CARRIER STATE

Surveillance cultures have shown that up to 20% of individuals in certain populations may have asymptomatic pharyngeal colonization with GAS. There are no definitive guidelines for management of these asymptomatic carriers or of asymptomatic patients who still have a positive throat culture after a full course of treatment for symptomatic pharyngitis. A reasonable course of action is to give a single 10-day course of penicillin for symptomatic pharyngitis and, if positive cultures persist, not to re-treat unless symptoms recur. Studies of the natural history of streptococcal carriage and infection have shown that the risk both of developing ARF and of transmitting infection to others is substantially lower among asymptomatic carriers than among individuals with symptomatic pharyngitis. Therefore, aggressive attempts to eradicate carriage probably are not justified under most circumstances. An exception is the situation in which an asymptomatic carrier is a potential source of infection to others. Outbreaks of food-borne infection and nosocomial puerperal infection have been traced to asymptomatic carriers who may harbor the organisms in the throat, vagina, or anus or on the skin.

TREATMENT

Asymptomatic Pharyngeal Colonization with GAS

When a carrier is transmitting infection to others, attempts to eradicate carriage are warranted. Data are limited on the best regimen to clear GAS after penicillin alone has failed. Regimens reported to have efficacy superior to that of penicillin alone for eradication of carriage include (1) a first-generation cephalosporin such as cephalexin (30 mg/kg; 500 mg maximum) twice daily for 10 days or (2) oral clindamycin (7 mg/kg; 300 mg maximum) three times daily for 10 days. A 10-day course of oral vancomycin (250 mg four times daily) and rifampin (600 mg twice daily) has eradicated rectal colonization. Single-dose azithromycin (20 mg/kg; 1000 mg maximum) has been used for mass prophylaxis/eradication of colonization in outbreak situations. In vitro susceptibility to clindamycin or azithromycin should be confirmed before prescribing either of these antibiotics for eradication of colonization.

FIGURE 153-2 Scarlet fever exanthem. Finely punctate erythema has become confluent (scarlatiniform); petechiae can occur and have a linear configuration within the exanthem in body folds (Pastia's lines). *(From TB Fitzpatrick, RA Johnson, K Wolff: Color Atlas and Synopsis of Clinical Dermatology, 4th ed, New York, McGraw-Hill, 2001, with permission.)*

Scarlet Fever Scarlet fever consists of streptococcal infection, usually pharyngitis, accompanied by a characteristic rash **(Fig. 153-2)**. The rash arises from the effects of one of several toxins, currently designated *streptococcal pyrogenic exotoxins* and previously known as *erythrogenic* or *scarlet fever toxins*. In the past, scarlet fever was thought to reflect infection of an individual lacking toxin-specific immunity with a toxin-producing strain of GAS. Susceptibility to scarlet fever was correlated with results of the Dick test, in which a small amount of erythrogenic toxin injected intradermally produced local erythema in susceptible individuals but elicited no reaction in those with specific immunity. Subsequent studies have suggested that development of the scarlet fever rash may reflect a hypersensitivity reaction requiring prior exposure to the toxin. For reasons that are not clear, scarlet fever has become less common in recent years, although large outbreaks have occurred recently in China and the United Kingdom. The symptoms of scarlet fever are the same as those of pharyngitis alone. The rash typically begins on the first or second day of illness over the upper trunk, spreading to involve the extremities but sparing the palms and soles. The rash is made up of minute papules, giving a characteristic "sandpaper" feel to the skin. Associated findings include circumoral pallor, "strawberry tongue" (enlarged papillae on a coated tongue, which later may become denuded), and accentuation of the rash in skin folds (*Pastia's lines*). Subsidence of the rash in 6–9 days is followed after several days by desquamation of the palms and soles. The differential diagnosis of scarlet fever includes other causes of fever and generalized rash, such as measles and other viral exanthems, Kawasaki disease, toxic shock syndrome, and systemic allergic reactions (e.g., drug eruptions).

Skin and Soft Tissue Infections GAS—and occasionally other streptococcal species—can cause a variety of infections involving the skin, subcutaneous tissues, muscles, and fascia. While several clinical syndromes offer a useful means for classification of these infections, not all cases fit exactly into one category. The classic syndromes are general guides to predicting the level of tissue involvement in a particular patient, the probable clinical course, and the likelihood that surgical intervention or aggressive life support will be required.

IMPETIGO (PYODERMA)

Impetigo, a superficial infection of the skin, is caused primarily by GAS and occasionally by other streptococci or *Staphylococcus aureus*. Impetigo is seen most often in young children, tends to occur during

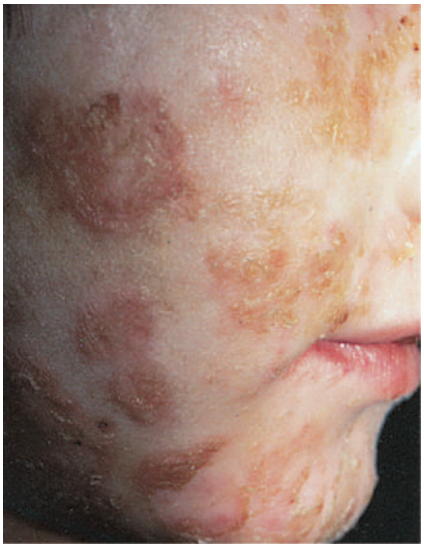

FIGURE 153-3 Impetigo is a superficial streptococcal or *Staphylococcus aureus* infection consisting of honey-colored crusts and erythematous weeping erosions. Occasionally, bullous lesions may be seen. *(Courtesy of Mary Spraker, MD; with permission.)*

warmer months, and is more common in semitropical or tropical climates than in cooler regions. Infection is more common among children living under conditions of poor hygiene. Prospective studies have shown that colonization of unbroken skin with GAS precedes clinical infection. Minor trauma, such as a scratch or an insect bite, may then serve to inoculate organisms into the skin. Impetigo is best prevented, therefore, by attention to adequate hygiene. The usual sites of involvement are the face (particularly around the nose and mouth) and the legs, although lesions may occur at other locations. Individual lesions begin as red papules, which evolve quickly into vesicular and then pustular lesions that break down and coalesce to form characteristic honeycomb-like crusts **(Fig. 153-3)**. Lesions generally are not painful, and patients do not appear ill. Fever is not a feature of impetigo and, if present, suggests either infection extending to deeper tissues or another diagnosis. The classic presentation of impetigo usually poses little diagnostic difficulty. Cultures of impetiginous lesions often yield *S. aureus* as well as GAS. In almost all cases, streptococci are isolated initially, and staphylococci appear later, presumably as secondary colonizing flora. In the past, penicillin was nearly always effective against these infections. However, an increasing frequency of penicillin treatment failure suggests that *S. aureus* may have become more prominent as a cause of impetigo. *Bullous impetigo* due to *S. aureus* is distinguished from typical streptococcal infection by more extensive, bullous lesions that break down and leave thin paper-like crusts instead of the thick amber crusts of streptococcal impetigo. Other skin lesions that may be confused with impetigo include herpetic lesions—either those of orolabial herpes simplex or those of chickenpox or zoster. Herpetic lesions can generally be distinguished by their appearance as more discrete, grouped vesicles and by a positive Tzanck test or by herpes simplex virus- or varicella-zoster virus-specific PCR. In difficult cases, cultures of vesicular fluid should yield GAS (or *Staphylococcus aureus*) in impetigo and the responsible virus in herpesvirus infections.

TREATMENT

Streptococcal Impetigo

Treatment of streptococcal impetigo is the same as that for streptococcal pharyngitis. In view of evidence that *S. aureus* has become a relatively frequent cause of impetigo, empirical regimens should cover both streptococci and *S. aureus*. For example, either dicloxacillin or cephalexin can be given at a dose of 250 mg four times daily for 10 days. Topical mupirocin ointment also is effective. Culture may be indicated to rule out methicillin-resistant *S. aureus*, especially if the response to empirical treatment is unsatisfactory. In most areas of the world, ARF is not a sequela to streptococcal skin infections, although PSGN may follow either skin or throat infection. The reason for this difference is not known. One hypothesis is that the immune response necessary for development of ARF occurs only after infection of the pharyngeal mucosa. In addition, the strains of GAS that cause pharyngitis are generally of different M protein types than those associated with skin infections; thus, the strains that cause pharyngitis may have rheumatogenic potential, while the skin-infecting strains may not. An exception to this general rule may occur among indigenous people in northern Australia and in certain Pacific Island groups. Acute rheumatic fever and rheumatic heart disease are prevalent in these populations as is streptococcal impetigo/pyoderma, but not pharyngitis. This epidemiologic pattern has led investigators to suggest that skin infection may trigger acute rheumatic fever in this setting.

CELLULITIS

Inoculation of organisms into the skin may lead to *cellulitis*: infection involving the skin and subcutaneous tissues. The portal of entry may be a traumatic or surgical wound, an insect bite, or any other break in skin integrity. Often, no entry site is apparent. One form of streptococcal cellulitis, *erysipelas*, is characterized by a bright red appearance of the involved skin, which forms a plateau sharply demarcated from surrounding normal skin **(Fig. 153-4)**. The lesion is warm to the touch, may be tender, and appears shiny and swollen. The skin often has a *peau d'orange* texture, which is thought to reflect involvement of superficial lymphatics; superficial blebs or bullae may form, usually 2–3 days after onset. The lesion typically develops over a few hours and is associated with fever and chills. Erysipelas tends to occur on the malar area of the face (often with extension over the bridge of the nose to the contralateral malar region) or on the lower extremities. After one episode, recurrence at the same site—sometimes years later—is not uncommon. Classic cases of erysipelas, with typical features, are almost always due to β-hemolytic streptococci, usually GAS and occasionally group C or G. Often, however, the appearance of streptococcal cellulitis is not sufficiently distinctive to permit a specific diagnosis on clinical grounds. The anatomic area involved may not be typical for erysipelas, the lesion may be less intensely red than usual and may fade into surrounding skin, and/or the patient may appear only mildly ill. In such cases, it is prudent to broaden the spectrum of empirical antimicrobial therapy to include other pathogens, particularly *S. aureus*, that can produce cellulitis with the same

FIGURE 153-4 Erysipelas is a streptococcal infection of the superficial dermis and consists of well-demarcated, erythematous, edematous, warm plaques.

appearance. Staphylococcal infection should be suspected if cellulitis develops around a wound or an ulcer.

Streptococcal cellulitis tends to develop at anatomic sites in which normal lymphatic drainage has been disrupted, such as sites of prior cellulitis, the arm ipsilateral to a mastectomy and axillary lymph node dissection, a lower extremity previously involved in deep venous thrombosis or chronic lymphedema, or the leg from which a saphenous vein has been harvested for coronary artery bypass grafting. The organism may enter via a dermal breach some distance from the eventual site of clinical cellulitis. For example, some patients with recurrent leg cellulitis following saphenous vein removal may stop having recurrent episodes only after treatment of tinea pedis on the affected extremity. Fissures in the skin presumably serve as a portal of entry for streptococci, which then produce infection more proximally in the leg at the site of previous injury. Streptococcal cellulitis may also involve recent surgical wounds. GAS is among the few bacterial pathogens that typically produce signs of wound infection and surrounding cellulitis within the first 24 h after surgery. These wound infections are usually associated with a thin exudate and may spread rapidly, either as cellulitis in the skin and subcutaneous tissue or as a deeper tissue infection (see below). Streptococcal wound infection or localized cellulitis may also be associated with *lymphangitis*, manifested by red streaks extending proximally along superficial lymphatics from the infection site.

TREATMENT

Streptococcal Cellulitis

See Table 153-3 and **Chap. 134.**

DEEP SOFT TISSUE INFECTIONS

Necrotizing fasciitis (*hemolytic streptococcal gangrene*) involves the superficial and/or deep fascia investing the muscles of an extremity or the trunk. The source of the infection is either the skin, with organisms introduced into tissue through trauma (sometimes trivial), or the bowel flora, with organisms released during abdominal surgery or from an occult enteric source, such as a diverticular or appendiceal abscess. The inoculation site may be inapparent and is often some distance from the site of clinical involvement; e.g., the introduction of organisms via minor trauma to the hand may be associated with clinical infection of the tissues overlying the shoulder or chest. Cases associated with the bowel flora are usually polymicrobial, involving a mixture of anaerobic bacteria (such as *Bacteroides fragilis* or anaerobic streptococci) and facultative organisms (usually gram-negative bacilli). Cases unrelated to contamination from bowel organisms are most commonly caused by GAS alone or in combination with other organisms (most often *S. aureus*). Overall, GAS is implicated in ~60% of cases of necrotizing fasciitis. The onset of symptoms is usually quite acute and is marked by severe pain at the site of involvement, malaise, fever, chills, and a toxic appearance. The physical findings, particularly early on, may not be striking, with only minimal erythema of the overlying skin. Pain and tenderness are usually severe. In contrast, in more superficial cellulitis, the skin appearance is more abnormal, but pain and tenderness are only mild or moderate. As the infection progresses (often over several hours), the severity and extent of symptoms worsen, and skin changes become more evident, with the appearance of dusky or mottled erythema and edema. The marked tenderness of the involved area may evolve into anesthesia as the spreading inflammatory process produces infarction of cutaneous nerves.

Although myositis is more commonly due to *S. aureus* infection, GAS occasionally produces abscesses in skeletal muscles (*streptococcal myositis*), with little or no involvement of the surrounding fascia or overlying skin. The presentation is usually subacute, but a fulminant form has been described in association with severe systemic toxicity, bacteremia, and a high mortality rate. The fulminant form may reflect the same basic disease process seen in necrotizing fasciitis, but with the necrotizing inflammatory process extending into the muscles themselves rather than remaining limited to the fascial layers.

TREATMENT

Deep Soft Tissue Streptococcal Infections

Once necrotizing fasciitis is suspected, early surgical exploration is both diagnostically and therapeutically indicated. Surgery reveals necrosis and inflammatory fluid tracking along the fascial planes above and between muscle groups, without involvement of the muscles themselves. The process usually extends beyond the area of clinical involvement, and extensive debridement is required. Drainage and debridement are central to the management of necrotizing fasciitis; antibiotic treatment is a critical adjunct (Table 153-3), but surgery is life-saving. Treatment for streptococcal myositis consists of surgical drainage—usually by an open procedure that permits evaluation of the extent of infection and ensures adequate debridement of involved tissues—and high-dose penicillin (Table 153-3). Infection models in animals and multiple retrospective clinical studies support the addition of clindamycin to the antibiotic treatment regimen for severe GAS necrotizing soft tissue infections. In vitro and animal models suggest that the growth of GAS slows after the organism reaches a high density in infected tissues and that penicillin and other beta-lactam antibiotics have reduced efficacy under these circumstances as they target cell wall biosynthesis. By contrast, protein synthesis inhibitors retain activity regardless of growth phase of the bacteria. If the infecting strain is not known to be susceptible to clindamycin, linezolid is an alternative.

Pneumonia and Empyema GAS is an occasional cause of pneumonia, generally in previously healthy individuals. The onset of symptoms may be abrupt or gradual. Pleuritic chest pain, fever, chills, and dyspnea are the characteristic manifestations. Cough is usually present but may not be prominent. Approximately one-half of patients with GAS pneumonia have an accompanying pleural effusion. In contrast to the sterile parapneumonic effusions typical of pneumococcal pneumonia, those complicating streptococcal pneumonia are almost always infected. The empyema fluid is usually visible by chest radiography on initial presentation, and its volume may increase rapidly. These pleural collections should be drained early, as they tend to become loculated rapidly, resulting in a chronic fibrotic reaction that may require thoracotomy for removal.

Bacteremia, Puerperal Sepsis, and Streptococcal Toxic Shock Syndrome In adults, GAS bacteremia is usually associated with an identifiable local infection, whereas children may have bacteremia without an associated focal infection. Bacteremia occurs rarely with otherwise uncomplicated pharyngitis, occasionally with cellulitis or pneumonia, and relatively frequently with necrotizing fasciitis. Bacteremia without an identified source raises the possibility of endocarditis, an occult abscess, or osteomyelitis. A variety of focal infections may arise secondarily from streptococcal bacteremia, including endocarditis, meningitis, septic arthritis, osteomyelitis, peritonitis, and visceral abscesses. GAS is occasionally implicated in infectious complications of childbirth, usually endometritis and associated bacteremia. In the preantibiotic era, puerperal sepsis was commonly caused by GAS; currently, it is more often caused by GBS. Several nosocomial outbreaks of puerperal GAS infection have been traced to an asymptomatic carrier, usually someone present at delivery. The site of carriage may be the skin, throat, anus, or vagina.

Beginning in the late 1980s, several reports described patients with GAS infections associated with shock and multisystem organ failure. This syndrome was called *streptococcal toxic shock syndrome* (*TSS*) because it shares certain features with staphylococcal TSS. A case definition for streptococcal TSS was formulated in 1993 and updated in 2010 **(Table 153-4)**. The general features of the illness include fever, hypotension, renal impairment, and respiratory distress syndrome. Various types of rash have been described, but rash usually does not develop. Laboratory abnormalities include a marked shift to the left in the white blood cell differential, with many immature granulocytes; hypocalcemia; hypoalbuminemia; and thrombocytopenia, which usually becomes more pronounced on the second or third day of illness.

TABLE 153-4 Case Definition for Streptococcal Toxic Shock Syndrome[a]

    6. Soft tissue necrosis, including necrotizing fasciitis or myositis; *or* gangrene

[a]An illness fulfilling criteria IA, IIA, and IIB is defined as a *definite* case. An illness fulfilling criteria IB, IIA, and IIB is defined as a *probable* case if no other etiology for the illness is identified.

Source: Modified from Streptococcal Toxic Shock Syndrome (STSS) (*Streptococcus pyogenes*) 2010 Case Definition: Centers for Disease Control and Prevention (*https://ndc.services.cdc.gov/case-definitions/streptococcal-toxic-shock-syndrome-2010/*).

In contrast to patients with staphylococcal TSS, the majority with streptococcal TSS are bacteremic. The most common associated infection is a soft tissue infection—necrotizing fasciitis, myositis, or cellulitis—although a variety of other associated local infections have been described, including pneumonia, peritonitis, osteomyelitis, and myometritis. Streptococcal TSS is associated with a mortality rate of ≥30%, with most deaths secondary to shock and respiratory failure. Because of its rapidly progressive and lethal course, early recognition of the syndrome is essential. Patients should receive aggressive supportive care (fluid resuscitation, pressors, and mechanical ventilation) in addition to antimicrobial therapy and, in cases associated with necrotizing fasciitis, should undergo surgical debridement. Exactly why certain patients develop this fulminant syndrome is not known. Early studies of the streptococcal strains isolated from these patients demonstrated a strong association with the production of pyrogenic exotoxin A. This association has been inconsistent in subsequent case series. Pyrogenic exotoxin A and several other streptococcal exotoxins act as superantigens to trigger release of inflammatory cytokines from T lymphocytes. Fever, shock, and organ dysfunction in streptococcal TSS may reflect, in part, the systemic effects of superantigen-mediated cytokine release.

TREATMENT

Streptococcal Toxic Shock Syndrome

High-dose penicillin is the agent of choice for streptococcal TSS. For empiric treatment of sepsis before the etiology is known, a broad-spectrum antibiotic regimen should include an agent with excellent activity against GAS such as an extended-spectrum penicillin, cephalosporin, or a carbapenem. In light of the possible role of pyrogenic exotoxins or other streptococcal toxins in streptococcal TSS, adjunctive treatment with clindamycin has been advocated by some authorities (Table 153-3), who argue that, through its direct action on protein synthesis, clindamycin is more effective in rapidly terminating toxin production than is penicillin—a cell-wall agent. As discussed previously (see "Treatment of Deep Soft Tissue Streptococcal Infections," above), support for this view comes from studies of an experimental model of streptococcal myositis, in which mice given clindamycin had a higher rate of survival than those given penicillin. Comparable data on the treatment of human infections are not available, although retrospective analysis has suggested a better outcome when patients with invasive soft tissue infection and streptococcal TSS are treated with clindamycin rather than with cell wall–active antibiotics alone. As clindamycin resistance occurs in 30% or more of invasive GAS isolates in the United States and many other countries, susceptibility to clindamycin should not be assumed in the absence of in vitro testing of the infecting strain. Linezolid is an appropriate alternative in the setting of clindamycin resistance or unknown susceptibility. IV immunoglobulin also has been used as adjunctive therapy for streptococcal TSS (Table 153-3). Pooled immunoglobulin preparations contain antibodies capable of neutralizing the effects of streptococcal toxins and may have opsonic activity against GAS. Intravenous immunoglobulin (IVIG) also has immunomodulatory properties, which may mitigate the pathophysiologic effects of inflammatory cytokines. Anecdotal reports and case series have suggested favorable clinical responses to IVIG, but no adequately powered, prospective, controlled trials have been reported. A meta-analysis of five studies of streptococcal TSS patients treated with clindamycin found that IVIG use was associated with a reduction in mortality rate from 33.7% to 15.7%.

PREVENTION

No vaccine against GAS is commercially available. A formulation that consists of recombinant peptides containing epitopes of 26 M-protein types has undergone phase 1 and 2 testing in volunteers. Early results indicate that the vaccine is well tolerated and elicits type-specific antibody responses. Vaccines based on a conserved region of M protein or on a mixture of other conserved GAS protein antigens are in earlier stages of development.

Household contacts of individuals with invasive GAS infection (e.g., bacteremia, necrotizing fasciitis, or streptococcal TSS) are at greater risk of invasive infection than the general population. Asymptomatic pharyngeal colonization with GAS has been detected in up to 25% of persons with >4 h/d of same-room exposure to an index case. However, the CDC does not recommend antibiotic prophylaxis routinely for contacts of patients with invasive disease because such an approach (if effective) would require treatment of hundreds of contacts to prevent a single case. Prophylaxis may be considered for contacts of unusually severe cases or for individuals at increased risk for invasive infection.

STREPTOCOCCI OF GROUPS C AND G

Group C and group G streptococci are β-hemolytic bacteria that occasionally cause human infections similar to those caused by GAS. Strains that form small colonies on blood agar (<0.5 mm) are generally members of the *Streptococcus milleri* group (*Streptococcus intermedius*, *Streptococcus anginosus*; see "Viridans Streptococci," below). Large-colony group C and G streptococci of human origin are now considered a single species, *Streptococcus dysgalactiae* subspecies *equisimilis* (SDSE). Genomic studies have demonstrated extensive overlap between the genomes of SDSE and GAS and evidence of cross-species recombination. These organisms have been associated with pharyngitis, cellulitis and soft tissue infections, pneumonia, bacteremia, endocarditis, and septic arthritis. Puerperal sepsis, meningitis, epidural abscess, intraabdominal abscess, urinary tract infection, and neonatal sepsis also have been reported. SDSE bacteremia most often affects elderly or chronically ill patients and, in the absence of obvious local infection, is likely to reflect endocarditis. Septic arthritis, sometimes involving multiple joints, may complicate endocarditis or develop in its absence. Distinct streptococcal species of Lancefield group C cause infections in domesticated animals, especially horses and cattle; some human infections are acquired through contact with animals or consumption of unpasteurized milk. These zoonotic organisms include *Streptococcus equi* subspecies *zooepidemicus* and *S. equi* subspecies *equi*.

TREATMENT

Group C or G Streptococcal Infection

Penicillin is the drug of choice for treatment of group C or G streptococcal infections. Antibiotic treatment is the same as for similar syndromes due to GAS (Table 153-3). Patients with bacteremia or septic arthritis should receive IV penicillin (2–4 mU every 4 h). All group C and G streptococci are sensitive to penicillin; nearly all are inhibited in vitro by concentrations of ≤0.03 μg/mL. Occasional isolates exhibit tolerance: although inhibited by low concentrations

of penicillin, they are killed only by significantly higher concentrations. The clinical significance of tolerance is unknown. Because of the poor clinical response of some patients to penicillin alone, the addition of gentamicin (1 mg/kg every 8 h for patients with normal renal function) is recommended by some authorities for treatment of endocarditis or septic arthritis due to group C or G streptococci; however, combination therapy has not been shown to be superior to penicillin treatment alone. Patients with joint infections often require repeated aspiration or open drainage and debridement for cure; the response to treatment may be slow, particularly in debilitated patients and those with involvement of multiple joints. Infection of prosthetic joints almost always requires prosthesis removal in addition to antibiotic therapy.

GROUP B STREPTOCOCCI

Identified first as a cause of mastitis in cows, streptococci belonging to Lancefield group B have since been recognized as a major cause of sepsis and meningitis in human neonates. GBS is also a frequent cause of peripartum fever in women and an occasional cause of serious infection in nonpregnant adults. Since the widespread institution of prenatal screening for GBS in the 1990s, the incidence of neonatal infection per 1000 live births has fallen from ~2–3 cases to ~0.6 case. During the same period, GBS infection in adults with underlying chronic illnesses has become more common; adults now account for a larger proportion of invasive GBS infections than do newborns. Lancefield group B consists of a single species, *S. agalactiae*, which is definitively identified with specific antiserum to the group B cell wall–associated carbohydrate antigen. A streptococcal isolate can be classified presumptively as GBS on the basis of biochemical tests, including hydrolysis of sodium hippurate (in which 99% of isolates are positive), hydrolysis of bile esculin (in which 99–100% are negative), bacitracin susceptibility (in which 92% are resistant), and production of CAMP factor (in which 98–100% are positive). CAMP factor is a phospholipase produced by GBS that causes synergistic hemolysis with β lysin produced by certain strains of *S. aureus*. Its presence can be demonstrated by cross-streaking of the test isolate and an appropriate staphylococcal strain on a blood agar plate. GBS organisms causing human infections are encapsulated by 1 of 10 antigenically distinct polysaccharides. The capsular polysaccharide is an important virulence factor. Antibodies to the capsular polysaccharide afford protection against GBS of the same (but not of a different) capsular type.

INFECTION IN NEONATES

Two general types of GBS infection in infants are defined by the age of the patient at presentation. *Early-onset infections* occur within the first week of life, with a median age of 20 h at onset. Approximately half of these infants have signs of GBS disease at birth. The infection is acquired during or shortly before birth from the colonized maternal genital tract. Surveillance studies have shown that 5–40% of women are vaginal or rectal carriers of GBS. Approximately 50% of infants delivered vaginally by carrier mothers become colonized, although only 1–2% develop clinically evident infection. Prematurity, prolonged labor, obstetric complications, and maternal fever are risk factors for early-onset infection. The presentation of early-onset infection is the same as that of other forms of neonatal sepsis. Typical findings include respiratory distress, lethargy, and hypotension. Essentially all infants with early-onset disease are bacteremic, one-third to one-half have pneumonia and/or respiratory distress syndrome, and one-third have meningitis.

Late-onset infections occur in infants 1 week to 3 months old and, in rare instances, in older infants (mean age at onset, 3–4 weeks). The infecting organism may be acquired during delivery (as in early-onset cases) or during later contact with a colonized mother, nursery personnel, or another source. Meningitis is the most common manifestation of late-onset infection and in most cases is associated with a strain of capsular type III. Infants present with fever, lethargy or irritability, poor feeding, and seizures. The various other types of late-onset infection include bacteremia without an identified source, osteomyelitis, septic arthritis, and facial cellulitis associated with submandibular or preauricular adenitis.

TREATMENT

Group B Streptococcal Infection in Neonates

Penicillin is the agent of choice for all GBS infections. Empirical broad-spectrum therapy for suspected bacterial sepsis, consisting of ampicillin and gentamicin, is generally administered until culture results become available. If cultures yield GBS, many pediatricians continue to administer gentamicin, along with ampicillin or penicillin, for a few days until clinical improvement becomes evident. Infants with bacteremia or soft tissue infection should receive penicillin at a dosage of 200,000 units/kg per day in divided doses. For meningitis, infants ≤7 days of age should receive 250,000–450,000 units/kg per d in three divided doses; infants >7 days of age should receive 450,000–500,000 units/kg per day in four divided doses. Meningitis should be treated for at least 14 days because of the risk of relapse with shorter courses.

Prevention The incidence of GBS infection is unusually high among infants of women with risk factors: preterm delivery, early rupture of membranes (>24 h before delivery), prolonged labor, fever, or chorioamnionitis. Because the usual source of the organisms infecting a neonate is the mother's birth canal, efforts have been made to prevent GBS infections by the identification of high-risk carrier mothers and their treatment with various forms of antibiotic prophylaxis or immunoprophylaxis. Prophylactic administration of ampicillin or penicillin to such patients during delivery reduces the risk of infection in the newborn. This approach has been hampered by logistical difficulties in identifying colonized women before delivery; the results of vaginal cultures early in pregnancy are poor predictors of carrier status at delivery. The CDC recommends screening for anogenital colonization at 35–37 weeks of pregnancy by a swab culture of the lower vagina and anorectum; intrapartum chemoprophylaxis is recommended for culture-positive women and for women who, regardless of culture status, have previously given birth to an infant with GBS infection or have a history of GBS bacteriuria during pregnancy. Women whose culture status is unknown and who develop premature labor (<37 weeks), prolonged rupture of membranes (>18 h), or intrapartum fever or who have a positive intrapartum nucleic acid amplification test for GBS also should receive intrapartum chemoprophylaxis. The recommended regimen for chemoprophylaxis is a loading dose of 5 million units of penicillin G followed by 2.5 million units every 4 h until delivery. Cefazolin is an alternative for women with a history of penicillin allergy who are thought not to be at high risk for anaphylaxis. For women with a history of immediate hypersensitivity, clindamycin may be substituted, but only if the colonizing isolate has been demonstrated to be susceptible. If susceptibility testing results are not available or indicate resistance, vancomycin should be used in this situation.

Treatment of all pregnant women who are colonized or have risk factors for neonatal infection will result in exposure of up to one-third of pregnant women and newborns to antibiotics, with the attendant risks of allergic reactions and selection for resistant organisms. Although still in the developmental stages, a GBS vaccine may ultimately offer a better solution to prevention. Because transplacental passage of maternal antibodies produces protective antibody levels in newborns, efforts are underway to develop a vaccine against GBS that can be given to childbearing-age women before or during pregnancy. Results of phase 1 clinical trials of GBS capsular polysaccharide–protein conjugate vaccines suggest that a multivalent conjugate vaccine would be safe and highly immunogenic.

INFECTION IN ADULTS

The majority of GBS infections in otherwise healthy adults are related to pregnancy and parturition. Peripartum fever, the most common manifestation, is sometimes accompanied by symptoms and signs of endometritis or chorioamnionitis (abdominal distention and uterine

or adnexal tenderness). Blood and vaginal swab cultures are often positive. Bacteremia is usually transitory but occasionally results in meningitis or endocarditis. Infections in adults that are not associated with the peripartum period generally involve individuals who are elderly or have an underlying chronic illness, such as diabetes mellitus or a malignancy. Among the infections that develop with some frequency in adults are cellulitis and soft tissue infection (including infected diabetic skin ulcers), urinary tract infection, pneumonia, endocarditis, and septic arthritis. Other reported infections include meningitis, osteomyelitis, and intraabdominal or pelvic abscesses. Relapse or recurrence of invasive infection weeks to months after a first episode is documented in ~4% of cases.

TREATMENT

Group B Streptococcal Infection in Adults

GBS is less sensitive to penicillin than GAS, requiring somewhat higher doses. Adults with serious localized infections (pneumonia, pyelonephritis, abscess) should receive divided doses of ~12 million units of penicillin G daily; patients with endocarditis or meningitis should receive 18–24 million units per day in divided doses. Vancomycin is an acceptable alternative for penicillin-allergic patients.

NONENTEROCOCCAL GROUP D STREPTOCOCCI

The main nonenterococcal group D streptococci that cause human infections were previously considered a single species, *Streptococcus bovis*. The organisms encompassed by *S. bovis* have been reclassified into two species, each of which has two subspecies: *Streptococcus gallolyticus* subspecies *gallolyticus*, *S. gallolyticus* subspecies *pasteurianus*, *Streptococcus infantarius* subspecies *infantarius*, and *S. infantarius* subspecies *coli*. Endocarditis caused by these organisms is often associated with neoplasms of the gastrointestinal tract—most frequently, a colon carcinoma or polyp—but is also reported in association with other bowel lesions. When occult gastrointestinal lesions are carefully sought, abnormalities are found in >60% of patients with endocarditis due to *S. gallolyticus* or *S. infantarius*. In contrast to the enterococci, nonenterococcal group D streptococci like these organisms are reliably killed by penicillin as a single agent, and penicillin is the agent of choice for the infections they cause.

VIRIDANS AND OTHER STREPTOCOCCI

VIRIDANS STREPTOCOCCI

Consisting of multiple species of α-hemolytic streptococci, the viridans streptococci are a heterogeneous group of organisms that are important agents of bacterial endocarditis **(Chap. 133)**. Several species of viridans streptococci, including *Streptococcus salivarius*, *Streptococcus mitis*, *Streptococcus sanguis*, and *Streptococcus mutans*, are part of the normal flora of the mouth, where they live in close association with the teeth and gingiva. Some species contribute to the development of dental caries.

Previously known as *Streptococcus morbillorum*, *Gemella morbillorum* has been placed in a separate genus, along with *Gemella haemolysans*, on the basis of genetic-relatedness studies. These species resemble viridans streptococci with respect to habitat in the human host and associated infections.

The transient viridans streptococcal bacteremia induced by eating, toothbrushing, flossing, and other sources of minor trauma, together with adherence to biologic surfaces, is thought to account for the predilection of these organisms to cause endocarditis **(see Fig. 133-1)**. Viridans streptococci are also isolated, often as part of a mixed flora, from sites of sinusitis, brain abscess, and liver abscess.

Viridans streptococcal bacteremia occurs relatively frequently in neutropenic patients, particularly after bone marrow transplantation or high-dose chemotherapy for cancer. Some of these patients develop a sepsis syndrome with high fever and shock. Risk factors for viridans streptococcal bacteremia include chemotherapy with high-dose cytosine arabinoside, prior treatment with trimethoprim-sulfamethoxazole or a fluoroquinolone, treatment with antacids or histamine antagonists, mucositis, and profound neutropenia.

The *S. milleri* group (also referred to as the *S. intermedius* or *S. anginosus* group) includes three species that cause human disease: *S. intermedius*, *S. anginosus*, and *Streptococcus constellatus*. These organisms are often considered viridans streptococci, although they differ somewhat from other viridans streptococci in their small colony size on solid medium (they typically form colonies <0.5 mm in diameter), their hemolytic pattern (they may be α-, β-, or nonhemolytic), and the disease syndromes they cause. This group commonly produces suppurative infections, particularly abscesses of brain and abdominal viscera, and infections related to the oral cavity or respiratory tract, such as peritonsillar abscess, sinusitis and complications such as orbital cellulitis, subdural and epidural abscess, and cerebral venous sinus thrombosis, lung abscess, and empyema.

TREATMENT

Infection with Viridans Streptococci

Isolates from neutropenic patients with bacteremia are often resistant to penicillin; thus, these patients should be treated presumptively with vancomycin until the results of susceptibility testing become available. Viridans streptococci isolated in other clinical settings usually are sensitive to penicillin. Susceptibility testing should be performed to guide treatment of serious infections.

ABIOTROPHIA AND *GRANULICATELLA* SPECIES (NUTRITIONALLY VARIANT STREPTOCOCCI)

Occasional isolates cultured from the blood of patients with endocarditis fail to grow when subcultured on solid media. These *nutritionally variant streptococci* require supplemental thiol compounds or active forms of vitamin B_6 (pyridoxal or pyridoxamine) for growth in the laboratory. The nutritionally variant streptococci are generally grouped with the viridans streptococci because they cause similar types of infections. However, they have been reclassified on the basis of 16S ribosomal RNA sequence comparisons into two separate genera: *Abiotrophia*, with a single species (*Abiotrophia defectiva*), and *Granulicatella*, with three species associated with human infection (*Granulicatella adiacens*, *Granulicatella para-adiacens*, and *Granulicatella elegans*).

TREATMENT

Infection with Nutritionally Variant Streptococci

Treatment failure and relapse appear to be more common in cases of endocarditis due to nutritionally variant streptococci than in those due to the usual viridans streptococci. Thus, the addition of gentamicin (1 mg/kg every 8 h for patients with normal renal function) to the penicillin regimen is recommended for endocarditis due to the nutritionally variant organisms.

OTHER STREPTOCOCCI

Streptococcus suis is an important pathogen in swine and has been reported to cause meningitis in humans, usually in individuals with occupational exposure to pigs. *S. suis* has been reported to be the most common cause of bacterial meningitis in Vietnam, and it has been responsible for outbreaks in China. Strains of *S. suis* associated with human infections have generally reacted with Lancefield group R typing serum and sometimes with group D typing serum as well. Isolates may be α- or β-hemolytic and are sensitive to penicillin. *Streptococcus iniae*, a pathogen of fish, has been associated with infections in humans who have handled live or freshly killed fish. Cellulitis of the hand is the most common form of human infection, although bacteremia and endocarditis have been reported. *Anaerobic streptococci*, or *peptostreptococci*, are part of the normal flora of the oral cavity, bowel, and vagina. **Infections caused by the anaerobic streptococci are discussed in Chap. 182.**

154 Enterococcal Infections

William R. Miller, Cesar A. Arias, Barbara E. Murray*

Enterococci have been recognized as potential human pathogens for well over a century, but only in recent years have these organisms acquired prominence as important causes of nosocomial infections. The ability of enterococci to survive and/or disseminate in the hospital environment and to acquire antibiotic resistance determinants makes the treatment of some enterococcal infections in critically ill patients a difficult challenge. Enterococci were first mentioned in the French literature in 1899; the "entérocoque" was found in the human gastrointestinal tract. The first pathologic description of an enterococcal infection dates to the same year. A clinical isolate from a patient who died as a consequence of endocarditis was initially designated *Micrococcus zymogenes*, was later named *Streptococcus faecalis* subspecies *zymogenes*, and would now be classified as *Enterococcus faecalis*. The ability of this isolate to cause severe disease in both rabbits and mice illustrated its potential lethality in the appropriate settings.

MICROBIOLOGY AND TAXONOMY

Enterococci are gram-positive organisms. In clinical specimens, they are usually observed as single cells, diplococci, or short chains **(Fig. 154-1)**, although long chains are noted with some strains. Enterococci were originally classified as streptococci because organisms of the two genera share many morphologic and phenotypic characteristics, including a generally negative catalase reaction. Only DNA hybridization studies and later 16S rRNA sequencing clearly demonstrated that enterococci should be grouped as a genus distinct from the streptococci. Unlike the majority of streptococci, enterococci hydrolyze esculin in the presence of 40% bile salts and grow at high salt concentrations (e.g., 6.5%) and at high temperatures (46°C). Enterococci are usually reported by the clinical laboratory to be nonhemolytic on the basis of their inability to lyse the ovine or bovine red blood cells (RBCs) commonly used in agar plates; however, some strains of *E. faecalis* do lyse RBCs from humans, horses, and rabbits due to the presence of an acquired hemolysin/cytolysin gene. The majority of clinically relevant enterococcal species hydrolyze pyrrolidonyl-β-naphthylamide (PYR); this characteristic is helpful in differentiating enterococci from organisms of the *Streptococcus gallolyticus* group (formerly known as *S. bovis*, which includes *S. gallolyticus*, *S. pasteurianus*, and *S. infantarius*) and from *Leuconostoc* species. Although many species of enterococci have been isolated from human infections, the overwhelming majority of cases are caused by two species, *E. faecalis* and *E. faecium*. Less frequently isolated species include *Enterococcus gallinarum*, *E. durans*, *E. hirae*, and *E. avium*.

PATHOGENESIS

Enterococci are normal inhabitants of the large bowel of human adults, although they usually make up <1% of the culturable intestinal microbiota. In the healthy human host, enterococci are typical symbionts that coexist with other gastrointestinal bacteria; in fact, the utility of certain enterococcal strains as probiotics in the treatment of diarrhea suggests their possible role in maintaining the homeostatic equilibrium of the bowel. These commensals play a role in *colonization resistance*, or the ability of a healthy gastrointestinal microbiota to impede the establishment of a population of drug-resistant bacteria such as vancomycin-resistant enterococci (VRE). Colonization resistance arises from a complex set of metabolic and immunologic interactions between the host, pathogen, and intestinal microbiota, many of which are disrupted in hospitalized or chronically ill patients.

Several studies have shown that a higher level of gastrointestinal colonization is a critical factor in the pathogenesis of enterococcal infections. Physical factors, such as stomach pH and the mucin layer on the interior of the intestinal lumen, provide a barrier and limit pathogen access to the intestinal epithelium. In the hospital setting, administration of medications that suppress stomach acid secretion, or degradation of the mucin layer by gut commensals during periods of decreased oral intake, can disrupt these protective layers. The availability of specific carbon sources also has been shown to influence the ability of enterococci to colonize the intestine. Depletion of fructose by members of the genus *Olsenella* leads to impaired growth and a decrease in the enteric burden of VRE in a mouse-colonization model, while the presence of lactose favors the outgrowth of enterococci. Further, enterococci may potentiate the fitness and virulence of pathogens such as *Clostridioides difficile* by altering the availability of fermentable amino acids, by promoting *C. difficile* fitness, and by depletion of arginine, which leads to increased *C. difficile* toxin production.

*Deceased.

One of the most important factors that promotes increased gastrointestinal colonization by enterococci is the administration of antimicrobial agents since enterococci are intrinsically resistant to a variety of commonly used antibacterial drugs. In particular, antibiotics that are excreted in the bile and have broad-spectrum activity (e.g., certain cephalosporins and antimicrobials with anaerobic activity) are usually associated with the recovery of higher numbers of enterococci from feces. However, the increased colonization by hospital-associated strains of *E. faecium* in the presence of antimicrobial agents appears to be due to more than the simple filling of a "biologic niche." Studies of colonization dynamics in mouse intestines suggest host-derived antimicrobial peptides produced by the innate immune system (such as the lectin RegIIIγ) and compounds such as lantibiotics or bacteriocins produced by members of the microbiota itself are important mediators of colonization resistance. Activation of Toll-like receptors by lipopolysaccharide (an important component of the gram-negative cell envelope) leads, in mice, to increased production of RegIIIγ, and loss of this stimulation by antibiotic-induced disruptions of commensal gram-negative bacteria impairs clearance of VRE from the intestines. Similarly, antimicrobial lantibiotics produced by commensal bacteria (such as *Blautia producta*) are active against VRE in vitro, but this organism may require a cooperative partnership with other members of the microbiota to effectively provide colonization resistance. Disruption of these partnerships by antibiotic administration can lead to an environment where VRE can flourish. Another factor that may contribute to enterococcal survival in the gastrointestinal tract is the production of bacteriocins (molecules that kill competing bacteria). Strains of *E. faecalis* harboring pheromone-producing plasmids that code for bacteriocins are capable of outcompeting enterococci lacking such plasmids, and conjugative transfer of these elements enhances the survival of recipient enterococci. In the absence of antibiotics, hospital-associated lineages of *E. faecium* seem to be less adapted for survival in the gastrointestinal tract than are commensal *E. faecium* strains. Studies examining the rate of carriage of VRE in patients after discharge from the hospital document a median time to clearance between 2 and 4 months in patients without ongoing risk factors, such as continued antibiotic use, residence in a long-term care facility, or need for hemodialysis.

Colonization by enterococci may also have important effects on the treatment of noninfectious syndromes. In hematopoietic stem cell transplant patients, domination of the gastrointestinal tract by enterococci is associated with increased inflammation and a greater severity of illness and mortality in graft-versus-host disease. Certain enterococcal species, such as *E. faecium*, *E. durans*, and *E. hirae*, modulate the host immune response and can potentiate the activity of anti-PD-L1 immune checkpoint inhibitor therapy. This effect is mediated by the presence of *salA*, a gene which encodes a peptidoglycan hydrolase with D,L-endopeptidase activity. The muropeptides generated by SalA induce host activation of NF-κB via NOD2, leading to an enhanced antitumor immune response.

Several vertebrate, worm, and insect models have been developed to study the role of possible pathogenic determinants in both *E. faecalis* and *E. faecium*. Three main groups of virulence factors may increase the ability of enterococci to colonize the gastrointestinal tract and/or cause disease. The first group, *enterococcal secreted factors*, are molecules released outside the bacterial cell that contribute to the process of infection. The best studied of these molecules include enterococcal hemolysin/cytolysin and two enterococcal proteases (gelatinase and serine protease). Enterococcal cytolysin is a heterodimeric toxin produced by some strains of *E. faecalis* that is capable of lysing human (as well as equine but not ovine) RBCs as well as polymorphonuclear leukocytes and macrophages. A newly described pore-forming toxin, Epx, specifically targets human leukocyte antigen type 1, and has been shown to be active against peripheral blood mononuclear cells and intestinal organoids in vitro. *E. faecalis* gelatinase and serine protease are thought to mediate virulence by several mechanisms, including the degradation of host tissues and the modification of critical components of the immune system. Mutants lacking the genes corresponding to these proteins are highly attenuated in experimental animal models of peritonitis, endocarditis, and endophthalmitis.

A second group of virulence factors, *enterococcal surface components*, includes adhesins and is thought to contribute to bacterial attachment to extracellular matrix molecules in the human host. Several molecules on the surface of enterococci have been characterized and shown to play a role in the pathogenesis of enterococcal infections. Among the characterized adhesins is *aggregation substance* of *E. faecalis*, which mediates the attachment of bacterial cells to each other, thereby facilitating conjugative plasmid exchange. Several lines of evidence indicate that aggregation substance and enterococcal cytolysin act synergistically to increase the virulence potential of *E. faecalis* strains in experimental endocarditis. The surface protein adhesin of collagen of *E. faecalis* (Ace) and its *E. faecium* homologue (Acm) are microbial surface components adhering to matrix molecules (MSCRAMMs); they recognize adhesive matrix molecules involved in bacterial attachment to host proteins such as collagen, fibronectin, and fibrinogen. Both Ace and Acm are collagen adhesins that are important in the pathogenesis of experimental endocarditis. Pili of both *E. faecalis* and *E. faecium* are important mediators of attachment to and invasion of host tissues. Mutants of *E. faecalis* lacking pili are attenuated in biofilm production, experimental endocarditis, and urinary tract infections (UTIs). Other surface proteins that share structural homology with MSCRAMMs and appear to play a role in enterococcal attachment to the host and in virulence include the *E. faecalis* surface protein Esp and its *E. faecium* homologue Esp_{fm}, the second collagen adhesin of *E. faecium* (Scm), the surface proteins of *E. faecium* (Fms), SgrA (which binds to components of the basal lamina), and EcbA (which binds to collagen type V). Additional surface components apparently associated with pathogenicity include the Erl protein (a protein from the WxL family) and polysaccharides, which are thought to interfere with phagocytosis of the organism by host immune cells. Teichoic acids on the enterococcal surface appear to be immunogenic, and antibodies to these molecules are protective in some animal models.

The third group of virulence factors has not been well characterized but includes the *E. faecalis* stress protein Gls24, which has been associated with enterococcal resistance to bile salts and appears to be important in the pathogenesis of endocarditis, and the hyl_{Efm}-containing plasmids of *E. faecium*, which are transferable between strains and increase gastrointestinal colonization by *E. faecium*. In mouse peritonitis, acquisition of these plasmids increased the lethality of a commensal strain of *E. faecium* and enhanced colonization of the uroepithelium. A gene encoding a regulator of oxidative stress (AsrR) has been identified as an important virulence factor of *E. faecium*.

EPIDEMIOLOGY

According to data collected from 2018 to 2021 by the National Healthcare Safety Network of the Centers for Disease Control and Prevention, enterococci are the third most common isolates (after *Escherichia coli* and staphylococci) from hospital-associated infections in the United States. Although *E. faecalis* remains the predominant species recovered from nosocomial infections, the isolation of *E. faecium* has increased substantially in the past 20 years and accounts for approximately one-third of all enterococcal infections identified to the species level. This point is important, since *E. faecium* is by far the most resistant and challenging enterococcal species to treat. More than 90% of *E. faecium* isolates are resistant to ampicillin (historically the most effective β-lactam agent against enterococci), while ampicillin resistance in *E. faecalis* is uncommon. Vancomycin resistance in *E. faecium* isolates ranges from 50–70% in acute care hospitals in the United States to up to 80% in long-term care facilities. Resistance to vancomycin in *E. faecalis* isolates is less common, with a higher prevalence in long-term care facilities (10–12%) than in acute care hospitals (2–5%).

The dynamics of enterococcal transmission and dissemination in the hospital environment have been extensively studied, with a focus on VRE. These studies have revealed that VRE colonization of the gastrointestinal tract is a critical step in the development of enterococcal disease and that a substantial proportion of patients colonized with VRE remain colonized for prolonged periods (sometimes >1 year) and are more likely than patients without VRE colonization to develop an *Enterococcus*-related illness (e.g., bacteremia). Important factors

associated with VRE colonization and persistence in the gut include prolonged hospitalization; long courses of antibiotic therapy; hospitalization in long-term care facilities, surgical units, and/or intensive care units; organ transplantation; renal failure (particularly in patients undergoing hemodialysis) and/or diabetes; high APACHE (Acute Physiology and Chronic Health Evaluation) scores; and physical proximity to patients infected or colonized with VRE or these patients' rooms. Once a patient becomes colonized with VRE, several key factors are involved in the organisms' dissemination in the hospital environment. VRE can survive exposure to heat and certain disinfectants and have been found on numerous inanimate objects in the hospital, including bed rails, medical equipment, doorknobs, gloves, telephones, and computer keyboards. Thus, health care workers and the environment play pivotal roles in enterococcal transmission from patient to patient, and infection control measures are crucial in breaking the chain of transmission. Moreover, two meta-analyses have found that, independent of the patient's clinical status, VRE infection increases the risk of death over that among individuals infected with a glycopeptide-susceptible enterococcal strain.

The epidemiology of enterococcal disease and the emergence of VRE have followed slightly different trends in other parts of the world than in the United States. In Europe, the emergence of VRE in the mid-1980s was seen primarily in isolates recovered from animals and healthy humans rather than from hospitalized patients. The presence of VRE was associated with the use of the glycopeptide avoparcin as a growth promoter in animal feeds; this association prompted the European Union to ban the use of this compound in animal husbandry in 1996. However, after an initial decrease in the isolation of VRE from animals and humans, the prevalence of hospital-associated VRE infections has slowly increased, from 8.1% in 2012 to 17.6% in 2022. Furthermore, there are important regional differences in rates of vancomycin resistance among *E. faecium*, with rates below 5–10% in most of western Europe and Scandinavia, and 25–50% across much of southern and eastern Europe. Despite regional differences, Europe has seen a general trend of increasing rates of VRE over the past decade, although these rates continue to be much lower than in the United States. The reasons are not totally understood, but it has been postulated that this difference is related to the higher levels of human antibiotic use in the United States. Recent data have also shown increasing rates of enterococcal resistance to vancomycin in Latin American countries, with 34% of clinical *E. faecium* isolates found to be resistant in a multicenter study including hospitals from Colombia, Venezuela, Ecuador, and Peru. In Asia, rates of vancomycin resistance among enterococci appear to be similar to those in U.S. hospitals.

The ability to sequence bacterial genomes has increased our understanding of bacterial diversity, evolution, pathogenesis, and mechanisms of antibiotic resistance. Ongoing collection of enterococcal isolates as a part of epidemiologic surveillance has allowed researchers to trace the evolutionary trajectory of enterococci from their origin to the emergence of hospital-adapted clones. Sequence analysis suggests the genus appeared ~400 million years ago with the advent of terrestrial animals. Several key features aided in this transition, including the ability to recombine large portions of chromosomal DNA from the *core genome* and a malleable *accessory genome* consisting of plasmids, phages, and mobile genetic elements. This genomic plasticity contributes to the rising rates of antibiotic resistance seen within the genus and, in particular, in *E. faecium*.

A large proportion of the genomes available for analysis belong to *E. faecium*, due to its importance as a nosocomial pathogen and the epidemiologic surveillance projects to track the spread of vancomycin-resistant strains. The population can be divided into two large groups, or clades, of organisms: a hospital-associated clade A and a community-associated clade B. The hospital-associated clade appears to be evolving rapidly via a series of historic and ongoing recombination events. Certain regions of the chromosome show a convergence of genomic diversity both within and between clades, suggesting there are several "hot spots" for recombination. Importantly, these regions contain the polysaccharide biosynthesis cluster, which has been implicated in altering the antigenic capsular polysaccharide in streptococci, and the LiaFSR locus, a major cell envelope stress system that mediates resistance to membrane-active antibiotics and host antimicrobial peptides. Strains belonging to clade A are more frequently identified as isolates causing invasive disease and are more likely to carry drug resistance determinants, whereas clade B isolates largely retain a susceptible phenotype.

One reason for the propensity of clade A strains to acquire resistance determinants is that they more frequently lack a functional CRISPR-Cas system (short for *c*lustered *r*egularly *i*nterspaced *s*hort *p*alindromic *r*epeats). These systems serve as a primitive "immune system" and provide a genome defense for bacteria to protect them from foreign DNA, such as phages, but they also serve to reduce the frequency of acquisition of resistance genes borne on mobile genetic elements. Another reason for their survival in the hospital environment is that clade A isolates tend to possess alleles of penicillin-binding protein 5 (PBP5) associated with high-level β-lactam resistance in *E. faecium* and may express higher levels of this enzyme than commensal strains.

A notable feature of the distribution of strains in clade A in some studies is that they share a relatively recent common ancestor with *E. faecium* of livestock origin. Use of antibiotics in animal husbandry as both therapeutics and growth promoters has been linked to resistance in several important contexts, including glycopeptides, as mentioned above. This phenomenon suggests that continued surveillance, and an expanding understanding of the population structure of enterococci, may help identify potential reservoirs of resistance and inform policy to limit their spread.

CLINICAL SYNDROMES

Urinary Tract Infection and Prostatitis Enterococci are well-known causes of nosocomial UTI—the most common infection caused by these organisms **(Chap. 140)**. Enterococcal UTIs are usually associated with indwelling catheterization, instrumentation, or anatomic abnormalities of the genitourinary tract, and it is often challenging to differentiate between true infection and colonization (particularly in patients with chronic indwelling catheters). Their role as pathogens in otherwise healthy premenopausal woman with acute cystitis is less clear, with data from one study suggesting that enterococci recovered from midstream urine cultures were not predictive of bacteriuria in a subsequent catheterized specimen. The presence of leukocytes in the urine in conjunction with systemic manifestations (e.g., fever) or local signs and symptoms of infection with no other explanation and a positive urine culture ($\geq 10^5$ CFU/mL) suggests the diagnosis. Moreover, enterococcal UTIs often occur in critically or chronically ill patients whose comorbidities may obscure the diagnosis. In many cases, removal of the indwelling catheter may suffice to eradicate the organism without specific antimicrobial therapy. In rare circumstances, UTIs caused by enterococci may run a complicated course, with the development of pyelonephritis and perinephric abscesses that may be a portal of entry for bloodstream infections (see below). Enterococci are also known causes of chronic prostatitis, particularly in men whose urinary tract has been manipulated surgically or endoscopically. These infections can be difficult to treat since the agents most potent against enterococci (i.e., aminopenicillins and glycopeptides) penetrate prostatic tissue poorly. Chronic prostatic infection can be a source of recurrent enterococcal bacteremia.

Bacteremia and Endocarditis Bacteremia without endocarditis is another frequently encountered presentation of enterococcal disease. Intravascular catheters and other devices are commonly associated with these bacteremic episodes **(Chap. 147)**. Other well-known sources of enterococcal bacteremia include the gastrointestinal and hepatobiliary tracts; pelvic and intraabdominal foci; and, less frequently, wound infections, UTIs, and bone infections. In the United States, enterococci are ranked second (after staphylococci) as etiologic agents of central line–associated bacteremia. Patients with enterococcal bacteremia usually have comorbidities and have been in the hospital for prolonged periods; they commonly have received several courses of antibiotics. Several studies indicate that the isolation of *E. faecium* from the blood may lead to worse outcomes and higher mortality

rates than when other enterococcal species are isolated; this finding may be related to the higher prevalence of vancomycin and ampicillin resistance in *E. faecium* than in other enterococcal species, with the consequent reduction of therapeutic options. In some cases (usually when the gastrointestinal tract is the source), enterococcal bacteremia may be polymicrobial, with gram-negative organisms isolated at the same time. In addition, several cases have been documented in which enterococcal bacteremia was associated with *Strongyloides stercoralis* hyperinfection syndrome in immunocompromised patients.

Enterococci are important causes of community- and health care–associated endocarditis, ranking second after staphylococci in the latter infections, and recent studies have implicated *E. faecalis* as the leading cause of endocarditis after transcatheter aortic valve implantation (TAVI). The presumed initial source of bacteremia leading to endocarditis is the gastrointestinal or genitourinary tract—e.g., in patients who have malignant and inflammatory conditions of the gut or have undergone procedures in which these tracts are manipulated. The affected patients tend to be male and elderly and to have other debilitating diseases and heart conditions. Both prosthetic and native valves can be involved; mitral and aortic valves are affected most often. Community-associated endocarditis (usually caused by *E. faecalis*) also occurs in patients with no apparent risk factors or cardiac abnormalities. Endocarditis in women of childbearing age was well described in the past. The typical presentation of enterococcal endocarditis is a subacute course of fever, weight loss, malaise, and cardiac murmur; typical stigmata of endocarditis (e.g., petechiae, Osler's nodes, Roth's spots) are found in only a minority of patients. Atypical manifestations include arthralgias and manifestations of metastatic disease (splenic abscesses, hiccups, pain in the left flank, pleural effusion, and spondylodiscitis). Embolic complications are variable and can affect the brain. Heart failure is a common complication of enterococcal endocarditis, and valve replacement may be critical in curing this infection, particularly when multidrug-resistant organisms or major complications are involved. A clinical scoring system (DENOVA) has been proposed to help differentiate enterococcal bacteremia from true endocarditis and determine the need for echocardiography. The duration of therapy is usually 4–6 weeks, with more prolonged courses suggested for multidrug-resistant isolates in the absence of valvular replacement. Risk of relapse for endocarditis due to *E. faecalis* varies across studies, but it is higher in patients who are treated with antibiotics alone (2–11%) than in those who undergo surgery (0–3%); relapse may occur out to 1-year post-treatment.

Meningitis Enterococcal meningitis is an uncommon disease (accounting for only ~4% of meningitis cases) that is usually associated with neurosurgical interventions and conditions such as shunts, central nervous system (CNS) trauma, and cerebrospinal fluid (CSF) leakage. In some instances—usually in patients with a debilitating condition, such as cardiovascular or congenital heart disease, chronic renal failure, malignancy, receipt of immunosuppressive therapy, or HIV/AIDS—presumed hematogenous seeding of the meninges is seen in infections such as endocarditis or bacteremia. Fever and changes in mental status are common, whereas overt meningeal signs are less so. CSF findings are consistent with bacterial infection—i.e., pleocytosis, with a predominance of polymorphonuclear leukocytes (average, ~500/μL), an elevated serum protein level (usually >100 mg/dL), and a decreased glucose concentration (average, 28 mg/dL). Gram's staining yields a positive result in about half of cases, with a high rate of organism recovery from CSF cultures; the most common species isolated are *E. faecalis* and *E. faecium*. Complications include hydrocephalus, brain abscesses, and stroke. As mentioned before for bacteremia, an association with *Strongyloides* hyperinfection also has been documented.

Intraabdominal, Pelvic, and Soft Tissue Infections As mentioned above, enterococci are part of the commensal microbiota of the gastrointestinal tract and can produce spontaneous peritonitis in cirrhotic individuals and in patients undergoing chronic ambulatory peritoneal dialysis **(Chap. 137)**. These organisms are commonly found (usually along with other bacteria, including enteric gram-negative species and anaerobes) in clinical samples from intraabdominal and pelvic collections. The presence of enterococci in intraabdominal infections is sometimes considered to be of little clinical relevance. Several studies have shown that the role of enterococci in intraabdominal infections originating in the community and involving previously healthy patients is minor since surgery and broad-spectrum antimicrobial drugs that do not target enterococci are often sufficient to treat these infections successfully. In the past few decades, however, these organisms have become prominent as a cause of intraabdominal infections in hospitalized patients because of the emergence and spread of vancomycin resistance among enterococci and the increase in rates of nosocomial infections due to multidrug-resistant *E. faecium* isolates. In fact, several studies have now documented treatment failures due to enterococci, with consequently increased rates of postoperative complications and death among patients with intraabdominal infections. Thus, anti-enterococcal therapy is recommended for nosocomial peritonitis in immunocompromised and severely ill patients who have had a prolonged hospital stay, have undergone multiple procedures, have persistent abdominal sepsis and collections, or have risk factors for the development of endocarditis (e.g., prosthetic or damaged heart valves). Conversely, specific treatment for enterococci in the first episode of intraabdominal infection originating in the community and affecting previously healthy patients with no important cardiac risk factors for endocarditis does not appear to be beneficial.

Enterococci are commonly isolated from soft tissue infections **(Chap. 134)**, particularly those involving surgical wounds **(Chap. 147)**. In fact, these organisms rank third as agents of nosocomial surgical-site infections, with *E. faecalis* the most frequently isolated species. The clinical relevance of enterococci in some of these infections—as in intraabdominal infections—is a matter of debate; differentiating between colonization and true infection is sometimes challenging, although in some cases, enterococci have been recovered from lung, liver, and skin abscesses. Diabetic foot and decubitus ulcers are often colonized with enterococci and may be the portal of entry for bone infections.

Other Infections Enterococci are well-known causes of neonatal infections, including sepsis (mostly late-onset), bacteremia, meningitis, pneumonia, and UTI. Outbreaks of enterococcal sepsis in neonatal units have been well documented. Risk factors for enterococcal disease in newborns include prematurity, low birth weight, indwelling devices, and abdominal surgery. Enterococci have also been described as etiologic agents of bone and joint infections, including vertebral osteomyelitis, usually in patients with underlying conditions such as diabetes or endocarditis. Similarly, enterococci have been isolated from bone infections in patients who have undergone arthroplasty or reconstruction of fractures with the placement of hardware. Since enterococci can produce a biofilm that is likely to alter the efficacy of anti-enterococcal agents, treatment of infections that involve foreign material is challenging, and removal of the hardware may be necessary to eradicate the infection. Rare cases of enterococcal pneumonia, lung abscess, and spontaneous empyema have been described.

TREATMENT

Enterococcal Infections

GENERAL PRINCIPLES

Enterococci are intrinsically resistant and/or tolerant to several antimicrobial agents. (*Tolerance* is defined as lack of killing by drug concentrations 32 times higher than the minimal inhibitory concentration [MIC].) Monotherapy for endocarditis with a β-lactam antibiotic (to which many enterococci are tolerant) has produced disappointing results, with high relapse rates after the end of therapy. However, the addition of an aminoglycoside to a cell wall–active agent (a β-lactam or a glycopeptide) increases cure rates and eradicates the organisms; moreover, this combination is synergistic and bactericidal in vitro. Therefore, for many decades, combination therapy with a cell wall–active agent and an aminoglycoside was the standard of care for endovascular infections caused by enterococci. This synergistic effect can be explained, at least in part,

by the increased penetration of the aminoglycoside into the bacterial cell, presumably as a result of cell-wall alterations produced by the β-lactam (or glycopeptide). Nonetheless, attaining synergistic bactericidal activity in the treatment of severe enterococcal infections—particularly those caused by *E. faecium*—has become increasingly difficult because of the development of resistance to virtually all antibiotics available for this purpose.

The treatment of *E. faecalis* differs substantially from that of *E. faecium* **(Tables 154-1 and 154-2)**, mainly because of differences in resistance profiles (see below). For example, resistance to ampicillin and vancomycin is rare in *E. faecalis*, whereas these antibiotics are only infrequently useful against current isolates of *E. faecium*. Moreover, as a consequence of the challenges and therapeutic limitations posed by the emergence of drug resistance in enterococci, valve replacement may need to be considered in the treatment of endocarditis caused by multidrug-resistant enterococci. Less severe infections are often related to indwelling intravascular catheters; removal of the catheter increases the likelihood of enterococcal eradication by a subsequent short course of appropriate antimicrobial therapy.

CHOICE OF ANTIMICROBIAL AGENTS

Among the β-lactams, the most active are the aminopenicillins (ampicillin, amoxicillin); next most active are penicillin G, imipenem, and ureidopenicillins (i.e., piperacillin). Cephalosporins are not active as monotherapy. The only two aminoglycosides recommended for synergistic therapy in severe enterococcal infections are gentamicin and streptomycin. This is because the most common acquired enzyme conferring high-level resistance to gentamicin also is active against tobramycin and amikacin but not streptomycin, and the resistance mechanisms causing high-level resistance to streptomycin do not affect gentamicin. The use of amikacin is strongly discouraged because it is infrequently active, and tobramycin should never be used for the treatment of *E. faecium* infections due to the presence of a chromosomally encoded, species-specific, tobramycin-modifying enzyme. Aminoglycoside monotherapy should not be employed. Vancomycin is an alternative to β-lactam drugs for the treatment of *E. faecalis* infections but is less useful against *E. faecium* because resistance is common.

As mentioned above, use of the aminoglycoside–ampicillin combination for *E. faecalis* infections has become increasingly problematic because of toxicity in critically ill patients and increased rates of high-level resistance to aminoglycosides. An observational, nonrandomized, comparative study encompassing a multicenter cohort was conducted in 17 Spanish hospitals and 1 Italian hospital; the results indicated that a 6-week course of ampicillin plus ceftriaxone is as effective as ampicillin plus gentamicin in the treatment of *E. faecalis* endocarditis, with less risk of toxicity. Therefore, this regimen should be considered in patients at risk for aminoglycoside toxicity or those with isolates displaying high-level resistance to aminoglycosides, and it is now recommended as first-line therapy for *E. faecalis* endocarditis. Use of dual β-lactam regimens for ampicillin-susceptible isolates of *E. faecium* has not been studied in the clinical setting. Limited in vitro data suggest that synergism between ampicillin and ceftriaxone is not reliably active against these isolates.

Linezolid is the only agent approved by the U.S. Food and Drug Administration (FDA) for the treatment of VRE infections (Table 154-2). Linezolid is not bactericidal, and its use in severe endovascular infections has produced mixed results; therefore, it is recommended only as an alternative to other agents for such infections. In addition, linezolid may cause significant toxicities (thrombocytopenia, peripheral neuropathy, optic neuritis, and lactic acidosis) when used in regimens given for >2 weeks. Nonetheless, linezolid may play a role in the treatment of enterococcal meningitis and other CNS infections, although clinical data are limited.

The lipopeptide daptomycin is a bactericidal antibiotic with in vitro activity against all enterococci. Although daptomycin is not approved by the FDA for the treatment of VRE or *E. faecium*

TABLE 154-1 Suggested Regimens for the Management of Infections Caused by *Enterococcus faecalis*

CLINICAL SYNDROME	SUGGESTED THERAPEUTIC OPTIONS[a]
Endovascular infections (including endocarditis)	• Ampicillin[b] (12 g/d IV in divided doses q4h) plus ceftriaxone (2 g IV q12h) • Ampicillin[b] (12 g/d IV in divided doses q4h or by continuous infusion) or penicillin (18–30 mU/d IV in divided doses q4h or by continuous infusion) *plus* an aminoglycoside[c] • Vancomycin[d] (15 mg/kg IV per dose) plus an aminoglycoside[c] • High-dose daptomycin[e] ± another active agent[f] • Ampicillin[b] plus imipenem
Nonendovascular bacteremia[g]	• Ampicillin[b] (12 g/d IV in divided doses q4h) or penicillin (18 mU/d IV in divided doses q4h) ± an aminoglycoside[c] or ceftriaxone • Vancomycin[d] (15 mg/kg IV per dose) • High-dose daptomycin[e] ± another active agent[f] • Linezolid (600 mg IV/PO q12h)
Meningitis	• Ampicillin (20–24 g/d IV in divided doses q4h) or penicillin (24 mU/d IV in divided doses q4h) *plus* an aminoglycoside[c,h] and consider adding ceftriaxone (2 g IV q12h) • Vancomycin (500–750 mg IV q6h)[d] *plus* an aminoglycoside[c] or rifampin • Linezolid • High-dose daptomycin[e] (plus intrathecal daptomycin) ± another active agent[f]
Urinary tract infections (uncomplicated)	• Amoxicillin (500 mg PO q8h) • Fosfomycin (3 g PO, one dose)[i] • Ampicillin (500 mg IV or PO q6h) • Nitrofurantoin (100 mg PO q6h)

[a]Authors' preferences are underlined for each category; many of the regimens are off-label. [b]In rare cases, β-lactamase-producing isolates may be present. Because these isolates are not detected by conventional determination of the minimal inhibitory concentration, additional tests (e.g., the nitrocefin disk) are recommended for isolates from endocarditis. The use of ampicillin/sulbactam (12–24 g/d) is suggested in these cases. If choosing a β-lactam other than ampicillin for an invasive infection, susceptibility testing for penicillin should be performed to identify penicillin-resistant, ampicillin-susceptible (PRASEF) isolates. Limited in vitro data suggest that synergistic killing by dual β-lactams (i.e., ampicillin and ceftriaxone) may be compromised in PRASEF isolates. Some suggest caution with the combination of ampicillin and ceftriaxone in PRASEF isolates and would consider an alternate therapy (such as daptomycin plus ampicillin) guided by susceptibility testing in cases of persistent bacteremia or signs of clinical failure. [c]Only if the organism does not exhibit high-level resistance (HLR) to aminoglycosides. This test is performed by the clinical microbiology laboratory only for gentamicin or streptomycin (growth of enterococci on agar containing gentamicin [500 μg/mL] or streptomycin [2000 μg/mL]). If HLR is documented, the aminoglycoside will not act synergistically with the other agent in the combination. However, HLR to one of these aminoglycosides does not indicate resistance to the other agent (as reported individually). HLR to gentamicin implies lack of synergism with tobramycin and with amikacin. Gentamicin (1–1.5 mg/kg IV q8h) and streptomycin (15 mg/kg per day IV/IM in two divided doses) are the only two recommended aminoglycosides. [d]Vancomycin is recommended only as an alternative to β-lactam agents in cases of allergy or toxicity plus the inability to desensitize. Specific pharmacologic targets for trough concentrations have not been clinically evaluated in enterococcal bacteremia; trough concentrations of 15–20 mg/L have been associated with increased rates of nephrotoxicity. Vancomycin-resistant strains of *E. faecalis* have been reported. [e]Consider doses of 10–12 mg/kg once daily, adjusted for renal function. Monitoring of creatine phosphokinase levels is recommended throughout therapy because of possible rhabdomyolysis. [f]Potentially active agents may include an aminoglycoside (if HLR is not detected), ampicillin, ceftaroline, tigecycline, eravacycline, or a fluoroquinolone (which, if the isolate is susceptible, may be favored in meningitis). The presence of mutations in LiaFSR seems to increase susceptibility to ampicillin and ceftaroline, and combinations of daptomycin with these compounds are bactericidal in vitro against such strains. [g]In selected cases of catheter-associated bacteremia, removal of the catheter and a short course of therapy (~5–7 days) may be sufficient. A single positive blood culture that is likely to be associated with a catheter in a patient who is otherwise doing well may not require therapy after removal of the catheter. Patients at high risk for endovascular infections or with severe disease may benefit from synergistic combination therapy. [h]The addition of intrathecal or intraventricular therapy with gentamicin (2–10 mg/d) if the organism does not exhibit HLR or with vancomycin (10–20 mg/d) when the isolate is susceptible has been suggested by some authorities. The addition of systemic rifampin (a good CSF-penetrating agent) may be considered. The combination of ampicillin and ceftriaxone may have clinical benefit (by analogy with endocarditis), but no cases treated with this combination have been reported; the authors would use this combination. [i]Approved by the U.S. Food and Drug Administration only for uncomplicated urinary tract infections caused by vancomycin-susceptible *E. faecalis*.

TABLE 154-2 Suggested Regimens for the Management of Infections Caused by Vancomycin- and Ampicillin-Resistant *Enterococcus faecium*

CLINICAL SYNDROME	SUGGESTED THERAPEUTIC OPTIONS[a]
Endovascular infections (including endocarditis)	• High-dose daptomycin[b] plus another agent[c] ± an aminoglycoside[d] • Linezolid (600 mg IV q12h) • High-dose ampicillin (if MIC is ≤64 μg/mL) ± an aminoglycoside[d]
Nonendovascular bacteremia[e]	• High-dose daptomycin[b] ± another agent[c] ± an aminoglycoside[d] • Linezolid (600 mg IV q12h)
Meningitis	• Linezolid (600 mg IV q12h) ± another CSF-penetrating active agent[f] • High-dose daptomycin[b] (plus intraventricular daptomycin) ± another CSF-penetrating active agent[f,g]
Urinary tract infections	• Fosfomycin (3 g PO, one dose)[h] • Nitrofurantoin (100 mg PO q6h) • Ampicillin or amoxicillin (2 g IV/PO q4–6h)[i]

[a]Authors' preferences are underlined for each category; many of these regimens are off-label. [b]Daptomycin at doses of 10–12 mg/kg once daily is suggested (off-label). Close monitoring of creatine phosphokinase levels is recommended throughout therapy because of possible rhabdomyolysis. [c]Potentially active agents may include ampicillin or ceftaroline (even if the infecting strain is resistant in vitro), tigecycline, eravacycline, or a fluroquinolone. In vitro synergism of daptomycin with ampicillin or ceftaroline has been observed against some isolates that subsequently become nonsusceptible to daptomycin during therapy. The synergism of daptomycin and β-lactams is associated with mutations in LiaFSR. The authors prefer use of combination therapy for all endovascular infections or for bacteremic patients in whom source control cannot be achieved, as in vitro data suggest combination therapy may prevent or delay the emergence of daptomycin resistance. [d]Only if the organism does not exhibit high-level resistance to aminoglycosides (see Table 154-1, footnote *c*). [e]In selected cases of catheter-associated bacteremia, removal of the catheter and a short course of therapy (~5–7 days) may be sufficient. A single positive blood culture that is likely to be associated with a catheter in a patient who is otherwise doing well may not require therapy after removal of the catheter. [f]Fluoroquinolones (e.g., moxifloxacin) and rifampin (if the isolate is susceptible to each agent) reach therapeutic levels in the cerebrospinal fluid. [g]Intrathecal gentamicin (2–10 mg/d) if high-level resistance is not detected. Intraventricular daptomycin has been used in two cases of meningitis. [h]Approved by the U.S. Food and Drug Administration (FDA) only for uncomplicated urinary tract infections caused by vancomycin-susceptible *E. faecalis*. [i]Concentrations of amoxicillin and ampicillin in urine far exceed those in serum and may be potentially effective even against isolates with high MICs. Doses up to 12 g/d are suggested for isolates with MICs of ≥64 μg/mL. Of note, quinupristin-dalfopristin (Q-D) lost FDA approval for infections due to vancomycin-resistant *Enterococcus*, and it was discontinued by the manufacturer in 2022.

infections, it has been used alone (at high dosage) or in combination with other agents (ampicillin, ceftaroline, and tigecycline) with apparent success against multidrug-resistant enterococcal infections (Tables 154-1 and 154-2). The main adverse reactions to daptomycin are elevated creatine phosphokinase levels and eosinophilic pneumonitis (rare). Daptomycin is not useful against pulmonary infections because the pulmonary surfactant inhibits its antibacterial activity.

Several meta-analyses have examined the question of which agent should be preferred for VRE bacteremia—linezolid or daptomycin. These studies concluded either no difference between the two drugs or favored linezolid due to lower all-cause and infection-related mortality, but they were limited by small patient numbers and heterogenous outcomes. A subsequent large retrospective observational study from the Veterans Affairs database reported lower rates of all-cause mortality at 30 days and less microbiologic failure (i.e., positive cultures despite therapy) with daptomycin compared to linezolid. One important observation from these investigations is that the efficacy of daptomycin is dependent on the dose, with improved outcomes seen with high-dose daptomycin therapy (≥10 mg/kg) compared to standard-dose therapy (6 mg/kg). Genome sequencing of clinical isolates has revealed that mutations in genes associated with daptomycin resistance are not uncommon (see "Antimicrobial Resistance," below) and were associated with the emergence of resistance to daptomycin at lower simulated dosing regimens (6 mg/kg) in experimental models of infection. These data led the Clinical Laboratory and Standards Institute (CLSI) to change the daptomycin breakpoints in 2019. For *E. faecium*, all isolates with an MIC of ≤4 mg/L are placed in a "susceptible dose-dependent" category based on a dosing regimen of 8–12 mg/kg, while those with an MIC ≥8 mg/L are considered resistant. For all other enterococci, isolates are considered susceptible with an MIC of ≤2 mg/L, intermediate with an MIC of 4 mg/L, and resistant with an MIC ≥8 mg/L.

The glycylcycline drug tigecycline is active in vitro against all enterococci, regardless of the isolates' vancomycin susceptibility. However, its use as monotherapy for endovascular or severe enterococcal infections is not recommended because of low attainable blood levels. Newer-generation tetracyclines, such as eravacycline and omadacycline, also display in vitro activity, but their role in the treatment of enterococcal infections remains to be evaluated.

Telavancin, a lipoglycopeptide approved by the FDA for the treatment of skin and soft tissue infections as well as hospital-associated pneumonia, is active against vancomycin-susceptible enterococci but not VRE. Likewise, dalbavancin, a lipoglycopeptide antibiotic with a long terminal half-life, has FDA approval for skin and soft tissue infections due to susceptible strains of *E. faecalis*, but no activity against VRE. Oritavancin, a novel glycopeptide with activity against VRE, has been approved for the treatment of acute bacterial skin and soft tissue infections caused by susceptible organisms, including vancomycin-susceptible *E. faecalis*. The MICs of oritavancin against VRE are low, and this compound may be a promising drug for VRE treatment in the future.

Lastly, tedizolid—a new oxazolidinone now available for clinical use—is approved only for the treatment of *E. faecalis* infections. Tedizolid is more potent than linezolid in vitro against VRE strains; however, its role in severe VRE infections remains to be determined.

ANTIMICROBIAL RESISTANCE

Resistance to β-lactam agents continues to be observed only infrequently in *E. faecalis* but is characteristic of *E. faecium*. The mechanism of ampicillin resistance in *E. faecium* is related to a penicillin-binding protein (PBP) designated PBP5, which is the critical target of β-lactam antibiotics. PBP5 exhibits low affinity for ampicillin and can synthesize cell wall in the presence of this antibiotic, even when other PBPs are inhibited. The version of this protein found in ampicillin-resistant hospital-associated strains has multiple amino-acid differences that even further decrease the affinity of PBP5 for ampicillin; recent structural work has demonstrated that these changes lead to a more dynamic binding pocket with an increase in the hydrolysis of ampicillin at the active site, thus allowing for increased turnover of the enzyme. Increased production of PBP5 is also seen in high-level ampicillin-resistant (e.g., MIC >32 μg/mL) clinical strains. In *E. faecalis*, ampicillin resistance is extremely rare; however, an emerging phenotype of penicillin-resistant but ampicillin-susceptible *E. faecalis* (PRASEF) has been described. Similar to *E. faecium*, changes in the promoter of PBP4 (the *E. faecalis* homologue of PBP5) or the amino-acid sequence of the enzyme itself are associated with increases in the MIC of ampicillin (although still below the susceptible breakpoint), penicillin, piperacillin, and imipenem; in vitro data suggest that these changes may also impair the synergistic activity of ampicillin and ceftriaxone against some PRASEF isolates.

Vancomycin is a glycopeptide antibiotic that inhibits cell-wall peptidoglycan synthesis in susceptible enterococci and has been widely used against enterococcal infections in clinical practice when the utility of β-lactams is limited by resistance, allergy, or adverse reactions. This effect is mediated by binding of the antibiotic to peptidoglycan precursors (UDP-MurNAc-pentapeptides) upon their exit from the bacterial cell cytoplasm. The interaction of vancomycin with the peptidoglycan is specific and involves the last two D-alanine residues of the precursor. The first isolates of VRE were documented in 1986, and vancomycin resistance (particularly in *E. faecium*) has since increased considerably around the world.

The mechanism involves the replacement of the last D-alanine residue of peptidoglycan precursors with D-lactate (e.g., VanA and VanB) or D-serine (e.g., VanC), with consequent high- and low-level resistance, respectively. There is significant heterogeneity among isolates, but either substitution substantially decreases the affinity of vancomycin for the peptidoglycan; with the D-lactate substitution, the affinity for binding to the pentapeptide precursor is decreased by ~1000-fold. Vancomycin-resistant organisms also produce enzymes that destroy the D-alanine-D-alanine ending precursors, ensuring that additional binding sites for vancomycin are not available.

The genes encoding the machinery responsible for vancomycin resistance are located in the *van* operon and likely originated in soil bacteria. Several variants of the operon have been described, but VanA is the most common in clinical isolates in the United States, Latin America, and Europe, whereas VanB isolates are more frequent in Australia. Two enterococcal species, *E. gallinarum* and *E. casseliflavus*, have intrinsic low-level resistance to vancomycin due to the presence of the VanC operon in the chromosome.

High-level resistance to aminoglycosides (of which gentamicin and streptomycin are the only two tested by clinical laboratories) abolishes the synergism observed between cell wall–active agents and the aminoglycoside. This important phenotype is routinely sought by the clinical laboratory in isolates from serious infections (Tables 154-1 and 154-2). Genes encoding aminoglycoside-modifying enzymes are usually the cause of high-level resistance to these compounds and are widely disseminated among enterococci, decreasing the options for the treatment of severe enterococcal infections. Additionally, ribosomal methyltransferases, enzymes that methylate rRNA and, as a consequence, disrupt the binding site for aminoglycosides, also can lead to high-level resistance.

Resistance to daptomycin has now been well documented in both *E. faecalis* and *E. faecium*. Daptomycin exerts its action by complexing with calcium and binding to phosphatidylglycerol in the bacterial membrane. After binding, daptomycin forms oligomers, with recent data suggesting that it displaces enzymes important for cell envelope synthesis (MurG and PlsX) and that it can form a complex with lipid II molecules critical for cell-wall synthesis, among other effects on the membrane. Resistance to this antibiotic in enterococci arises via two main pathways. The first involves mutations in genes that coordinate the cell-wall and cell-membrane stress response, most commonly a three-component system designated LiaFSR (for *l*ipid II *i*nterfering *a*ntibiotics). These mutations lead to activation of the system, with increased expression of an extracellular protein known as LiaX capable of binding daptomycin and enhancing the signaling response. In clinical isolates, mutations in LiaFSR may lead to tolerance (loss of bactericidal activity)—usually in isolates with MICs near the daptomycin breakpoint (i.e., 3–4 mg/L). The second pathway involves changes in genes involved in phospholipid metabolism. It is thought that mutations priming the stress response system occur first, with the subsequent accrual of phospholipid changes leading to a fully resistant phenotype. Prior exposure to daptomycin has been identified as a risk factor for the emergence of daptomycin-resistant *E. faecium* in cancer patients. Resistance in the absence of exposure to the drug has also been well described, possibly due to the similarity of this antibiotic to antimicrobial peptides of the innate immune system. Thus, careful consideration of patient characteristics, bacterial phenotype, and daptomycin dose is warranted, and it is advisable to obtain infectious diseases consultation in complicated VRE infections.

The oxazolidinones (linezolid and tedizolid) act by binding to the ribosome and inhibiting the binding of aminoacyl-tRNAs, thus preventing protein synthesis. Resistance to this class of antibiotics is usually due to alterations of the binding site, either via mutations in the 23S rRNA genes or via the presence of an rRNA methylase. Since enterococci carry multiple copies of the gene encoding the 23S rRNA, prolonged exposure to oxazolidinones can select for increasing levels of resistance by favoring propagation of the resistance allele via recombination. Changes in accessory ribosomal proteins have also been associated with linezolid resistance and may act to mitigate the fitness defects of mutations in the rRNA. More concerning is the emergence of transferable resistance genes, which can readily move between enterococcal strains. Several of these genes were first recognized in bacterial isolates of animal origin, likely under the selective pressure of antibiotics such as florfenicol. The *cfr* (*c*hloramphenicol-*f*lorfenicol *r*esistance) gene encodes an rRNA methylase that modifies the 23S rRNA, leading to increases in the MIC of linezolid. Tedizolid tends to exhibit lower MICs in the presence of *cfr*; however, animal models suggest that some variants of the enzyme may compromise the activity of this drug. Two other transmissible resistance genes, *optrA* and *poxtA*, encode a ribosomal protection factor that has been implicated in linezolid resistance in enterococcal strains of human and animal origin. While still relatively rare to encounter in clinical practice, these determinants have been identified across the globe and could be an emerging source of resistance.

Newer tetracycline agents, such as tigecycline, omadacycline, and eravacycline, retain activity in the presence of typical tetracycline resistance determinants, including drug efflux pumps and ribosomal protection factors. However, resistance has been documented and appears to be related to changes in the S10 ribosomal protein, which is situated near the binding site for the drug.

Acknowledgment

The authors dedicate this chapter to the memory of Dr. Barbara Murray, a trailblazer in infectious diseases and a fearless leader. Dr. Murray was an exceptional scientist and an avid adventurer. She will be remembered as an everlasting mentor who touched many lives with her wisdom. Her indelible legacy will remain with us forever.

155 Diphtheria and Other Corynebacterial Infections

William R. Bishai, John R. Murphy

DIPHTHERIA

Diphtheria is a nasopharyngeal and skin infection caused by *Corynebacterium diphtheriae*. Toxigenic strains of *C. diphtheriae* produce a protein toxin that causes systemic toxicity, myocarditis, and polyneuropathy. The toxin is associated with the formation of pseudomembranes in the pharynx during respiratory diphtheria. While toxigenic strains most frequently cause pharyngeal diphtheria, nontoxigenic strains commonly cause cutaneous disease.

ETIOLOGY

C. diphtheriae is a gram-positive bacillus that is unencapsulated, nonmotile, and nonsporulating. The organism was first identified microscopically in 1883 by Klebs and a year later was isolated in pure culture by Löffler in Robert Koch's laboratory. The bacteria have a characteristic club-shaped bacillary appearance and typically form clusters of parallel rays, or *palisades*, that are referred to as "Chinese characters." The specific laboratory media recommended for the cultivation of *C. diphtheriae* rely upon tellurite, colistin, or nalidixic acid for the organism's selective isolation from other autochthonous pharyngeal microbes. *C. diphtheriae* may be isolated from individuals with both nontoxigenic (tox^-) and toxigenic (tox^+) phenotypes. Uchida and Pappenheimer demonstrated that corynebacteriophage beta carries the structural gene *tox*, which encodes diphtheria toxin, and that a family of closely related corynebacteriophages are responsible for toxigenic conversion of tox^- *C. diphtheriae* to the tox^+ phenotype. Moreover, lysogenic conversion from a nontoxigenic to a toxigenic phenotype has been shown to occur in situ. Growth of toxigenic strains of *C. diphtheriae* under iron-limiting conditions leads to the optimal expression of diphtheria toxin and is believed to be a pathogenic mechanism during human infection. Less commonly, diphtheria-like disease may be caused by *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis*, which express the same toxin and are considered members of the *C. diphtheriae* group (discussed below).

EPIDEMIOLOGY

While in many areas diphtheria has been controlled in recent years with effective vaccination, there have been sporadic outbreaks throughout the 1970s in the United States and the 1990s in Europe. Diphtheria is still common in parts of Africa, Asia, Latin America, and the Caribbean where mass immunization programs are not enforced. Large-scale epidemics of diphtheria have occurred in the post–Soviet Union independent states in the late 1990s and, more recently, in Nigeria and Yemen during 2022–2023. In temperate regions, respiratory diphtheria occurs year-round but is most common during winter months.

C. diphtheriae is transmitted via the aerosol route, usually during close contact with an infected person. Untreated individuals with respiratory diphtheria are thought to be infectious for ~18.5 days and the R_0 (basic reproduction number) is 1.7–4.3. There are no significant reservoirs other than humans. The mean incubation period for respiratory diphtheria is 1.4 days, but disease onset has occurred as late as 10 days after exposure. Prior to the vaccination era, most individuals over the age of 10 were immune to *C. diphtheriae*; infants were protected by maternal IgG antibodies but became susceptible after ~6 months of age. Thus, the disease primarily affected children and nonimmune young adults.

Cutaneous diphtheria is usually a secondary infection that follows a primary skin lesion due to trauma, allergy, or autoimmunity. Most often, these isolates lack the *tox* gene and thus do not express diphtheria toxin. In tropical latitudes, cutaneous diphtheria is more common than respiratory diphtheria. Toxin-producing diphtheria in symptomatic individuals, regardless of site (respiratory or cutaneous), is a reportable disease in the United States, while nontoxigenic disease is not. Nontoxigenic strains of *C. diphtheriae* have been associated with pharyngitis in Europe, causing outbreaks among men who have sex with men and persons who use illicit IV drugs.

The development of diphtheria antitoxin in 1898 by von Behring and of the diphtheria toxoid vaccine in 1924 by Ramon led to the near elimination of diphtheria in Western countries. The annual incidence rate in the United States peaked in 1921, with 206,000 cases (191 cases per 100,000) and 15,520 deaths. In contrast, current U.S. rates are exceeding low, with only 14 cases reported from 1996–2018, with the last case of respiratory diphtheria occurring in 2003 in a returning traveler from Haiti. Nevertheless, pockets of colonization persist in North America, and groups or individuals who resist vaccination remain at risk. Immunity to diphtheria induced by childhood vaccination gradually decreases in adulthood. An estimated 30% of men 60–69 years old have antitoxin titers below the protective level. In addition to older age and lack of vaccination, risk factors for diphtheria outbreaks include alcoholism, low socioeconomic status, crowded living conditions, and Native American ethnic background. An outbreak of diphtheria in Seattle, Washington, between 1972 and 1982 comprised 1100 cases, most of which were cutaneous. During the 1990s in the states of the former Soviet Union, a much larger diphtheria epidemic included more than 140,000 cases and more than 4000 deaths; at its peak in 1995, more than 50,412 cases were reported. Clonally related toxigenic *C. diphtheriae* strains of the ET8 complex were associated with this outbreak. Beginning in 1998, this epidemic was controlled by mass vaccination programs, and between 2000 and 2009, the diphtheria incidence fell by >95%, with high-burden countries such as Latvia reporting fewer than 10 cases.

Despite the World Health Organization (WHO) estimate that ~84% of the global population of children have been adequately vaccinated, 8638 diphtheria cases were reported globally in 2021, and many more cases are likely to have gone unreported. The recent coronavirus disease 2019 (COVID-19) pandemic, socioeconomic instability, migration, vaccine hesitancy, and other factors remain as threats to diphtheria control. For example, the WHO reported that the percentage of children who received three doses of diphtheria, tetanus, and pertussis immunization fell by 5% (86% to 81%) during 2019–2021 due to health system strains from COVID-19. Additionally, multiple European nations have reported high rates of diphtheria (often cutaneous disease) among unvaccinated asylum seekers, with West Africa and Afghanistan as common source regions.

PATHOGENESIS AND IMMUNOLOGY

Diphtheria toxin produced by tox^+ strains of *C. diphtheriae* is the primary virulence factor in clinical disease. The toxin is synthesized in precursor form; is released as a 535-amino-acid, single-chain protein; and, in sensitive species (e.g., guinea pigs and humans, but not mice or rats), has a 50% lethal dose of ~100 ng/kg of body weight. The toxin is produced in the pseudomembranous lesion in the pharynx and is taken up in the bloodstream with subsequent distribution to all organs. Once bound to its cell surface receptor (a heparin-binding epidermal growth factor–like precursor), the toxin is internalized by receptor-mediated endocytosis and enters the cytosol from an acidified early endosomal compartment. In vitro, the toxin may be separated into two chains by digestion with serine proteases: the N-terminal A fragment and the C-terminal B fragment. Delivery of the A fragment into the eukaryotic cell cytosol results in irreversible inhibition of protein synthesis by NAD^+-dependent ADP-ribosylation of elongation factor 2 and subsequent cell death.

In 1926, Ramon at the Institut Pasteur found that formalinization of diphtheria toxin resulted in the production of a nontoxic but highly immunogenic diphtheria toxoid. Subsequent studies showed that immunization with diphtheria toxoid elicited antibodies that neutralized the toxin and prevented most disease manifestations. In the 1930s, mass immunization of children and susceptible adults with diphtheria toxoid commenced in the United States and Europe.

Individuals with a diphtheria antitoxin titer of >0.01 U/mL are at low risk of disease. In populations where a majority of individuals have protective antitoxin titers, the carrier rate for toxigenic strains of *C. diphtheriae* decreases, and the overall risk of diphtheria among susceptible individuals is reduced. Nevertheless, individuals with nonprotective titers may contract diphtheria either through travel or exposure to individuals who have recently returned from regions where the disease is endemic.

Characteristic pathologic findings of diphtheria include mucosal ulcers with a pseudomembranous coating composed of an inner band of fibrin and a luminal band of neutrophils. Initially white and firmly adherent, in advanced diphtheria the pseudomembranes turn gray or even green or black as necrosis progresses. Mucosal ulcers result from toxin-induced necrosis of the epithelium accompanied by edema, hyperemia, and vascular congestion of the submucosal base. A significant fibrinosuppurative exudate from the ulcer develops into the pseudomembrane. Ulcers and pseudomembranes in severe respiratory diphtheria may extend from the pharynx into medium-sized bronchial

airways. Expanding and sloughing membranes may result in fatal airway obstruction.

APPROACH TO THE PATIENT

Diphtheria

Diphtheria, although rare in the United States and other developed countries, should be considered when a patient has severe pharyngitis, particularly when there is difficulty swallowing, respiratory compromise, or signs of systemic disease (e.g., myocarditis or generalized weakness). The leading causes of pharyngitis are respiratory viruses (rhinoviruses, influenza viruses, parainfluenza viruses, coronaviruses, adenoviruses; ~25% of cases), group A streptococci (15–30%), group C streptococci (~5%), atypical bacteria such as *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* (15–20% in some series), and other viruses such as herpes simplex virus (~4%) and Epstein-Barr virus (<1% in infectious mononucleosis). Less common causes are acute HIV infection, gonorrhea, fusobacterial infection (e.g., Lemierre's syndrome), thrush due to *Candida albicans* or other *Candida* species, and diphtheria. The presence of a pharyngeal pseudomembrane or an extensive exudate should prompt consideration of diphtheria **(Fig. 155-1)**.

CLINICAL MANIFESTATIONS

Respiratory Diphtheria The clinical diagnosis of diphtheria is based on the constellation of sore throat; adherent tonsillar, pharyngeal, or nasal pseudomembranous lesions; and low-grade fever. In addition, diagnosis requires the isolation of *C. diphtheriae* or histopathologic isolation of compatible gram-positive organisms. The Centers for Disease Control and Prevention (CDC) recognizes *confirmed* respiratory diphtheria (laboratory proven or epidemiologically linked to a culture-confirmed case) and *probable* respiratory diphtheria (clinically compatible but not laboratory proven or epidemiologically linked). Carriers are defined as individuals who have positive cultures for *C. diphtheriae* and who either are asymptomatic or have symptoms but lack pseudomembranes. Most patients seek medical care for sore throat and fever several days into the illness. Occasionally, weakness, dysphagia, headache, and voice change are the initial manifestations. Neck edema and difficulty breathing are evident in more advanced cases and carry a poor prognosis.

The systemic manifestations of diphtheria stem from the effects of diphtheria toxin and include weakness as a result of neurotoxicity and cardiac arrhythmias or congestive heart failure due to myocarditis. Most commonly, the pseudomembranous lesion is located in the tonsillopharyngeal region. Less commonly, the lesions are located in the larynx, nares, and trachea or bronchial passages. Large pseudomembranes are associated with severe disease and a poor prognosis. A few patients develop massive swelling of the tonsils and present with "bull-neck" diphtheria, which results from edema of the submandibular and paratracheal region and is further characterized by foul breath, thick speech, and stridorous breathing. The diphtheritic pseudomembrane is gray or whitish and sharply demarcated. Unlike the exudative lesion associated with streptococcal pharyngitis, the pseudomembrane in diphtheria is tightly adherent to the underlying tissues. Attempts to dislodge the membrane may cause bleeding. Hoarseness suggests laryngeal diphtheria, in which laryngoscopy may be diagnostically helpful.

Cutaneous Diphtheria This dermatosis is characterized by punched-out ulcerative lesions with necrotic sloughing or pseudomembrane formation **(Fig. 155-2)**. The diagnosis requires cultivation of *C. diphtheriae* from lesions, which most commonly occur on the lower and upper extremities, head, and trunk.

Infections Due to Non-*diphtheriae Corynebacterium* Species and Nontoxigenic *C. diphtheriae* Non-*diphtheriae* species of *Corynebacterium* and related genera (discussed below) as well as nontoxigenic strains of *C. diphtheriae* itself have been found in bloodstream and respiratory infections, often in individuals with immunosuppression or chronic respiratory disease. These organisms can cause disease manifestations and should not necessarily be dismissed as colonizers.

Other Clinical Manifestations *C. diphtheriae* causes rare cases of endocarditis and septic arthritis, most often in patients with preexisting risk factors, such as abnormal cardiac valves, injection drug use, or cirrhosis.

FIGURE 155-1 Respiratory diphtheria due to toxigenic *C. diphtheriae* producing exudative pharyngitis in a child displaying a pseudomembrane extending from the uvula to the pharyngeal wall. The characteristic white pseudomembrane is caused by diphtheria toxin–mediated necrosis of the respiratory epithelial layer, producing a fibrinous coagulative exudate. Submucosal edema adds to airway narrowing. The pharyngitis is acute in onset, and respiratory obstruction from the pseudomembrane may occur in severe cases. Inoculation of pseudomembrane fragments or submembranous swabs onto Löffler's or tellurite selective medium reveals *C. diphtheriae. (Photograph courtesy of the Centers for Disease Control and Prevention and Immunization Action Coalition, used by permission.)*

COMPLICATIONS

Airway obstruction poses a significant early risk in patients presenting with advanced diphtheria and accounts for 60–65% of deaths typically in the first 1–2 weeks after symptom onset. Pseudomembranes may slough and obstruct the airway or may advance to the larynx or into the tracheobronchial tree. Children are particularly prone to obstruction because of their small airways.

Cardiomyopathy and polyneuropathy are late toxic manifestations of diphtheria arising 1 week or more after respiratory symptoms. Based on systematic reviews, toxic cardiomyopathy accounted for 20–25% of deaths and is typically associated with arrhythmias and dilated cardiomyopathy.

Polyneuropathy is seen 3–5 weeks after the onset of diphtheria and has a slow indolent course but may account for 15% of deaths. Patients may develop severe and prolonged neurologic abnormalities. The disorders typically occur in the mouth and neck, with lingual or facial numbness as well as dysphonia, dysphagia, and cranial nerve paresthesias. More ominous signs include weakness of respiratory and abdominal muscles and paresis of the extremities. Sensory manifestations and sensory ataxia also are observed. Cranial nerve dysfunction typically precedes disturbances of the trunk and extremities because of proximity to the site of infection. Autonomic dysfunction also is associated with polyneuropathy and can lead to hypotension. Polyneuropathy is typically reversible in patients who survive the acute phase.

Other complications of diphtheria include pneumonia, renal failure, encephalitis, cerebral infarction, pulmonary embolism, and serum sickness from antitoxin therapy.

DIAGNOSIS

The diagnosis of diphtheria is based on clinical signs and symptoms plus laboratory confirmation. Respiratory diphtheria should be considered in patients with sore throat, pharyngeal exudates, and fever. Other symptoms may include hoarseness, stridor, or palatal paralysis. The presence of a pseudomembrane should prompt strong consideration of diphtheria. Once a clinical diagnosis of diphtheria is made, diphtheria antitoxin should be obtained and administered as rapidly as possible.

Laboratory diagnosis of diphtheria is based either on cultivation of *C. diphtheriae* or toxigenic *C. ulcerans* from the site of infection or on the demonstration of local lesions with characteristic histopathology. *Corynebacterium pseudodiphtheriticum*, a nontoxigenic organism, is a common component of the normal throat flora and does not pose a significant risk. Throat samples should be submitted to the laboratory for culture with the notation that diphtheria is being considered. This information should prompt cultivation on special selective medium and subsequent biochemical testing to differentiate *C. diphtheriae* from other nasopharyngeal commensal corynebacteria. All laboratory isolates of toxigenic *C. diphtheriae* should be reported to the state health department.

A diagnosis of cutaneous diphtheria requires laboratory confirmation since the lesions are not characteristic and are indistinguishable from other dermatoses. Diphtheritic ulcers occasionally—but not consistently—have a punched-out appearance (Fig. 155-2). Patients in whom cutaneous diphtheria is identified should have the nasopharynx cultured for *C. diphtheriae*. The laboratory medium for cutaneous diphtheria specimens is the same as that used for respiratory diphtheria: Löffler's or Tinsdale's selective medium in addition to nonselective medium such as blood agar. As has been mentioned, isolation of toxigenic strains of *C. diphtheriae* in symptomatic individuals is notifiable disease in the United States, regardless of the body site of origin.

TREATMENT

Diphtheria

DIPHTHERIA ANTITOXIN

Prompt administration of diphtheria antitoxin is critical in the management of respiratory diphtheria. Diphtheria antitoxin, a horse antiserum, is effective in reducing the extent of local disease as well as the risk of complications of myocarditis and neuropathy. Rapid institution of antitoxin therapy is also associated with a significant reduction in mortality risk. Because diphtheria antitoxin cannot neutralize cell-bound toxin, prompt initiation is important. This product, which is no longer commercially available in the United States, can be obtained from the CDC Emergency Operations Center at 770-488-7100 (*www.cdc.gov/diphtheria/hcp/dat/index.html*) after first contacting the state health department. The current protocol for the use of diphtheria antitoxin involves a test dose to rule out immediate hypersensitivity. Patients who demonstrate hypersensitivity require desensitization before a full therapeutic dose of antitoxin is administered.

Given that the world supply of equine anti–diphtheria toxin is limited, a human monoclonal antibody with the potential to provide a safer alternative to equine antitoxin therapy is being developed.

ANTIMICROBIAL THERAPY

Antibiotics are used in the management of diphtheria primarily to prevent transmission to susceptible contacts. Antibiotics also prevent further toxin production and may reduce the severity of local infection. Recommended treatment options for patients with respiratory diphtheria are as follows:

- Erythromycin, 500 mg IV q6h (for children: 40–50 mg/kg per day IV in two or four divided doses) until the patient can swallow comfortably; then 500 mg PO qid to complete a 14-day course
- Procaine penicillin G, 600,000 U IM q12h (for children: 12,500–25,000 U/kg IM q12h) until the patient can swallow comfortably; then oral penicillin V, 125–250 mg qid to complete a 14-day course

A clinical study in Vietnam found that penicillin was associated with a more rapid resolution of fever and a lower rate of bacterial resistance than erythromycin; however, relapses were more common in the penicillin group. Erythromycin therapy targets protein synthesis and thus offers the presumed benefit of stopping toxin synthesis more quickly than a cell wall–active β-lactam agent. Alternative therapeutic agents for patients who are allergic to penicillin or cannot take erythromycin include rifampin and clindamycin. Other reasonable antibiotics are clarithromycin, azithromycin, linezolid, and vancomycin, although they have not been studied in comparison to the agents above.

Eradication of *C. diphtheriae* should be documented after antimicrobial therapy is complete. A repeat throat culture 2 weeks later is recommended. For patients in whom the organism is not eradicated after a 14-day course of erythromycin or penicillin, an additional 10-day course followed by repeat culture is recommended. Drug-resistant strains of *C. diphtheriae* exist and are appearing at higher frequency; several reports have described multidrug-resistant strains. Drug resistance should be considered when efforts at pathogen eradication fail.

Cutaneous diphtheria should be treated as described above for respiratory disease. Individuals infected with toxigenic strains should receive antitoxin. It is important to treat the underlying cause of the dermatoses in addition to the superinfection with *C. diphtheriae*.

Patients who recover from respiratory or cutaneous diphtheria should have antitoxin levels measured. If diphtheria antitoxin has been administered, this test should be performed 6 months later. Patients who recover from respiratory or cutaneous diphtheria should receive the appropriate vaccine to ensure the development of protective antibody titers.

MANAGEMENT STRATEGIES

Patients in whom diphtheria is suspected should be hospitalized in respiratory isolation rooms with close monitoring of cardiac and respiratory function. A cardiac workup is recommended to assess the possibility of myocarditis. In patients with extensive pseudomembranes, an anesthesiology or an ear, nose, and throat

consultation is recommended because of the possible need for tracheostomy or intubation. In some settings, pseudomembranes can be removed surgically. Treatment with glucocorticoids has not been shown to reduce the risk of myocarditis or polyneuropathy.

PROGNOSIS

A systematic review of over 20 reported outbreaks found the diphtheria case fatality ratio among unvaccinated, untreated individuals to be 29%, with children under the age of 5 being at a 1.5-fold higher risk of mortality. Fatal pseudomembranous diphtheria typically occurs in patients with nonprotective antibody titers and in unimmunized patients. The pseudomembrane may actually increase in size from the time it is first noted. Risk factors for death include bullneck diphtheria; myocarditis with ventricular tachycardia; atrial fibrillation; complete heart block; an age of >60 years or <6 months; alcoholism; extensive pseudomembrane elongation; and laryngeal, tracheal, or bronchial involvement. Another important predictor of fatal outcome is the interval between the onset of local disease and the administration of antitoxin. Cutaneous diphtheria has a low mortality rate and is rarely associated with myocarditis or peripheral neuropathy.

PREVENTION

Vaccination Diphtheria toxoid-based vaccine efficacy is estimated to be 87% in the prevention of symptomatic disease, and sustained campaigns for vaccination of children and adequate boosting vaccination of adults are responsible for the exceedingly low incidence of diphtheria in most developed nations. Diphtheria toxoid vaccine has typically been coadministered with tetanus vaccine (with or without acellular pertussis). DTaP (full-level diphtheria toxoid, tetanus toxoid, and acellular pertussis vaccine) is currently recommended for children in five doses up to the age of 6 years; DTaP replaced the earlier whole-cell pertussis vaccine DTP in 1997. Tdap is a tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine formulated for adolescents and adults and is the recommended booster for children 11–12 years old. Tdap is recommended for all adults if they have not received it previously regardless of the interval since the last dose of Td (tetanus and reduced-dose diphtheria toxoids, adsorbed). Tdap vaccination is a priority for health care workers, pregnant women, adults anticipating contact with infants, and adults not previously vaccinated for pertussis. Adults who have received acellular pertussis vaccine should continue to receive decennial Td booster vaccinations. In 2018, a hexavalent vaccine that combined diphtheria-tetanus toxoids, acellular pertussis adsorbed (DTaP), inactivated poliovirus (IPV), *Haemophilus influenzae* type b (Hib) conjugate, and recombinant hepatitis B (HepB) known as DTaP-IPV-Hib-HepB was approved by the U.S. Food and Drug Administration; this product may be used to replace the initial three childhood doses of DTaP (2, 4, and 6 months) or as part of a catch-up schedule in children under 5 years old. **The vaccine schedule is detailed in Chap. 129.**

Prophylaxis Administration to Contacts Close contacts of diphtheria patients should undergo throat culture to determine whether they are carriers. After samples for throat culture are obtained, antimicrobial prophylaxis should be considered for all contacts, even those whose cultures are negative. The options are 7–10 days of oral erythromycin or one dose of IM benzathine penicillin G (1.2 million units for persons ≥6 years of age or 600,000 units for children <6 years of age).

Contacts of diphtheria patients whose immunization status is uncertain should receive the appropriate diphtheria toxoid–containing vaccine. The Tdap vaccine (rather than Td) is now the booster vaccine of choice for adults who have not recently received an acellular pertussis–containing vaccine. Carriers of *C. diphtheriae* in the community should be treated and vaccinated when identified.

OTHER CORYNEBACTERIAL AND *RHODOCOCCUS* INFECTIONS

Nondiphtherial corynebacteria, referred to as *diphtheroids* or *coryneforms*, are frequently considered colonizers or contaminants; however, they have been associated with invasive disease, particularly in immunocompromised patients. Importantly, even though they are termed nondiphtherial corynebacteria, *C. ulcerans* and *C. pseudotuberculosis* may produce diphtheria toxin and therefore cause severe human illness. These organisms have been isolated from the bloodstream, especially in association with catheter infection, endocarditis, prosthetic valve infection, meningitis, brain abscess, osteomyelitis, and peritonitis. Risk factors include indwelling intravenous or peritoneal catheters and neurosurgical shunts. Patients infected with these organisms are often immunosuppressed or have significant medical comorbidities. The nondiphtherial coryneforms are a collection of bacteria that are taxonomically grouped together in the genus *Corynebacterium* on the basis of their 16S rDNA signature nucleotides. Despite the shared rDNA signatures, these isolates are quite diverse. For example, their guanine-cytosine content ranges from 45 to 70%. Several nondiphtheroid corynebacteria, including *Corynebacterium jeikeium* and *Corynebacterium urealyticum*, are associated with resistance to multiple antibiotics. *Rhodococcus equi* is associated with necrotizing pneumonia and granulomatous infection, particularly in immunocompromised individuals.

MICROBIOLOGY AND LABORATORY DIAGNOSIS

These organisms are non-acid-fast, catalase-positive, aerobic or facultatively anaerobic rods. Their colonial morphologies on blood agar vary widely; some species are small and α-hemolytic (similar to lactobacilli), whereas others form large white colonies (similar to yeasts). Many nondiphtherial coryneforms require special media, such as Löffler's, Tinsdale's, or tellurite medium. These cultivation idiosyncrasies have led to a complex taxonomic categorization of the organisms.

EPIDEMIOLOGY

Humans are the natural reservoirs for several nondiphtherial coryneforms, including *C. xerosis, C. pseudodiphtheriticum*, *C. striatum*, *C. minutissimum*, *C. jeikeium*, *C. urealyticum*, and *Arcanobacterium haemolyticum*. Animal reservoirs including milk are responsible for carriage of *C. ulcerans* and *C. pseudotuberculosis*. Soil is the natural reservoir for *R. equi*.

CLINICAL MANIFESTATIONS

C. ulcerans This organism causes a diphtheria-like illness and produces both diphtheria toxin and a dermonecrotic toxin. The organism is a commensal in horses and cattle and has been isolated from cow's milk. In contrast to diphtheria, this infection is considered a zoonosis, and cases have been traced to contact with animal carriers, including dogs and pigs. *C. ulcerans* causes exudative pharyngitis, primarily during summer months, in rural areas, and among individuals exposed to animals. Treatment with antitoxin and antibiotics should be initiated when respiratory *C. ulcerans* is identified, and a contact investigation should be conducted (including throat cultures to determine the need for antimicrobial prophylaxis and, in unimmunized contacts, administration of the appropriate diphtheria toxoid–containing vaccine). The organism grows on Löffler's, Tinsdale's, and tellurite agars as well as blood agar. In addition to exudative pharyngitis, cutaneous disease due to *C. ulcerans* has been reported. *C. ulcerans* is susceptible to a wide panel of antibiotics. Erythromycin and other macrolides appear to be the first-line agents.

C. pseudotuberculosis Infection caused by *C. pseudotuberculosis* is an important animal pathogen (most notably of sheep) that rarely causes human disease. *C. pseudotuberculosis* causes suppurative granulomatous lymphadenitis and an eosinophilic pneumonia syndrome among individuals who handle sheep; horses, cattle, goats, deer, and raw milk has also been implicated. Surgical excision of affected lymph nodes should be performed when feasible, and successful treatment with erythromycin or tetracycline has been reported. Some strains express diphtheria toxin and produce a diphtheria-like disease, which should be treated with antitoxin.

***C. jeikeium* (Group JK)** Originally described in American hospitals, *C. jeikeium* infection was subsequently reported in Europe. After a 1976 survey of diseases caused by nondiphtherial corynebacteria,

CDC group JK emerged as an important opportunistic pathogen among neutropenic and HIV-infected patients. The organism has now been designated a separate species. *C. jeikeium* forms small, gray to white, glistening, nonhemolytic colonies on blood agar. It lacks urease and nitrate reductase and does not ferment most carbohydrates. The predominant syndrome associated with *C. jeikeium* is sepsis, sometimes with associated pneumonia, endocarditis, meningitis, osteomyelitis, or epidural abscess. Risk factors for *C. jeikeium* infection include hematologic malignancy, neutropenia from comorbid conditions, prolonged hospitalization, exposure to multiple antibiotics, and skin disruption. There is evidence that *C. jeikeium* is part of the inguinal, axillary, genital, and perirectal flora of hospitalized patients.

Broad-spectrum antimicrobial therapy appears to select for colonization. The organisms appear as gram-positive coccobacillary forms slightly resembling streptococci. *C. jeikeium* is resistant to the majority of antibiotic classes except oxazolidinones (e.g., linezolid) and glycopeptides (e.g., vancomycin). Effective therapy involves removal of the infectious source, whether a catheter, prosthetic joint, or prosthetic valve. Efforts have been made to prevent *C. jeikeium* infection with strict institution of infection control protocols for high-risk patients, particularly those in intensive care units.

***C. urealyticum* (Group D2)** Identified as a urease-positive nondiphtherial *Corynebacterium* in 1972, *C. urealyticum* is an opportunistic pathogen causing sepsis and urinary tract infection. *C. urealyticum* appears to be the etiologic agent of a severe urinary tract syndrome known as *alkaline-encrusted cystitis*, a chronic inflammatory bladder infection associated with deposition of ammonium magnesium phosphate on the surface and walls of ulcerating lesions in the bladder. In addition, *C. urealyticum* has been associated with pneumonia, peritonitis, endocarditis, osteomyelitis, and wound infection. It is similar to *C. jeikeium* in its resistance to most antibiotics except oxazolidinones and glycopeptides. Vancomycin therapy has been used successfully in severe infections.

***C. minutissimum* (Erythrasma)** Erythrasma is a cutaneous infection producing reddish-brown, macular, scaly, pruritic intertriginous patches. The dermatologic presentation under the Wood's lamp is of coral red fluorescence. *C. minutissimum* appears to be a common cause of erythrasma, although there is evidence for a polymicrobial etiology in certain settings. This microbe has also been associated with bacteremia in patients with hematologic malignancy. Erythrasma responds to topical erythromycin, clarithromycin, clindamycin, or fusidic acid, although more severe infections may require oral macrolide therapy.

Other Nondiphtherial Corynebacteria *C. xerosis* is a human commensal found in the conjunctiva, nasopharynx, and skin. This nontoxigenic organism is occasionally identified as a source of invasive infection in immunocompromised or postoperative patients and prosthetic joint recipients. *C. amycolatum* is a closely related species but tends to demonstrate more antibiotic resistance. *C. striatum* is found in the anterior nares, skin, face, and upper torso of healthy individuals. Also nontoxigenic, this organism has been associated with invasive opportunistic infections in severely ill or immunocompromised patients. *C. glucuronolyticum* is a nonlipophilic species that causes male genitourinary tract infections such as prostatitis and urethritis. These infections may be successfully treated with a wide variety of antibacterial agents, including β-lactams, rifampin, aminoglycosides, or vancomycin; however, the organism appears to be resistant to fluoroquinolones, macrolides, and tetracyclines. *C. imitans* has been identified in eastern Europe as a nontoxigenic cause of pharyngitis. *C. auris* has been identified in children with otitis media; it is susceptible to fluoroquinolones, rifampin, tetracycline, and vancomycin but resistant to penicillin G and variably susceptible to macrolides. *C. pseudodiphtheriticum* is a nontoxigenic species that is part of the normal human flora. Human infections—particularly endocarditis of either prosthetic or natural valves and invasive pneumonia—have been reported only rarely. Although *C. pseudodiphtheriticum* may be isolated from the nasopharynx of patients with suspected diphtheria, it is part of the normal flora and does not produce diphtheria toxin. *C. propinquum*, a close relative of *C. pseudodiphtheriticum*, is part of CDC group D-1 and has been isolated from the human respiratory tract and blood. *C. afermentans* and subspecies belong to CDC group ANF-1; it is a rare human pathogen that has been isolated from human blood and abscesses.

Rhodococcus *Rhodococcus* species are phylogenetically related to the corynebacteria. These gram-positive coccobacilli have been associated with tuberculosis-like infections in humans with granulomatous pathology. While *R. equi* is best known, other near-relative species have been identified in human infections including *R. fascians*, *R. erythropolis*, *R. rhodochrous*, *Gordonia bronchialis*, *G. sputi*, *G. terrae*, and *Tsukamurella paurometabola*.

R. equi has been recognized as a cause of pneumonia in horses since the 1920s and as a cause of related infections in cattle, sheep, and swine. It is found in soil as an environmental microbe. The organisms vary in length; appear as spherical to long, curved, clubbed rods; and produce large irregular mucoid colonies. *R. equi* cannot ferment carbohydrates or liquefy gelatin and is often acid fast. An intracellular pathogen of macrophages, *R. equi* can cause granulomatous necrosis and caseation. This organism has most commonly been identified in pulmonary infection, but infections of brain, bone, and skin also have been reported. Most commonly, *R. equi* disease manifests as nodular and/or cavitary pneumonia of the upper lobe—a picture similar to that seen in tuberculosis or nocardiosis. Most patients are immunocompromised, often by HIV infection. Subcutaneous nodular lesions also have been identified. The involvement of *R. equi* should be considered when any patient presents with a tuberculosis-like syndrome.

Infection due to *R. equi* has been treated successfully with antibiotics that penetrate intracellularly, including macrolides, clindamycin, rifampin, and trimethoprim-sulfamethoxazole. β-Lactam antibiotics have not been useful. The organism is routinely susceptible to vancomycin, which is considered the drug of choice.

Arcanobacteria *Arcanobacterium haemolyticum* was identified as an agent of wound infections in U.S. soldiers in the South Pacific during World War II. It appears to be a human commensal of the nasopharynx and skin, but it is known to cause true pharyngitis as well as chronic skin ulcers. In contrast to the much more common pharyngitis caused by *Streptococcus pyogenes*, *A. haemolyticum* pharyngitis is associated with a scarlatiniform rash on the trunk and proximal extremities in about half of cases; this illness is occasionally confused with toxic shock syndrome. Because *A. haemolyticum* pharyngitis primarily affects teenagers, it has been postulated that the rash–pharyngitis syndrome may represent co-pathogenicity, synergy, or opportunistic secondary infection with Epstein-Barr virus. *A. haemolyticum* has also been reported as a cause of bacteremia, soft tissue infections, osteomyelitis, and cavitary pneumonia, predominantly in the setting of underlying diabetes mellitus. The organism is susceptible to most β-lactams, macrolides, fluoroquinolones, clindamycin, vancomycin, and doxycycline. However, resistance to trimethoprim-sulfamethoxazole as well as tetracycline is common.

156 *Listeria monocytogenes* Infections

Karen P. Neil, Jennifer P. Collins, Patricia M. Griffin

Listeria monocytogenes is a ubiquitous environmental saprophyte and an intracellular pathogen in several animals. Humans develop *L. monocytogenes* infection—listeriosis—primarily through foodborne transmission. The clinical spectrum of listeriosis ranges from febrile gastroenteritis in healthy persons to invasive disease, including bacteremia and meningoencephalitis. The major risk groups for invasive disease are pregnant women and their neonates, older adults, and immunocompromised persons. Febrile gastroenteritis is rarely diagnosed because *Listeria* are not detected by routine stool cultures or in rapid diagnostic tests for stool specimens, so the term listeriosis generally refers to invasive infection.

MICROBIOLOGY

L. monocytogenes lives in soil and decaying vegetable matter. Numerous bird and mammal species are reservoirs. *L. monocytogenes* is a nonsporulating, facultatively anaerobic, short, gram-positive rod that grows well on blood agar, demonstrating small zones of β-hemolysis. Organisms sometimes appear gram-variable and resemble cocci, diplococci, or diphtheroids; this appearance can obscure the diagnosis. On light microscopy, *L. monocytogenes* demonstrates characteristic tumbling motility. It grows optimally at 30–37°C but can grow at refrigerator temperatures as low as 4°C. In addition to its ability to grow at cold temperatures, *Listeria*'s tolerance to low-pH and high-salt environments facilitates its environmental survival. Serotypes are usually determined on the basis of somatic (O) and flagellar (H) antigens. Nearly all human illness is caused by serotypes 1/2a, 1/2b, and 4b.

PATHOGENESIS

Infection with *L. monocytogenes* typically occurs through ingestion of contaminated food. The infectious dose has not been well established but is likely to be very low for persons with severely impaired cellular immunity. Increased gastric pH, such as that due to proton pump inhibitors, probably promotes the organism's survival in the gastrointestinal tract. After transcytosis across the intestinal epithelium, the bacteria travel via mesenteric lymph nodes and the bloodstream to the liver and spleen, its target organs; dissemination to other organs can occur. *L. monocytogenes* can also migrate across the blood-brain barrier and the placenta.

Virulence factors include internalins (InlA, InlB), which promote invasion into normally nonphagocytic host cells. A pore-forming cytolysin (listeriolysin O; LLO) and phospholipases facilitate evasion of intracellular killing by mediating escape from the internalization vacuole into the cell cytosol. The surface protein ActA facilitates direct cell-to-cell movement within the cytosol, allowing *L. monocytogenes* to avoid encountering components of the host immune system, such as antibodies and complement, during dissemination. Iron promotes growth of the organism in vitro, an effect that explains why listeriosis has been associated with iron-overload conditions, including hemochromatosis.

IMMUNE RESPONSE

Although *L. monocytogenes* is ubiquitous in the environment, infection is rare because of both innate and adaptive host immune responses. Studies of mice have contributed to a detailed understanding of the immune response to infection. Activation of innate immunity is important for host survival. Interferon γ and tumor necrosis factor α (TNF-α) are among the key cytokines involved in this response. T cells are the primary drivers of the adaptive immune response, furthering the clearance of infected cells. Cytotoxic (CD8+) T cells are the main contributors to long-term immunity.

These immune mechanisms explain the association between invasive listeriosis and immunocompromising conditions, particularly impaired cellular immunity. In light of numerous reports of invasive listeriosis in patients treated with TNF-α inhibitors, the U.S. Food and Drug Administration added listeriosis to the boxed warning for this drug class. Because *L. monocytogenes* induces a vigorous cell-mediated immune response, attenuated strains that express foreign antigens are undergoing clinical trials as a cancer immunotherapy.

EPIDEMIOLOGY

L. monocytogenes was first reported as a human pathogen in 1929. Foodborne transmission was not identified until over 50 years later, when a 1983 outbreak investigation implicated coleslaw. It is now known that *L. monocytogenes* transmission is almost always foodborne. Listeriosis is a nationally notifiable disease in the United States. According to the Centers for Disease Control and Prevention's (CDC's) Foodborne Diseases Active Surveillance Network (FoodNet), the incidence of invasive listeriosis was 2.1–3.3 cases per million persons during 2011–2022 **(Fig. 156-1)**. Although illness is uncommon, listeriosis is a substantial contributor to morbidity from foodborne illness because virtually all patients are hospitalized and 18% die.

Only about 3% of reported cases of listeriosis are part of a recognized outbreak—i.e., have a source determined; however, outbreak investigations provide data on major foods linked to illness. Strains of *L. monocytogenes* have survived in production facilities for years. Refrigerated, ready-to-eat foods are of particular concern because the organism's ability to grow at refrigerator temperatures can result in a small amount of contamination during production growing to much higher levels. PulseNet, the laboratory network for bacterial foodborne disease surveillance, implemented routine subtyping for *L. monocytogenes* in the United States in 1998 and transitioned to whole-genome sequencing in 2013. Improvements in the ability to detect and investigate outbreaks using laboratory-based surveillance has provided more information on known food sources and facilitated recognition of new food sources.

Hot dogs and deli meats were the major sources of U.S. outbreaks until after 2002, when an outbreak linked to turkey deli meat resulted in eight deaths and the recall of >30 million pounds of meat. After that outbreak, the U.S. Department of Agriculture's Food Safety and Inspection Service (FSIS) issued new regulations requiring validated *L. monocytogenes* control programs and intensified testing for *L. monocytogenes* in ready-to-eat meat and poultry plants. Isolations of *L. monocytogenes* from ready-to-eat meats continued to decline during 2003–2012 (Fig. 156-1), and outbreaks linked to these products decreased. However, the incidence of listeriosis, which had declined markedly from 1989 through 2001, has not declined significantly since the measures were implemented (Fig. 156-1). Dairy products remain an important source, especially soft cheese made with raw (unpasteurized) milk or produced from pasteurized milk in unsanitary facilities; ice cream and raw milk also have caused outbreaks. Raw produce has been increasingly linked to outbreaks; implicated items include packaged salad, sprouts, enoki mushrooms, cantaloupe and other fruit, caramel apples, and frozen vegetables.

Most people with invasive listeriosis are older adults, whose risk increases with each decade over 59 years of age. Most other patients have impaired cellular immunity associated with hematologic malignancy, solid organ or bone marrow transplantation, HIV infection, or receipt of glucocorticoid or other immunosuppressive drugs. The group at highest risk of infection is pregnant women, who almost always have only mild flulike symptoms but who transmit the infection to the fetus through the placenta. Some neonates may acquire infection in the hospital, as illustrated by an outbreak associated with contaminated mineral oil. Rarely, children and adults with no recognized risk factors develop invasive listeriosis, probably through highly contaminated food.

The diagnosis of listeriosis in a hospitalized patient with new symptoms should prompt investigation into the food provided during hospitalization as a source. In fact, outbreaks have been traced to food served to hospitalized patients, especially those with immunocompromising

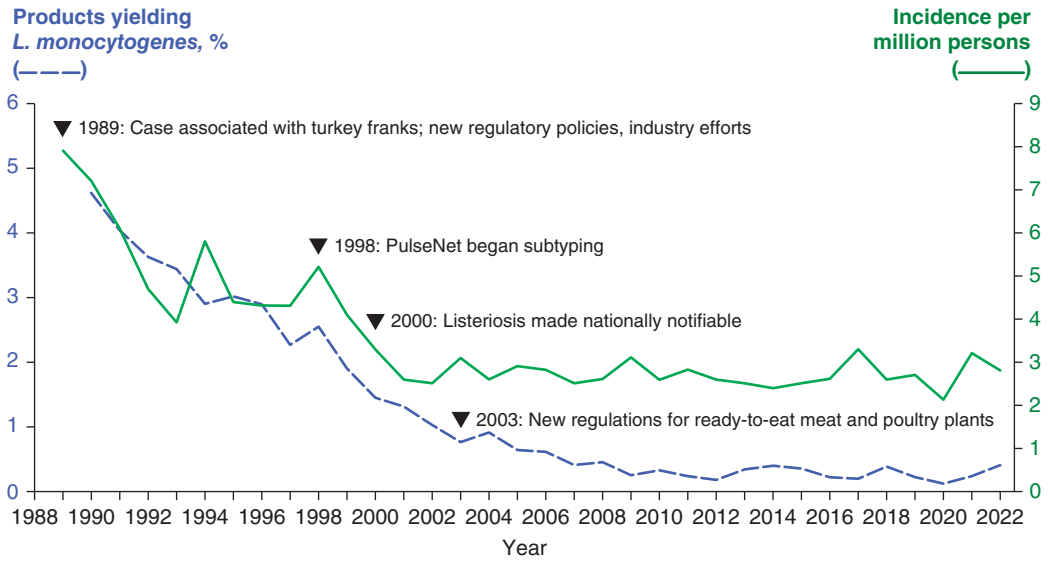

FIGURE 156-1 Incidence of listeriosis and percentage of ready-to-eat meat and poultry products from Food Safety and Inspection Service (FSIS) testing with cultures that yielded *L. monocytogenes*, United States, 1989–2022. Incidence data are from the Centers for Disease Control and Prevention's active sentinel site surveillance and include data from an early surveillance system (1986–1995) and from the Foodborne Diseases Active Surveillance Network (FoodNet) database (1996–2022). The incidence was 7.3 cases per million in 1986. Product data for 1990–2022 are from the U.S. Department of Agriculture Food Safety and Inspection Service Microbiological Testing Program for Ready-to-Eat Meat and Poultry Products and related publications (P Levine et al: J Food Prot 64:1188, 2001; SW Mamber et al: J Food Prot 83:1598, 2020; and the 2010 FSIS Comparative Risk Assessment for *L. monocytogenes* in RTE Meat and Poultry Deli Meats).

conditions; implicated foods include sandwiches, butter, precut celery, Camembert cheese, sausage, tuna salad, and ice cream. Although very rare, transmission of *L. monocytogenes* has also occurred through transfusion of platelet products, and febrile illness with bacteremia has occurred in persons who received an attenuated strain as a vaccine vector.

Listeriosis is an important problem worldwide. A large 2017–2018 outbreak of listeriosis in South Africa, linked to a ready-to-eat processed meat product, disproportionately affected people living with HIV and pregnant women. No outbreak-associated cases were detected in the 15 countries that imported the product; this discrepancy suggests that listeriosis is underrecognized in low- to middle-income countries, particularly those with a high prevalence of HIV infection.

CLINICAL MANIFESTATIONS

L. monocytogenes infection can manifest in several ways. The incubation period differs according to host factors and dose consumed: on average, this interval is <24 h for gastroenteritis and ~11 days for invasive disease, although it can be much longer. Data from outbreak investigations suggest that the incubation period is longer in pregnant women than in nonpregnant adults.

Febrile Gastroenteritis *Listeria* organisms typically pass through healthy people without causing symptoms, but acute febrile gastroenteritis can occur. Outbreak investigations of *L. monocytogenes* febrile gastroenteritis have identified high organism density in implicated foods, suggesting that a large inoculum must be ingested to cause illness. Major manifestations are fever, diarrhea, headache, and constitutional symptoms. Illness is usually self-limited, with symptoms lasting an average of 1–3 days.

Bacteremia Bacteremia without a focus is the most common manifestation of invasive listeriosis. Major features are fever, chills, myalgias, and arthralgias, sometimes preceded by nausea or diarrhea—markers of the initial gut infection. Bacteremia can cause neurolisteriosis or localized infection at other sites, in which case the diagnosis may be suggested by neurologic or other focal findings. In a large French cohort study, the 3-month mortality rate for *L. monocytogenes* bacteremia was 46%; factors associated with death included multiorgan failure, neoplasia, worsening of preexisting comorbidities, monocytopenia (<200 cells/μL), older age, and female sex.

Neurolisteriosis *L. monocytogenes* has an affinity for the central nervous system. Neurolisteriosis is the second most common manifestation of invasive listeriosis. Signs of meningitis along with altered mental status, seizures, or focal neurologic findings suggest meningoencephalitis. A French cohort study found that 84% of patients with neurolisteriosis presented with meningoencephalitis.

The onset of neurologic disease can be sudden or subacute and occur over several days. Patients typically present with signs and symptoms similar to those in other bacterial meningitides. Compared with other bacterial meningitides, cerebrospinal fluid (CSF) pleocytosis and CSF neutrophil predominance are typically less pronounced; most patients (~60–75%) have CSF white blood cell counts of <1000/μL, but some have high levels. Approximately 30–40% of patients have low CSF glucose levels. Gram's staining of CSF sediment can show the expected gram-positive rods but commonly shows no organisms and sometimes shows gram-positive cocci, diplococci, or diphtheroids. In a U.S. study, *L. monocytogenes* caused <5% of cases of community-acquired bacterial meningitis in adults.

Uncommon neurolisteriosis manifestations include cerebritis, focal abscess, and rhombencephalitis (encephalitis of the cerebellum and brainstem). Patients with macroscopic abscesses often have positive blood cultures, but CSF findings may be normal in the absence of concurrent meningitis. Abscesses may be misdiagnosed as a primary or metastatic malignancy; they rarely occur in the cerebellum or spinal cord. Rhombencephalitis disproportionately affects otherwise healthy older adults. The classic presentation is biphasic, beginning with fever and headache and continuing after several days with signs of brainstem or cerebellar involvement, such as asymmetric cranial nerve palsies, ataxia, tremor, hemiparesis, or hemisensory deficits. Nearly half of patients with rhombencephalitis experience respiratory failure. The diagnosis may be delayed by the subacute course and by CSF findings, which are often only minimally abnormal. Magnetic resonance imaging (MRI) is superior to computed tomography (CT) for the diagnosis of neurolisteriosis, including rhombencephalitis.

Overall, the 3-month mortality rate for neurolisteriosis was 30% in a French cohort study; death was associated with the same risk factors as those documented for bacteremia. Neurolisteriosis-associated mortality was also higher among patients with a positive blood culture and among those treated with dexamethasone. Nearly half of survivors had long-term neurologic impairment.

Focal Infections Hematogenous dissemination of *L. monocytogenes* infrequently causes endocarditis, pneumonia, localized abscesses in the liver or other internal organs, peritonitis, septic arthritis, osteomyelitis, urinary tract infection, or skin lesions. Direct inoculation has

been reported as a rare cause of ocular infection, skin infection, and lymphadenitis.

Infection in Pregnant Women and Neonates The risk of *Listeria* infection during pregnancy is increased due to impaired maternal cell-mediated immunity. Pregnancy-associated listeriosis is most common in the third trimester, although this may in part reflect underdiagnosis of earlier infections. Typically, pregnant women are either asymptomatic or have a mild, flulike illness with fever, headache, myalgias, or arthralgias. Neurolisteriosis and death are rare in pregnant women without other risk factors. Although nearly all infected women fully recover, only a minority (~5%) have a normal delivery and postpartum course, and three-quarters of the live-born infants are ill. In a French cohort study with 107 pregnancies in which *L. monocytogenes* was isolated from the mother, fetus, or neonate, 24% ended with fetal loss, 45% with premature birth, 6% with late-onset listeriosis in the neonate, and 21% with term delivery with fever or signs of fetal distress (i.e., meconium release into amniotic fluid, abnormal fetal heart rate). Fetal loss is uncommon after 29 weeks of gestation. Granulomatosis infantiseptica is a severe in utero infection caused by *L. monocytogenes* and characterized by disseminated microabscesses and granulomas in the skin, liver, and spleen; most infants with this condition are stillborn or die soon after birth. Neonatal listeriosis usually manifests in one of two ways: early-onset sepsis is hypothesized to result from in utero infection because it is typically diagnosed within 48 h after birth and is often associated with prematurity, whereas late-onset meningitis is thought to result from infection acquired at or soon after birth because it is typically diagnosed at ~2 weeks of age in full-term infants. A recent update from the above study that included additional years of data found that 70% of the 189 live-born infants developed early-onset listeriosis and 6% developed late-onset listeriosis; the other infants appeared uninfected (i.e., had negative cultures) and were well (14%) or had nonspecific signs (10%) that the authors attributed likely to prematurity. Overall, 3% of the 189 live-born infants died.

DIAGNOSIS

Because symptoms of listeriosis overlap with those of other infections, a high index of suspicion can facilitate timely diagnosis. Pregnant women with suspected listeriosis should have blood drawn for cultures, although blood cultures are positive only about half the time. Isolation of *L. monocytogenes* from a normally sterile site, such as blood, CSF, amniotic fluid, placental tissue, or fetal tissue, is diagnostic. *Listeria* must be distinguished from other gram-positive rods, especially diphtheroids. *L. monocytogenes* can be isolated from sterile specimens on routine medium; selective enrichment medium (such as PALCAM *Listeria* Selective Agar or Oxford Agar) enhances the capacity for isolation of the organism from nonsterile specimens, such as stool. Stool culture is not indicated in the evaluation of invasive listeriosis; culture on selective medium can be helpful for outbreak investigations of febrile gastroenteritis. Commercially available multiplex polymerase chain reaction panels for CSF specimens include *L. monocytogenes* as a target and may be a useful adjunct to culture. Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry can rapidly identify an isolate as *L. monocytogenes.* Whole-genome sequencing has been a valuable tool for solving outbreaks, including a nosocomial outbreak associated with ice cream served in hospital milkshakes.

TREATMENT

Infections Caused by *Listeria monocytogenes*

L. monocytogenes treatment has not been evaluated in clinical trials. Recommendations are based on in vitro animal studies and observational clinical data. High-dose ampicillin (adult dose, 2 g IV every 4 h) or penicillin G (adult dose, 4 million units IV every 4 h) constitutes first-line therapy. Because penicillins are only weakly bactericidal against *L. monocytogenes*, many experts recommend adding gentamicin for synergy (1.0–1.7 mg/kg every 8 h if renal function is normal), particularly if the infection is severe. Small studies have had varying results with regard to the benefits of gentamicin. A large study provided evidence favoring amoxicillin-gentamicin as first-line therapy. Patients who are allergic to penicillin should undergo desensitization or be treated with trimethoprim-sulfamethoxazole (TMP-SMX; 5 mg/kg per dose of the trimethoprim component, given IV every 6–12 h). TMP-SMX should be avoided during the first trimester because it has been associated with neural tube and cardiovascular defects and in the perinatal period because it may increase the risk of kernicterus. Resistance to TMP-SMX has been reported; thus, antibiotic susceptibility testing should be performed if this drug is considered. Treatment failures have been reported with meropenem despite in vitro susceptibility of the organism. *L. monocytogenes* is susceptible in vitro to several other drugs, including vancomycin, linezolid, tetracycline, macrolides, and fourth-generation fluoroquinolones (e.g., moxifloxacin), but relevant clinical reports are limited. Cephalosporins are not effective. A study with 252 patients with neurolisteriosis found significantly reduced survival rates among the 32 patients treated with adjunctive dexamethasone; the authors suggest avoiding this drug in neurolisteriosis. Prepartum antibiotic treatment of pregnant women with listeriosis, initiated at least 1 day before delivery, enhances the chance of delivering a healthy infant.

The optimal duration of antibiotic therapy has not been established. Treatment duration usually depends on the clinical syndrome, disease severity, patient attributes, and response to treatment. The typical minimal treatment duration is 2 weeks for bacteremia, 2 weeks for early-onset neonatal disease, 3 weeks for meningitis, 4–6 weeks for endocarditis, and 6–8 weeks for brain abscess or encephalitis. Longer courses may be needed when patients are immunocompromised or are not improving as expected. Patients with neurolisteriosis do not routinely require a follow-up lumbar puncture if they are improving clinically during antibiotic therapy.

PREVENTION

Implementation of general precautions to prevent foodborne illness can help prevent listeriosis. These measures include fully cooking meats; washing fresh produce; cleaning hands, utensils, and kitchen surfaces after handling uncooked foods; and avoiding unpasteurized dairy products. Persons at increased risk for listeriosis should take additional precautions, including avoiding unpasteurized milk, soft cheeses (particularly those made with unpasteurized milk), refrigerated pâté or meat spreads, and premade deli salads (e.g., coleslaw; potato, tuna, or chicken salad). Hot dogs, fermented or dry sausages, and refrigerated, ready-to-eat delicatessen foods (e.g., smoked fish, deli meat, cheese sliced at a deli) should be avoided or heated until the internal temperature is 165°F or until they are steaming hot. Additional CDC recommendations can be found at *www.cdc.gov/listeria/prevention.html.* Testing and treatment are not indicated for an asymptomatic person who has eaten a product recalled because of *L. monocytogenes* contamination, even if the person has risk factors for invasive listeriosis. Hospital dietary services should implement safe food-preparation procedures for immunocompromised patients and should not serve these patients higher-risk foods. Care of patients with listeriosis includes only standard precautions because person-to-person transmission is rare. TMP-SMX given as prophylaxis for *Pneumocystis jirovecii* infection (e.g., to people infected with HIV or organ transplant recipients) helps prevent listeriosis.

157 Tetanus

C. Louise Thwaites, Hai Duong Ha Thi

Tetanus is a preventable disease manifested by skeletal muscle spasms and autonomic nervous system disturbance. It is caused by a powerful neurotoxin produced by the bacterium *Clostridium tetani*, which is found globally. Tetanus commonly occurs in areas with low vaccination coverage. In developed countries, the disease is seen occasionally in individuals who are incompletely vaccinated. Even though the mortality rate has decreased significantly over the past two decades, the disease causes around 50,000 deaths annually worldwide. The mortality rate of tetanus varies depending on staff skills, clinical practices, and equipment capacity.

DEFINITION

Tetanus diagnosis is based on clinical manifestations with limited supportive laboratory confirmation. Case definitions are often used to facilitate clinical and epidemiologic assessments. The Centers for Disease Control and Prevention (CDC) defines probable tetanus as "in the absence of a more likely diagnosis, an acute illness with muscle spasms or hypertonia, and diagnosis of tetanus by a health care provider." *Neonatal* tetanus is defined by the World Health Organization (WHO) as "an illness occurring in a child who has the normal ability to suck and cry in the first 2 days of life but who loses this ability between days 3 and 28 of life and becomes rigid and has spasms." Given the unique presentation of neonatal tetanus, the history generally permits accurate classification of the illness with a high degree of probability. *Maternal* tetanus is defined by the WHO as "tetanus during pregnancy or within 6 weeks after the end of pregnancy (whether with birth, miscarriage, or abortion)."

ETIOLOGY

C. tetani is an anaerobic, gram-positive, spore-forming rod whose spores are highly resilient and can survive readily in the environment throughout the world. The spores resist boiling and many disinfectants. *C. tetani* spores and bacilli survive in the intestinal systems of many animals, and fecal carriage is common. The spores or bacteria enter the body through abrasions, wounds, or the umbilical stump (in the case of neonates). Once in a suitable anaerobic environment, the organisms grow, multiply, and release tetanus toxin that enters the nervous system and causes disease.

Approximately 20–30% tetanus cases have unclear entry wounds. Superficial abrasions to the limbs are the most common entry sites in adults. Deeper injuries or infections (e.g., open fractures, drug injection) are associated with more severe clinical presentations. Home delivery with unhygienic umbilical cutting and inadequate umbilical-cord care are the main causes of neonatal tetanus. Circumcision or ear-piercing also can result in neonatal tetanus.

Tetanus occurs when immunity is lacking. Unvaccinated individuals or those with incomplete vaccination history are at increased risk of developing tetanus.

EPIDEMIOLOGY

The incidence of tetanus has decreased gradually over the past few decades as vaccine coverage has increased. This disease is rare in developed countries. In 2022, 28 tetanus cases were reported in the United States. Most tetanus cases occur in individuals who have not received recommended tetanus vaccinations and booster shots every 10 years.

In the United States between 2009 and 2017, tetanus cases occurred primarily in those between the ages of 20 and 64 (64%), with only 13% of cases occurring in those younger than 20. Three cases of neonatal tetanus were reported in this period. Diabetes and intravenous drug use were associated with increased tetanus risk.

The global incidence of neonatal tetanus has reduced significantly following a concerted elimination program by WHO partnering with the United Nations Children's Fund (UNICEF) and the United Nations Population Fund (UNFPA); however, approximately 25,000 neonates with tetanus died in 2018. The incidence of tetanus among older children and adults (who have a high risk of tetanus due to the deterioration of immunity and lack of booster shots) is unknown. As few countries have good surveillance systems, in 2015, there were estimated to be between 30,000 and 62,000 deaths from tetanus in older children and adults.

PATHOGENESIS

Genome sequencing of *C. tetani* has allowed identification of several exotoxins and virulence factors. Only those bacteria producing tetanus toxin can cause tetanus. Tetanus toxin undergoes retrograde transport into the central nervous system (CNS) and thus produces clinical effects.

Tetanus toxin is intra-axonally transported to motor nuclei of the cranial nerves or ventral horns of the spinal cord. This toxin is produced as a single 150-kDa protein that is cleaved to produce heavy (100-kDa) and light (50-kDa) chains linked by a disulfide bond and noncovalent forces. The carboxy terminal of the heavy chain binds to specific membrane components in presynaptic α-motor nerve terminals; evidence suggests binding to both polysialogangliosides and membrane proteins. This binding results in toxin internalization and uptake into the nerves. Once inside the neuron, the toxin enters a retrograde transport pathway, whereby it is carried proximally to the motor neuron body. It is known that tetanus toxin exhibits several different pH-dependent conformations and therefore can interact with a variety of different receptors. During its passage from the periphery to the central nervous system, tetanus toxin can access neuronal trafficking systems and evade degradation.

Following retrograde transport in the motor neuron, the tetanus toxin undergoes translocation across the synapse to the GABA-ergic presynaptic inhibitory interneuron terminals. Here the light chain, which is a zinc-dependent endopeptidase, cleaves vesicle-associated membrane protein 2 (VAMP2, also known as *synaptobrevin*). This molecule is necessary for presynaptic binding and release of neurotransmitter; thus, tetanus toxin prevents transmitter release and effectively blocks inhibitory interneuron discharge. The result is unregulated activity in the motor nervous system. Similar activity in the autonomic system accounts for the characteristic features of skeletal muscle spasm and autonomic system disturbance. The increased circulating catecholamine levels in severe tetanus are associated with cardiovascular complications.

Relatively little is known about the processes of recovery from tetanus. Recovery can take several weeks. Peripheral nerve sprouting is involved in recovery from botulism, and similar CNS sprouting may occur in tetanus. Other evidence suggests toxin degradation as a mechanism of recovery.

APPROACH TO THE PATIENT

Tetanus

The clinical manifestations of tetanus occur only after tetanus toxin has reached presynaptic inhibitory nerves. Treatment should not be delayed once the diagnosis of tetanus is confirmed. Management

strategies aim to neutralize remaining unbound toxin, support vital functions, treat symptoms, and control complications until the effects of the toxin have worn off. Patients usually recover after 4–6 weeks (see "Treatment," below).

CLINICAL MANIFESTATIONS

Clinical presentations of tetanus are diverse and are divided into the following categories: generalized, localized, cephalic, and neonatal tetanus. In the mild form of local tetanus, only isolated areas of the body are affected and only small areas of local muscle spasm may be apparent. Localized tetanus can progress to generalized tetanus. If the cranial nerves are involved in localized cephalic tetanus, the pharyngeal or laryngeal muscles may spasm, with consequent aspiration, respiratory failure, or airway obstruction. Generalized tetanus is the most common form of clinical presentation, characterized by muscle rigidity and generalized spasms. Neonates with tetanus typically present with an inability to suck, poor feeding, and generalized spasms.

The most common initial symptoms are trismus (lockjaw), which progresses to neck and body muscle rigidity, difficulty swallowing, and pharyngeal and laryngeal spasms. As the disease progresses, generalized muscle spasms develop and cause pain. Laryngeal spasm can cause respiratory failure or apnea and is a life-threatening event; without immediate respiratory support, this is the most common cause of death in tetanus.

Autonomic nervous system disturbance (ANSD) occurs during the second week of severe tetanus, and death due to cardiovascular events becomes the major risk. Clinical symptoms of ANSD include fluctuated heart rate (tachycardia or bradycardia) accompanied by a fluctuation in blood pressure (hypertension or hypotension) resulting from alteration in the activities of the sympathetic or parasympathetic nervous systems. Autonomic involvement is evidenced by gastrointestinal stasis, sweating, and increased tracheal secretions.

The Ablett score classifications of the clinical presentation of tetanus are outlined in **Table 157-1**.

DIAGNOSIS

The diagnosis of tetanus is based on clinical findings. Confirmatory laboratory tests are limited. Positive culture of *C. tetani* from wounds cannot confirm a diagnosis of tetanus. Serum antitetanus immunoglobulin G may also be measured in a sample taken before the administration of antitoxin or immunoglobulin; levels >0.1 IU/mL (measured by standard enzyme-linked immunosorbent assay) are deemed protective and do not support the diagnosis of tetanus. If levels are below this threshold, a bioassay for serum tetanus toxin may be helpful, but a negative result does not exclude the diagnosis, and these levels are not generally performed. Polymerase chain reaction and recombinase polymerase amplification have been developed to detect the tetanus neurotoxin gene; these techniques have proven promising in recent years.

A diagnosis of tetanus requires differentiation from other diseases. The few conditions that mimic generalized tetanus include strychnine poisoning, dystonic reactions to antidopaminergic drugs, somatic symptom disorder, stiff person syndrome, and neuroleptic malignant syndrome. Abdominal muscle rigidity is characteristically continuous in tetanus and should be differentiated from peritonitis or acute abdominal emergency. Cephalic tetanus can be confused with trismus of other etiologies, such as oropharyngeal infection, cranial nerve diseases, intracranial hemorrhage, submaxillary lymphadenitis, or peritonsillar infections. Hypocalcemia and meningoencephalitis are included in the differential diagnosis of neonatal tetanus.

TABLE 157-1 Ablett Classification of Severity of Tetanus

GRADE	SEVERITY	SYMPTOMS
I	Mild	Mild trismus, general spasticity, no respiratory compromise, no spasms, no dysphagia
II	Moderate	Moderate trismus, rigidity, short spasms, mild dysphagia, moderate respiratory involvement, respiratory rate >30 breaths/min
III	Severe	Severe trismus, generalized rigidity, prolonged spasms, severe dysphagia, apneic spells, pulse >120 beats/min, respiratory rate >40 breaths/min
IV	Very severe	Grade 3 with autonomic dysfunction

TREATMENT

Tetanus

If possible, the entry wound should be identified, cleaned, and debrided of necrotic material in order to remove anaerobic foci of infection and prevent further toxin production. Wound care should be performed several hours after anti-toxin administration. Failure to remove devitalized tissue and treat infection may result in recurrent or prolonged tetanus. Metronidazole (400 mg rectally or 500 mg IV every 6 h for 7 days) is preferred for antibiotic therapy. Although not a first choice for therapy, an alternative is penicillin (100,000–200,000 IU/kg per day); this drug theoretically may exacerbate spasms due to its ability to bind to the GABA receptor and, in one study, was associated with increased mortality.

Antitoxin should be given early in an attempt to deactivate any circulating tetanus toxin and prevent its uptake into the nervous system. Two preparations are available: human tetanus immunoglobulin (HTIG) and equine antitoxin. HTIG is the preparation of choice, as it is less likely to be associated with anaphylactoid reactions. A single IM dose (500–5000 IU) is given. Equine-derived antitoxin is available widely and is used in low- and middle-income countries; after hypersensitivity testing, 10,000–20,000 U is administered IM. According to a recent randomized controlled trial in Vietnam, there were no significant differences in the outcome and complications between groups using either intramuscular equine antitoxin or HTIG. Additional intrathecal antitoxin (HTIG) showed no benefit.

Benzodiazepines are commonly used to control spasms, and patients can tolerate them in high doses. The use of intermittent or continuous sedation depends on the severity of spasms and the availability of appropriate resources, e.g., mechanical ventilators. High-dose diazepam may cause hyperosmolarity and lactic acidosis. Midazolam is another option for controlling spasms in tetanus; it has fewer side effects and can be used continuously. Infusions of propofol can be used to control spasms and provide sedation; however, consideration should be given to the likely long duration of therapy. Sedatives should be reduced in the elderly and patients who have liver diseases due to drug accumulation and slow excretion.

When sedatives alone cannot control spasms, a combination of neuromuscular blocking agents is recommended. Nondepolarizing neuromuscular blockers are used in clinical practice, depending upon availability. IV magnesium sulfate has been used as a muscle relaxant. Patients who are using these agents require mechanical ventilation support. In those settings with limited availability of mechanical ventilators, controlling spasms while maintaining adequate ventilation is problematic. Patients may require ventilator support for several weeks.

It is important to establish a secure airway early in severe tetanus. Ideally, patients should be nursed in calm, quiet environments because light and noise can trigger spasms. Dysphagia due to pharyngeal involvement combined with hyperactivity of laryngeal muscles makes endotracheal intubation difficult. Tracheostomy is the better option for securing the airway in severe tetanus.

Magnesium sulfate has been used in autonomic nervous system dysfunction to control high blood pressure and tachycardia; maintaining a plasma concentration of 2–4 mmol/L is recommended. If magnesium alone cannot control tachycardia, short-acting beta-blockers (labetalol, propranolol, esmolol) or calcium antagonists can be used with strict monitoring. When the parasympathetic nervous system predominates—resulting in prolonged low blood pressure and bradycardia—vasopressors are required.

A complication arising from treatment with diazepam injection is thrombophlebitis. Long-term hospitalization with high-dose sedation

creates a high risk of hospital-acquired infections (ventilator-associated pneumonia, bloodstream infection, urinary tract infection, sepsis), deep vein thrombosis, pneumonia emboli, myocardiopathy, myocardial infarction, stress ulcers, muscle weakness, and pressure sores. Many of these patients require long-term rehabilitation.

Patients must be given a full primary course of immunization as tetanus toxin is poorly immunogenic and the immune response following natural infection is inadequate.

PROGNOSIS

Rapid development of tetanus is associated with more severe disease; it is important to note time of onset and length of incubation period. More sophisticated modeling has revealed other important predictors of prognosis. In many adults, particularly in the elderly, surviving tetanus is associated with reduced long-term functional outcome measures. Studies of children and neonates have suggested a higher incidence of neurologic sequelae. Neonates may be at increased risk of learning disabilities, behavioral problems, cerebral palsy, and deafness. Tetanus has a high survival rate if complications can be controlled and interventions conducted promptly.

In assessing prognosis, the incubation period (time from wound to first symptom) and the period of onset (time from first symptom to first generalized spasm or pharyngeal or laryngeal spasm) are of particular significance. The shorter these periods, the worse is the prognosis. Among the three main scales available to predict the severity and outcome of tetanus, the Tetanus Severity Score (TSS) **(Table 157-2)** is superior to the Dakar and Philips scores, with a sensitivity of 66% and a specificity of 91%.

PREVENTION

Tetanus is prevented by good wound management and vaccination **(Chap. 129)**. Safe delivery, hygienic umbilical-cord care, and maternal vaccination are recommended to prevent neonatal tetanus. Individuals sustaining wounds should undergo passive immunization (see "Treatment of Tetanus," above) if their vaccination status is incomplete or unknown or if their last booster was given >10 years earlier. Vaccination programs and recommended prevention measures vary somewhat according to individual countries.

The rate of primary vaccination coverage in infancy (three doses of DTP [diphtheria, pertussis, and tetanus]) is 86%, but rates for the subsequent boosters necessary for long-term protection are unknown. WHO guidelines for tetanus vaccination consist of a primary course of three doses and should start at 6 weeks of age; the interval between doses is 4 weeks. The first booster is given from 12–23 months of age. The second and third boosters are at 4–7 and 9–15 years of age, respectively. There should be at least 4 years between booster doses.

In 2022, the CDC reported the rate of infants who had received a full primary vaccination course of three doses of the diphtheria, tetanus toxoid (DTP3), and pertussis vaccine was 94%. There is a lack of data about boosters in older children, adolescents, and adults in many countries. The CDC recommends five doses of tetanus vaccine for infants and children at 2 months, 4 months, 6 months, 15 through 18 months, and 4 through 6 years of age, an additional booster dose at 11–12 years of age, and every 10 years thereafter. For those with delayed primary vaccination, catch-up immunization schedules are recommended. There are separate schedules for children ages 4 months through 6 years of age and from ages 7 through 18 years of age.

Complete maternal vaccination reduces the incidence of neonatal tetanus by an estimated 94%. WHO recommends that pregnant women who have not been vaccinated with the tetanus vaccine should receive at least two doses, with an interval of 4 weeks between doses. The second dose should be given at least 2 weeks before delivery. The third dose should be received at least 6 months later, with the fourth and fifth doses following an interval of 1 year or during subsequent pregnancies. A total of five doses can provide long-term immunity. The CDC provides a special schedule for those with partial vaccination. In high-risk areas, women of childbearing age should receive a primary course of vaccination and education on safe delivery and postnatal practices.

TABLE 157-2 Tetanus Severity Score (TSS) (Sensitivity 66%, Specificity 91%), Cutoff Point to Predict Death ≥8

VARIABLES	SCORE
Age (year)

Since March 2022, 47 countries have achieved maternal and neonatal tetanus elimination. Despite this relative success, immunization programs need to be continued and promoted to maintain individual long-term protective immunity and to eliminate the incidence of tetanus gradually. Dedicated public health initiatives still need to be improved, and the continuing reports of sizable case series in the medical literature suggest that tetanus continues to pose a significant global health burden.

158 Botulism

Carolina Lúquez, Jeremy Sobel

Botulism is a rare, life-threatening disease characterized by cranial nerve palsies and symmetric descending flaccid paralysis. Four forms of naturally occurring botulism have been described: foodborne botulism, infant botulism, wound botulism, and adult intestinal colonization. Other forms of botulism include iatrogenic botulism and inhalational botulism. Effective treatment depends on early clinical diagnosis.

ETIOLOGY AND PATHOGENESIS

Botulism is caused by botulinum neurotoxins (BoNTs), which are produced by *Clostridium botulinum*. Rare strains of *Clostridium butyricum* and *Clostridium baratii* can also produce BoNTs. Seven distinct serotypes of BoNT (A through G) are well characterized; serotypes A, B, E, and F reportedly cause disease in humans. Novel serotypes—BoNT/FA (or H or HA), BoNT/En, and BoNT/X—have been proposed, but the scientific community has not yet reached a consensus as to whether each represents a new serotype or a combination of known serotypes, as in the case of BoNT/FA (or H or HA), or whether they represent true toxins or botulinum-like proteins, as in the case of BoNT/En and BoNT/X. BoNTs are encoded by the *bont* gene, which is also diverse in its DNA sequence. At least 40 unique subtypes of BoNT have been identified within serotypes A, B, E, and F. By definition, a variant of BoNT represents a new subtype when its amino acid sequence differs by at least 2.6% from those of all known subtypes within that particular serotype. Although 2.6% is an arbitrary threshold, this figure has provided the basis for genetic subtype designations for the past decade, aiding in the classification of BoNTs as new DNA or amino acid sequences become publicly available. In addition, *bont* genes typically reside within two types of gene clusters. One type includes *ha* genes encoding hemagglutinin proteins, which facilitate the absorption of toxins across the epithelial barrier. The other type of cluster includes *orfX* genes that encode proteins with unknown functions. Both cluster types include an *ntnh* gene, which encodes for a nontoxic nonhemagglutinin protein. It has been proposed that these accessory proteins form a complex with BoNTs and protect them from external proteolytic activity.

Despite their structural variability, BoNTs all have a similar mechanism of action: they target neurons and block neurotransmission by cleaving SNARE-family proteins in the host, with consequent inhibition of acetylcholine release. BoNTs are metalloproteases composed of a light chain and a heavy chain. The light chain has catalytic activity, and the heavy chain contains a translocation domain and a receptor-binding domain. The receptor-binding domain of the heavy chain mediates the neurospecific binding of BoNTs, which leads to its internalization within endocytic compartments. Interaction of the translocation domain of the heavy chain with the membrane of endocytic vesicles leads to the translocation of the light chain into the cytosol. Once in the cytosol, the light chain cleaves specific SNARE-family proteins. Serotypes A and E cleave SNAP-25; serotypes B, D, F, and G cleave VAMP; and serotype C cleaves SNAP-25 and syntaxin. Cleavage of any of these proteins disrupts the assembly of synaptic fusion complexes, and this disruption inhibits the fusion of the membrane of the synaptic vesicle containing acetylcholine with the neuronal cell membrane. Clinically, the result is flaccid paralysis of voluntary muscles. The irreversible binding of BoNTs to their targets has a clinical consequence: once toxin binding has occurred, the resulting paralysis persists for weeks or months, until nerve endings have been regenerated.

BoNTs are produced by *C. botulinum* and a few strains of *C. butyricum* and *C. baratii*, which are all gram-positive, rod-shaped, spore-forming, anaerobic bacteria. Under most environmental conditions, *C. botulinum* exists as spores that are heat-resistant and ubiquitous in soil. In general, *C. botulinum* spores require temperatures above boiling to ensure destruction; their thermal resistance increases with higher pH and lower salt content. Spores present in foods can survive most preservation methods and, if the conditions allow it, can germinate and produce BoNTs in significant amounts to cause disease. Commercial retort canning reliably destroys botulinal spores.

BoNTs are among the most toxic substances known. Extremely small amounts of BoNT can cause severe disease and death. Severity of disease varies with dose, serotype, and route of exposure. The lethal dose of BoNT in humans is not known but can be estimated by extrapolation of toxicity data from animal studies. The estimated human lethal dose of BoNT acquired via the IV or IM route is 0.1–1 ng/kg of body weight. The human lethal dose of BoNT acquired by inhalation of aerosolized toxin is estimated at 1–75 ng/kg. The degree of toxicity of BoNT acquired by the oral route is estimated to be much lower: 0.1–1 μg/kg.

As stated above, four naturally occurring and two non–naturally occurring forms of botulism are known. Foodborne botulism is caused by the ingestion of foods contaminated with BoNT. Wound botulism occurs when spores of BoNT-producing species of *Clostridium* contaminate a wound and then germinate, multiply, and produce toxin. Infant botulism is caused by BoNT-producing species of *Clostridium* colonizing the intestinal tract of infants ≤1 year of age. Adult intestinal colonization is similar to infant botulism but affects persons >1 year of age. Iatrogenic botulism occurs when a patient given injections of BoNT experiences signs of systemic botulism. BoNTs can also be aerosolized and used as a bioweapon, entering the human body by inhalation.

Foodborne Botulism Foodborne botulism is the most common form reported in many countries. Every case of foodborne botulism represents a public health emergency because of the potential for causing outbreaks. Foodborne botulism is an intoxication in which food containing preformed toxin is ingested. Spores of BoNT-producing

species of *Clostridium* are ubiquitous in soil and can be found on vegetables and other foodstuffs. *C. botulinum* type E is commonly found in aquatic environments and in aquatic animals. Because the spores are found in many foods, improper preparation or storage may produce the confluence of conditions that allow germination and growth of BoNT-producing species of *Clostridium*, which in turn result in production of BoNT. Both historically and at the present time, canned foods are of concern because they create anaerobic environments. To render these foods safe, proper processing procedures in conditions of enough heat and pressure to inactivate *Clostridium* spores, along with sufficient acidity, salinity, or other preservative methods to limit the organism's growth and its production of BoNT, are required. Low-acidity foods, such as corn, peppers, potatoes, and beets, represent a higher risk. A series of botulism outbreaks from commercially canned foods in the early twentieth century resulted in standardization of retort canning methods and promulgation and enforcement of production safety codes. Consumption of fish or other foods of marine origin can cause botulism if prepared or conserved improperly. Most foodborne botulism cases in the United States are caused by home-canned vegetables such as green beans; however, commercially prepared foods, including chicken broth, carrot juice, hot dog chili sauce, and nacho cheese, also have been implicated in recent outbreaks. Marine mammal and fish products traditionally prepared by Alaskan Natives and First Peoples are the main source of botulism in Alaska and Canada.

Wound Botulism Wound botulism is caused by germination and growth of *C. botulinum* spores in a wound or necrotic tissue where they produce BoNT, which then enters circulation and produces systemic disease. Few cases of wound botulism were described in the United States until 1981, when the first case associated with injection drug use was reported. Since then, botulism cases due to injection drug use, especially in association with subcutaneous or tissue injection (skin popping) of black tar heroin, have substantially increased in the United States. Black tar heroin was introduced into the United States in the 1970s and, since the late 1980s, has become the predominant form of heroin west of the Mississippi River. Black tar heroin is contaminated with by-products of the manufacturing process, adulterants, and diluents and therefore is considered the most probable source of *C. botulinum* spores. In recent decades, the few cases of wound botulism not associated with injection drug use have been associated with vehicle crashes, gunshot wounds, open-fracture wounds, and penetrating wounds caused by contaminated objects.

Infant Botulism Infant botulism is the most common form of botulism in the United States. It affects infants ≤1 year old, with a mean age at onset of 14 weeks. It has been suggested that the intestinal microbiota in infants may induce susceptibility to botulism; animal models seem to support this claim. Spores of BoNT-producing species of *Clostridium* can enter the body by ingestion. The highly resistant spores survive passage through the stomach and colonize the intestine, where they germinate, grow, and produce BoNT in situ. Infants can continue excreting *C. botulinum* for weeks after clinical recovery. Spores of BoNT-producing species of *Clostridium* have been found in honey. Consumption of honey has been epidemiologically implicated in infant botulism; therefore, honey should not be fed to babies ≤1 year of age. Honey exposure, however, explains only a small proportion of cases. As spores are found in dust and soil, most infant botulism patients probably acquire BoNT-producing species of *Clostridium* by swallowing dust particles. Why only a few dozen infants are affected each year when presumably most infants regularly ingest clostridial spores remains unknown.

Adult Intestinal Botulism Similar to infant botulism, adult intestinal colonization is caused by spores of BoNT-producing species of *Clostridium* colonizing the large intestine, growing, and producing BoNT in situ. Although spores are routinely ingested and excreted by humans, the adult intestinal tract does not support spore germination and toxin production under normal circumstances. Adult intestinal colonization is usually associated with inborn anatomic abnormalities, gastrointestinal surgery, or prolonged use of antibiotics, which may alter the normal intestinal microbiota and facilitate colonization by BoNT-producing species of *Clostridium*. Although these associated conditions are relatively common, fewer than 30 cases of adult intestinal colonization have been reported worldwide.

Iatrogenic Botulism Iatrogenic botulism occurs in patients injected with large doses of BoNT for treatment of muscle complications related to such conditions as cerebral palsy and spastic dystonia. The small doses of botulinum toxin used for wrinkle elimination in dermatologic practice are usually insufficient to cause systemic disease. In 2004, an outbreak of four cases caused by the injection of an unlicensed, highly concentrated BoNT product for cosmetic purposes occurred in the United States. Similarly, in 2017, an outbreak of nine cases occurred in Egypt in association with an unlicensed, highly concentrated BoNT preparation.

Weaponized Inhalational Botulism BoNTs were weaponized by the biological weapons programs of several countries in the twentieth century. Aerosolized BoNTs can be used as a bioweapon, exerting their effect by entering the body through inhalation. In the United States, BoNTs are designated as Tier 1 select agents—i.e., agents that present the greatest risk of deliberate misuse with significant potential for mass casualties or devastating effects on the economy, critical infrastructure, or public confidence. Tier 1 agents pose a severe threat to public health and safety. Terrorists have attempted to use BoNT as a bioweapon: Aum Shinrikyo, a Japanese cult, tried unsuccessfully to aerosolize BoNT in terrorism attacks at multiple sites in Japan between 1990 and 1995.

EPIDEMIOLOGY

Foodborne Botulism In the United States, foodborne botulism is the third most common form of botulism. From 2001 to 2019, 362 foodborne botulism cases were reported, with a mean of 19 cases per year. Most cases (64%) were caused by serotype A BoNT, which was followed in frequency by serotype E (26%). Serotypes B and F caused 7% and 2% of foodborne botulism cases, respectively. Outbreaks caused by serotype E usually had a shorter incubation period, those caused by type A had higher numbers of patients who required mechanical ventilation, and those caused by type B had lower numbers of deaths.

Foodborne botulism cases are usually sporadic (i.e., cases occur singly), but small and large outbreaks also can occur. From 2001 to 2019, 5 foodborne botulism outbreaks affecting 10 or more people were reported in the United States (Table 158-1). Every case of foodborne botulism is considered a public health emergency because it may be the first in an outbreak involving additional patients.

Most foodborne botulism cases in the United States are due to a wide variety of home-canned vegetables and pickled vegetables (e.g., beets, green beans, carrots, mushrooms, asparagus, peppers, beans, mustard greens, corn, tomato sauce, olives, pumpkin butter), vegetables baked in aluminum foil (e.g., potatoes, beets), home-canned meat-based foods (e.g., tuna, pickled pigs' feet, stew, pasta in meat sauce),

TABLE 158-1 Total Foodborne Botulism Outbreaks of 10 or More Cases Reported in the United States Between 2001 and 2019

YEAR	STATE	FOOD SOURCE	NO. OF CONFIRMED CASES
2001	Texas	Chili	16
2007	Multistate	Commercially canned hot dog chili sauce	10
2015	Ohio	Home-canned potatoes used to prepare a potato salad, served at a church potluck	27
2016	Mississippi	Pruno, illegal alcoholic beverage consumed by persons who were incarcerated at a federal facility	19
2017	California	Commercially produced nacho cheese, sold at a convenience store	10

oil-based foods (e.g., pasta and jarred pesto, homemade garlic-infused oil), herbal deer antler tea, home-prepared fermented tofu, commercial clam chowder, or commercial grain and vegetable products. In Alaska, traditional Alaskan Native foods linked to foodborne botulism cases have included seal oil, seal blubber, dried herring in seal oil, fermented seal flipper, stinkheads and other fermented fish heads, stinkfish, salmon eggs, beaver tail, whitefish, fish eggs, fermented beluga, and whale blubber.

Commercial food manufacturing processes include retort canning, in which high temperature and pressure destroy the highly resistant clostridial spores, and manipulations that inhibit bacterial growth, such as acidification or addition of growth inhibitors that prevent germination and growth of BoNT-producing species of *Clostridium* and the production of BoNT. However, commercial foods occasionally still cause botulism if safe manufacturing processes are not followed or fail or if foods are stored or used inappropriately by the retailer or consumer. For instance, an outbreak of 10 cases associated with commercially canned hot dog chili sauce occurred in 2007 as a result of deficiencies in the canning process. Other commercial food–associated outbreaks that occurred in the United States between 2001 and 2019 include a 2001 outbreak of 16 cases linked to chili that was stored at inappropriate temperatures and later served at a church event in Texas and a 2006 outbreak linked to commercial carrot juice, which included four cases in the United States and two cases in Canada. The investigation of the latter outbreak led to an international product recall. The juice, which had no added sugar, salt, or preservatives, was stored at inappropriate temperatures.

Pruno, an illicit prison-brewed alcoholic beverage, first caused a botulism outbreak in a California prison in 2004, affecting 4 prisoners. In 2011, a second outbreak due to pruno was reported and involved 8 patients at a prison in Utah. In 2012, 2 outbreaks associated with pruno occurred in a single prison in Arizona, with 4 and 8 cases, respectively. The largest outbreak from pruno occurred in 2016 in a Mississippi prison; 31 cases were identified, including 19 confirmed and 12 suspected.

Wound Botulism Wound botulism was once rare in the United States, but its frequency has been increasing for decades, and it is now the second most common form of botulism. Between 2001 and 2019, 452 cases of wound botulism were reported, with an average of 24 cases per year. Most cases (92%) were caused by BoNT serotype A and by serotype B (5%). Most cases (96%) were among persons who injected drugs (mainly black tar heroin), and the remaining 4% of cases were due to traumatic injuries.

Infant Botulism Infant botulism is the most common form of botulism in the United States. Between 2001 and 2019, 2172 infant botulism cases were reported. BoNT serotypes A and B caused most cases (40% and 58%, respectively). Only 2 cases were due to serotype E. Of these 2 cases, 1 was due to *C. botulinum* type E and the other to *C. butyricum* type E; both cases represented the first report anywhere in this country of infant botulism due to those respective organisms. A small fraction (<1%) of cases were caused by serotype F. Of note, 22 infant botulism cases were due to strains of *C. botulinum* that can produce two BoNT serotypes (A and B or B and F).

Botulism of Other Etiologies Between 2001 and 2019, 51 cases were reported as being of "unknown or other etiology." This category includes laboratory-confirmed botulism cases that do not meet the definition of foodborne, infant, or wound botulism. Most of these cases were caused by serotype A (63%) and serotype F (27%). Many were thought to be cases of adult intestinal colonization, although confirmation of this form of botulism is not always possible.

CLINICAL MANIFESTATIONS

Botulism produces a syndrome characterized by bilateral cranial nerve palsies that may be followed by symmetric, descending flaccid paralysis that may cause respiratory arrest. There are no sensory deficits; patients are fully conscious, with normal intellectual function, although cranial nerve palsies may give a mistaken impression of altered consciousness. The typical incubation period (based on data for foodborne botulism cases, where exposure can be identified) is 1 or 2 days, but a range of 6 h to >7 days has been reported. Several recent systematic reviews substantiate long-known observations that the syndrome is essentially identical for all types of botulism in patients of all ages, although elicitation of the typical signs and symptoms may be challenging in infants and young children. A recent systematic review of 16 cases of botulism in pregnant women reported the same clinical syndrome as in nonpregnant individuals. In all botulism syndromes, the first neurologic manifestation usually is ptosis, which can be striking. Ocular findings of fuzzy vision or frank diplopia are caused by extraocular muscle paralysis due to palsies of cranial nerves III, IV, and VI. Flat, youthfully unlined, expressionless facies are produced by cranial nerve VII (facial nerve) palsy. Dysarthria is also a prominent manifestation. Oral and nasal regurgitation of foods or beverages is caused by cranial nerve IX (glossopharyngeal nerve) palsy. The autonomic system may be affected, producing anhidrosis manifesting as severe pharyngeal pain and erythema that has been mistaken for pharyngitis; paradoxically, other patients experience an inability to manage copious oral secretions. Autonomic dysfunction may produce hemodynamic instability requiring monitoring. Cranial nerve palsy may produce pharyngeal muscle flaccidity, causing airway collapse and respiratory arrest early in the course of illness, while reduction in diaphragmatic and accessory muscle function may cause respiratory compromise hours or days later. Cranial nerve palsies may be followed by descending symmetric flaccid paralysis of the muscles of the neck, shoulders, upper limbs, and lower limbs; proximal muscle groups of each limb are affected before distal muscle groups.

A recent analysis of 332 U.S. botulism cases found the following frequencies for patient-reported symptoms: difficulty swallowing, 86%; fatigue, 85%; blurred vision, 80%; slurred speech, 78%; double vision, 76%; shortness of breath, 65%; and dry mouth, 62%. The analysis also reported the following frequencies of observed signs: afebrile body temperature, 99%; descending paralysis, 93%; alert and oriented status, 93%; ptosis, 81%; limb weakness, 78%; decreased palatal reflex, 54%; facial palsy, 47%; and dilated pupils, 20%. Sixty-six percent of patients were intubated and received mechanical ventilation. These findings are similar to those reported in many smaller series. Rarely, asymmetry of cranial nerve palsies or distal muscle paralysis is reported and, at least in some cases (especially those described in reports based on chart abstractions), may reflect an incomplete or incompletely recorded neurologic examination. Despite intact sensorium, symptoms such as ptosis, dysarthria, and gait instability may be mistaken for diminished consciousness and lack of coordination and may be erroneously attributed to intoxication from alcohol or other substances. Paresthesias have been reported in some patients; these sensations are not explained by the known activity of botulinum toxin. Paralysis of the diaphragm and accessory muscles of respiration may occur, producing respiratory compromise. Distal tendon reflexes diminish symmetrically. Constipation due to intestinal paralysis develops in almost all patients. Nausea and vomiting may occur in foodborne botulism, preceding neurologic symptoms. Whether these manifestations are due to BoNT, other products of BoNT-producing species of *Clostridium*, or other contaminants of spoiled food is unknown. These gastrointestinal symptoms have not been reported in wound botulism.

Death in untreated patients during the first hours to days of illness is caused by airway obstruction resulting from pharyngeal muscle paralysis and inadequate tidal volume resulting from paralysis of diaphragmatic and accessory respiratory muscles. The combination of expressionless facies from cranial nerve paralysis and immobility from voluntary muscle paralysis may give patients with botulism a placid appearance that masks the agitation expected with respiratory distress. Respiratory compromise occurs early in the course of disease in a substantial proportion of patients: the largest systematic literature review to date of foodborne and wound botulism cases (402 patients) reported that the average time from symptom onset to hospitalization was 2 days and that, at hospital admission, 42% of patients had respiratory symptoms; of these patients, 42% presented with no extremity weakness. In the same review, 87% of patients who required mechanical ventilation

were intubated during the first 2 days of hospitalization. The severity of disease varies greatly between patients and is probably governed by the dose of toxin to which they have been exposed. Without treatment, some patients do not progress beyond ptosis and mild palsy in one or two cranial nerves; others experience fulminant cranial nerve palsies and rapidly progressive descending flaccid paralysis eventually affecting most or all voluntary muscles as well as respiratory failure requiring intubation and mechanical ventilation within hours.

The different BoNT serotypes are associated with variations in the botulism syndrome. BoNT type A is associated with more rapid disease progression, more frequent respiratory compromise and mechanical ventilation, and longer duration of paralysis. Type B is associated with a milder syndrome, with less severe and shorter-duration paralysis. Intoxication with the rarely occurring type F produces a syndrome of rapidly progressing paralysis that often leads to respiratory failure, with more rapid recovery than occurs with other toxin types. However, all toxin types causing human illness can cause severe disease; the clinical approach is the same for all.

The paralysis of botulism can last for weeks or months—the time required for regeneration of affected nerve endings and recovery of voluntary muscle function. For severely affected patients with extensive paralysis, management consists of protracted intensive care, with detection and treatment of attendant risks not specific to botulism, such as ventilator-associated pneumonia, decubitus ulcers, and psychological trauma. More than 95% of noninfant botulism patients in the United States recover; hospital discharge is often followed by protracted rehabilitative care. The survival rate for infant botulism is near 100%.

CLINICAL DIAGNOSIS AND LABORATORY CONFIRMATION

Rapid clinical diagnosis is essential. A diagnostic aid for botulism, "Clinical Criteria to Trigger Suspicion of Botulism," has been published by botulism consultants at the Centers for Disease Control and Prevention (CDC; accessible at *academic.oup.com/cid/article/66/suppl_1/S38/4780423*). The paralysis of botulism lasts for weeks or months, and administration of equine-source botulinum antitoxin (BAT)—the specific therapy to arrest the progression of paralysis—depends on the correct diagnosis. At this time, laboratory confirmation of botulism, which may require ≥24 h, must take place at a specialized public health laboratory. Therefore, effective, timely treatment relies on rapid clinical diagnosis of botulism in a patient with clinically compatible findings, without awaiting laboratory confirmation. A clinician suspecting noninfant botulism in a patient should immediately contact the state health department's emergency 24-h line. The state will connect the clinician with a botulism clinical consultant at the CDC (or, in Alaska, California, and Colorado, at the state health department), who will review the case with the clinician, assist in the shipping of appropriate specimens to a public health laboratory for definitive diagnosis, and, when indicated, arrange for immediate shipping of BAT from the federal stockpile at no charge. A clinician suspecting infant botulism in a patient should immediately contact the Infant Botulism Treatment and Prevention Program's on-call physician at (510)231-7600, who will provide consultation, assist with specimen collection, and, when indicated, assist with the provision of human-derived botulinum antitoxin (BabyBIG), a specific treatment licensed for treatment of infant botulism.

The neurologic examination is the key to clinical diagnosis of botulism, as it readily uncovers the cranial nerve deficits that are invariably present in botulism and focuses the differential diagnosis. In principle, the distinct syndrome of bilateral cranial palsies and descending flaccid paralysis in a fully conscious patient should render the diagnosis and prompt treatment of botulism straightforward. The presentation of two or more patients with this syndrome is almost pathognomonic, since other illnesses considered during the differential diagnosis of botulism do not produce outbreaks. In practice, however, sporadic (lone) cases of botulism are misdiagnosed, and sometimes the diagnosis is missed even in the setting of an outbreak. In part, these failures may be due to the rarity of botulism and the clinician's unfamiliarity with its presentation. A possible cause of misdiagnosis is failure to perform a complete neurologic examination; indeed, review of some botulism patients' charts reveals documentation of the first neurologic examination, which suggested the correct diagnosis, days after hospital admission. As stated earlier, the combination of ptosis, dysarthria, and perceived gait instability from muscle paralysis in some cases may be misinterpreted as intoxication from alcohol or other substances. In other cases, rapidly progressing botulism may result in pharyngeal collapse and respiratory distress relatively early in the course, leading the clinical team to focus on airway management and primary respiratory diagnoses and thus delaying the neurologic evaluation.

Standard clinical studies, including bloodwork and radiology, are not useful in diagnosing botulism. In contrast to the findings in Guillain-Barré syndrome (GBS; see below), lumbar-puncture cerebrospinal fluid (CSF) values—and specifically the protein level—are usually normal in botulism. The CSF protein level may be very slightly elevated in a minority of botulism cases. The fact that botulism produces no abnormal findings on brain imaging may help rule out rare basilar strokes that produce nonlateralizing symptoms. Serological antibody tests and rapid nerve stimulation tests can rule out myasthenia gravis. Electromyography, when performed by an experienced practitioner, can provide support for the diagnosis. Botulism is indicated by findings consistent with neuromuscular junction blockage, normal axonal conduction, and potentiation with rapid repetitive stimulation in affected muscles.

Once a neurologic examination reveals the cranial nerve palsies of botulism and any additional bilateral flaccid paralysis, the differential diagnosis may include GBS, myasthenia gravis, Lambert-Eaton syndrome, and tick paralysis. Less likely conditions include tetrodotoxin or shellfish poisoning, antimicrobial-associated paralysis, and rarer poisonings. A careful history and physical examination can further narrow the range of diagnoses. GBS is a rare (~1 case per 100,000 population per year in the United States) autoimmune demyelinating polyneuropathy that follows acute infection by *Campylobacter jejuni*, certain viruses, and other bacteria. In 95% of cases, GBS presents as an ascending paralysis. Recent reports from Peru indicate massive outbreaks of GBS of unknown cause, challenging the previously held notion that conditions causing flaccid paralysis other than botulism occur only as sporadic cases. The 5% of GBS cases presenting as the Miller Fisher variant are characterized by the triad of ophthalmoplegia, ataxia, and areflexia, which may resemble early descending paralysis. The CSF protein level is elevated in GBS, but the increase may take place days after symptom onset; thus, normal CSF levels should be taken into account along with the duration of symptoms, and lumbar puncture may need to be repeated. Electromyography performed by an experienced operator may yield findings indicative of GBS and not botulism. Serological antibody tests or rapid nerve stimulation tests can confirm myasthenia gravis; borderline positive Tensilon tests have been reported in botulism patients. In most stroke patients, the physical examination should reveal asymmetric paralysis and upper motor neuron signs; brain imaging can help reveal rare basilar strokes that can produce symmetric bulbar palsies. The history and physical examination should rule out Lambert-Eaton syndrome, which is characterized by proximal limb weakness in patients with advanced cancer.

Laboratory testing confirms clinically diagnosed botulism cases and determines the BoNT serotype causing the disease. In addition, laboratory testing can confirm epidemiologic data by demonstrating presence of BoNT in the suspected food. Botulism cases are confirmed by the laboratory when BoNT is identified in serum or stool specimens or when a BoNT-producing species of *Clostridium* is isolated from stool specimens or wound cultures. Identification of preformed BoNT in food consumed by patients also confirms foodborne botulism.

The gold standard for identification and serotyping of BoNT in clinical or food specimens is the mouse bioassay. The drawback is that this highly sensitive and specific method requires the use of animals. Specimens are injected IP into the mice with and without antitoxin; the mice are then observed for up to 96 h for signs of botulism. If the specimen contains BoNT at levels sufficient to affect the mice quickly, results may be available within 24 h of injection. Low levels of toxin

may produce signs later, so mice should be monitored for 4 days after injection. Many in vitro methods have been developed for detection of BoNT and BoNT-producing species of *Clostridium* in clinical and food specimens. For instance, public health laboratories in the United States can use a real-time polymerase chain reaction test that detects *bont* genes encoding serotypes A through G. This test is a useful screening method to determine whether BoNT-producing species of *Clostridium* are present in cultures of clinical specimens, but positive results must be confirmed. Another in vitro method, the Endopep mass spectrometry (Endopep-MS) assay, is highly sensitive and specific and can detect BoNT in clinical specimens and foods. The advantage of Endopep-MS is that it detects active BoNT and therefore represents an ideal alternative to the mouse bioassay. Immune-based assays can provide rapid and sensitive results; their main limitation is that they detect antigens, which may not necessarily represent active BoNT. Cell-based in vitro assays are also a possible alternative to the mouse bioassay as they detect biologic activity of BoNT.

TREATMENT

Botulism

Treatment for botulism consists of two components: meticulous monitoring and supportive care, including admittance to the intensive care unit when indicated, and administration of botulinum antitoxin, the only specific therapy for botulism, as quickly as possible. Paralysis from botulism can be rapidly progressive. Vital capacity, and often hemodynamic parameters, should be frequently monitored and mechanical ventilation instituted immediately if needed. Paralysis induced by BoNT lasts weeks or months, and patients with extensive paralysis require painstaking care to avoid complications associated with protracted immobilization, including respirator-dependent pneumonia, decubitus ulcers, and psychological trauma. Patients who have recovered from severe botulism report that their appearance and immobility often led caregivers to assume they were unconscious; as a consequence, patients were sometimes subjected to painful procedures without warning and to insensitive comments. Signage should remind all caregivers that botulism patients are conscious but "locked in." Psychological support should be instituted for intubated botulism patients from the outset. With proper supportive care, >95% of botulism patients in the United States recover, even without antitoxin therapy; however, antitoxin, if promptly administered, can substantially reduce the extent and duration of illness (see below).

Botulinum antitoxin is the only specific treatment for botulism. The antitoxin prevents the progression of paralysis but does not reverse existing paralysis. If given early enough in the course of disease, it may avert respiratory compromise, obviate mechanical intubation, and forestall protracted paralysis and hospitalization along with associated complications. Accordingly, it is essential to administer antitoxin as soon as possible. A recent systematic literature review and meta-analysis covering nearly a century of the published literature in noninfant botulism patients confirmed long-known findings from smaller studies by showing significantly reduced mortality rates among patients treated with equine antitoxin, especially when treatment was administered within 48 h of symptom onset. Another large systematic literature review of pediatric noninfant botulism recently showed significantly reduced mortality risk among children treated with equine antitoxin. Published studies have demonstrated a substantial reduction in the duration and severity of illness among patients with infant botulism who are treated with human-derived botulinum antitoxin.

The equine botulinum antitoxin used to treat noninfant botulism consists of antibodies produced in horses immunized with botulinum toxoids (inactivated toxins) and toxins. The antibodies are type-specific (anti-A neutralizes BoNT type A and so forth). The currently licensed antitoxin product in the United States, heptavalent botulinum antitoxin (BAT), contains antibodies to BoNT types A, B, C, D, E, F, and G. These equine antibodies have undergone despeciation to reduce antigenicity and the risk of anaphylaxis to foreign protein. A recent systematic literature review, along with studies of BAT use, indicated that <2% of recipients experience serious adverse reactions. Administration of one vial of BAT elicits circulating antitoxin concentrations sufficient to neutralize toxin levels one to two orders of magnitude higher than those found in the serum of most botulism patients. As noted earlier, clinicians suspecting botulism in a patient should immediately call their state health department's emergency contact to be put in touch with a botulism clinical consultant who will review the case and assist in its management, including shipment of BAT from the federal stockpile at no charge. The botulinum antitoxin used to treat infants, BabyBIG, consists of human antibodies obtained from hyperimmunized volunteers. The product is licensed for treatment of infant botulism due to BoNT types A and B and, as noted earlier, can be obtained through the Infant Botulism Treatment and Prevention Program.

There is no prophylactic treatment for botulism. Persons who may have been exposed to botulinum toxin should be evaluated by a physician and carefully observed for the development of symptoms of botulism. If symptoms appear, the patient should be treated immediately with botulinum antitoxin.

PREVENTION

No vaccine is licensed for the prevention of botulism. In the United States, a botulinum toxoid vaccine was available through the CDC until 2011, but it was discontinued because of a decline in immunogenicity of some serotypes and an increase in occurrence of moderate local reactions. Several vaccine candidates are currently in clinical trials.

Because most foodborne botulism cases are caused by home-canned or home-preserved foods, the prevention of foodborne botulism depends mainly on proper preparation and preservation that ensures the destruction of spores of BoNT-producing species of *Clostridium* that may be present in the food or on the creation of an environment that will not allow the germination and growth of these spores, such as low pH or low water activity. Water activity is a measure of how much water is free, unbound, and thus available to microorganisms to use for growth. If foods have low water activity, it means they do not have much free water, and growth of *C. botulinum* will be limited or inhibited. Using pressure canners and properly cleaning items employed in the canning process can reduce the risk of foodborne botulism. Among other resources, the *USDA Complete Guide to Home Canning* provides a detailed description of safe home-canning practices. Other ways of preventing foodborne botulism include refrigerating homemade oils infused with garlic or herbs and discarding any of these oils that have not been used after 4 days; maintaining baked potatoes or similar foods wrapped in aluminum foil at temperatures above 140°F until served and then refrigerating leftovers; refrigerating canned or pickled foods after opening; and boiling home-canned foods before eating, especially those foods that are low in acid.

Wound botulism largely affects people who inject drugs, especially black tar heroin. Using safe injection practices may help prevent wound botulism and many other infections, such as HIV and hepatitis C virus infections. Thus, educating injection drug users on the prevention of wound botulism and other infections is vital in protecting their health. As wound botulism can also follow traumatic injuries, keeping wounds clean is key.

The risk factors for infant botulism are not fully understood, but possible sources of spores of BoNT-producing species of *Clostridium* include foods and dust. In most cases of infant botulism, no source of spores is identified. Honey is the only food that has been identified as an epidemiologically associated reservoir of spores of BoNT-producing species of *Clostridium*. Honey should not be fed to infants ≤1 year of age.

GLOBAL CONSIDERATIONS

Botulism has been reported from all parts of the world. The European Centre for Disease Prevention and Control has reported an average of 110 botulism cases each year from 2007 to 2018. During that period,

1315 botulism cases were reported from 25 countries, with the most cases in Italy (311 cases), Romania (239 cases), and Poland (202 cases). Foodborne botulism is the most common form of botulism in Europe. Most laboratory-confirmed cases reported from Italy, Romania, and Poland were due to BoNT serotype B. The country of Georgia has a high incidence of botulism (0.9 case per 100,000 persons) relative to rates in the European Union (<0.1/100,000) and the United States (0.01/100,000). From 1980 to 2002, a total of 879 cases of botulism were reported in Georgia; all of them were foodborne, most were associated with home-preserved vegetables, and the majority were due to serotype B. From 1958 to 1983, 986 foodborne botulism outbreaks affecting 4377 individuals were reported from China. Most cases were due to serotype A and were associated with bean products. Botulism in Thailand has been associated with fermented bamboo shoots and fermented soybeans. In 2006, a large foodborne botulism outbreak associated with bamboo shoots occurred in Thailand and affected 209 people who attended a local festival. In South America, Brazil and Argentina have reported several outbreaks of foodborne botulism. For instance, between 2001 and 2008, Brazil reported 18 outbreaks, most of which were associated with meat-based foods such as home-canned meat, homemade pork liver pâté, and commercially canned liver pâté. From 1994 to 2007, Argentina reported 36 outbreaks, most frequently involving home-canned vegetables. Although reports of foodborne botulism in Africa are rare, 5 outbreaks were reported in South Africa between 1959 and 2002, with the majority due to serotype B and associated with noncommercial foods. In addition, 1 outbreak of 91 cases was reported in Egypt in 1991 and was due to serotype E associated with a traditional salted fish.

Wound botulism cases have been reported most frequently from the United States, next most frequently from the United Kingdom, and occasionally from Italy, France, and Australia. Clusters of wound botulism are rare, but, according to a report from the European Centre for Disease Prevention and Control, 23 cases of wound botulism among people who had injected heroin were reported in Norway and Scotland between December 2014 and February 2015. Other countries that have reported wound botulism cases include Argentina, China, and Ecuador.

Although rarely reported, infant botulism cases have been noted on all continents except Africa. Outside the United States (where there were 2419 cases), Argentina reported the largest number of cases (366) and Australia the next largest number (32) between 1976 and 2006. Canada, Italy, and Japan also reported a relatively large number of cases (27, 26, and 22, respectively).

159 Gas Gangrene and Other Clostridial Infections

Amy E. Bryant, Dennis L. Stevens

The genus *Clostridium* encompasses >60 species that may be commensals of the gut microflora or may cause a variety of infections in humans and animals through the production of a plethora of proteinaceous exotoxins. *C. tetani* and *C. botulinum*, for example, cause specific clinical disease by elaborating single but highly potent toxins. In contrast, *C. perfringens* and *C. septicum* cause aggressive necrotizing infections that are attributable to multiple toxins, including bacterial proteases, phospholipases, and cytotoxins.

ETIOLOGIC AGENT

Vegetative cells of *Clostridium* species are pleomorphic, rod-shaped, and arranged singly or in short chains **(Fig. 159-1)**; the cells have rounded or sometimes pointed ends. Although clostridia stain gram-positive in the early stages of growth, they may appear to be gram-negative or gram-variable later in the growth cycle or in infected tissue specimens. Most strains are motile by means of peritrichous flagella; *C. septicum* swarms on solid media. Nonmotile species include *C. perfringens*, *C. ramosum*, and *C. innocuum*. Most species are obligately anaerobic, although clostridial tolerance to oxygen varies widely; some species (e.g., *C. septicum*, *C. tertium*) will grow but will not sporulate in air.

Clostridia produce more protein toxins than any other bacterial genus, and more than 25 clostridial toxins lethal to mice have been identified. These proteins include neurotoxins, enterotoxins, cytotoxins,

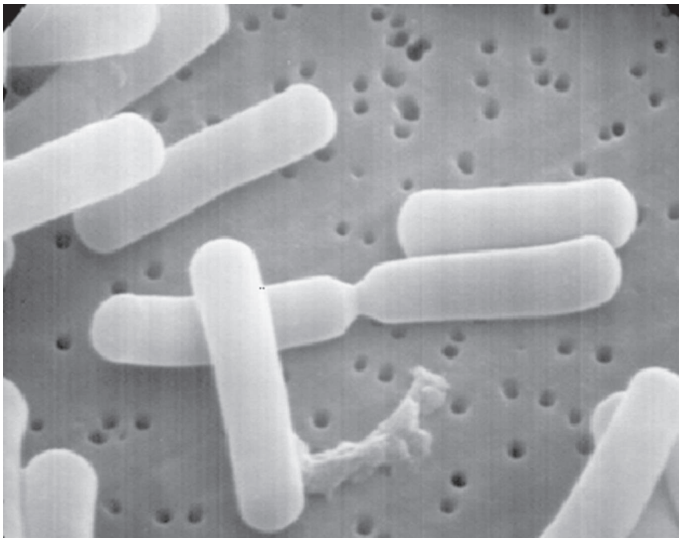

FIGURE 159-1 Scanning electron micrograph of *C. perfringens*.

collagenases, permeases, necrotizing toxins, lipases, lecithinases, hemolysins, proteinases, hyaluronidases, DNases, ADP-ribosyltransferases, and neuraminidases. Botulinum and tetanus neurotoxins are the most potent toxins known, with lethal doses of 0.2–10 ng/kg for humans. Epsilon toxin, a 33-kDa protein produced by *C. perfringens* types B and D, causes edema and hemorrhage in the brain, heart, spinal cord, and kidneys of animals. It is among the most lethal of the clostridial toxins and is considered a potential agent of bioterrorism **(Chap. S4)**. The genomic sequences of some pathogenic clostridia are now available and are likely to facilitate a comprehensive approach to understanding the virulence factors involved in clostridial pathogenesis.

EPIDEMIOLOGY AND TRANSMISSION

Clostridium species are widespread in nature, forming endospores that are commonly found in soil, feces, sewage, and marine sediments. The ecology of *C. perfringens* in soil is greatly influenced by the degree and duration of animal husbandry in a given location and is relevant to the incidence of gas gangrene caused by contamination of wounds with soil. For example, the incidence of clostridial gas gangrene is higher in agricultural regions of Europe than in the Sahara Desert of Africa. Similarly, the incidences of tetanus and food-borne botulism are clearly related to the presence of clostridial spores in soil, water, and many foods. Clostridia are present in large numbers in the indigenous microbiota of the intestinal tract of humans and animals, in the female genital tract, and on the oral mucosa. It should be noted that not all commensal clostridia are toxigenic.

Clostridial infections remain a serious public health concern worldwide. In developing nations, food poisoning, necrotizing enterocolitis, and gas gangrene are common because large portions of the population are poor and have little or no immediate access to health care. These infections remain prevalent in developed countries as well. Gas gangrene commonly follows knife or gunshot wounds or vehicular accidents or develops as a complication of surgery or gastrointestinal carcinoma. Severe clostridial infections have emerged as a health threat to injection drug users and to women undergoing childbirth or abortion. Historically, clostridial gas gangrene has been the scourge of the battlefield. The global political situation portends another possible scenario involving mass casualties of war or terrorism, with extensive injuries conducive to gas gangrene. Therefore, there is an ongoing need to develop novel strategies to prevent or attenuate the course of clostridial infections in both civilians and military personnel. Vaccination against exotoxins important in pathogenesis would be of great benefit in developing nations and could also be used safely in at-risk populations such as the elderly, patients with diabetes who may require lower-limb surgery due to trauma or poor circulation, and those undergoing intestinal surgery. Moreover, a hyperimmune globulin would be a valuable tool for prophylaxis in victims of acute traumatic injury or for attenuation of the spread of infection in patients with established gas gangrene.

CLINICAL SYNDROMES

Life-threatening clostridial infections range from intoxications (e.g., food poisoning, tetanus) to necrotizing enteritis/colitis, bacteremia, myonecrosis, and toxic shock syndrome (TSS). **Tetanus and botulism are discussed in Chaps. 157 and 158, respectively. Colitis due to *C. difficile* is discussed in Chap. 139.**

CLOSTRIDIAL WOUND CONTAMINATION

Of open traumatic wounds, 30–80% reportedly are contaminated with clostridial species. In the absence of devitalized tissue, the presence of clostridia does not necessarily lead to infection. In traumatic injuries, clostridia are isolated with equal frequency from both suppurative and well-healing wounds. Thus, diagnosis and treatment of clostridial infection should be based on clinical signs and symptoms and not solely on bacteriologic findings.

POLYMICROBIAL INFECTIONS INVOLVING CLOSTRIDIA

Clostridial species may be found in polymicrobial infections also involving microbial components of the endogenous flora. In these infections, clostridia often appear in association with non-spore-forming anaerobes and facultative or aerobic organisms. Head and neck infections, conjunctivitis, brain abscess, sinusitis, otitis, aspiration pneumonia, lung abscess, pleural empyema, cholecystitis, septic arthritis, and bone infections all may involve clostridia. These conditions are often associated with severe local inflammation but may lack the characteristic systemic signs of toxicity and rapid progression seen in other clostridial infections. In addition, clostridia are isolated from ~66% of intraabdominal infections in which the mucosal integrity of the bowel or respiratory system has been compromised. In this setting, *C. ramosum*, *C. perfringens*, and *C. bifermentans* are the most commonly isolated species. Their presence does not invariably lead to a poor outcome. Clostridia have been isolated from suppurative infections of the female genital tract (e.g., ovarian or pelvic abscess) and from diseased gallbladders. Although the most frequently isolated species is *C. perfringens*, gangrene is not typically observed; however, gas formation in the biliary system can lead to emphysematous cholecystitis, especially in diabetic patients. *C. perfringens* in association with mixed aerobic and anaerobic microbes can cause aggressive life-threatening type I necrotizing fasciitis or Fournier's gangrene.

The treatment of mixed aerobic/anaerobic infection of the abdomen, perineum, or gynecologic organs should be based on Gram staining, culture, and antibiotic sensitivity information. Reasonable empirical treatment consists of ampicillin or ampicillin/sulbactam combined with either clindamycin or metronidazole **(Table 159-1)**.

TABLE 159-1 Treatment of Clostridial Infections

CONDITION	ANTIBIOTIC TREATMENT	PENICILLIN ALLERGY	ADJUNCTIVE TREATMENT/NOTE
Wound contamination	None	—	Treatment should be based on clinical signs and symptoms as listed below and not solely on bacteriologic findings.
Polymicrobial anaerobic infections involving clostridia (e.g., abdominal wall, gynecologic)	Ampicillin (2 g IV q4h) ***plus*** Clindamycin (600–900 mg IV q6–8h) ***plus*** Ciprofloxacin (400 mg IV q6–8h)	Vancomycin (1 g IV q12h) ***plus*** Metronidazole (500 mg IV q6h) ***plus*** Ciprofloxacin (400 mg IV q6–8h)	Empirical therapy should be initiated. Therapy should be based on Gram stain and culture results and on sensitivity data when available. Add gram-negative coverage if indicated (see text).
Clostridial sepsis	Penicillin (3–4 mU IV q4–6h) ***plus*** Clindamycin (600–900 mg IV q6–8h)	Clindamycin alone ***or*** Metronidazole (as above) ***or*** Vancomycin (as above)	Transient bacteremia without signs of systemic toxicity may be clinically insignificant.
Gas gangrene	Penicillin G (4 mU IV q4–6h) ***plus*** Clindamycin (600–900 mg IV q6–8h)	Cefoxitin (2 g IV q6h) ***plus*** Clindamycin (600–900 mg IV q6–8h)	Emergent surgical exploration and thorough debridement are extremely important. Hyperbaric oxygen therapy may be considered after surgery and antibiotic initiation.

Broader gram-negative coverage may be necessary if the patient has recently been hospitalized or treated with antibiotics. Such coverage can be obtained by substituting ticarcillin/clavulanic acid, piperacillin/sulbactam, or a carbapenem antibiotic for ampicillin or by adding a fluoroquinolone or an aminoglycoside to the regimen. Empirical treatment should be given for 10–14 days or until the patient's clinical condition improves.

ENTERIC CLOSTRIDIAL INFECTIONS

C. perfringens type A is one of the most common bacterial causes of food-borne illness in the United States and Canada. The foods typically implicated include improperly cooked meat and meat products (e.g., gravy) in which residual spores germinate and proliferate during slow cooling or insufficient reheating. Illness results from the ingestion of food containing at least ~10^8 viable vegetative cells, which sporulate in the alkaline environment of the small intestine, producing *C. perfringens* enterotoxin in the process. The diarrhea that develops within 7–30 h of ingestion of contaminated food is generally mild and self-limiting; however, in the very young, the elderly, and the immunocompromised, symptoms are more severe and occasionally fatal. Enterotoxin-producing *C. perfringens* has been implicated as an etiologic agent of persistent diarrhea in elderly patients in nursing homes and tertiary-care institutions and has been considered to play a role in antibiotic-associated diarrhea without pseudomembranous colitis.

C. perfringens strains associated with food poisoning possess the gene (*cpe*) coding for enterotoxin, which acts by forming pores in host cell membranes. *C. perfringens* strains isolated from non-food-borne diseases, such as antibiotic-associated and sporadic diarrhea, carry *cpe* on a plasmid that may be transmitted to other strains. Several methods have been described for the detection of *C. perfringens* enterotoxin in feces, including cell culture assay (Vero cells), enzyme-linked immunosorbent assay, reversed-phase latex agglutination, and polymerase chain reaction (PCR) amplification of *cpe*. Each method has its advantages and limitations. Interestingly, spores from these strains are particularly resistant to heat, cold, and chemical preservatives. In addition, the extracellular sialidase produced by *C. perfringens* facilitates pathogenesis.

Enteritis necroticans (gas gangrene of the bowel) is a fulminating clinical illness characterized by extensive necrosis of the intestinal mucosa and wall. Cases can occur sporadically in adults or as epidemics in people of all ages. Enteritis necroticans is caused by α toxin– and β toxin–producing strains of *C. perfringens* type C; β toxin is located on a plasmid and is mainly responsible for pathogenesis. This life-threatening infection causes ischemic necrosis of the jejunum. In Papua New Guinea during the 1960s, enteritis necroticans (known in that locale as *pigbel*) was found to be the most common cause of death in childhood; it was associated with pig feasts and occurred both sporadically and in outbreaks. Intramuscular immunization against the β toxin resulted in a decreased incidence of the disease in Papua New Guinea, although the condition remains common. Enteritis necroticans has also been recognized in the United States, the United Kingdom, Germany (where it is known as *darmbrand*), and other developed nations; especially affected are adults who are malnourished or who have diabetes, alcoholic liver disease, or neutropenia.

Necrotizing enterocolitis, a disease resembling enteritis necroticans but associated with *C. perfringens* type A, has been found in North America in previously healthy adults. It is also a serious gastrointestinal disease of low-birth-weight (premature) infants hospitalized in neonatal intensive care units. The etiology and pathogenesis of this disease have remained enigmatic for more than four decades. Pathologic similarities between necrotizing enterocolitis and enteritis necroticans include the pattern of small-bowel necrosis involving the submucosa, mucosa, and muscularis; the presence of gas dissecting the tissue planes; and the degree of inflammation. In contrast to enteritis necroticans, which most commonly involves the jejunum, necrotizing enterocolitis affects the ileum and frequently the ileocecal valve. Both diseases may manifest as intestinal gas cysts, although this feature is more common in necrotizing enterocolitis. The sources of the gas, which contains hydrogen, methane, and carbon dioxide, are probably the fermentative activities of intestinal bacteria, including clostridia. Epidemiologic data support an important role for *C. perfringens* or other gas-producing microorganisms (e.g., *C. neonatale*, certain other clostridia, or *Klebsiella* species) in the pathogenesis of necrotizing enterocolitis.

Patients with suspected clostridial enteric infection should undergo nasogastric suction and receive IV fluids. Pyrantel is given by mouth, and the bowel is rested by fasting. Benzylpenicillin (1 mU) is given IV every 4 h, and the patient is observed for complications requiring surgery. Patients with mild cases recover without surgical intervention. However, if surgical indications are present (gas in the peritoneal cavity, absent bowel sounds, rebound tenderness, abdominal rigidity), the mortality rate ranges from 35 to 100%; a fatal outcome is due in part to perforation of the intestine.

As pigbel continues to be a common disease in Papua New Guinea, consideration should be given to the use of a *C. perfringens* type C β toxoid vaccine in local areas. Two doses given 3–4 months apart are preventive.

CLOSTRIDIAL BACTEREMIA

Clostridium species are important causes of bloodstream infections. Molecular epidemiologic studies of anaerobic bacteremia have identified *C. perfringens* and *C. tertium* as the two most frequently isolated species; these organisms cause up to 79 and 5%, respectively, of clostridial bacteremias. Occasionally, *C. perfringens* bacteremia occurs in the absence of an identifiable infection at another site. When associated with myonecrosis, bacteremia has a grave prognosis.

C. septicum is also commonly associated with bacteremia. This species is isolated only rarely from the feces of healthy individuals but may be found in the normal appendix. More than 50% of patients whose blood cultures are positive for this organism have some gastrointestinal anomaly (e.g., diverticular disease) or underlying malignancy (e.g., carcinoma of the colon). In addition, a clinically important association of *C. septicum* bacteremia with neutropenia of any origin—and, more specifically, with neutropenic enterocolitis involving the terminal ileum or cecum—has been observed. Patients with diabetes mellitus, severe atherosclerotic cardiovascular disease, or anaerobic myonecrosis (gas gangrene) also may develop *C. septicum* bacteremia. *C. septicum* has been recovered from the bloodstream of cirrhotic patients, as have *C. perfringens*, *C. bifermentans*, and other clostridia. Infections of the bloodstream by *C. sordellii* and *C. perfringens* have been associated with TSS. Of note, Clostridium sordellii has been recently renamed Paeniclostridium sordellii. However, throughout this text, the authors have used the original nomenclature for this pathogen.

Bloodstream infection by *C. tertium*, either alone or in combination with *C. septicum* or *C. perfringens*, can be found in patients with serious underlying disease such as malignancy or acute pancreatitis, with or without neutropenic enterocolitis; the frequency has not been systematically studied. *C. tertium* may present special problems in terms of both identification and treatment. This organism may stain gram-negative; is aerotolerant; and is resistant to metronidazole, clindamycin, and cephalosporins.

Other clostridia from the *C. clostridioforme* group (including *C. clostridioforme*, *C. hathewayi*, and *C. bolteae*) can cause bacteremia.

The clinical importance of recognizing clostridial bacteremia—especially that due to *C. septicum*—and starting appropriate treatment immediately (Table 159-1) cannot be overemphasized. Patients with this condition usually are gravely ill, and infection may metastasize to distant anatomic sites, resulting in spontaneous myonecrosis (see next section). Alternative methods to identify bacteremia-causing clostridial species, such as PCR or other rapid diagnostic tests, are not currently available. Anaerobic blood cultures and Gram's stain interpretation remain the best diagnostic tests at this point.

CLOSTRIDIAL SKIN AND SOFT TISSUE INFECTIONS

Histotoxic clostridial species such as *C. perfringens*, *C. histolyticum*, *C. septicum*, C. *novyi*, and *C. sordellii* cause aggressive necrotizing infections of the skin and soft tissues. These infections are attributable

in part to the elaboration of bacterial proteases, phospholipases, and cytotoxins. Necrotizing clostridial soft tissue infections are rapidly progressive and are characterized by marked tissue destruction, gas in the tissues, and shock; they frequently end in death. Severe pain, crepitus, brawny induration with rapid progression to skin sloughing, violaceous bullae, and marked tachycardia are characteristics found in the majority of patients.

Clostridial Myonecrosis (Gas Gangrene)

• TRAUMATIC GAS GANGRENE *C. perfringens* myonecrosis (gas gangrene) is one of the most fulminant gram-positive bacterial infections of humans. Even with appropriate antibiotic therapy and management in an intensive care unit, tissue destruction can progress rapidly. Gas gangrene is accompanied by bacteremia, hypotension, and multiorgan failure and is invariably fatal if untreated. Gas gangrene is a true emergency and requires immediate surgical debridement.

The development of gas gangrene requires an anaerobic environment and contamination of a wound with spores or vegetative organisms. Devitalized tissue, foreign bodies, and ischemia reduce locally available oxygen levels and favor outgrowth of vegetative cells and spores. Thus, conditions predisposing to traumatic gas gangrene include crush-type injury, laceration of large or medium-sized arteries, and open fractures of long bones that are contaminated with soil or bits of clothing containing the bacterial spores. Gas gangrene of the abdominal wall and flanks follows penetrating injuries such as knife or gunshot wounds that are sufficient to compromise intestinal integrity, with resultant leakage of the bowel contents into the soft tissues. Proximity to fecal sources of bacteria is a risk factor for cases following hip surgery, adrenaline injections into the buttocks, or amputation of the leg for ischemic vascular disease. In addition, cutaneous gas gangrene caused by *C. perfringens*, *C. novyi*, and *C. sordellii* has been described in the United States and northern Europe among persons injecting black-tar heroin subcutaneously.

The incubation period for traumatic gas gangrene can be as short as 6 h and is usually <4 days. The infection is characterized by the sudden onset of excruciating pain at the affected site and the rapid development of a foul-smelling wound containing a thin serosanguineous discharge and gas bubbles. Brawny edema and induration develop and give way to cutaneous blisters containing bluish to maroon-colored fluid. Such tissue later may become liquefied and slough. The margin between healthy and necrotic tissue often advances several inches per hour despite appropriate antibiotic therapy, and radical amputation remains the single best life-saving intervention. Shock and organ failure frequently accompany gas gangrene; when patients become bacteremic, the mortality rate exceeds 50%.

Diagnosis of traumatic gas gangrene is not difficult because the infection always begins at the site of significant trauma, is associated with gas in the tissue, and is rapidly progressive. Gram staining of drainage or tissue biopsy is usually definitive, demonstrating large gram-positive (or gram-variable) rods, an absence of inflammatory cells, and widespread soft tissue necrosis.

SPONTANEOUS (NONTRAUMATIC) GAS GANGRENE Spontaneous gas gangrene generally occurs via hematogenous seeding of normal muscle with histotoxic clostridia—principally *C. perfringens*, *C. septicum*, and *C. novyi* and occasionally *C. tertium*—from a gastrointestinal tract portal of entry (as in colonic malignancy, inflammatory bowel disease, diverticulitis, necrotizing enterocolitis, cecitis, or distal ileitis or after gastrointestinal surgery, including colonoscopic polypectomy). These gastrointestinal pathologies permit bacterial access to the bloodstream; consequently, aerotolerant *C. septicum* can proliferate in normal tissues. Patients surviving bacteremia or spontaneous gangrene due to *C. septicum* should undergo aggressive diagnostic studies to rule out gastrointestinal pathology.

Additional predisposing host factors include leukemia, lymphoproliferative disorders, cancer chemotherapy, radiation therapy, and AIDS. Cyclic, congenital, or acquired neutropenia also is strongly associated with an increased incidence of spontaneous gas gangrene due to *C. septicum*; in such cases, necrotizing enterocolitis, cecitis, or distal ileitis is common, particularly among children.

FIGURE 159-2 Radiograph of patient with spontaneous gas gangrene due to *C. septicum,* demonstrating gas in the affected arm and shoulder.

The first symptom of spontaneous gas gangrene may be confusion followed by the abrupt onset of excruciating pain in the absence of trauma. These findings, along with fever, should heighten suspicion of spontaneous gas gangrene. However, because of the lack of an obvious portal of entry, the correct diagnosis is frequently delayed or missed. The infection is characterized by rapid progression of tissue destruction with demonstrable gas in the tissue **(Fig. 159-2)**. Swelling increases, and bullae filled with clear, cloudy, hemorrhagic, or purplish fluid appear. The surrounding skin has a purple hue, which may reflect vascular compromise resulting from the diffusion of bacterial toxins into surrounding tissues. Invasion of healthy tissue rapidly ensues, with quick progression to shock and multiple-organ failure. Mortality rates in this setting range from 67 to 100% among adults; among children, the mortality rate is 59%, with the majority of deaths occurring within 24 h of onset.

PATHOGENESIS OF GAS GANGRENE In traumatic gas gangrene, organisms are introduced into devitalized tissue. It is important to recognize that for *C. perfringens* and *C. novyi*, trauma must be sufficient to interrupt the blood supply and thereby to establish an optimal anaerobic environment for growth of these species. These conditions are not strictly required for the more aerotolerant species such as *C. septicum* and *C. tertium*, which can seed normal tissues from gastrointestinal lesions. Once introduced into an appropriate niche, the organisms proliferate locally and elaborate exotoxins.

The major *C. perfringens* extracellular toxins implicated in gas gangrene are α toxin and θ toxin. A lethal hemolysin that has both phospholipase C and sphingomyelinase activities, α toxin has been implicated as the major virulence factor of *C. perfringens*: immunization of mice with the C-terminal domain of α toxin provides protection against lethal challenge with *C. perfringens*, and isogenic α toxin–deficient mutant strains of *C. perfringens* are not lethal in a murine model of gas gangrene. Recently, a human single chain recombinant antibody against α toxin has been developed having significant preventative and therapeutic efficacy in mice.

It has been shown in experimental models that the severe pain, rapid progression, marked tissue destruction, and absence of neutrophils in *C. perfringens* gas gangrene are attributable in large part to

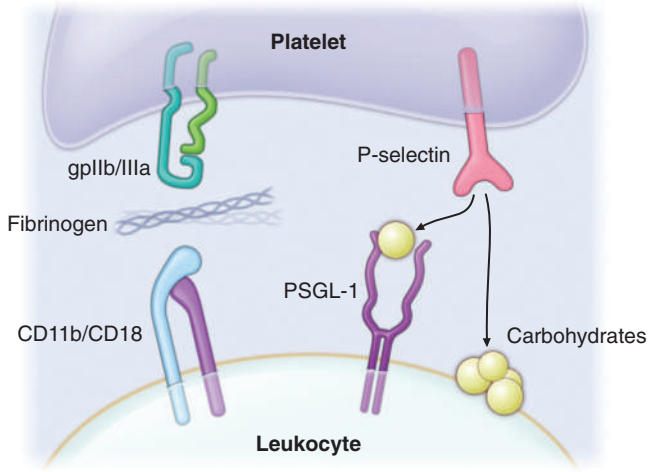

FIGURE 159-3 Schematic illustration of the molecular mechanisms of *C. perfringens* α toxin–induced platelet/neutrophil aggregates. Homotypic aggregates of platelets (not shown) and heterotypic aggregates of platelets and leukocytes are due to α toxin–induced activation of the platelet fibrinogen receptor gpIIb/IIIa and upregulation of leukocyte CD11b/CD18. Binding of fibrinogen (*red*) bridges the connection between these adhesion molecules on adjacent cells. An auxiliary role for α toxin–induced upregulation of platelet P-selectin and its binding to leukocyte P-selectin glycoprotein ligand 1 (PSGL-1) or other leukocyte surface carbohydrates also has been demonstrated.

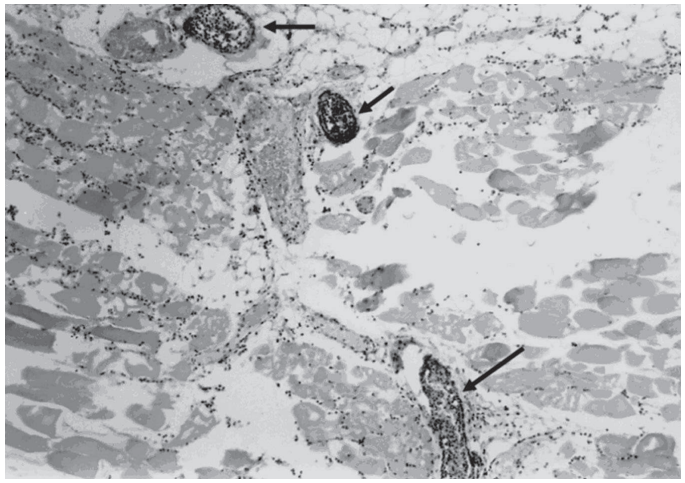

FIGURE 159-4 Histopathology of experimental gas gangrene due to *C. perfringens*, demonstrating widespread muscle necrosis, a paucity of leukocytes in infected tissues, and accumulation of leukocytes in adjacent vessels (*arrows*). These features are due to the effects of α and θ toxins on muscle cells, platelets, leukocytes, and endothelial cells.

α toxin–induced occlusion of blood vessels by heterotypic aggregates of platelets and neutrophils. The formation of these aggregates, which occurs within minutes, is largely mediated by α toxin's ability to activate the platelet adhesion molecule gpIIb/IIIa **(Fig. 159-3)**; the implication is that platelet glycoprotein inhibitors (e.g., eptifibatide, abciximab) may be therapeutic for maintaining tissue blood flow.

C. perfringens θ toxin (*perfringolysin,* PFO) is a member of the thiol-activated cytolysin family known as cholesterol-dependent cytolysins, which includes streptolysin O from group A *Streptococcus*, pneumolysin from *Streptococcus pneumoniae*, and several other toxins. Cholesterol-dependent cytolysins bind as oligomers to cholesterol in host cell membranes. At high concentrations, these toxins form ring-like pores resulting in cell lysis. At sublytic concentrations, PFO hyperactivates phagocytes and vascular endothelial cells. PFO-mediated activation of the macrophage inflammasome, with production of IL-1β, has also been reported.

Cardiovascular collapse and end-organ failure occur late in the course of *C. perfringens* gas gangrene and are largely attributable to both direct and indirect effects of α and θ toxins. In experimental models, θ toxin causes markedly reduced systemic vascular resistance but increased cardiac output (i.e., "warm shock"), probably via induction of endogenous mediators (e.g., prostacyclin, platelet-activating factor) that cause vasodilation. This effect is similar to that observed in gram-negative sepsis. In sharp contrast, α toxin directly suppresses myocardial contractility; the consequence is profound hypotension due to a sudden reduction in cardiac output. The roles of other endogenous mediators, such as cytokines (e.g., tumor necrosis factor, interleukins 1 and 6) and vasodilators (e.g., bradykinin) have not been fully elucidated.

C. septicum produces four main toxins—α toxin (lethal, hemolytic, necrotizing activity), β toxin (DNase), γ toxin (hyaluronidase), and Δ toxin (septicolysin, an oxygen-labile hemolysin)—as well as a protease and a neuraminidase. Unlike the α toxin of *C. perfringens*, that of *C. septicum* does not possess phospholipase activity. The mechanisms remain to be fully elucidated, but it is likely that each of these toxins contributes uniquely to *C. septicum* gas gangrene.

TREATMENT

Gas Gangrene

Patients with suspected gas gangrene (either traumatic or spontaneous) should undergo prompt surgical inspection of the infected site. Direct examination of a gram-stained smear of the involved tissues is of major importance. Characteristic histologic findings in clostridial gas gangrene include widespread tissue destruction, a paucity of leukocytes in infected tissues in conjunction with an accumulation of leukocytes in adjacent vessels **(Fig. 159-4)**, and the presence of gram-positive rods (with or without spores). Computed tomography (CT) and magnetic resonance imaging (MRI) are invaluable for determining whether the infection is localized or is spreading along fascial planes, and needle aspiration or punch biopsy may provide an etiologic diagnosis in at least 20% of cases. However, these techniques should not replace surgical exploration, Gram's staining, and histopathologic examination. When spontaneous gas gangrene is suspected, blood should be cultured since bacteremia usually precedes cutaneous manifestations by several hours.

For patients with evidence of clostridial gas gangrene, thorough emergent surgical debridement is of extreme importance. All devitalized tissue should be widely resected back to healthy viable muscle and skin so as to remove conditions that allow anaerobic organisms to continue proliferating. Closure of traumatic wounds or compound fractures should be delayed for 5–6 days until it is certain that these sites are free of infection.

Antibiotic treatment of traumatic or spontaneous gas gangrene (Table 159-1) consists of the administration of penicillin and clindamycin for 10–14 days. Penicillin is recommended on the basis of in vitro sensitivity data; clindamycin is recommended because of its superior efficacy over penicillin in animal models of *C. perfringens* gas gangrene and in some clinical reports. Controlled clinical trials comparing the efficacy of these agents in humans have not been performed. In the penicillin-allergic patient, clindamycin may be used alone. The superior efficacy of clindamycin is probably due to its ability to inhibit bacterial protein toxin production, its insensitivity to the size of the bacterial load or the stage of bacterial growth, and its ability to modulate the host immune response.

Although *C. perfringens* remains largely susceptible to first-line antibiotics, antibiotic resistance has been reported. Case reports from the United Kingdom and from Spain found clindamycin-resistant *C. perfringens* in cellulitis and in a spontaneous abscess, respectively. Larger studies from Canada and Taiwan also showed increasing resistance to clindamycin among bloodstream isolates. In 2014, Marchand-Austin et al. published a 2-year prospective Canadian study that examined antimicrobial susceptibility of anaerobic bacteria isolated from blood, body fluids, and abscesses. Of 1412 isolates submitted for susceptibility testing, 68 were *C. perfringens*. Of these, all were universally susceptible to penicillin, but 3.8% were clindamycin-resistant. Notably, for *Clostridium* species other than *C. perfringens* (n = 289), 14.2% were penicillin-resistant

and 21.6% clindamycin-resistant. A more recent study from Iran found that 21.2% of *C. perfringens* isolates were resistant to penicillin. Lastly, a 2019 study from Hungary found resistance to penicillin (2.6%) and clindamycin (3.8%) among *C. perfringens* isolates (n = 313) from tissues with gas gangrene. Among the non-perfringens gas gangrene isolates (n = 59), higher resistance to penicillin and clindamycin was observed (6.8% and 8.5%, respectively). These findings, though not universal, highlight the importance of good anaerobic microbiology susceptibility testing to provide up-to-date information to guide optimal clinical management decisions for clostridial infections.

C. tertium is resistant to penicillin, cephalosporins, and clindamycin. Appropriate antibiotic therapy for *C. tertium* infection is vancomycin (1 g every 12 h IV) or metronidazole (500 mg every 8 h IV).

The value of adjunctive treatment with hyperbaric oxygen (HBO) for gas gangrene remains controversial. Basic science studies suggest that HBO can inhibit the growth of *C. perfringens* but not that of the more aerotolerant *C. septicum*. In vitro, blood and macerated muscle inhibit the bactericidal potential of HBO. Numerous studies in animals demonstrate little efficacy of HBO alone, whereas antibiotics alone—especially those that inhibit bacterial protein synthesis—confer marked benefits. Addition of HBO to the therapeutic regimen provides some additional benefit, but only if surgery and antibiotic administration precede HBO treatment.

In conclusion, gas gangrene is a rapidly progressive infection whose outcome depends on prompt recognition, emergent surgery, and timely administration of antibiotics that inhibit toxin production. Gas gangrene associated with bacteremia probably represents a later stage of illness and is associated with the worst outcomes. Emergent surgical debridement is crucial to ensure survival, and ancillary procedures (e.g., CT or MRI) or transport to HBO units should not delay this intervention. Some trauma centers associated with HBO units may have special expertise in managing these aggressive infections, but proximity and speed of transfer must be carefully weighed against the need for haste.

PROGNOSIS OF GAS GANGRENE The prognosis for patients with gas gangrene is more favorable when the infection involves an extremity rather than the trunk or visceral organs, since debridement of the latter sites is more difficult. Gas gangrene is most likely to progress to shock and death in patients with associated bacteremia and intravascular hemolysis. Mortality rates are highest for patients in shock at the time of diagnosis. Mortality rates are relatively high among patients with spontaneous gas gangrene, especially that due to *C. septicum*. Survivors of gas gangrene may undergo multiple debridements and face long periods of hospitalization and rehabilitation.

PREVENTION OF GAS GANGRENE Initial aggressive debridement of devitalized tissue can reduce the risk of gas gangrene in contaminated deep wounds. Interventions to be avoided include prolonged application of tourniquets and surgical closure of traumatic wounds; patients with compound fractures are at significant risk for gas gangrene if the wound is closed surgically. Vaccination against α toxin is protective in experimental animal models of *C. perfringens* gas gangrene but has not been investigated in humans. In addition, as mentioned above, a hyperimmune globulin would represent a significant advance for prophylaxis in victims of acute traumatic injury or for attenuation of the spread of infection in patients with established gas gangrene.

Toxic Shock Syndrome Clostridial infection of the endometrium, particularly that due to *C. sordellii*, can develop after gynecologic procedures, childbirth, or abortion (spontaneous or elective, surgical, or medical) and, once established, proceeds rapidly to TSS and death. Systemic manifestations, including edema, effusions, profound leukocytosis, and hemoconcentration, are followed by the rapid onset of hypotension and multiple-organ failure. Elevation of the hematocrit to 75–80% and leukocytosis of 50,000–200,000 cells/μL, with a left shift, are characteristic of *C. sordellii* infection. Pain may not be a prominent feature, and fever is typically absent. In one series, 18% of 45 cases of *C. sordellii* infection were associated with normal childbirth, 11% with medically induced abortion, and 0.4% with spontaneous abortion; the case-fatality rate was 100% in these groups. Of the infections in this series that were not related to gynecologic procedures or childbirth, 22% occurred in injection drug users, and 50% of these patients died. Other infections followed trauma or surgery (42%), mostly in healthy persons, and 53% of these patients died. Overall, the mortality rate was 69% (31 of 45 cases). Of patients who succumbed, 85% died within 2–6 days after infection onset or following procedures. Rapidly fatal spontaneous *C. bifermentans* necrotizing endometritis with toxic shock, leukemoid reaction, and capillary leak has also been described.

Early diagnosis of *C. sordellii* infections often proves difficult for several reasons. First, the prevalence of these infections is low. Second, the initial symptoms are nonspecific and frankly misleading. Early in the course, the illness resembles any number of infectious diseases, including viral syndromes. Given these vague symptoms and an absence of fever, physicians usually do not aggressively pursue additional diagnostic tests. The absence of local evidence of infection and the lack of fever make early diagnosis of *C. sordellii* infection particularly problematic in patients who develop deep-seated infection following childbirth, therapeutic abortion, gastrointestinal surgery, or trauma. Such patients are frequently evaluated for pulmonary embolization, gastrointestinal bleeding, pyelonephritis, or cholecystitis. Unfortunately, such delays in diagnosis increase the risk of death, and as in most necrotizing soft tissue infections, patients are hypotensive with evidence of organ dysfunction by the time local signs and symptoms become apparent. In contrast, infection is more readily suspected in injection drug users presenting with local swelling, pain, and redness at injection sites; early recognition probably contributes to the lower mortality rates in this group.

Physicians should suspect *C. sordellii* infection in patients who present within 2–7 days after injury, surgery, drug injection, childbirth, or abortion and who report pain, nausea, vomiting, and diarrhea but are afebrile. There is little information regarding appropriate treatment for *C. sordellii* infections. In fact, the interval between onset of symptoms and death is often so short that there is little time to initiate empirical antimicrobial therapy. Indeed, anaerobic cultures of blood and wound aspirates are time-consuming, and many hospital laboratories do not routinely perform antimicrobial sensitivity testing on anaerobes. Antibiotic susceptibility data from older studies suggest that *C. sordellii*, like most clostridia, is susceptible to β-lactam antibiotics, clindamycin, tetracycline, and chloramphenicol but is resistant to aminoglycosides and sulfonamides. Antibiotics that suppress toxin synthesis (e.g., clindamycin) may possibly prove useful as therapeutic adjuncts since they are effective in necrotizing infections due to other toxin-producing gram-positive organisms. With the adoption of restrictive legislation that reduces or prohibits access to medically supervised abortions, the incidence of these deadly clostridial infections could increase as patients undergo unsafe pregnancy termination.

Other Clostridial Skin and Soft-Tissue Infections *Crepitant cellulitis* (also called *anaerobic cellulitis*) occurs principally in diabetic patients and characteristically involves subcutaneous tissues or retroperitoneal tissues, whereas the muscle and fascia are not involved. This infection can progress to fulminant systemic disease.

Cases of *C. histolyticum* infection with cellulitis, abscess formation, or endocarditis have also been documented in injection drug users. Endophthalmitis due to *C. sordellii* or *C. perfringens* has been described. *C. ramosum* is also isolated frequently from clinical specimens, including blood and both intraabdominal and soft tissues. This species may be resistant to clindamycin and multiple cephalosporins.

Section 6 Diseases Caused by Gram-Negative Bacteria

160 Meningococcal Infections

Manish Sadarangani, Andrew J. Pollard

DEFINITION

Infection with *Neisseria meningitidis* most commonly manifests as asymptomatic colonization in the nasopharynx of healthy adolescents and adults. Invasive disease occurs rarely, usually presenting as either bacterial meningitis or meningococcal septicemia. Patients may also present with occult bacteremia, pneumonia, septic arthritis, conjunctivitis, and chronic meningococcemia.

ETIOLOGY AND MICROBIOLOGY

N. meningitidis is a gram-negative aerobic diplococcus that colonizes humans only and causes disease after transmission to a susceptible individual. Several related neisserial organisms have been recognized, including the pathogen *N. gonorrhoeae* and the commensals *N. lactamica*, *N. flavescens*, *N. mucosa*, *N. sicca*, and *N. subflava*. *N. meningitidis* is a catalase- and oxidase-positive organism that utilizes glucose and maltose to produce acid.

Meningococci associated with invasive disease are usually encapsulated with polysaccharide, and the antigenic nature of the capsule determines an organism's capsular group (serogroup) (Table 160-1).

TABLE 160-1 Structure of the Polysaccharide Capsule of Common Disease-Causing Meningococci

MENINGOCOCCAL CAPSULAR GROUP	CHEMICAL STRUCTURE OF OLIGOSACCHARIDE	CURRENT DISEASE EPIDEMIOLOGY
A	2-Acetamido-2-deoxy-D-mannopyranosyl phosphate	Epidemic disease mainly in sub-Saharan Africa; sporadic cases worldwide
B	α-2,8-*N*-acetylneuraminic acid	Sporadic cases worldwide; propensity to cause hyperendemic disease
C	α-2,9-*O*-acetylneuraminic acid	Small outbreaks and sporadic disease
Y	4-*O*-α-D-glucopyranosyl-*N*-acetylneuraminic acid	Sporadic disease and occasional small institutional outbreaks
W	4-*O*-α-D-galactopyranosyl-*N*-acetylneuraminic acid	Sporadic disease; outbreaks of disease associated with mass gatherings; epidemics in sub-Saharan Africa
X	(α1→4) *N*-acetyl-D-glucosamine-1-phosphate	Sporadic disease and large outbreaks in the meningitis belt of Africa

In total, 12 capsular groups have been identified (A–C, X–Z, E, W, H–J, and L), but just six of these—A, B, C, X, Y, and W (formerly W135)—account for the majority of cases of invasive disease. Group D is often listed as the thirteenth capsular group but has been identified as an unencapsulated variant of group C. Meningococci are commonly isolated from the nasopharynx in studies of carriage; the lack of capsule often is a result of phase variation of capsule expression, but as many as 16% of isolates lack the genes for capsule synthesis and assembly. These "capsule-null" meningococci and those that express capsules other than A, B, C, X, Y, and W are only rarely associated with invasive disease and are most commonly identified in the nasopharynx of asymptomatic carriers.

Beneath the capsule, meningococci are surrounded by an outer phospholipid membrane containing lipopolysaccharide (LPS, endotoxin) and multiple outer-membrane proteins (Figs. 160-1 and 160-2). Antigenic variability in porins expressed in the outer membrane defines the serotype (PorB) and serosubtype (PorA) of the organism, and structural differences in LPS determine the immunotype. Serologic methods for typing meningococci are restricted by the limited availability of serologic reagents that can distinguish among the organisms' highly variable surface proteins. Where available, high-throughput antigen gene sequencing has superseded serology for

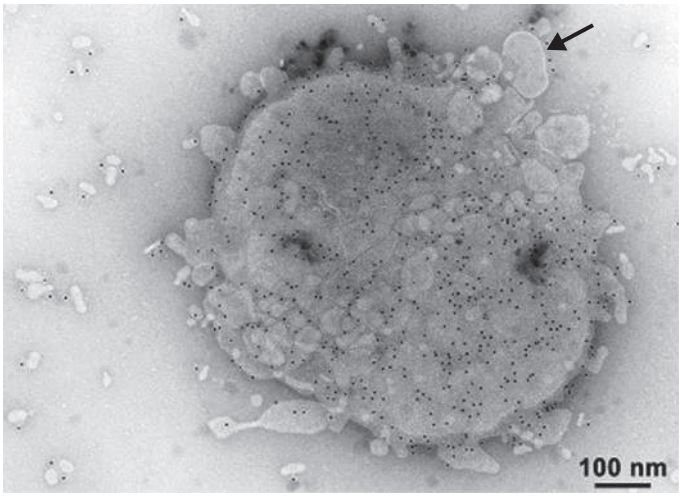

FIGURE 160-1 Electron micrograph of *Neisseria meningitidis*. Black dots are gold-labeled polyclonal antibodies binding surface opacity proteins. Blebs of outer membrane can be seen being released from the bacterial surface (*arrow*). *(Photo courtesy of D. Ferguson, Oxford University.)*

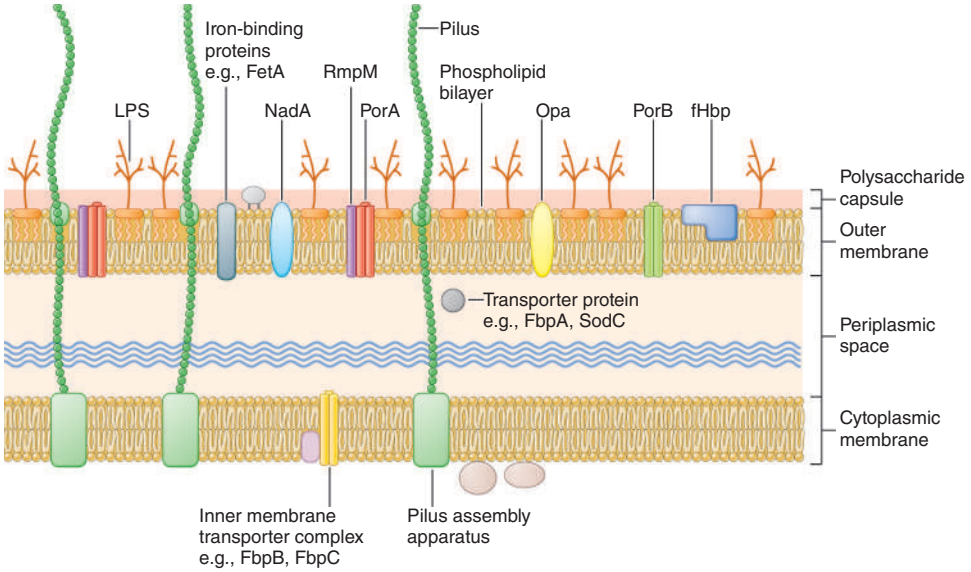

FIGURE 160-2 Cross-section through surface structures of *Neisseria meningitidis*. LPS, lipopolysaccharide. *(Reproduced with permission from M Sadarangani, AJ Pollard: Serogroup B meningococcal vaccines–an unfinished story. Lancet Infect Dis 10:112, 2010.)*

meningococcal typing. A large database of antigen gene sequences for the outer-membrane proteins PorA, PorB, FetA, Opa, NadA, neisserial heparin binding antigen (NHBA), and factor H–binding protein (fHbp) is available online (*pubmlst.org/organisms/neisseria-spp*). The number of specialized iron-regulated proteins found in the meningococcal outer membrane (e.g., FetA and transferrin-binding proteins) highlights the organisms' dependence on iron from human sources. A thin peptidoglycan cell wall separates the outer membrane from the cytoplasmic membrane.

The structure of meningococcal populations involved in local and global spread was first studied with multilocus enzyme electrophoresis (MLEE), which characterizes isolates according to differences in the electrophoretic mobility of cytoplasmic enzymes, followed by multilocus sequence typing (MLST), in which meningococci are characterized by sequence types assigned on the basis of sequences of internal fragments of seven housekeeping genes and, more recently, whole genome sequencing (>60,000 genomes are listed in PubMLST [*https://pubmlst.org/organisms/neisseria-spp/*]). While many distinct genotypes exist, a limited number of hyperinvasive lineages of *N. meningitidis* have been recognized, persist over decades, and are responsible for the majority of cases of invasive meningococcal disease worldwide. Hyperinvasive lineages may be associated with more than one capsular group. The apparent genetic stability of these meningococcal clones over decades and during wide geographic spread indicates that they are well adapted to the nasopharyngeal environment of the host and to efficient transmission.

The group B meningococcal genome is >2 megabases in length and contains 2158 coding regions. Many genes undergo phase variation that makes it possible to control their expression; this capacity is likely to be important in meningococcal adaptation to the host environment and evasion of the immune response. Meningococci can obtain DNA from their environment and can acquire new genes—including the capsular operon—such that *capsule switching* from one capsular group to another can occur.

EPIDEMIOLOGY

Patterns of Disease Up to 500,000 cases of meningococcal disease are thought to occur worldwide each year, although the numbers have been declining recently as a result of both immunization programs and secular trends. About 10% of affected individuals die. There are several patterns of disease: epidemic, outbreak (small clusters of cases), hyperendemic, and sporadic or endemic.

Epidemics have continued since the original descriptions of meningococcal disease, especially affecting the sub-Saharan meningitis belt of Africa, where tens to hundreds of thousands of cases (caused mainly by capsular group A but also by capsular groups C, W, and X) may be reported over a season and rates may be as high as 1000 cases per 100,000 population. Capsular group A epidemics took place in Europe and North America after the First and Second World Wars, and capsular group A outbreaks have been documented over the past 40 years in New Zealand, China, Nepal, Mongolia, India, Pakistan, Poland, and Russia. However, 65% of outbreaks reported in the meningitis belt between 2010 and 2017 were caused by capsular group C and 35% by capsular group W meningococci, following an immunization campaign to control capsular group A outbreaks. New vaccines covering A, C, W, Y, and X are becoming available globally to extend control of outbreaks.

Clusters of cases occur where there is an opportunity for increased transmission—i.e., in closed or semi-closed communities such as schools, colleges, universities, military training centers, and refugee camps. Over the past 4 decades, such clusters have been especially strongly linked with a particular clone (sequence type 11) that is mainly associated with capsular group C or W but was first described in association with capsular group B. Clusters of capsular group W disease associated with the Hajj pilgrimage in 2000/2001 led to a requirement for vaccination against meningococcal disease for travel to Saudi Arabia. Wider and more prolonged community outbreaks (hyperendemic disease) due to single clones of capsular group B meningococci account for ≥10 cases per 100,000. Regions affected in the past 35 years include the U.S. Pacific Northwest, New Zealand (both islands), and the province of Normandy in France.

Most countries experience predominantly sporadic cases (0.0–2.8 cases per 100,000 population, but recently rates up to 10 cases per 100,000 have been reported in Africa), with many different disease-causing clones involved and usually no clear epidemiologic link between one case and another. The disease rate and the distribution of meningococcal strains vary in different regions of the world and also in any one location over time. For example, in the United States, the rate of meningococcal disease fell from 1.2 cases per 100,000 population in 1997 to 0.06 cases per 100,000 in 2021 **(Fig. 160-3)**. Meningococcal disease in the United States was previously dominated by capsular groups B and C; however, in 2011–2021, group B alone was predominant in children age <5 years, whereas disease in children over 11 years of age, adolescents, and adults was dominated by capsular groups C, W, and Y **(Fig. 160-4)**. There has been a sharp, but small, increase in capsular group Y starting in 2022, with the highest rates in Americans of black ethnicity, individuals over 30 years of age, and those living with HIV. In contrast, rates of disease in England and Wales rose to >5 cases per 100,000 during the 1990s because of an increase in cases caused by the ST11 capsular group C clone. A mass immunization program against capsular group C was undertaken beginning in 1999 and resulted in a large impact against the disease, leaving capsular group B meningococci as the predominant cause of infection in the past quarter century (87% of United Kingdom cases in 2021–2022). Introduction of a group B meningococcal (MenB) vaccine for infants in the United Kingdom in 2015 also led to a significant reduction in group B cases. A hyperinvasive ST11 clone bearing a W capsule emerged in South America and spread to various countries in Europe and in Australia with cases peaking in 2016 in the United Kingdom. During the same decade, increases in capsular group Y disease were noted in various countries including Europe, Canada, and South Africa, highlighting the continuing emergence and re-emergence of capsular groups and genotypes over time. Nevertheless, over the past 15 years, most industrialized nations have observed a decrease in meningococcal disease linked to the introduction of immunization against capsular group C meningococci

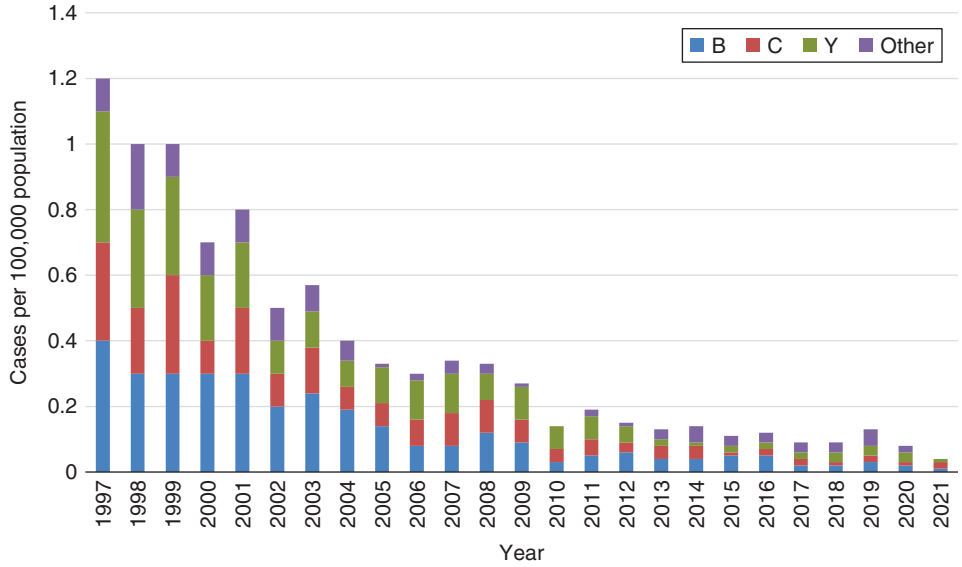

FIGURE 160-3 Meningococcal disease in the United States, 1997–2021. ABCs, active bacterial cores. *(Adapted from ABC Surveillance data, Centers for Disease Control and Prevention; https://www.cdc.gov/abcs/reports-findings/surv-reports.html.)*

in young children or teenagers and the use of adolescent immunization programs for capsular groups A, C, Y, and W. However, other factors, including changes in natural population immunity (induced by exposure from nasopharyngeal colonization) and prevalent clones of meningococci (factors that, in combination, probably explain the historical cyclic nature of meningococcal disease rates) as well as a reduction in smoking and passive exposure to tobacco smoke (driven by bans on smoking in buildings and public spaces) across wealthy countries, are likely to have contributed to the fall in cases. There are also data from the United Kingdom indicating that reductions in contacts between individuals during the COVID-19 pandemic led to further substantial declines in meningococcal disease and that contact patterns remain altered and could have a sustained effect on transmission.

Factors Associated with Disease Risk and Susceptibility The principal determinant of disease susceptibility is age, with the peak incidence in the first year of life (Fig. 160-5). The susceptibility of the very young presumably results from an absence of specific adaptive immunity in combination with very close contact with colonized individuals, including parents. Compared with other age groups, infants appear to be particularly susceptible to capsular group B disease: >30% of capsular group B cases in the United States occur during the first year of life. In the early 1990s prior to use of vaccines in North America, the median ages for patients with disease due to capsular groups B, C, Y, and W were 6, 17, 24, and 33 years, respectively. In populations where capsular group A, C, W, and Y vaccines are being used with good coverage, disease from these capsular groups has become very rare in children.

After early childhood, a second peak of disease occurs among adolescents and young adults (15–25 years of age) in Europe and North America. It is thought that this peak relates to social behaviors and environmental exposures in this age group, as discussed below. Most cases of infection with *N. meningitidis* in developed countries today are sporadic, and the rarity of the disease suggests that individual

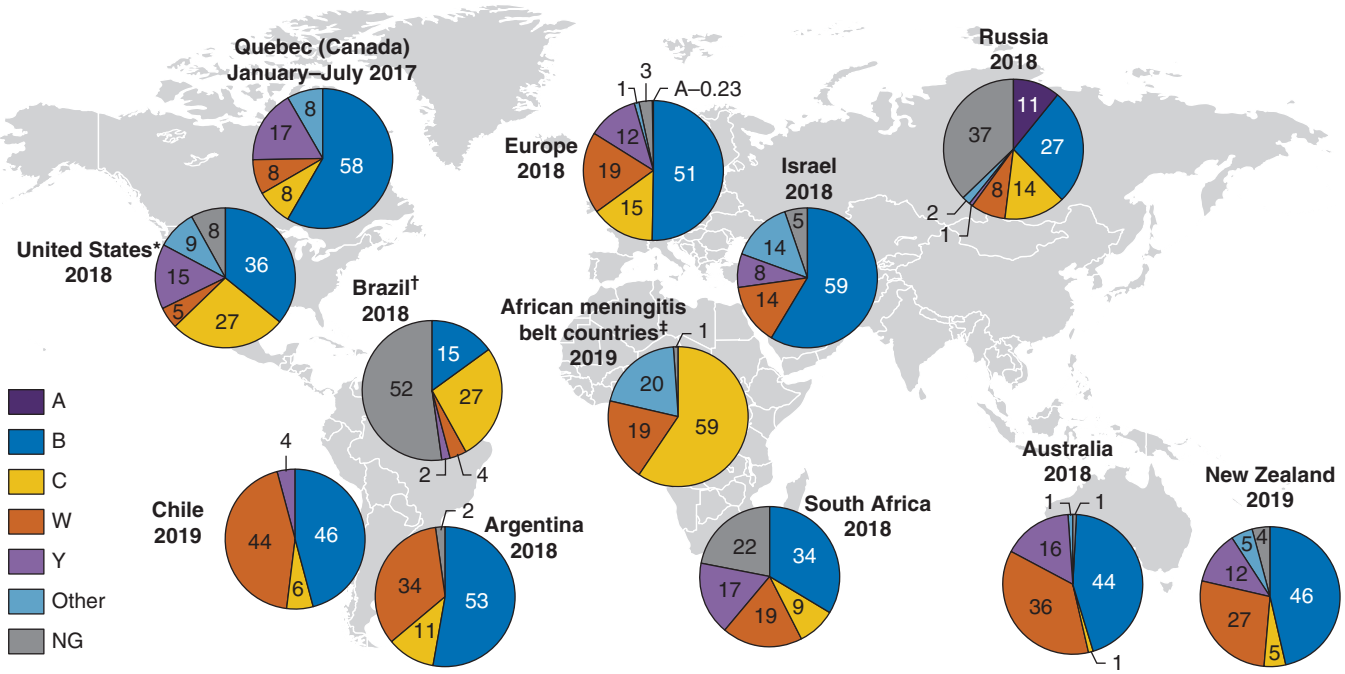

FIGURE 160-4 Global percentage distribution of meningococcal capsular groups causing invasive meningococcal disease, 2017–2019. NG, non-groupable plus capsular groups other than B, C, W, and Y. *(Adapted from C Pardo de Santayana et al: Epidemiology of invasive meningococcal disease worldwide from 2010–2019: A literature review. Epidemiol Infect 151:e57, 2023.)*

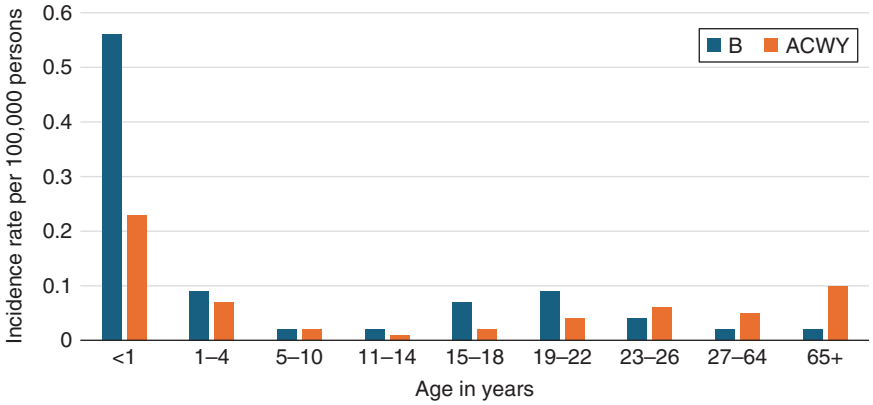

FIGURE 160-5 Age distribution of capsular groups B and ACWY meningococcal disease United States, 2012–2021. *(Adapted from https://www.cdc.gov/meningococcal/php/surveillance/.)*

susceptibility may be important. A number of factors probably contribute to individual susceptibility, including the host's genetic constitution, environment, and contact with a carrier or a case.

The best-documented genetic association with meningococcal disease is complement deficiency, chiefly of the terminal complement components (C5–9), properdin, or factor D or those treated with complement inhibitors such as eculizumab; such a deficiency increases the risk of disease by up to 600-fold and may result in recurrent attacks. Complement components are believed to be important for the bactericidal activity of serum, which is considered the principal mechanism of immunity against invasive meningococcal disease. However, when investigated, complement deficiency is found in only a very small proportion of individuals with meningococcal disease (0.3%). Conversely, 7–20% of persons whose disease is caused by the less common capsular groups (W, X, Y, Z, E) have a complement deficiency. Complement deficiency appears to be associated with capsular group B disease only rarely. Individuals with recurrences of meningococcal disease, particularly those caused by non-B capsular groups, should be assessed for complement deficiency by measurement of total hemolytic complement activity. There is also limited evidence that hyposplenism (through reduction in phagocytic capacity), hypogammaglobulinemia (through absence of specific antibody), and HIV increase the risk of meningococcal disease. Genetic studies have revealed various associations with disease susceptibility, including complement and mannose-binding lectin deficiency, single-nucleotide polymorphisms in Toll-like receptor (TLR) 4 and complement factor H, and variants of Fc gamma receptors.

Factors that increase the chance of a susceptible individual's acquiring *N. meningitidis* via the respiratory route also increase the risk of meningococcal disease. Acquisition occurs through close contact with carriers as a result of overcrowding (e.g., in poor socioeconomic settings, in refugee camps, during the Hajj pilgrimage to Mecca, during freshman-year residence in college dormitories), recruitment into the military, and certain social behaviors (e.g., attendance at bars and nightclubs, kissing). Secondary cases may occur in close contacts of an index case (e.g., household members, persons kissing the infected individual); the risk to these contacts may be as high as 1000 times the background rate in the population. Factors that damage the nasopharyngeal epithelium also increase the risk of both colonization with *N. meningitidis* and invasive disease. The most important of these factors are tobacco smoking (odds ratio, 4.1) and passive exposure to tobacco smoke. In addition, recent viral respiratory tract infection, infection with *Mycoplasma* species, and winter or the dry season (in sub-Saharan Africa) have been associated with meningococcal disease; all of these factors presumably either increase the expression of adhesion molecules in the nasopharynx, thus enhancing meningococcal adhesion, or facilitate meningococcal invasion of the bloodstream.

PATHOGENESIS

N. meningitidis has evolved as an effective colonizer of the human nasopharynx, with asymptomatic infection rates of >25% described in some series of adolescents and young adults and among residents of crowded communities. Point-prevalence studies reveal widely divergent rates of carriage for different types of meningococci. This variation suggests that some types may be adapted to a short duration of carriage with frequent transmission to maintain the population, while others may be less efficiently transmitted but may overcome this disadvantage by colonizing for a long period. Despite the high rates of carriage among adolescents and young adults, only ~10% of adults carry meningococci, and colonization is very rare in early childhood. Many of the same factors that increase the risk of meningococcal disease also increase the risk of carriage. Colonization of the nasopharynx involves a series of interactions of meningococcal adhesins (e.g., Opa proteins and pili) with their ligands on the epithelial mucosa. *N. meningitidis* produces an IgA1 protease that is likely to reduce interruption of colonization by mucosal IgA.

Colonization should be considered the normal state of meningococcal infection, with an increased risk of invasion being the unfortunate consequence (for both host and organism) of adaptations of hyperinvasive meningococcal lineages to favor their survival. The meningococcal capsule is an important virulence factor: acapsular strains only very rarely cause invasive disease. The capsule provides resistance to phagocytosis and may be important in preventing desiccation during transmission between hosts. Antigenic diversity in surface structures and an ability to vary levels of their expression probably have evolved as important factors in maintaining meningococcal populations within and between individual hosts.

Invasion through the mucosa into the bloodstream occurs rarely, usually within a few days of acquisition of an invasive strain by a susceptible individual. Only occasional cases of prolonged colonization prior to invasion have been documented. Once the organism is in the bloodstream, its growth may be limited if the individual is partially immune, although bacteremia may allow seeding of another site, such as the meninges or the joints. Alternatively, unchecked proliferation may continue, resulting in high bacterial counts in the circulation. During growth, meningococci release blebs of outer membrane (Fig. 160-1) containing outer-membrane proteins and LPS. Endotoxin binds cell-bound CD14 in association with TLR4 to initiate an inflammatory cascade with the release of high levels of various mediators, including tumor necrosis factor (TNF) α, soluble TNF receptor, interleukin (IL) 1, IL-1 receptor antagonist, IL-1β, IL-6, IL-8, IL-10, plasminogen-activator inhibitor 1 (PAI-1), and leukemia inhibitory factor. Soluble CD14-bound endotoxin acts as a mediator of endothelial activation. The severity of meningococcal disease is related both to the levels of endotoxin in the blood and to the magnitude of the inflammatory response. The latter is determined to some extent by polymorphisms in the inflammatory response genes (and their inhibitors), and the release of the inflammatory cascade heralds the development of meningococcal septicemia (meningococcemia). Endothelial injury is central to many clinical features of meningococcemia, including increased vascular permeability, pathologic changes in vascular tone, loss of thromboresistance, intravascular coagulation, and myocardial dysfunction. Endothelial injury leads to increased vascular permeability (attributed to loss of glycosaminoglycans and endothelial proteins), with subsequent gross proteinuria. Leakage of fluid and electrolytes into the tissues from capillaries ("capillary leak syndrome") leads to hypovolemia, tissue edema, and pulmonary edema. Initial compensation results in vasoconstriction and tachycardia, although cardiac output eventually falls. While resuscitation fluids may restore circulating volume, tissue edema will continue to increase, and, in the lung, the consequence may be respiratory failure.

Intravascular thrombosis (caused by activation of procoagulant pathways in association with upregulation of tissue factor on the endothelium) occurs in some patients with meningococcal disease and results in purpura fulminans and infarction of areas of skin or even of whole limbs. At the same time, multiple anticoagulant pathways

are downregulated through loss of endothelial thrombomodulin and protein C receptors and decreases in levels of antithrombin III, protein C, protein S, and tissue factor pathway inhibitor. Thrombolysis is also profoundly impaired in meningococcal sepsis through the release of high levels of PAI-1.

Shock in meningococcal septicemia appears to be attributable to a combination of factors, including hypovolemia, which results from the capillary leak syndrome secondary to endothelial injury, and myocardial depression, which is driven by hypovolemia, hypoxia, metabolic derangements (e.g., hypocalcemia), and cytokines (e.g., IL-6). Decreased perfusion of tissues as a result of intravascular thrombosis, vasoconstriction, tissue edema, and reduced cardiac output in meningococcal septicemia can cause widespread organ dysfunction, including renal impairment and—later in the disease—a decreased level of consciousness due to central nervous system involvement.

Bacteria that reach the meninges cause a local inflammatory response—with release of a spectrum of cytokines similar to that seen in septicemia—that presents clinically as meningitis and is thought to determine the severity of neuronal injury. Local endothelial injury may result in cerebral edema and rapid onset of raised intracranial pressure in some cases.

CLINICAL MANIFESTATIONS

As discussed above, the most common form of infection with *N. meningitidis* is asymptomatic carriage of the organism in the nasopharynx. Despite the location of infection in the upper airway, meningococcal pharyngitis is rarely reported; however, upper respiratory tract symptoms are common prior to presentation with invasive disease. It is not clear whether these symptoms relate to preceding viral infection (which may promote meningococcal acquisition and/or invasion) or to meningococcal acquisition itself. After acquiring the organism, susceptible individuals develop disease manifestations in 1–10 days (usually <4 days, although colonization for 11 weeks has been documented).

Along the spectrum of presentations of meningococcal disease, the most common clinical syndromes are meningitis and meningococcal septicemia. In fulminant cases, death may occur within hours of the first symptoms. Occult bacteremia is also recognized and, if untreated, progresses in two-thirds of cases to focal infection, including meningitis or septicemia. Meningococcal disease may also present as pneumonia, pyogenic arthritis or osteomyelitis, purulent pericarditis, endophthalmitis, conjunctivitis, primary peritonitis, or (rarely) urethritis. Perhaps because it is difficult to diagnose, meningococcal pneumonia is not commonly reported but is associated with capsular groups Y, W, and Z and appears most often to affect individuals >10 years of age.

Rash A nonblanching rash (petechial or purpuric) develops in >80% of cases of meningococcal disease; however, the rash is often absent early in the illness. Usually initially blanching in nature (macules, maculopapules, or urticaria) and indistinguishable from more common viral rashes, the rash of meningococcal infection becomes petechial or frankly purpuric over the hours after onset. In the most severe cases, large purpuric lesions develop (purpura fulminans; **Fig. A1-41**). Some patients (including those with overwhelming sepsis) may have no rash. While petechial rash and fever are important signs of meningococcal disease, <10% of children (and, in some clinical settings, <1% of patients) with this presentation are found to have meningococcal disease. Most patients presenting with a petechial or purpuric rash have a viral infection **(Table 160-2)**. The skin lesions exhibit widespread endothelial necrosis and occlusion of small vessels in the dermis and subcutaneous tissues, with a neutrophilic infiltrate.

Meningitis Meningococcal meningitis commonly presents as nonspecific manifestations, including fever, vomiting, and (especially in infants and young children) irritability, and is indistinguishable from other forms of bacterial meningitis unless there is an associated petechial or purpuric rash, which occurs in two-thirds of cases. Headache is rarely reported in early childhood but is more common in later childhood and adulthood. When headache is present, the following features, in association with fever or a history of fever, are suggestive of bacterial meningitis: neck stiffness, photophobia, decreased level of consciousness, seizures or status epilepticus, and focal neurologic signs. Classic signs of meningitis, such as neck stiffness and photophobia, are often absent in infants and young children with bacterial meningitis, who more usually present with fever and irritability and may have a bulging fontanelle.

While 30–50% of patients present with a meningitis syndrome alone, up to 40% of meningitis patients also present with some features of septicemia. Most deaths from meningococcal meningitis alone (i.e., without septicemia) are associated with raised intracranial pressure presenting as a reduced level of consciousness, relative bradycardia and hypertension, focal neurologic signs, abnormal posturing, and signs of brainstem involvement—e.g., unequal, dilated, or poorly reactive pupils; abnormal eye movement; and impaired corneal responses **(Chap. 30)**.

Septicemia Meningococcal septicemia alone accounts for up to 20% of cases of meningococcal disease. The condition may progress from early nonspecific symptoms to death within hours. Mortality rates among children with this syndrome have been high (25–40%), but early aggressive management (as discussed below) may reduce the figure to <10%. Early symptoms are nonspecific and suggest an influenza-like illness with fever, headache, and myalgia accompanied by vomiting and abdominal pain. As discussed above, the rash, if present, may appear to be viral early in the course until petechiae or purpuric lesions develop. Purpura fulminans occurs in severe cases **(Fig. A1-41)**, with multiple large purpuric lesions and signs of peripheral ischemia. Surveys of patients have indicated that limb pain, pallor (including a mottled appearance and cyanosis), and cold hands and feet may be prominent. Shock is manifested by tachycardia, poor peripheral perfusion, tachypnea, and oliguria. Decreased cerebral perfusion leads to confusion, agitation, or decreased level of consciousness. With progressive shock, multiorgan failure ensues; hypotension is a late sign in children, who more commonly present with compensated shock (tachycardia, poor peripheral perfusion, and normal blood pressure). Poor outcome is associated with an absence of meningism, hypotension, young age, coma, relatively low temperature (<38°C), leukopenia, and thrombocytopenia. Spontaneous hemorrhage (pulmonary, gastric, or cerebral) may result from consumption of coagulation factors and thrombocytopenia.

Chronic Meningococcemia Chronic meningococcemia, which is rarely recognized, presents as repeated episodes of petechial rash **(Fig. A1-42)** associated with fever, joint pain, features of arthritis, and splenomegaly that may progress to acute meningococcal septicemia if untreated. During the relapsing course, bacteremia characteristically clears without treatment and then recurs. The differential diagnosis includes bacterial endocarditis, acute rheumatic fever, Henoch-Schönlein purpura, infectious mononucleosis, disseminated gonococcal infection, and immune-mediated vasculitis. This condition has been associated with complement deficiencies in some cases and with inadequate sulfonamide therapy in others.

TABLE 160-2 Common Causes of Petechial or Purpuric Rashes

Enteroviruses
Influenza and other respiratory viruses
Measles virus
Epstein-Barr virus
Cytomegalovirus
Parvovirus
Deficiency of protein C or S (including post-varicella protein S deficiency)
Platelet disorders (e.g., idiopathic thrombocytopenic purpura, drug effects, bone marrow infiltration)
Henoch-Schönlein purpura, connective tissue disorders, trauma (including nonaccidental injuries in children)
Pneumococcal, streptococcal, staphylococcal, or gram-negative bacterial sepsis

A study from the Netherlands found that half of isolates from patients with chronic meningococcemia had an underacylated lipid A (part of the surface LPS molecule) due to an *lpxL1* gene mutation, which markedly reduces the inflammatory response to endotoxin.

Postmeningococcal Reactive Disease In a small proportion of patients, an immune complex disease develops ~4–10 days after the onset of meningococcal disease, with manifestations that include a maculopapular or vasculitic rash (2% of cases), arthritis (up to 8% of cases), iritis (1%), pericarditis, and/or polyserositis associated with fever. The immune complexes involve meningococcal polysaccharide antigen and result in immunoglobulin and complement deposition with an inflammatory infiltrate. These features resolve spontaneously without sequelae. It is important to recognize this condition since a new onset of fever and rash, and/or arthritis, can lead to concerns about relapse of meningococcal disease and unnecessarily prolonged antibiotic treatment.

DIAGNOSIS

Like other invasive bacterial infections, meningococcal disease may produce elevations of the white blood cell (WBC) count and of values for inflammatory markers (e.g., C-reactive protein and procalcitonin levels or the erythrocyte sedimentation rate). Values may be normal or low in rapidly progressive disease, and a lack of rise in these laboratory test values does not exclude the diagnosis. However, in the presence of fever and a petechial rash, these elevations are suggestive of meningococcal disease. In patients with severe meningococcal septicemia, common laboratory findings include hypoglycemia, acidosis, hypokalemia, hypocalcemia, hypomagnesemia, hypophosphatemia, anemia, and coagulopathy.

Although meningococcal disease is often diagnosed on clinical grounds, in suspected meningococcal meningitis or meningococcemia, blood should routinely be sent for culture to confirm the diagnosis and to facilitate public health investigations; blood cultures are positive in up to 75% of cases. Culture media containing sodium polyanethol sulfonate, which may inhibit meningococcal growth, should be avoided. Meningococcal viability is reduced if there is a delay in transport of the specimen to the microbiology laboratory for culture or in plating of cerebrospinal fluid (CSF) samples. In countries where treatment with antibiotics before hospitalization is recommended for meningococcal disease, the majority of clinically suspected cases are culture negative. Real-time polymerase chain reaction (PCR) analysis of whole-blood samples increases the diagnostic yield by >40%, and results obtained with this method may remain positive for several days after administration of antibiotics.

Unless contraindications exist (raised intracranial pressure, uncorrected shock, disordered coagulation, thrombocytopenia, respiratory insufficiency, local infection, ongoing convulsions), lumbar puncture should be undertaken to identify and confirm the etiology of suspected meningococcal meningitis, whose presentation cannot be distinguished from that of meningitis of other bacterial causes. Some authorities have recommended a computed tomography (CT) brain scan prior to lumbar puncture because of the risk of cerebral herniation in patients with raised intracranial pressure. However, a normal CT scan is not uncommon in the presence of raised intracranial pressure in meningococcal meningitis, and the decision to perform a lumbar puncture should be made on clinical grounds. CSF features of meningococcal meningitis (elevated protein level and WBC count, decreased glucose level) are indistinguishable from those of other types of bacterial meningitis unless a gram-negative diplococcus is identified. (Gram's staining is up to 80% sensitive for meningococcal meningitis.) CSF should be submitted for culture (sensitivity, 90%) and (where available) PCR analysis. CSF antigen testing with latex agglutination is insensitive and should be replaced by molecular diagnosis when possible.

Lumbar puncture should generally be avoided in meningococcal septicemia, as positioning for the procedure may critically compromise the patient's circulation in the context of hypovolemic shock. Delayed lumbar puncture may still be useful when the diagnosis is uncertain, particularly if molecular diagnostic technology is available.

In other types of focal infection, culture and PCR analysis of normally sterile body fluids (e.g., synovial fluid) may aid in the diagnosis. Although some authorities have recommended cultures of scrapings or aspirates from skin lesions, this procedure adds little to the diagnostic yield when compared with a combination of blood culture and PCR analysis. Urinary antigen testing also is insensitive, and serologic testing for meningococcal infection has not been adequately studied. Because *N. meningitidis* is a component of the normal human nasopharyngeal flora, identification of the organism on throat swabs has limited diagnostic value, but strains identified in the nasopharynx in the context of a probable case are likely to be those responsible for disease.

TREATMENT

Meningococcal Infections

Death from meningococcal disease is associated most commonly with hypovolemic shock (meningococcemia) and occasionally with raised intracranial pressure (meningococcal meningitis). Therefore, management should focus on the treatment of these urgent clinical issues in addition to the administration of specific antibiotic therapy. Delayed recognition of meningococcal disease or its associated physiologic derangements, together with inadequate emergency management, is associated with poor outcome. Since the disease is rare, protocols for emergency management have been developed (see *https://www.meningitis.org/healthcare-professionals/resources*).

Airway patency may be compromised if the level of consciousness is depressed as a result of shock (impaired cerebral perfusion) or raised intracranial pressure; this situation may require intervention. In meningococcemia, pulmonary edema and pulmonary oligemia (presenting as hypoxia) require oxygen therapy or elective endotracheal intubation. In cases with shock, aggressive fluid resuscitation (with replacement of the circulating volume several times in severe cases) and inotropic support may be necessary to maintain cardiac output. If shock persists after volume resuscitation at 40 mL/kg, the risk of pulmonary edema is high, and elective intubation is recommended to improve oxygenation and decrease the work of breathing. Metabolic derangements, including hypoglycemia, acidosis, hypokalemia, hypocalcemia, hypomagnesemia, hypophosphatemia, anemia, and coagulopathy, should be anticipated and corrected. However, aggressive fluid resuscitation with unbuffered electrolyte solutions was found to increase mortality in febrile African children. Studies of the effects of lower volumes of buffered solutions and similar studies in resource-rich settings are required. In the presence of raised intracranial pressure, management includes correction of coexistent shock and neurointensive care to maintain cerebral perfusion.

Empirical antibiotic therapy for suspected meningococcal disease consists of a third-generation cephalosporin such as ceftriaxone (75–100 mg/kg per d [maximum, 4 g/d] in one or two divided IV doses) or cefotaxime (200 mg/kg per day [maximum, 8 g/d] in four divided IV doses) to cover the various other (potentially penicillin-resistant) bacteria that may produce an indistinguishable clinical syndrome. In many settings, vancomycin (usually 4–60 mg/kg per d in two to four divided IV doses) is also recommended for the empiric management of sepsis and/or suspected bacterial meningitis. Although unusual in most isolates, reduced meningococcal sensitivity to penicillin (a minimal inhibitory concentration of 0.12–1.0 μg/mL) has been reported. Use of penicillin is appropriate once information on antimicrobial resistance patterns is available.

Both meningococcal meningitis and meningococcal septicemia are conventionally treated for 7 days, although courses of 3–5 days may be equally effective. Furthermore, a single dose of ceftriaxone or an oily suspension of chloramphenicol has been used successfully in resource-poor settings. No data are available to guide the duration of treatment for meningococcal infection at other foci (e.g., pneumonia, arthritis); antimicrobial therapy is usually continued until clinical and laboratory evidence of infection has resolved. Cultures usually become sterile within 24 h of initiation

of appropriate antibiotic chemotherapy. Eye infections (including keratoconjunctivitis and endophthalmitis) should be treated with a combination of topical and systemic IV therapy, with some small studies suggesting an increased risk of bacteremia when treated with topical therapy alone.

The use of glucocorticoids for adjunctive treatment of meningococcal meningitis remains controversial since no relevant studies have had sufficient power to determine true efficacy in this condition. One large study in adults did indicate a trend toward benefit, and in clinical practice, a decision to use glucocorticoids would best precede a definite microbiologic diagnosis. Therapeutic doses of glucocorticoids are not recommended in meningococcal septicemia, but many intensivists recommend replacement glucocorticoid doses for patients who have refractory shock in association with impaired adrenal gland responsiveness, management that is supported by limited evidence.

Various other adjunctive therapies for meningococcal disease have been considered, but few have been subjected to clinical trials and none can currently be recommended. An antibody to LPS (HA1A) failed to confer a demonstrable benefit. Recombinant bactericidal/permeability-increasing protein (which is not currently available) was tested in a study that had inadequate power to show an effect on mortality rates; however, there were trends toward lower mortality rates among patients who received a complete infusion, and this group also had fewer amputations, fewer blood-product transfusions, and a significantly improved functional outcome. Given that protein C concentrations are reduced in meningococcal disease, the use of activated protein C has been considered. A survival benefit was demonstrated in adult sepsis trials; however, trials in pediatric sepsis (of particular relevance for meningococcal disease) found no benefit and indicated a potential risk of bleeding complications with use of activated protein C.

The postmeningococcal immune-complex inflammatory syndrome has been treated with nonsteroidal anti-inflammatory agents until spontaneous resolution occurs.

COMPLICATIONS

About 10% of patients with meningococcal disease die despite the availability of antimicrobial therapy and other intensive medical interventions. The most common complication of meningococcal disease (10% of cases) is scarring after necrosis of purpuric skin lesions, for which skin grafting may be necessary. The lower limbs are most often affected; next in frequency are the upper limbs, the trunk, and the face. On average, 13% of the skin surface area is involved. Amputations are necessary in 1–2% of survivors of meningococcal disease because of a loss of tissue viability after peripheral ischemia or compartment syndromes. Unless there is local infection, amputation should usually be delayed to allow the demarcation between viable and nonviable tissue to become apparent. Approximately 5% of patients with meningococcal disease suffer hearing loss, and 7% have neurologic complications. In one study, pain was reported by 21% of survivors, and in an analysis of capsular group B meningococcal disease (the MOSAIC study), as many as one-quarter of survivors had psychological disorders. In some investigations, the rate of complications is higher for capsular group C disease (mostly associated with the ST11 clone) than for capsular group B disease. In patients with severe hypovolemic shock, renal perfusion may be impaired and prerenal failure is common, but permanent renal replacement therapy is rarely needed.

Several studies suggest adverse psychosocial outcomes after meningococcal disease, with reduced quality of life, lowered self-esteem, and poorer neurologic development, including increased rates of attention deficit/hyperactivity disorder and special educational needs. Other studies have not found evidence of such outcomes.

PROGNOSIS

Several prognostic scoring systems have been developed to identify patients with meningococcal disease who are least likely to survive. Factors associated with a poorer prognosis are shock; young age (infancy), old age, and adolescence; coma; purpura fulminans; disseminated intravascular coagulation; thrombocytopenia; leukopenia; absence of meningitis; metabolic acidosis; low plasma concentrations of antithrombin and proteins S and C; high blood levels of PAI-1; and a low erythrocyte sedimentation rate or C-reactive protein level. The Glasgow Meningococcal Septicaemia Prognostic Score (GMSPS) performs well and may be clinically useful for severity assessment in meningococcal disease. However, scoring systems do not direct the clinician to specific interventions, and the priority in management should be recognition of compromised airways, breathing, or circulation and direct, urgent intervention. Most patients improve rapidly with appropriate antibiotics and supportive therapy. Fulminant meningococcemia is more likely to result in death or ischemic skin loss than is meningitis; optimal emergency management may reduce mortality rates among the most severely affected patients.

PREVENTION

Since mortality rates in meningococcal disease remain high despite improvements in intensive care management, immunization is the only rational approach to prevention at a population level. Secondary cases are common among household and "kissing" contacts of cases, and secondary prophylaxis with antibiotics is widely recommended for these contacts (see below).

Polysaccharide Vaccines Purified meningococcal capsular polysaccharide was first used for immunization in the 1960s. Meningococcal polysaccharide vaccines were formulated as either bivalent (capsular groups A and C) or quadrivalent (capsular groups A, C, Y, and W), with 50 μg of each polysaccharide per dose. Local reactions (erythema, induration, and tenderness) occurred in up to 40% of vaccinees, but serious adverse events (including febrile convulsions in young children) are very rarely reported. In adults, the vaccines are immunogenic, but immunity is relatively short-lived (with antibody levels above baseline for only 2–10 years), and booster doses do not induce a further rise in antibody concentration. Indeed, a state of immunologic hyporesponsiveness has been widely reported to follow booster doses of plain polysaccharide vaccines. The repeating sugar units of these vaccines cross-link B-cell receptors to drive specific memory B cells to become plasma cells and produce protective antibody. Because meningococcal polysaccharides are T cell–independent antigens, no memory B cells are produced after immunization, and the memory B-cell pool is depleted such that fewer polysaccharide-specific cells are available to respond to a subsequent dose of vaccine **(Fig. 160-6)**. The clinical relevance of hyporesponsiveness is unknown. Plain polysaccharide vaccines generally are not immunogenic in early childhood, possibly because marginal-zone B cells are involved in polysaccharide responses and maturation of the splenic marginal zone is not complete until 18 months to 2 years of age. The efficacy of the meningococcal capsular group C component is >90% in young adults, but there is no protection in infants; no efficacy data are available for the capsular group Y and W polysaccharides in this age group.

Group A meningococcal polysaccharides are exceptional in that they are effective in preventing disease at all ages. Two doses administered 2–3 months apart to children 3–18 months of age or a single dose administered to older children or adults has a protective efficacy rate of >95%. The vaccine was previously used widely in the control of outbreaks of meningococcal disease in the African meningitis belt, providing protection for 3–5 years. The plain polysaccharide vaccines have been largely superseded by protein–polysaccharide conjugate vaccines.

There is no meningococcal capsular group B plain polysaccharide vaccine because α-2,8-*N*-acetylneuraminic acid is expressed on the surface of neural cells in the fetus such that the B polysaccharide is perceived as "self" and therefore is not immunogenic in humans.

Conjugate Vaccines The poor immunogenicity of plain polysaccharide vaccines in infancy has been overcome by chemical conjugation of the polysaccharides to a carrier protein (CRM_{197}, tetanus toxoid, or diphtheria toxoid). Conjugates that contain monovalent capsular group C polysaccharide and quadrivalent vaccines with A, C, Y, and W polysaccharides were developed, and vaccines with other antigen

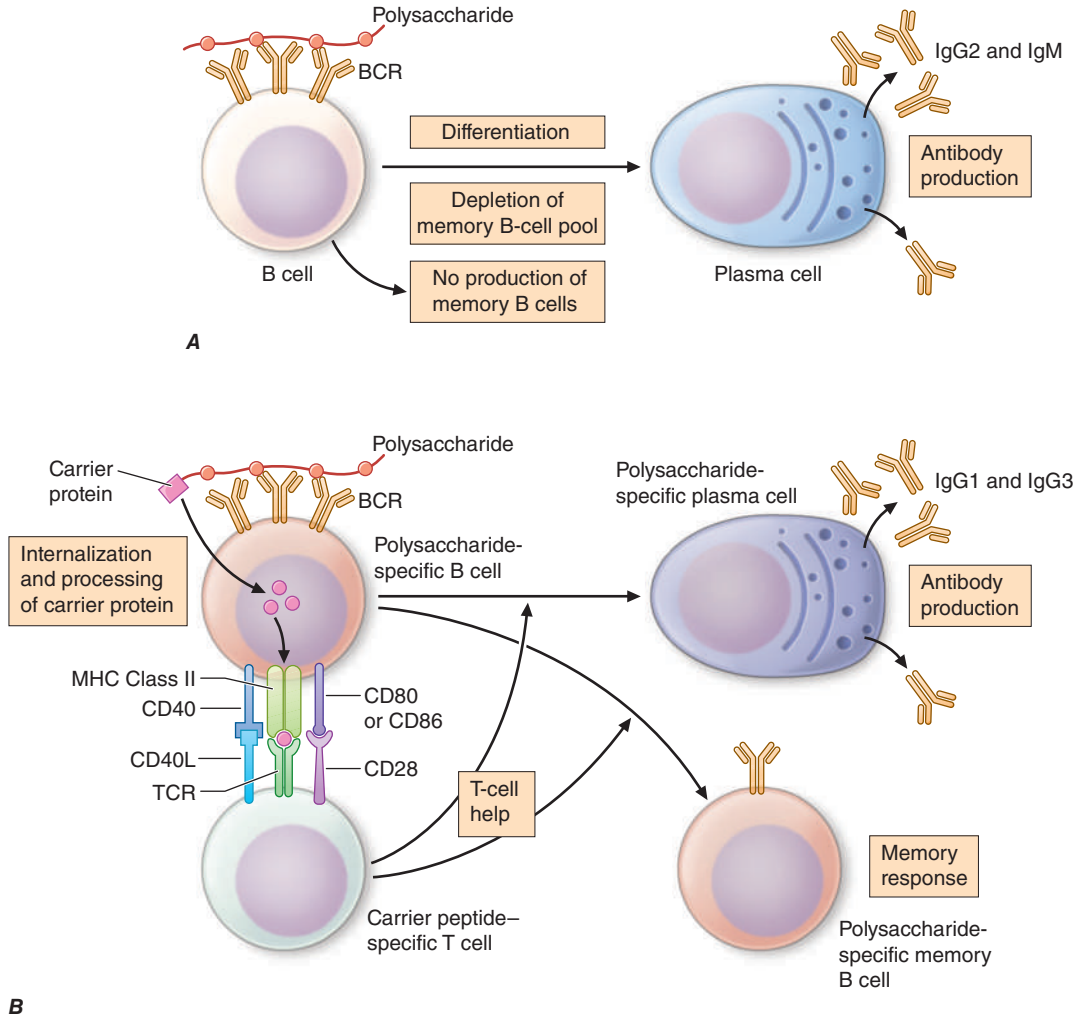

FIGURE 160-6 ***A.*** Polysaccharides from the encapsulated bacteria that cause disease in early childhood stimulate B cells by cross-linking the B-cell receptor (BCR) and driving the production of immunoglobulins. There is no production of memory B cells, and the B-cell pool may be depleted by this process such that subsequent immune responses are decreased. ***B.*** The carrier protein from protein–polysaccharide conjugate vaccines is processed by the polysaccharide-specific B cell, and peptides are presented to carrier peptide–specific T cells, with the consequent production of both plasma cells and memory B cells. MHC, major histocompatibility complex; TCR, T-cell receptor. *(Reproduced with permission from AJ Pollard: Maintaining protection against invasive bacteria with protein–polysaccharide conjugate vaccines. Nat Rev Immunol 9:213, 2009.)*

combinations were produced for some markets (e.g., tetanus conjugates with capsular group C and/or Y polysaccharide and *Haemophilus influenzae* type b polysaccharide). After immunization, peptides from the carrier protein are conventionally thought to be presented by polysaccharide-specific B cells to peptide-specific T cells in association with major histocompatibility complex (MHC) class II molecules. (Some data suggest that carrier protein peptide may actually be presented in association with an oligosaccharide and MHCII.) The result is a T cell–dependent immune response that allows production of antibody and generation of an expanded B-cell memory pool. Unlike responses to booster doses of plain polysaccharides, responses to booster doses of conjugate vaccines have the characteristics of memory responses. Indeed, conjugate vaccines overcome the hyporesponsiveness induced by plain polysaccharides by replenishing the memory pool. The reactogenicity of conjugate vaccines is similar to that of plain polysaccharide vaccines.

The first widespread use of capsular group C meningococcal conjugate vaccine (MenC) came in 1999 in the United Kingdom after a rise in capsular group C disease. A mass vaccination campaign involving all individuals <19 years of age was undertaken, and the number of laboratory-confirmed capsular group C cases fell from 955 in 1998–1999 to just 29 in 2011–2012. The effectiveness of the immunization program was attributed both to direct protection of immunized persons and to reduced transmission of the organism in the population as a result of decreased rates of colonization among the immunized (i.e., herd immunity). Data on immunogenicity and effectiveness have shown that the duration of protection is short when the vaccine is administered in early childhood; thus, booster doses are needed to maintain population immunity. In contrast, immunity after a dose of vaccine given in adolescence appears to be more prolonged.

In 2005, the first quadrivalent conjugate meningococcal vaccine containing A, C, Y, and W polysaccharides conjugated to diphtheria toxoid was initially recommended for all children >11 years of age in the United States and for persons 2–55 years of age in Canada. Such vaccines are now recommended by the Advisory Committee on Immunization Practices (ACIP) for routine administration to individuals 11–12 years of age, with a booster dose at 16 years of age; only a single dose is given to persons >16 years of age. These vaccines are also recommended for high-risk persons from 2 months to 55 years of age (see *https://www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm*).

Uptake was slow initially, but U.S. data show an efficacy rate of 82% in the first year after vaccination and 69% at 8 years (diphtheria conjugate vaccine). Early reports of an increase in the risk of Guillain-Barré syndrome after immunization with the diphtheria conjugate vaccine have not been substantiated with further observation. Quadrivalent conjugate vaccines with tetanus or CRM_{197} as carrier protein are now available in many countries and are used for high-risk groups and in routine programs for toddlers and adolescents. Use of the A, C, W, and Y conjugate vaccine for adolescents since 2015 in the United Kingdom has led to a large reduction in meningococcal disease caused by these

capsular groups. This conjugate vaccine provided direct protection for vaccinated individuals (combined vaccine effectiveness of 94% against C, W, and Y disease) and marked reductions in carriage—a 36% reduction in carriage of capsular groups C, W, and Y combined at 2 months postvaccination—along with evidence of herd immunity. Indeed, modeling of the decline of cases and carriage in the United Kingdom indicates elimination of these capsular groups over the coming decade.

A monovalent capsular group A vaccine, manufactured in India, was licensed in 2010 and rolled out to countries in the sub-Saharan African meningitis belt in a mass immunization campaign. There is strong evidence that this vaccine has been highly effective in controlling epidemic meningococcal disease in the region, with >90% reduction in disease in vaccinated populations. New combination vaccines covering A, C, W, X, and Y have been developed and are set to replace monovalent MenA vaccines in Africa as part of the WHO's global roadmap "Defeating Meningitis by 2030" (*https://www.who.int/publications/i/item/9789240026407*).

Vaccines Based on Subcapsular Antigens The lack of immunogenicity of the group B capsule has led to the development of vaccines based on subcapsular antigens. Various surface components have been studied in early-phase clinical trials. Outer-membrane vesicles (OMVs) containing outer-membrane proteins, phospholipid, and LPS can be extracted from cultures of *N. meningitidis* by detergent treatment **(Fig. 160-7)**. OMVs prepared in this way were used in efficacy trials with a Norwegian outbreak strain and reduced the incidence of group B disease among 14- to 16-year-old schoolchildren by 53%. Similarly, OMV vaccines constructed from local outbreak strains in Cuba and New Zealand have had reported efficacy rates of >70%. These OMV vaccines appear to produce strain-specific immune responses, with only limited cross-protection, and are therefore best suited to clonal outbreaks (e.g., those in Cuba and New Zealand as well as others in Norway and the province of Normandy in France).

Several purified surface proteins have been evaluated in phase 1 clinical trials but have not yet been developed further because of antigenic variability or poor immunogenicity (e.g., transferrin-binding proteins, neisserial surface protein A). Other vaccine candidates have been identified since sequencing of the meningococcal genome. The combination vaccine 4CMenB, which includes the New Zealand OMV vaccine and three recombinant proteins (neisserial adhesin A, factor H–binding protein, and neisserial heparin-binding antigen), is immunogenic from infancy and has been licensed for use in the United States, Canada, Europe, and Australia. This vaccine has been used with apparent success in the control of several university outbreaks in the United States and in a community outbreak in an area of Quebec, Canada. The 4CMenB vaccine has an acceptable safety profile, with fever prominent among infants and injection-site pain frequently reported among older children and adults. In September 2015, 4CMenB was recommended for routine use in the United Kingdom for all infants born from May 2015 onward; a recent analysis reported a 75% reduction in age groups that were fully eligible for vaccination, with a high coverage rate of 95%. The licensed schedule is three priming doses before 6 months of age and a booster dose at 12 months of age (but is used in the United Kingdom as two priming doses under 6 months of age and a booster at 1 year). A nonsignificant vaccine effectiveness of 53% was seen after two doses, and 59% effectiveness was found after the booster dose at 1 year of age. As of 2022, protein-based MenB vaccines were authorized in 58 countries. Of these countries, 15 have a universal program in at least one age group, 21 have a recommendation for high-risk groups based on medical conditions, and 13 have a recommendation based on increased risk of exposure (e.g., laboratory staff).

FIGURE 160-7 Illustration of meningococcal outer-membrane vesicle containing outer-membrane structures.

Because the disease is so rare, the cost-effectiveness of capsular group B vaccine in infant immunization programs, as assessed with conventional thresholds, is borderline in the United Kingdom. Since infants are not commonly colonized with capsular group B meningococci, any impact on the total population burden of carried organisms will be small. It is therefore unlikely that an infant immunization program will provide additional value through induction of herd immunity. Rates of capsular group B carriage are higher among teenagers and young adults than at other ages (apart from infancy). A large cluster-randomized trial in Australia found no effect of 4CMenB on carriage of disease-causing meningococci, highlighting that the benefit of this vaccine is likely to be via direct protection only.

An immunogenic vaccine based on two variants of the lipoprotein factor H–binding protein (MenB-fHBP) has been developed for use in adolescents and is licensed in the United States and Europe. The vaccine is immunogenic against representative indicator strains, inducing fourfold rises in bactericidal antibody titer in 50–92% of individuals. MenB-fHBP has an acceptable safety profile, with pain at the injection site, fatigue, and headache commonly reported. This vaccine can be used with a range of vaccines routinely administered in adolescence, including Tdap (tetanus–diphtheria–acellular pertussis), human papillomavirus, and MenACWY vaccines. MenB-fHBP has been used to control outbreaks of meningococcal disease in educational institutions in the United States, but no formal studies of its effectiveness have yet been undertaken due to the absence of any public health programs with this vaccine. Studies in the United Kingdom are currently evaluating the impact of both 4CMenB and MenB-fHBP against meningococcal carriage among teenagers.

Both of the new capsular group B meningococcal vaccines are licensed for use in the United States for persons 10–25 years of age but are not recommended for routine use. ACIP advises that the vaccines can be used in a two-dose schedule following shared decision-making between the doctor, patient, and/or family. In addition, ACIP recommends their administration to individuals at high risk of capsular group B disease in a two-dose schedule (4CMenB) or a three-dose schedule (MenB-fHBP).

MANAGEMENT OF CONTACTS

Close (household and kissing) contacts of individuals with meningococcal disease are at increased risk of developing secondary disease (up to 1000 times the rate for the general population); a secondary case follows as many as 3% of sporadic cases. About one-fifth of secondary cases are actually co-primary cases—i.e., cases that occur soon after the primary case and in which transmission is presumed to have originated from the same third party. The rate of secondary cases is highest during the week after presentation of the index case. The risk falls rapidly but remains above baseline for up to 1 year after the index case; 30% of secondary cases occur in the first week, 20% in the second week, and most

of the remainder over the next 6 weeks. In outbreaks of meningococcal disease, mass prophylaxis has been used; however, limited data support population intervention, and significant concerns have arisen about adverse events and the development of resistance. For these reasons, prophylaxis is usually restricted to (1) persons at greatest risk who are intimate and/or household contacts of the index case and (2) health care workers who have been directly exposed to respiratory secretions. In most cases, members of wider communities (e.g., at schools or colleges) are not offered prophylaxis.

The aim of prophylaxis is to eradicate colonization of close contacts with the strain that has caused invasive disease in the index case. Prophylaxis should be given to all contacts at the same time to avoid recolonization by meningococci transmitted from untreated contacts and should also be used as soon as possible to treat early disease in secondary cases. If the index patient is treated with an antibiotic that does not reliably clear colonization (e.g., penicillin), the patient should be given a prophylactic agent at the end of treatment to prevent relapse or onward transmission. Although rifampin has been most widely used and studied, it is not the optimal agent because it fails to eradicate carriage in 15–20% of cases, rates of adverse events have been high, compliance is affected by the need for four doses, and emerging resistance has been reported. Ceftriaxone as a single IM or IV injection is highly (97%) effective in carriage eradication and can be used at all ages and in pregnancy. Reduced susceptibility of isolates to ceftriaxone has occasionally been reported. Ciprofloxacin or ofloxacin is preferred in some countries; these agents are highly effective and can be administered by mouth but are not recommended in pregnancy. Resistance to fluoroquinolones has been reported in some meningococci in North America, Europe, and Asia.

In documented capsular group A, B, C, Y, or W disease, contacts may be offered immunization (with either the MenACWY conjugate vaccine or the MenB vaccine, as appropriate) in addition to chemoprophylaxis to provide protection beyond the duration of antibiotic therapy. Mass vaccination has been used successfully to control disease during outbreaks in closed communities (educational and military establishments) as well as during epidemics in open communities.

161 Gonococcal Infections

Sanjay Ram, Peter A. Rice

DEFINITION

Gonorrhea is a sexually transmitted infection (STI) of epithelium and commonly manifests as cervicitis, urethritis, proctitis, and conjunctivitis. If untreated, infections at these sites can lead to local complications such as endometritis, salpingitis, tuboovarian abscess, bartholinitis, peritonitis, and perihepatitis in female patients; periurethritis and epididymitis in male patients; and ophthalmia neonatorum in newborns. Disseminated gonococcemia is an uncommon event whose manifestations include skin lesions, tenosynovitis, septic arthritis, and (in rare cases) endocarditis or meningitis.

MICROBIOLOGY

Neisseria gonorrhoeae is a gram-negative, nonmotile, non-spore-forming organism that grows singly and in pairs (i.e., as monococci and diplococci, respectively). Exclusively a human pathogen, the gonococcus contains, on average, three genome copies per coccal unit; this polyploidy permits a high level of antigenic variation and the survival of the organism in its host. Gonococci, like all other *Neisseria* species, are oxidase positive. They are distinguished from other neisseriae by their ability to grow on selective media and to use glucose but not maltose, sucrose, or lactose.

EPIDEMIOLOGY

The incidence of gonorrhea had been declining steadily in the United States, but in 2021, there were ~710,000 newly reported cases—up 136% since their historic low in 2009. With 82.4 million cases estimated by the World Health Organization to have occurred globally in 2020 among adults aged 15 to 49 years, gonorrhea remains a major public health problem worldwide, is a significant cause of morbidity in developing countries, and may play a role in enhancing transmission of HIV.

Gonorrhea predominantly affects young, nonwhite, unmarried, less educated members of urban populations. The number of reported cases probably represents half of the true number of cases—a discrepancy resulting from underreporting, self-treatment, nonspecific treatment without a laboratory-proven diagnosis, and asymptomatic infection. The number of reported new cases of gonorrhea in the United States rose from ~250,000 in the early 1960s to a high of 1.01 million in 1978. The recorded incidence of gonorrhea in modern times peaked in 1975, with 468 reported new cases per 100,000 population in the United States. This peak was attributable to the interaction of several variables, including improved accuracy of diagnosis, changes in patterns of contraceptive use, and changes in sexual behavior. A decline in the overall incidence of gonorrhea in the United States over the past quarter-century may have reflected increased condom use resulting from public health efforts to curtail HIV transmission. Nevertheless, in 2019, 214 new cases per 100,000 population were reported in this country, representing a 1-year increase of 4.6%; this figure is the highest among industrialized countries. Simultaneously, antibiotic resistance is increasing in the United States and other countries, prompting the U.S. Centers for Disease Control and Prevention (CDC) to name antibiotic-resistant *N. gonorrhoeae* as one of the three most urgent threats of its kind. At present, the attack rate in the United States is highest among 15- to 24-year-old women (730.5 per 100,000) and 20- to 29-year-old men (813.6 per 100,000); >70% of all reported cases occur in these two groups. From the standpoint of ethnicity, rates are highest among African Americans (652.9 per 100,000) and lowest among persons of Asian descent (37.8 per 100,000).

The incidence of gonorrhea is higher in developing countries than in industrialized nations. The exact incidence of any STI is difficult to ascertain in developing countries because of limited surveillance and variable diagnostic criteria. Extremely high rates of gonorrhea have

been reported among aboriginal populations in Namibia and Australia. Studies in Africa have clearly demonstrated that nonulcerative STIs such as gonorrhea (in addition to ulcerative STIs) are an independent risk factor for the transmission of HIV **(Chap. 208)**.

Gonorrhea is transmitted from males to females more efficiently than in the opposite direction. The rate of transmission to a woman during a single unprotected sexual encounter with an infected man is ~50–80%. Oropharyngeal gonorrhea occurs in ~20% of women who practice fellatio with infected partners. Transmission in either direction by cunnilingus is rare.

In any population, there exists a small minority of individuals who have high rates of new-partner acquisition. These "core-group members" or "high-frequency transmitters" are vital in sustaining STI transmission at the population level. Another instrumental factor in sustaining gonorrhea in the population is the large number of infected individuals who are asymptomatic or have minor symptoms that are ignored. These persons, unlike symptomatic individuals, may not cease sexual activity and therefore may continue to transmit the infection. This situation underscores the importance of contact tracing and empirical treatment of the sex partners of index cases.

PATHOGENESIS, IMMUNOLOGY, AND ANTIMICROBIAL RESISTANCE

Outer-Membrane Proteins • **PILI** Fresh clinical isolates of *N. gonorrhoeae* initially form piliated (fimbriated) colonies distinguishable on translucent agar. Pilus expression is rapidly switched off with unselected subculture because of rearrangements in pilus genes. This change is a basis for antigenic variation of gonococci. Piliated strains adhere better to cells derived from human mucosal surfaces and are more virulent in organ culture models and human inoculation experiments than nonpiliated variants. In a fallopian tube explant model, pili mediate gonococcal attachment to nonciliated columnar epithelial cells. This event initiates gonococcal adherence, invasion and transport through these cells to intercellular spaces near the basement membrane or directly into the subepithelial tissue. Pili are also essential for genetic competence and transformation of *N. gonorrhoeae*, which permit horizontal transfer of genetic material between different gonococcal lineages in vivo.

OPACITY-ASSOCIATED PROTEIN Another gonococcal surface protein that is important in adherence to epithelial cells is opacity-associated protein (Opa; formerly called protein II). Opa contributes to intergonococcal adhesion, which is responsible for the opaque nature of gonococcal colonies on translucent agar and the organism's adherence to a variety of eukaryotic cells, including polymorphonuclear leukocytes (PMNs). Certain Opa variants promote invasion of epithelial cells, and this effect has been linked with the ability of Opa to bind vitronectin, heparan sulfate proteoglycans, and several members of the carcinoembryonic antigen–related cell adhesion molecule (CEACAM) receptor family. Epithelial CEACAM-binding gonococci prevent exfoliation of epithelium through a mechanism that involves nitric oxide that is produced during anaerobic bacterial metabolism and upregulation of CD105 (a member of the transforming growth factor-beta receptor family), which may interfere with bacterial clearance. *N. gonorrhoeae* Opa proteins that bind CEACAM1, which is expressed by primary CD4+ T lymphocytes, suppress the activation and proliferation of these lymphocytes. Select Opa proteins can engage CEACAM3, which is expressed on neutrophils, with consequent nonopsonic phagocytosis (i.e., phagocytosis independent of antibody and complement) and killing of bacteria.

PORIN Porin (previously designated protein I) is the most abundant gonococcal surface protein. Porin molecules exist as trimers that provide anion-transporting aqueous channels through the otherwise hydrophobic outer membrane. Porin exhibits stable interstrain antigenic variation and forms the basis for gonococcal serotyping. Two main serotypes have been identified; PorB.1A strains are often associated with disseminated gonococcal infection (DGI), whereas PorB.1B strains usually cause local genital infections only. DGI strains are generally resistant to the killing action of normal human serum and do not incite a significant local inflammatory response; therefore, they may not cause symptoms at genital sites. These characteristics may be related to the ability of PorB.1A strains to bind to complement-inhibitory molecules, resulting in a diminished inflammatory response. Porin can translocate to the cytoplasmic membrane of host cells—a process that could initiate gonococcal endocytosis and invasion. PorB.1B present in outer membrane vesicles shed during bacterial growth inhibits the ability of dendritic cells to induce T-cell proliferation and may contribute to the ability of gonococci to subvert adaptive immunity.

OTHER OUTER-MEMBRANE PROTEINS Other notable outer-membrane proteins include H.8, a lipoprotein that is present in high concentration on the surface of all gonococcal strains and is an excellent target for antibody-based diagnostic testing. Transferrin-binding proteins (Tbp1 and Tbp2), lactoferrin-binding proteins (LbpA and LbpB), and hemoglobin/haptoglobin binding proteins (HpuA and HpuB) are required for scavenging iron from transferrin, lactoferrin, and heme in vivo. Transferrin and iron have been shown to enhance the attachment of iron-deprived *N. gonorrhoeae* to human endometrial cells. TdfH and TdfJ enable gonococci to scavenge host zinc from calprotectin and S100 calcium binding protein A7 (psoriasin). IgA1 protease is produced by *N. gonorrhoeae* and may protect the organism from the action of mucosal IgA.

Lipooligosaccharide Gonococcal lipooligosaccharide (LOS) consists of a lipid A and a core oligosaccharide that lacks the repeating O-carbohydrate antigenic side chain seen in many other gram-negative bacteria. Gonococcal LOS possesses marked endotoxic activity and contributes to the local cytotoxic effect in a fallopian tube model. LOS core sugars undergo a high degree of phase variation under different conditions of growth; this variation reflects genetic regulation and expression of glycotransferase genes that dictate the carbohydrate structure of LOS. These phenotypic changes may affect interactions of *N. gonorrhoeae* with elements of the humoral immune system (antibodies and complement) and may also influence direct binding of organisms to both professional phagocytes and nonprofessional phagocytes (epithelial cells). For example, gonococci that are sialylated at their LOS sites inhibit the classic pathway of complement by reducing binding of IgG and also bind complement factor H to inhibit the alternative pathway of complement. LOS sialylation may also decrease nonopsonic Opa-mediated association with neutrophils and inhibit the oxidative burst in PMNs. The binding of the unsialylated terminal lactosamine residue of LOS to an asialoglycoprotein receptor on male epithelial cells facilitates adherence and subsequent gonococcal invasion of these cells. Moreover, oligosaccharide structures in LOS can modulate host immune responses. For example, the terminal monosaccharide expressed by LOS determines the C-type lectin receptor on dendritic cells that is targeted by the bacteria. In turn, the specific C-type lectin receptor engaged influences whether a T_H1- or T_H2-type response is elicited; the latter response may be less favorable for clearance of gonococcal infection.

Host Factors In addition to gonococcal structures that interact with epithelial cells, host factors seem to be important in mediating entry of gonococci into nonphagocytic cells. Activation of phosphatidylcholine-specific phospholipase C and acidic sphingomyelinase by *N. gonorrhoeae*, which results in the release of diacylglycerol and ceramide, is a requirement for the entry of *N. gonorrhoeae* into epithelial cells. Ceramide accumulation within cells leads to apoptosis, which may disrupt epithelial integrity and facilitate entry of gonococci into subepithelial tissue. Release of chemotactic factors as a result of complement activation contributes to inflammation, as does the toxic effect of LOS and peptidoglycan in provoking the release of inflammatory cytokines.

The importance of humoral immunity in host defenses against neisserial infections is best illustrated by the predisposition of persons deficient in terminal complement components (C5 through C9) to have recurrent bacteremic gonococcal infections and recurrent meningococcal meningitis or meningococcemia. Gonococcal porin induces

T cell–proliferative responses in persons with urogenital gonococcal disease. A significant increase in porin-specific interleukin (IL) 4–producing CD4+ as well as CD8+ T lymphocytes is seen in individuals with mucosal gonococcal disease. A portion of these lymphocytes that show a porin-specific T_H2-type response could traffic to mucosal surfaces and play a role in immune protection against the disease. Few data clearly indicate that protective immunity is acquired from a previous gonococcal infection, although bactericidal and opsonophagocytic antibodies to porin and LOS may offer partial protection. On the other hand, women who are infected and acquire high levels of antibody to another outer-membrane protein, Rmp (reduction modifiable protein, formerly called protein III), may be especially likely to become reinfected with *N. gonorrhoeae* because Rmp antibodies block the effect of bactericidal antibodies to porin and LOS. Rmp shows little, if any, interstrain antigenic variation; therefore, Rmp antibodies potentially may block antibody-mediated killing of all gonococci. The mechanism of blocking has not been fully characterized, but Rmp antibodies may noncompetitively inhibit binding of porin and LOS antibodies because of the proximity of these structures in the gonococcal outer membrane. In male volunteers who have no history of gonorrhea, the net effect of these events may influence the outcome of experimental challenge with *N. gonorrhoeae*. Because Rmp bears extensive homology to enterobacterial OmpA and meningococcal class 4 proteins, it is possible that these blocking antibodies result from prior exposure to cross-reacting proteins from these species and also play a role in first-time infection with *N. gonorrhoeae*.

Gonococcal Resistance to Antimicrobial Agents It is no surprise that *N. gonorrhoeae*, with its remarkable capacity to alter its antigenic structure and adapt to changes in the microenvironment, has become resistant to numerous antibiotics. The first effective agents against gonorrhea were the sulfonamides, which were introduced in the 1930s and became ineffective within a decade. Penicillin was then used as the drug of choice for the treatment of gonorrhea. By 1965, 42% of gonococcal isolates had developed low-level resistance to penicillin G. Resistance due to the production of penicillinase arose later.

Gonococci become fully resistant to antibiotics either by chromosomal mutations or by acquisition of R factors (plasmids). Two types of chromosomal mutations have been described. The first type, which is drug specific, is a single-step mutation leading to high-level resistance. The second type involves mutations at several chromosomal loci that combine to determine the level as well as the pattern of resistance. Strains with mutations in chromosomal genes were first observed in the late 1950s. As recently as 2007, chromosomal mutations accounted for resistance to penicillin, tetracycline, or both in ~16% of strains surveyed in the United States.

β-Lactamase (penicillinase)–producing strains of *N. gonorrhoeae* (PPNG) carrying β-lactamase plasmids had rapidly spread worldwide by the early 1980s. *N. gonorrhoeae* strains with plasmid-borne tetracycline resistance (TRNG) can mobilize some β-lactamase plasmids, and PPNG and TRNG occur together, sometimes along with strains exhibiting chromosomally mediated resistance (CMRNG). Penicillin, ampicillin, and tetracycline are no longer reliable for the treatment of gonorrhea and should not be used.

Quinolone-containing regimens also were recommended for treatment of gonococcal infections; the fluoroquinolones offered the advantage of antichlamydial activity when administered for 7 days. However, quinolone-resistant *N. gonorrhoeae* (QRNG) appeared soon after these agents were first used to treat gonorrhea. QRNG is particularly common in the Pacific Islands (including Hawaii) and Asia, where, in certain areas, all gonococcal strains are now resistant to quinolones. At present, QRNG is also common in parts of Europe and the Middle East. In the United States, QRNG has been identified in all areas but predominantly in states on the Pacific coast, where resistant strains were first seen. Alterations in DNA gyrase and topoisomerase IV have been implicated as mechanisms of fluoroquinolone resistance.

Third-generation cephalosporins have remained highly effective as single-dose therapy for gonorrhea, but the recent isolation of strains highly resistant to ceftriaxone (minimal inhibitory concentrations [MICs], 2 μg/mL) in Asia, some European countries and recently, in the United States, is cause for concern. Even though the MICs of ceftriaxone against certain strains may reach 0.015–0.125 μg/mL (higher than the MICs of 0.0001–0.008 μg/mL for fully susceptible strains), these levels are greatly exceeded in the blood, the urethra, and the cervix when the routinely recommended parenteral dose of ceftriaxone is administered. The rising MICs of oral cefixime (the previously recommended alternative oral third-generation cephalosporin) against *N. gonorrhoeae*, combined with this drug's limited capacity to reach levels sufficiently higher than MICs in the blood, the urethra, the cervix, and especially the pharynx, have resulted in the removal of cefixime from the list of first-line agents for treatment of uncomplicated gonorrhea. *N. gonorrhoeae* strains with reduced susceptibility to ceftriaxone and cefixime (i.e., cephalosporin-intermediate/resistant strains) contain mutations in (1) the *penA* allele, which is the principal resistance determinant and encodes a penicillin-binding protein (PBP2) whose sequence can differ in up to 60–70 amino acids from that of wild-type PBP2; (2) the *m*ultiple *t*ransferable *r*esistance *r*egulator (*mtrR*) gene that results in increased drug efflux through the MtrCDE efflux pump; and (3) *penB*, which decreases drug influx through PorB.

Spectinomycin has been used as an alternative agent because it is not associated with resistance to other antibiotics and can be reserved for use against multidrug-resistant strains of *N. gonorrhoeae*. In China, spectinomycin is recommended as an alternative agent for primary treatment of urogenital gonorrhea and is often used there instead of ceftriaxone. Nevertheless, outbreaks caused by strains resistant to spectinomycin have been documented in Korea and England when the drug had been used for primary treatment of gonorrhea.

Resistance to azithromycin can result from alterations of the ribosomal binding target by azithromycin and—as with cephalosporins—the over- and underexpression of efflux and influx systems. Combined resistance to cephalosporins and azithromycin has been reported in several instances throughout the world.

CLINICAL MANIFESTATIONS

Gonococcal Infections in Men Acute urethritis is the most common clinical manifestation of gonorrhea in male patients. However, there is a reservoir of infected men who remain asymptomatic. The usual incubation period after exposure is 2–7 days before symptoms develop although the interval can be longer. Strains of the PorB.1A serotype tend to cause a greater proportion of cases of mild and asymptomatic urethritis than do PorB.1B strains. When they occur, urethral discharge and dysuria, usually without urinary frequency or urgency, are the major symptoms. The discharge initially is scant and mucoid but becomes profuse and purulent within a day or two. Gram staining of the urethral discharge may reveal PMNs and gram-negative intracellular monococci and diplococci **(Fig. 161-1)**. The clinical manifestations of gonococcal urethritis are usually more severe and overt than

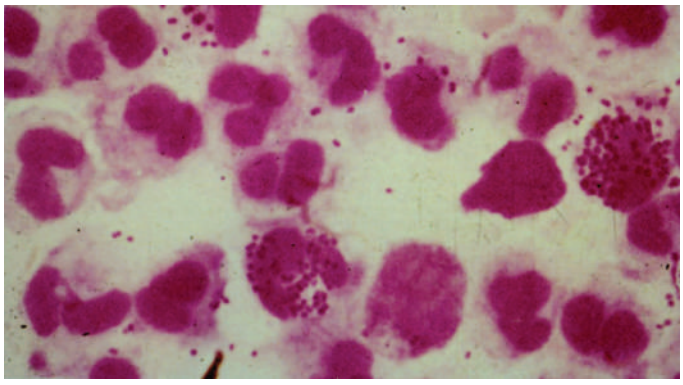

FIGURE 161-1 Gram stain of urethral discharge from a male patient with gonorrhea shows gram-negative intracellular monococci and diplococci. *(Source: © All rights reserved. Canadian Guidelines on Sexually Transmitted Infections. Public Health Agency of Canada, modified 2020. Adapted and reproduced with permission from the Minister of Health, 2021.)*

those of nongonococcal urethritis, including urethritis caused by *Chlamydia trachomatis* **(Chap. 194)**; however, exceptions are common, and it is often impossible to differentiate the causes of urethritis on clinical grounds alone. The majority of cases of urethritis seen in the United States today are not caused by *N. gonorrhoeae* and/or *C. trachomatis*. Although a number of other organisms may be responsible, many cases do not have a specific etiologic agent identified. Certain clones of *Neisseria meningitidis*, the second member of the pathogenic *Neisseria* species, have been associated with urethritis in men who have sex with men (MSM) in Europe and in heterosexual men in the southern and midwestern United States.

Most symptomatic men with gonorrhea seek treatment and cease to be infectious. The remaining men, who are largely asymptomatic, accumulate in number over time and constitute the majority of all infected men at any point in time; together with men incubating the organism who shed the organism but have yet to become symptomatic, they serve as the source of spread of infection. Before the antibiotic era, symptoms of urethritis persisted for ~8 weeks. Epididymitis is now an uncommon complication, and gonococcal prostatitis occurs rarely, if at all. Other unusual local complications of gonococcal urethritis include edema of the penis due to dorsal lymphangitis or thrombophlebitis, submucous inflammatory "soft" infiltration of the urethral wall, periurethral abscess or fistula, inflammation or abscess of Cowper's gland, and seminal vesiculitis. Balanitis may develop in uncircumcised men.

Gonococcal Infections in Women • **GONOCOCCAL CERVICITIS** Mucopurulent cervicitis is a common STI diagnosis in American women and may be caused by *N. gonorrhoeae*, *C. trachomatis*, and other organisms, including *Mycoplasma genitalium* **(Chap. 193)**. Cervicitis is often associated with more that one bacterial species, for example, coinfection with *C. trachomatis*, and may also coexist with candidal or trichomonal vaginitis. *N. gonorrhoeae* primarily infects the columnar epithelium of the cervical os. Bartholin's glands occasionally become infected.

About one-half of women infected with *N. gonorrhoeae* develop symptoms. Women who either remain asymptomatic or have only minor symptoms may delay seeking medical attention. These minor symptoms may include scant vaginal discharge issuing from the inflamed cervix (without vaginitis or vaginosis per se) and dysuria (often without urgency or frequency) that may be associated with gonococcal urethritis. Although the incubation period of gonorrhea is less well defined in women than in men, symptoms usually develop within 10 days of infection and are more acute and intense than those of chlamydial cervicitis.

The speculum examination reveals a mucopurulent discharge (mucopus) issuing from the cervical os or a reddened (inflamed) cervix even in the absence of reported symptoms. Because Gram stain is not sensitive for the diagnosis of gonorrhea in women, specimens should be submitted for culture or a nonculture assay (see "Laboratory Diagnosis," below). Edematous and friable cervical ectopy and endocervical bleeding induced by gentle swabbing are more often seen in chlamydial infection. Gonococcal infection may extend deep enough to produce dyspareunia and lower abdominal or back pain. In such cases, it is imperative to consider a diagnosis of pelvic inflammatory disease (PID) and to administer treatment for that disease **(Chaps. 141 and 194)**.

N. gonorrhoeae may also be recovered from the urethra and rectum of women with cervicitis, but these are rarely the only infected sites. Urethritis in women may produce symptoms of internal dysuria, which is often attributed to "cystitis." Pyuria in the absence of bacteriuria visible on Gram stain of unspun urine, accompanied by urine cultures that fail to yield $>10^2$ colonies of bacteria usually associated with urinary tract infection, signifies the possibility of urethritis usually due to *C. trachomatis*. Urethral infection with *N. gonorrhoeae* also may occur in this context, but in this instance, urethral cultures are usually positive.

GONOCOCCAL VAGINITIS The vaginal mucosa of healthy women is lined by stratified squamous epithelium and is rarely infected by *N. gonorrhoeae*. However, gonococcal vaginitis can occur in anestrogenic women (e.g., prepubertal girls and postmenopausal women), in whom the vaginal stratified squamous epithelium is often thinned down to the basilar layer, which can be infected by *N. gonorrhoeae*. The intense inflammation of the vagina makes the physical (speculum and bimanual) examination extremely painful. The vaginal mucosa is red and edematous, and an abundant purulent discharge is often present. Infection in the urethra and in Skene's and Bartholin's glands often accompanies gonococcal vaginitis. Inflamed cervical erosion or abscesses in nabothian cysts may also occur. Coexisting cervicitis may result in pus in the cervical os.

Anorectal Gonorrhea Because the female anatomy permits the spread of cervical exudate to the rectum, *N. gonorrhoeae* is sometimes recovered from the rectum of women with uncomplicated gonococcal cervicitis. The rectum is the sole site of infection in only 5% of women with gonorrhea. Such women are usually asymptomatic but occasionally have acute proctitis manifested by anorectal pain or pruritus, tenesmus, purulent rectal discharge, and rectal bleeding. Among MSM, the frequency of gonococcal infection, including rectal infection, fell by ≥90% throughout the United States in the early 1980s. A resurgence of gonorrhea among MSM has been documented in several cities since the 1990s; the estimated rates of reported cases having more than doubled in a recent 3-year period. Gonococcal isolates from the rectum of MSM tend to be more resistant to antimicrobial agents than are gonococcal isolates from other sites. Gonococcal isolates with a mutation in *mtrR* or in the promoter region of the gene that encodes for this transcriptional regulator develop increased resistance to antimicrobial hydrophobic agents such as bile acids and fatty acids in feces and thus are found with increased frequency in MSM. This situation may have been responsible for higher rates of failure of treatment for rectal gonorrhea with older regimens consisting of penicillin or tetracyclines.

Pharyngeal Gonorrhea Pharyngeal gonorrhea is usually mild or asymptomatic, although symptomatic pharyngitis does occasionally occur with cervical lymphadenitis. The mode of acquisition is oral–genital sexual exposure, with fellatio being a more efficient means of transmission than cunnilingus. In certain female adolescent populations in the United States, pharyngeal gonorrhea has become as common as genital gonorrhea. Most cases resolve spontaneously and transmission from the pharynx to sexual contacts is rare. Pharyngeal infection almost always coexists with genital infection. Swabs from the pharynx should be plated directly onto gonococcal selective media. Pharyngeal colonization with *N. meningitidis* needs to be differentiated from that with other *Neisseria* species. Because commensal oropharyngeal neisseriae are often resistant to antimicrobials, horizontal gene transfer between these organisms and *N. gonorrhoeae* may be important in the development of antimicrobial resistance of *N. gonorrhoeae*.

Ocular Gonorrhea in Adults Ocular gonorrhea in an adult usually results from autoinoculation of *N. gonorrhoeae* from an infected genital site. As in genital infection, the manifestations range from severe to occasionally mild or asymptomatic disease. The variability in clinical manifestations may be attributable to differences in the ability of the infecting strain to elicit an inflammatory response. Infection may result in a markedly swollen eyelid, severe hyperemia and chemosis, and a profuse purulent discharge. The massively inflamed conjunctiva may be draped over the cornea and limbus. Lytic enzymes from the infiltrating PMNs occasionally cause corneal ulceration and rarely cause perforation.

Prompt recognition and treatment of this condition are of paramount importance. Gram stain and culture of the purulent discharge establish the diagnosis. Genital cultures also should be performed.

Gonorrhea in Pregnant Women, Neonates, and Children Gonorrhea in pregnancy can have serious consequences for both the mother and the infant. Recognition of gonorrhea early in pregnancy also identifies a population at risk for other STIs, particularly chlamydial infection, syphilis, and trichomoniasis. The risks of salpingitis and PID—conditions associated with a high rate of fetal loss—are highest during the first trimester. Pharyngeal infection, most often asymptomatic, may be more common during pregnancy because of altered sexual

practices. Prolonged rupture of the membranes, premature delivery, chorioamnionitis, funisitis (infection of the umbilical cord stump), and sepsis in the infant (with *N. gonorrhoeae* detected in the newborn's gastric aspirate during delivery) are common complications of maternal gonococcal infection at term. Other conditions and microorganisms, including *Mycoplasma hominis*, *Mycoplasma genitalium, Ureaplasma urealyticum*, *C. trachomatis*, and bacterial vaginosis (often accompanied by infection with *Trichomonas vaginalis*), have been associated with similar complications.

The most common form of gonorrhea in neonates is ophthalmia neonatorum, which results from exposure to infected cervical secretions during parturition. Ocular neonatal instillation of 0.5% erythromycin ophthalmic ointment, a prophylactic agent, prevents ophthalmia neonatorum but is not effective for its treatment, which requires systemic antibiotics. One-percent (1%) silver nitrate eye drops and ointments that contain silver nitrate or tetracycline can also be used for prophylaxis but are no longer available in the United States. The clinical manifestations are acute and usually begin 2–5 days after birth. An initial nonspecific conjunctivitis with a serosanguineous discharge is followed by tense edema of the eyelids, chemosis, and a profuse, thick, purulent discharge. Corneal ulcerations that result in nebulae or perforation may lead to anterior synechiae, anterior staphyloma, panophthalmitis, and blindness. Infections described at other mucosal sites in infants, including vaginitis, rhinitis, and anorectal infection, are likely to be asymptomatic. Pharyngeal colonization has been demonstrated in 35% of infants with gonococcal ophthalmia, and coughing is the most prominent symptom in these cases. Septic arthritis (see below) is the most common manifestation of systemic infection or disseminated gonococcal infection (DGI) in the newborn. The onset usually comes at 3–21 days of age, and polyarticular involvement is common. Sepsis, meningitis, and pneumonia are seen in rare instances.

Any STI in children beyond the neonatal period raises the possibility of sexual abuse. Gonococcal vulvovaginitis is the most common manifestation of gonococcal infection in children beyond infancy. Anorectal and pharyngeal infections are common in these children and are frequently asymptomatic. The urethra, Bartholin's and Skene's glands, and upper genital tract are rarely involved. All children with gonococcal infection should also be evaluated for chlamydial infection, syphilis, and possibly HIV infection.

Gonococcal Arthritis Disseminated gonococcal infection (DGI; gonococcal arthritis) results from gonococcal bacteremia. In the 1970s, DGI occurred in ~0.5–3% of persons with untreated gonococcal mucosal infection. The lower incidence of DGI at present is probably attributable to a decline in the prevalence of particular strains that are likely to disseminate. Nonetheless, sporadic outbreaks of DGI still occur in North America. DGI strains resist the bactericidal action of human serum and generally do not incite inflammation at genital sites, probably because of limited generation of chemotactic factors. Strains recovered from DGI cases in the 1970s were often of the PorB.1A serotype, were highly susceptible to penicillin, and had special growth requirements—including arginine, hypoxanthine, and uracil—that made the organism more fastidious and more difficult to isolate.

Menstruation is a risk factor for dissemination, and approximately two-thirds of cases of DGI are in women. In about half of affected women, symptoms of DGI begin within 7 days of onset of menses. Complement deficiencies, especially of the components involved in the assembly of the membrane attack complex (C5 through C9), predispose to neisserial bacteremia, and persons with more than one episode of DGI should be screened with an assay for total hemolytic complement activity. DGI is also associated with the use of the complement C5–blocking monoclonal antibody eculizumab.

The clinical manifestations of DGI have sometimes been classified into two stages: a bacteremic stage, which is less common today, and a joint-localized stage with suppurative arthritis. A clear-cut progression usually is not evident. Patients in the bacteremic stage have higher temperatures, and chills more frequently accompany their fever. Painful joints are common and often occur together with tenosynovitis and skin lesions. Polyarthralgias usually include the knees, elbows, and more distal joints; the axial skeleton is generally spared. Skin lesions are seen in ~75% of patients and include papules and pustules, often with a hemorrhagic component **(Fig. 161-2; see also Fig. A1-43 in the Atlas of Rashes Associated with Fever)**. Other manifestations of noninfectious dermatitis, such as nodular lesions, urticaria, and erythema multiforme, have been described. These lesions are usually on the extremities and number between 5 and 40. The differential diagnosis of the bacteremic stage of DGI includes reactive arthritis, acute rheumatoid arthritis, sarcoidosis, erythema nodosum, drug-induced arthritis, and viral infections (e.g., hepatitis B and acute HIV infection). The distribution of joint symptoms in reactive arthritis differs from that in DGI **(Fig. 161-3)**, as do the skin and genital manifestations **(Chap. 374)**.

Suppurative arthritis involves one or two joints, most often the knees, wrists, ankles, and elbows (in decreasing order of frequency); other joints occasionally are involved. Most patients who develop gonococcal septic arthritis do so without prior polyarthralgias or skin lesions; in the absence of symptomatic genital infection, this disease cannot be distinguished from septic arthritis caused by other pathogens. The differential diagnosis of acute arthritis in young adults is discussed in **Chap. 135**. Rarely, osteomyelitis complicates septic arthritis involving small joints of the hand.

Gonococcal endocarditis, although rare today, was a relatively common complication of DGI in the preantibiotic era, accounting for about one-quarter of reported cases of endocarditis. Another unusual complication of DGI is meningitis.

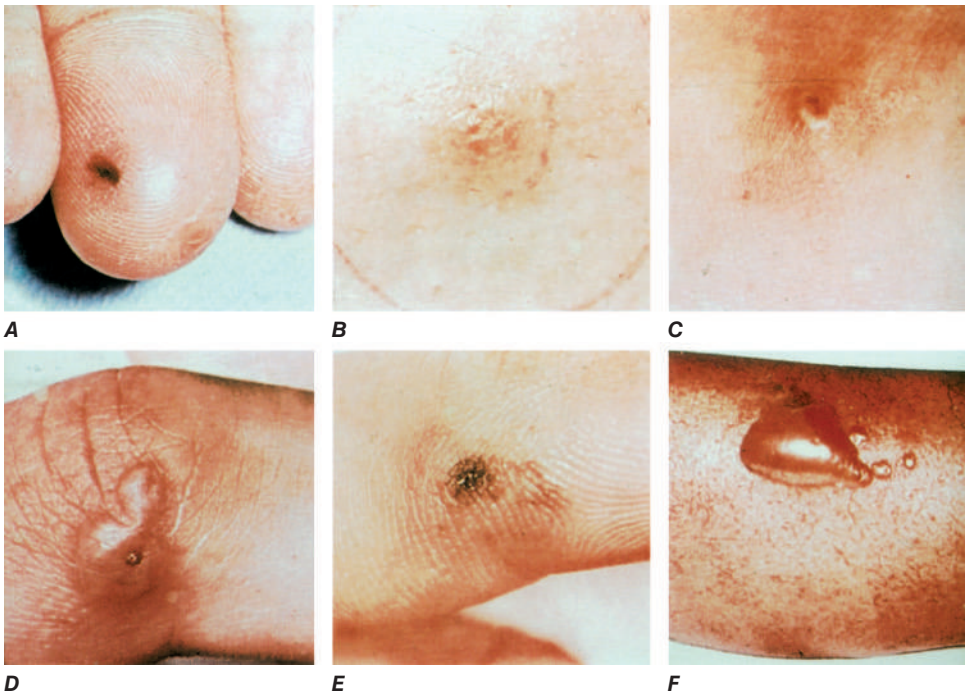

FIGURE 161-2 Characteristic skin lesions in patients with proven gonococcal bacteremia. The lesions are in various stages of evolution. ***A.*** Very early petechia on finger. ***B.*** Early papular lesion, 7 mm in diameter, on lower leg. ***C.*** Pustule with central eschar resulting from early petechial lesion. ***D.*** Pustular lesion on finger. ***E.*** Mature lesion with central necrosis (*black*) on hemorrhagic base. ***F.*** Bullae on anterior tibial surface. *(Reprinted with permission from KK Holmes et al: Disseminated gonococcal infection. Ann Intern Med 74:979, 1971.)*

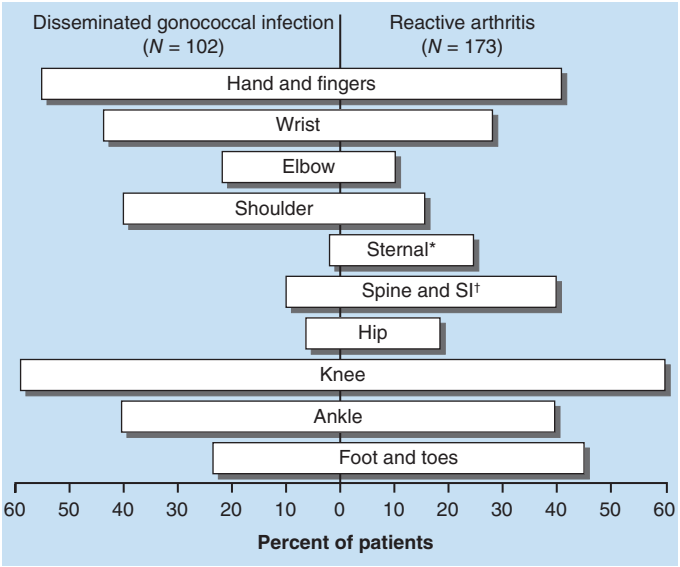

FIGURE 161-3 Distribution of joints with arthritis in 102 patients with disseminated gonococcal infection and 173 patients with reactive arthritis. *Includes the sternoclavicular joints. †SI, sacroiliac joint.

Gonococcal Infections in HIV-Infected Persons The association between gonorrhea and the acquisition of HIV has been demonstrated in several well-controlled studies, mainly in Kenya and Zaire. The nonulcerative STIs enhance the transmission of HIV three- to fivefold; transmission of HIV-infected immune cells and increased viral shedding by persons with urethritis or cervicitis may contribute **(Chap. 208)**. HIV has been detected by polymerase chain reaction (PCR) more commonly in ejaculates from HIV-positive men with gonococcal urethritis than in those from HIV-positive men with nongonococcal urethritis. PCR positivity diminishes twofold after appropriate therapy for urethritis. Not only does gonorrhea enhance the transmission of HIV, but it may also increase the individual's risk for acquisition of HIV. A proposed mechanism is the significantly greater number of CD4+ T lymphocytes and dendritic cells that can be infected by HIV in endocervical secretions from women with nonulcerative STIs than in those from women with ulcerative STIs.

LABORATORY DIAGNOSIS

A rapid diagnosis of gonococcal infection in men may be obtained by Gram staining of urethral exudates (Fig. 161-1). The detection of gram-negative intracellular monococci and diplococci is usually highly specific and sensitive in diagnosing gonococcal urethritis in symptomatic males but is only ~50% sensitive in diagnosing gonococcal cervicitis. Samples should be collected with Dacron or rayon swabs. Part of the sample should be inoculated onto a plate of modified Thayer-Martin or other gonococcal selective medium for culture. It is important to process all samples immediately because gonococci do not tolerate drying. If plates cannot be incubated immediately, they can be held safely for several hours at room temperature in candle extinction jars prior to incubation. If processing is to occur within 6 h, transport of specimens may be facilitated by the use of nonnutritive swab transport systems such as Stuart or Amies medium. For longer holding periods (e.g., when specimens for culture are to be mailed), culture media with self-contained CO_2-generating systems (such as the JEMBEC or Gono-Pak systems) may be used. Specimens should also be obtained for the diagnosis of chlamydial infection **(Chap. 194)**.

PMNs are often seen in the endocervix on a Gram stain, and an abnormally increased number (≥30 PMNs per field in five 1000× oil-immersion microscopic fields) establishes the presence of an inflammatory discharge. Unfortunately, the presence or absence of gram-negative intracellular monococci or diplococci in cervical smears does not accurately predict which patients have gonorrhea, and the diagnosis in this setting should be made by culture or another suitable nonculture diagnostic method. The sensitivity of a single endocervical culture is ~80–90%. If a history of rectal sex is elicited, a rectal wall swab (uncontaminated with feces) should be cultured. A presumptive diagnosis of gonorrhea cannot be made on the basis of gram-negative diplococci in Gram-stained smears from the pharynx, where other *Neisseria* species are also components of the pharyngeal flora.

Several nucleic acid amplification tests (NAATs), including the Roche COBAS AMPLICOR, Gen-Probe Aptima Combo 2, Cepheid Xpert® CT/NG Assay and BD ProbeTec ET, are now widely available on semiautomated or fully automated platforms and are commonly employed diagnostic tests for gonorrhea. These tests also detect *C. trachomatis* and are more sensitive than culture for identification of either *N. gonorrhoeae* or *C. trachomatis*. These tests offer the advantage that urine samples can be tested with a sensitivity similar to or greater than that obtained when urethral or cervical swab samples are assessed by other non-NAATs or culture, respectively. NAAT tests performed on self-collected vaginal swabs are as sensitive and specific as physician-collected samples and may be used in women to facilitate sample collection when a pelvic exam is not indicated as part of their clinic evaluation. A point-of-care NAAT-based test (Binx *io*®) for gonorrhea and chlamydia with a 30-minute turnaround time is now approved by the U.S. Food and Drug Administration (FDA). In MSM, it is important to screen the rectum and pharynx because screening urine alone will miss the majority of cases. A disadvantage of non-culture-based assays is that *N. gonorrhoeae* cannot be grown from the transport systems. Thus, a culture-confirmatory test and formal antimicrobial susceptibility testing, if needed, cannot be performed.

Because of the legal implications, the preferred method for the diagnosis of gonococcal infection in children is a standardized culture. Two positive NAATs, each targeting a different nucleic acid sequence, may be substituted for culture of the cervix or the urethra as legal evidence of infection in children. Although nonculture tests for gonococcal infection have not been approved by the FDA for use with specimens obtained from the pharynx and rectum of infected children, NAATs from these sites are preferred for diagnostic evaluation in adult victims of suspected sexual abuse, especially if the NAATs have been evaluated by the local laboratory and found to be superior. Cultures should be obtained from the pharynx and anus of both girls and boys, the urethra of boys, and the vagina of girls; cervical specimens are not recommended for prepubertal girls. For boys with a urethral discharge, a meatal specimen of the discharge is adequate for culture. Presumptive colonies of *N. gonorrhoeae* should be identified definitively by at least two independent methods.

Blood should be cultured in suspected cases of DGI. The use of Isolator blood culture tubes may enhance the yield. The probability of positive blood cultures decreases after 48 h of illness. Synovial fluid should be inoculated into blood culture broth medium and plated onto chocolate agar rather than selective medium because this fluid is not likely to be contaminated with commensal bacteria. Gonococci are infrequently recovered from early joint effusions containing <20,000 leukocytes/μL but may be recovered from effusions containing >80,000 leukocytes/μL. The organisms are seldom recovered from blood and synovial fluid of the same patient.

TREATMENT

Gonococcal Infections

Treatment failure can lead to continued transmission and the emergence of antibiotic resistance. The importance of adequate treatment with a regimen that the patient will adhere to cannot be overemphasized. Single-dose regimens have been developed for uncomplicated gonococcal infections. The Centers for Disease Control and Prevention (CDC) Gonorrhea Treatment Recommendations in 2020 and the 2021 Sexually Transmitted Infections (STI) Treatment Guidelines are summarized in **Table 161-1**. The third-generation cephalosporin ceftriaxone is now recommended as the first-line regimen for use at twice the previous dose (now,

TABLE 161-1 Recommended Treatment for Gonococcal Infections: Adapted from the 2021 Guidelines for Gonococcal Infection of the Centers for Disease Control and Prevention

DIAGNOSIS	TREATMENT OF CHOICE[a]
Uncomplicated gonococcal infection of the cervix, urethra, pharynx,[b] or rectum	
First-line regimen	Ceftriaxone (500 mg IM, single dose) ***plus*** Doxycycline (100 mg orally twice a day for 7 days) for treatment of chlamydial infection if chlamydial infection cannot be excluded
Alternative regimens if ceftriaxone is not available	Gentamicin (240 mg IM, single dose) plus azithromycin (2 g orally as a single dose)[c] ***or*** Cefixime (800 mg PO, single dose) *or* spectinomycin (2 g IM, single dose)[d,e] ***plus*** Doxycycline (100 mg orally twice a day for 7 days) for treatment of chlamydial infection if chlamydial infection cannot be excluded
Epididymitis	**See Chap. 141**
Pelvic inflammatory disease	**See Chap. 141**
Gonococcal conjunctivitis in an adult	Ceftriaxone (1 g IM, single dose)[f]
Ophthalmia neonatorum[g]	Ceftriaxone (25–50 mg/kg IV, single dose, not to exceed 125 mg)
Disseminated gonococcal infection[h]	
Initial therapy[i]	
Patient tolerant of β-lactam drugs	Ceftriaxone (1 g IM or IV q24h; recommended) *or* cefotaxime (1 g IV q8h) *or* ceftizoxime (1 g IV q8h)
Patients allergic to β-lactam drugs	Spectinomycin (2 g IM q12h)[d]
Continuation therapy[j]	Cefixime (400 mg PO bid)
Meningitis or endocarditis	See text for specific recommendations[k]

[a]True failure of treatment with a recommended regimen is rare and should prompt an evaluation for reinfection, infection with a drug-resistant strain, or an alternative diagnosis. [b]Ceftriaxone is the most reliable agent recommended for treatment of pharyngeal infection. [c]In vitro synergistic killing of *N. gonorrhoeae* by gentamicin plus azithromycin is mild to moderate; azithromycin is for treatment chlamydial infection, primarily. [d]Spectinomycin is unavailable in the United States; in uncomplicated gonococcal infection it should be used at a higher dose (4 g IM, single dose) in areas of the world where increased resistance to spectinomycin exists. [e]Spectinomycin may be ineffective for the treatment of pharyngeal gonorrhea. [f]Plus lavage of the infected eye with saline solution (once). [g]Prophylactic regimens are discussed in the text. [h]Hospitalization is indicated if the diagnosis is uncertain, if the patient has the joint-localized stage with suppurative arthritis, or if the patient cannot be relied on to adhere to treatment. [i]All initial regimens should also include doxycycline (100 mg orally twice a day for 7 days) for treatment of chlamydial infection if chlamydial infection cannot be excluded; [j]gonococcal therapy should be continued for 24–48 h after clinical improvement begins, at which time the switch may be made to an oral agent (e.g., cefixime) if antimicrobial susceptibility can be documented by culture of the causative organism. If no organism is isolated and the diagnosis is secure, then treatment with ceftriaxone should be continued for at least 1 week. [k]Hospitalization is indicated to exclude suspected meningitis or endocarditis.

500 mg IM, single dose) based on doubling of mean inhibitory concentrations (MICs) of current strains compared with MICs over 20 years ago. The development of decreased sensitivity to ceftriaxone throughout the world will require the development of new effective regimens. Azithromycin, which had been recommended to provide additional treatment of gonorrhea (also to include treatment of chlamydial infection) is no longer recommended as part of a first line regimen. Resistance to azithromycin of U.S. isolates of *N. gonorrhoeae*, which had been less than 0.6% over a number of years, has increased more than sevenfold to 4.7% in 2021. If chlamydial infection cannot be excluded, concurrent treatment with doxycycline (100 mg orally twice a day for 7 days) is recommended. The recommendations for uncomplicated gonorrhea apply to HIV-infected as well as HIV-uninfected patients.

The currently recommended regimen for the treatment of uncomplicated gonococcal infection of the urethra, cervix, rectum, or pharynx (a single IM dose of ceftriaxone) almost always results in an effective cure. Quinolone-containing regimens are no longer recommended in the United States as first-line treatment because of widespread resistance. Rising MICs of cefixime worldwide have led the CDC to discontinue its recommendation of this agent as first-line treatment for uncomplicated gonorrhea. Multicenter trials of treatment for uncomplicated gonorrhea in the United States have shown ≥99.5% efficacy of two combination regimens and 96% efficacy in one single-agent regimen: gemifloxacin (320 mg, single oral dose) plus azithromycin (2 g, single oral dose); gentamicin (a single IM dose of 240 mg or, in individuals who weigh ≤45 kg, 5 mg/kg) plus azithromycin (2 g, single oral dose), and zoliflodacin (2 or 3 g, single oral dose). At this time, however, none of these regimens is recommended by CDC as first-line treatment; gentamicin plus azithromycin is recommended as an alternative regimen.

Co-infection with *C. trachomatis* occurs frequently; concurrent treatment with doxycycline (100 mg orally twice daily for 7 days) is effective against chlamydial infection. Spectinomycin has been used as an alternative agent for the treatment of uncomplicated gonococcal infections in penicillin-allergic persons outside the United States but is not currently available in the United States. Of note, the limited effectiveness of spectinomycin and gentamicin for the treatment of pharyngeal infection reduces the utility of this regimen in populations among whom gonococcal infection is common, such as MSM.

Persons with uncomplicated genital or rectal infections who receive ceftriaxone or an alternative regimen do not need a test of cure; however, cultures for *N. gonorrhoeae* should be performed if symptoms persist after therapy with an established regimen, and any gonococci isolated should be tested for antimicrobial susceptibility. Persons with pharyngeal infection should undergo a test of cure regardless of the treatment regimen, 7–14 days after treatment to ensure eradication or detection of a possible treatment failure. Symptomatic gonococcal pharyngitis is more difficult to eradicate than genital infection. Persons who cannot tolerate cephalosporins may be treated with an alternative regimen. Treatment with spectinomycin results in a cure rate of ≤52%; persons given spectinomycin should have a subsequent pharyngeal sample cultured early (3–5 days) following treatment as a test of cure. A single 2-g dose of azithromycin may be used if the infecting organism is known to be sensitive or in areas where rates of resistance to azithromycin are low. Quinolones may be used if the infecting organism is known to be sensitive. If culture is not readily available and NAAT is positive, every effort should be made to perform a confirmatory culture. All isolates from test-of-cure cultures should undergo antimicrobial susceptibility testing. Because of high rates of reinfection with *N. gonorrhoeae* (and *C. trachomatis*) within 6–12 months, persons previously treated for gonorrhea should be retested 3 months after treatment.

Treatments for gonococcal epididymitis and PID are discussed in **Chap. 141**. Ocular gonococcal infections in older children and adults should be managed with a single dose of ceftriaxone combined with saline irrigation of the conjunctivae (both undertaken expeditiously), and patients should undergo a careful ophthalmologic evaluation that includes a slit-lamp examination.

DGI, particularly the joint-localized stage with suppurative arthritis, may require higher dosages and longer durations of therapy (Table 161-1). Hospitalization is indicated if the diagnosis is uncertain, if the patient has localized suppurative arthritis that requires aspiration, or if the patient cannot be relied on to comply with treatment. Open drainage is necessary only occasionally—e.g., for management of hip infections that may be difficult to drain percutaneously. Nonsteroidal anti-inflammatory agents may be indicated to alleviate pain and hasten clinical improvement of affected joints.

Gonococcal meningitis and endocarditis should be treated in the hospital with high-dose IV ceftriaxone (1–2 g IV every 12–24 h); therapy should continue for 10–14 days for meningitis and for at least 4 weeks for endocarditis. All persons who experience more than one episode of DGI should be evaluated for complement deficiency.

PREVENTION AND CONTROL

Condoms, if properly used, provide effective protection against the transmission and acquisition of gonorrhea as well as other infections that are transmitted to and from genital mucosal surfaces. Spermicidal preparations used with a diaphragm or cervical sponges impregnated with nonoxynol-9 offer some protection against gonorrhea and chlamydial infection. However, the frequent use of preparations that contain nonoxynol-9 is associated with mucosal disruption that paradoxically may enhance the risk of HIV infection in the event of exposure. All patients should be instructed to refer sex partners for evaluation and treatment. All sex partners of persons with gonorrhea should be evaluated and treated for *N. gonorrhoeae* and *C. trachomatis* infections if their last contact with the patient took place within 60 days before the onset of symptoms or the diagnosis of infection in the patient. If the patient's last potential sexual exposure to infection was >60 days before onset of symptoms or diagnosis, the patient's most recent sex partner should be treated. Partner-delivered medications or prescriptions for medications to treat gonorrhea and chlamydial infection diminish the likelihood of reinfection (or relapse) in the infected patient. This approach is permissible (or potentially allowable) in all 50 states and is an option for partner management. Patients should be instructed to abstain from sexual intercourse until therapy is completed and until they and their sex partners no longer have symptoms. Greater emphasis must be placed on prevention by public health education, individual patient counseling, and behavior modification, particularly the use of condoms. Sexually active persons, especially adolescents, should be offered screening for STIs. For most male patients, NAAT of urine or a urethral swab may be used for screening. Preventing the spread of gonorrhea may help reduce the transmission of HIV. No effective vaccine for gonorrhea is yet available, but efforts to test several candidates are underway including a field trial of a licensed group B meningococcal vaccine (4CMenB or Bexsero®), which in retrospective epidemiologic analyses has been associated with reduced rates of gonorrhea.

162 *Haemophilus* and *Moraxella* Infections

Kristian Riesbeck, Timothy F. Murphy

HAEMOPHILUS INFLUENZAE

MICROBIOLOGY

Haemophilus influenzae was first recognized in 1892 by Pfeiffer, who erroneously concluded that the bacterium was the cause of influenza. *H. influenzae* is a small (1- × 0.3-μm) gram-negative organism of variable shape; thus, it is often described as a pleomorphic coccobacillus. In clinical specimens such as cerebrospinal fluid (CSF) and sputum, *H. influenzae* frequently stains only faintly with safranin and therefore can easily be overlooked.

H. influenzae grows both aerobically and anaerobically. As the Latin name implies, *Haemophilus* is the "blood-loving bacterium." A prerequisite for growth is a requirement for the media to contain blood, but the blood substrate needs to be preheated; hence, *H. influenzae* grows on chocolate agar plates (slowly heated to 80°C [176°F]), whereas ordinary blood plates (without preheating) will not sustain growth. Its aerobic growth requires two factors: hemin (designated X factor) and nicotinamide adenine dinucleotide (V factor). While MALDI-ToF (Matrix-Assisted Laser Desorption/Ionization - Time of Flight) is now widely used for bacterial identification, these requirements are still sometimes applied in clinical laboratories. However, using phenotypic methods for differentiating among *Haemophilus* species has limitations, as the growing number of whole-genome sequences of *Haemophilus* isolates from the human respiratory tract is revealing complex genetic relationships among *Haemophilus* species (see "Diagnosis," below).

Six major serotypes of *H. influenzae* have been identified; designated *a* through *f*, they are based on antigenically distinct polysaccharide capsules. In addition, some strains lack a polysaccharide capsule and are referred to as *nontypeable* strains. Type b and nontypeable strains are the most relevant strains clinically **(Table 162-1)**, although encapsulated strains other than type b can cause disease. An *H. influenzae* type b isolate was the first free-living organism to have its entire genome sequenced in the early 1990s.

The antigenically distinct type b capsule is a linear polymer composed of ribosyl-ribitol phosphate. Strains of *H. influenzae* type b (Hib) cause disease primarily in infants and children <6 years of age, although it is nowadays rare due to effective vaccine campaigns. Nontypeable strains are primarily mucosal pathogens but occasionally cause invasive disease, particularly in immunocompromised hosts and the elderly.

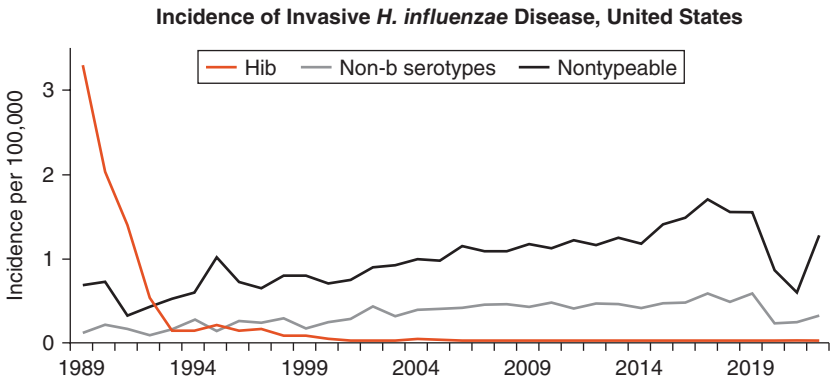
EPIDEMIOLOGY AND TRANSMISSION

H. influenzae, an exclusively human pathogen, is spread by airborne droplets or by direct contact with secretions or fomites. Between

TABLE 162-1 Characteristics of Type b and Nontypeable Strains of *Haemophilus influenzae*

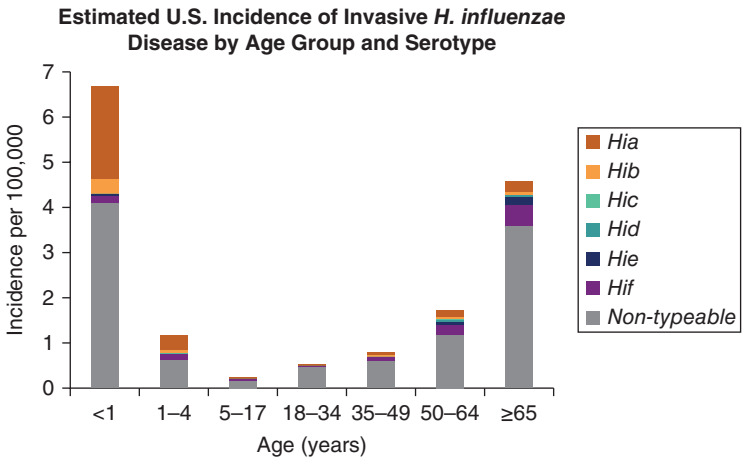
FEATURE	TYPE b STRAINS	NONTYPEABLE STRAINS
Capsule	Ribosyl-ribitol phosphate	Unencapsulated
Pathogenesis	Invasive infections due to hematogenous spread	Mucosal infections due to contiguous spread
Clinical manifestations	Meningitis and invasive infections in incompletely immunized infants and children	Otitis media in infants and children; lower respiratory tract infections in adults with chronic bronchitis
Evolutionary history	Basically clonal	Genetically diverse
Vaccine	Highly effective conjugate vaccines	Protein D used as carrier protein in pneumococcal vaccine approved in Europe: GSK Synflorix. Others under development

30 and 60% of healthy preschool children are intermittent carriers. Colonization with nontypeable *H. influenzae* is a dynamic process; new strains are acquired and other strains are replaced periodically. This is particularly evident in patients with chronic obstructive pulmonary disease (COPD).



The widespread use of Hib conjugate vaccines in many industrialized countries has resulted in striking decreases in the rate of nasopharyngeal colonization by Hib and in the incidence of Hib infection **(Fig. 162-1)**. On a global basis, invasive Hib disease occurs predominantly in unimmunized children and in those who have not completed the primary immunization series. Most World Health Organization member countries have introduced Hib conjugate vaccination, but a large number of the world's children remain unimmunized, principally in countries without national vaccine programs. In addition to immunocompromised hosts, certain groups have a higher incidence of invasive disease with encapsulated *H. influenzae* (along with capsular serotypes other than Hib) than the general population, including African Americans, Australian Aboriginal children, and Native American groups. Although this increased incidence has not yet been accounted for, several factors may be relevant, including age at exposure to the bacterial species, socioeconomic conditions, and genetic differences.

PATHOGENESIS



Hib strains cause systemic disease by invasion and hematogenous spread from the respiratory tract to distant sites such as the meninges, bones, and joints. The type b polysaccharide capsule is an important virulence factor affecting the bacterium's ability to avoid opsonization and cause systemic disease.

Nontypeable strains cause disease by local invasion of mucosal surfaces. Otitis media results when bacteria reach the middle ear by way of the eustachian tube. Adults with COPD experience recurrent lower respiratory tract infection due to nontypeable strains. In addition, nontypeable *H. influenzae* persist in the lower airways of adults with COPD in both extracellular and intracellular locations, contributing to the airway inflammation that is a hallmark of the disease. Nontypeable strains that cause infection in adults with COPD differ in pathogenic potential and genome content from strains that cause otitis media. In the middle ear, nontypeable strains form biofilms. More resistant to host clearance mechanisms and to antibiotics than are planktonic bacteria, biofilms are associated with chronic and recurrent otitis media. Nontypeable *H. influenzae* persist in the human respiratory tract and cause infection by altering expression of genes through slipped-strand mispairing and through phase-variable expression of DNA methylase genes that control the expression of multiple genes that play a role in virulence.

The incidence of invasive disease caused by nontypeable strains is low but appears to have increased over the past decade; one possible explanation for this increase might be that unencapsulated and hence nontypeable *H. influenzae* were overlooked in the past during the prevaccine era due to the high incidence of Hib. Most strains that cause invasive disease are genetically and phenotypically diverse.

In 2020–2021, disease caused by non-b serotypes and nontypeable bacteria increased. ***B.*** Estimated incidence rates (per 100,000) of invasive *H. influenzae* disease by serotype and age in the United States, 2018–2022. *(Source: Active Bacterial Core surveillance, Centers for Disease Control and Prevention, https://www.cdc.gov/hi-disease/surveillance.html.)*

IMMUNE RESPONSE

Antibody to the capsule is important in protection from infection by Hib strains. The level of (maternally acquired) serum antibody to the capsular polysaccharide, which is a polymer of polyribitol ribose phosphate (PRP), declines from birth to 6 months of age and, in the absence of vaccination, remains low until ~2 or 3 years of age. The age at the antibody nadir correlates with that of the peak incidence of type b disease. Antibody to PRP then appears partly due to exposure to Hib or cross-reacting antigens. Systemic Hib disease is unusual after the age of 6 years because of the presence of protective antibody. Vaccines in which PRP is conjugated to protein carrier molecules have been developed and are now used widely. These vaccines generate an antibody response to PRP in infants and effectively prevent invasive infections in infants and children.

Since nontypeable strains lack a capsule, the immune response to infection is directed at noncapsular antigens. These antigens have generated considerable interest as immune targets and potential vaccine components. The human immune response to nontypeable strains appears to be strain-specific, a characteristic that accounts in part for the propensity of these strains to cause recurrent otitis media and recurrent exacerbations of chronic bronchitis in immunocompetent hosts.

CLINICAL MANIFESTATIONS

Hib The most serious manifestation of infection with Hib is *meningitis* **(Chap. 143)**, which primarily affects children <2 years of age. The clinical manifestations of Hib meningitis are similar to those of meningitis caused by other bacterial pathogens. Fever and altered central nervous system function are the most common features at presentation. Nuchal rigidity may or may not be evident. Subdural effusion, the most common complication, is suspected when, despite 2 or 3 days of appropriate antibiotic therapy, the infant has seizures, hemiparesis, or continued obtundation. The overall mortality rate from Hib meningitis is ~5%, and the morbidity rate is high. Of survivors, 6% have

permanent sensorineural hearing loss, and about one-fourth have a significant disability of some type. If more subtle disabilities are sought, up to half of survivors are found to have some neurologic sequelae, such as partial hearing loss and delayed language development.

Epiglottitis **(Chap. 37)** is a life-threatening Hib infection involving cellulitis of the epiglottis and supraglottic tissues. It can lead to acute upper-airway obstruction. Its unique epidemiologic features are its occurrence in an older age group (2–7 years old) than other Hib infections and its absence among Navajo Native Americans and Alaskan Eskimos. Sore throat and fever rapidly progress to dysphagia, drooling, and airway obstruction. In countries with Hib vaccine child immunization programs, epiglottitis now occurs primarily in adults.

Cellulitis **(Chap. 134)** due to Hib occurs in young children. The most common location is on the head or neck; the involved area sometimes takes on a characteristic bluish-red color. Most patients have bacteremia, and 10% have an additional focus of infection.

Hib causes *pneumonia* in infants. The infection is clinically indistinguishable from other types of bacterial pneumonia (e.g., pneumococcal pneumonia) except that Hib is more likely to involve the pleura. Several less common invasive conditions can be important clinical manifestations of Hib infection in children. These include osteomyelitis, septic arthritis, pericarditis, orbital cellulitis, endophthalmitis, urinary tract infection, abscesses, and bacteremia without an identifiable focus.

Non–type b encapsulated strains of *H. influenzae* (types a, c, d, e, and f) are unusual causes of invasive infection manifested predominantly by bacteremia and pneumonia. *H. influenzae* type a infections are seen with increased frequency in indigenous populations of North America, and these strains are predominantly clonal. Most infections due to non–type b encapsulated strains occur in the setting of underlying conditions including immunosuppression.

Nontypeable *H. influenzae* Nontypeable *H. influenzae* is the most common bacterial cause of exacerbations of COPD; these exacerbations are characterized by increased cough, sputum production, and shortness of breath. Fever is low-grade, and no infiltrates are evident on chest x-ray. Nontypeable strains also cause community-acquired bacterial pneumonia in adults, especially among patients with COPD or HIV or other immunocompromised hosts. The clinical features of *H. influenzae* pneumonia are similar to those of other types of bacterial pneumonia, including pneumococcal pneumonia. In recent years, pneumonia due to nontypeable *H. influenzae* has been more common than pneumonia caused by *Streptococcus pneumoniae* **(Fig. 162-2)**.

Nontypeable *H. influenzae* is one of the three most common causes of childhood otitis media (the other two being *S. pneumoniae* and *Moraxella catarrhalis*) **(Chap. 37)**. Infants are febrile and irritable, while older children report ear pain. Symptoms of viral upper-respiratory infection often precede otitis media. The diagnosis is made by pneumatic otoscopy. An etiologic diagnosis, although not routinely sought, can be established by tympanocentesis and culture of middle-ear fluid. Clinical features associated with *H. influenzae* otitis media include a history of recurrent episodes, treatment failure, concomitant conjunctivitis, bilateral otitis media, and recent antimicrobial therapy. The increasing use of pneumococcal polysaccharide conjugate vaccines in most countries has resulted in an overall decrease in otitis media and its complications. However, a relative increase in the proportion of otitis media caused by *H. influenzae* in children failing initial antimicrobial therapy or with recurrent episodes has occurred. Continued monitoring of the incidence and etiology of otitis media will be important.

Nontypeable *H. influenzae* also causes puerperal sepsis and is an important cause of neonatal bacteremia. These nontypeable strains, provisionally named *Haemophilus quentini*, are closely related to but distinct from *H. haemolyticus*, tend to be of biotype IV, and cause invasive disease after colonizing the female genital tract.

Nontypeable *H. influenzae* causes sinusitis **(Chap. 37)** in adults and children. In addition, the bacterium is a less common cause of various invasive infections. These infections include bacteremia, empyema, adult epiglottitis, pericarditis, cellulitis, septic arthritis, osteomyelitis, endocarditis, cholecystitis, intraabdominal infections, urinary tract infections, mastoiditis, and aortic graft infection. Most *H. influenzae* invasive infections in countries where Hib vaccines are used widely are caused by nontypeable strains, and a recent increased incidence of such infections has been observed. Although most strains of nontypeable *H. influenzae* that cause invasive infections are genetically diverse, recent localized clusters of infections have been caused by clonally related strains. Continued monitoring will be important. Many patients with *H. influenzae* bacteremia have an underlying condition, such as HIV infection, cardiopulmonary disease, alcoholism, or cancer.

DIAGNOSIS

The most reliable method for establishing a diagnosis of invasive *H. influenzae* infection is recovery of the organism in culture in a normally sterile body site, such as blood, CSF, or joint fluid. Isolation of bacteria is important for antimicrobial susceptibility testing. Rapid polymerase chain reactions (PCR) and other DNA-based methods are commonly used in modern clinical laboratories.

H. influenzae isolated from the respiratory tract must be distinguished from a complex flora and from other *Haemophilus* species. Particular caution must be used to distinguish *H. influenzae* from *Haemophilus haemolyticus*, a respiratory tract commensal with identical growth requirements. *H. haemolyticus* has classically been distinguished from *H. influenzae* by the hemolysis of the former species on horse blood agar. However, a significant proportion of isolates of *H. haemolyticus* have now been recognized as nonhemolytic. Analysis of

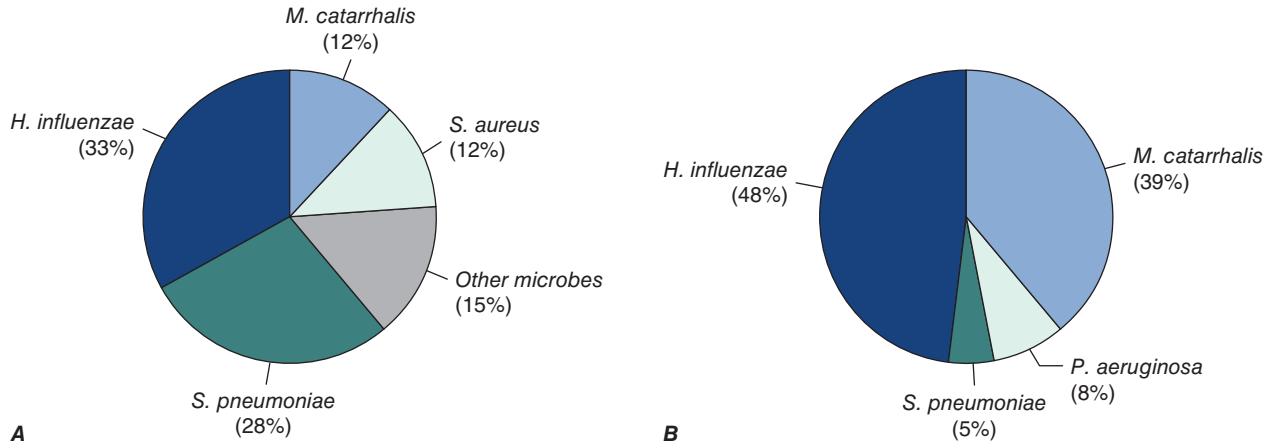

FIGURE 162-2. Importance of nontypeable *Haemophilus influenzae* and *Moraxella catarrhalis* in community-acquired pneumonia (CAP) and in exacerbations of COPD patients. ***A.*** Meta-analysis of bacterial detection in lower respiratory tract specimens using molecular panels or quantitative assays from patients with CAP. ***B.*** Cumulative results of a prospective study (1994–2004) of bacterial infection in chronic obstructive pulmonary disease (COPD) showing etiology of exacerbations. Numbers of exacerbations shown indicate acquisition of a new strain simultaneous with clinical symptoms of an exacerbation. *(Data source for A: NJ Gadsby et al: Clin Infect Dis 62:817, 2016; DN Gilbert et al: Diagn Microbiol Infect Dis 99:115246, 2021; S Serigstad et al: Sci Rep 12:326, 2022; M Fally et al: Infect Dis (Lond) 53:122, 2021.)*

various genotypic markers, including 16S ribosomal sequences, superoxide dismutase, outer-membrane protein P6, protein D, and fuculose kinase, can be used to distinguish these two species. The availability of whole genome sequences of an increasing number of *Haemophilus* isolates from the human upper respiratory tract has revealed complex genomic relationships among *Haemophilus* species, suggesting a genetic continuum between some *Haemophilus* species.

The presence of gram-negative coccobacilli in Gram-stained CSF is strong evidence for Hib meningitis. Recovery of the organism or detection of *H. influenzae* DNA from CSF confirms the diagnosis. The same applies for other normally sterile body fluids, such as blood, joint fluid, pleural fluid, pericardial fluid, and subdural effusion, and are thus also confirmatory in other infections.

Because nontypeable *H. influenzae* is primarily a mucosal pathogen, it is a component of a mixed flora; thus, etiologic diagnosis is challenging. Nontypeable *H. influenzae* infection is strongly suggested by the predominance of gram-negative coccobacilli among abundant polymorphonuclear leukocytes in a Gram-stained sputum specimen from a patient in whom pneumonia is suspected. Although bacteremia is detectable in a small proportion of patients with pneumonia due to nontypeable *H. influenzae*, most such patients have negative blood cultures.

A diagnosis of otitis media is based on the detection by pneumatic otoscopy of fluid in the middle ear. An etiologic diagnosis requires tympanocentesis but is not routinely sought. An invasive procedure is also required to determine the etiology of sinusitis; thus, treatment is often empirical once the diagnosis is suspected in light of clinical symptoms and sinus radiographs.

TREATMENT

Haemophilus influenzae

Initial therapy for meningitis due to Hib should consist of a cephalosporin such as ceftriaxone or cefotaxime. For children, the dosage of ceftriaxone is 75–100 mg/kg daily given in two doses 12 h apart. The pediatric dosage of cefotaxime is 200 mg/kg daily given in four doses 6 h apart. Adult dosages are 2 g every 12 h for ceftriaxone and 2 g every 4–6 h for cefotaxime. An alternative regimen for initial therapy is ampicillin (200–300 mg/kg daily in four divided doses) plus chloramphenicol (75–100 mg/kg daily in four divided doses). Therapy should continue for a total of 1–2 weeks.

Administration of glucocorticoids to patients with Hib meningitis reduces the incidence of neurologic sequelae. The presumed mechanism is reduction of the inflammation induced by bacterial cell-wall mediators of inflammation when cells are killed by antimicrobial agents. Dexamethasone (0.6 mg/kg per day intravenously in four divided doses for 2 days) is recommended for the treatment of Hib meningitis in children >2 months of age.

Invasive infections other than meningitis are treated with the same antimicrobial agents. For epiglottitis, the dosage of ceftriaxone is 50 mg/kg daily, and the dosage of cefotaxime is 150 mg/kg daily, given in three divided doses 8 h apart. Epiglottitis constitutes a medical emergency, and maintenance of an airway is critical. The duration of therapy is determined by the clinical response. A course of 1–2 weeks is usually appropriate.

Many infections caused by nontypeable strains of *H. influenzae*, such as otitis media, sinusitis, and exacerbations of COPD, can be treated with oral antimicrobial agents. Approximately 30–40% of nontypeable strains produce β-lactamase (with the exact proportion depending on geographic location), and these strains are resistant to ampicillin as well as amoxicillin. Several agents have excellent activity against nontypeable *H. influenzae*, including amoxicillin/clavulanic acid, various extended-spectrum cephalosporins, and the macrolides azithromycin and clarithromycin. Fluoroquinolones are highly active against *H. influenzae* and are useful in adults with exacerbations of COPD. However, fluoroquinolones are not currently recommended for the treatment of children or pregnant women because of possible effects on articular cartilage.

In addition to β-lactamase production, alteration of penicillin-binding proteins—a second mechanism of ampicillin resistance—has been detected in isolates of *H. influenzae*. Although still rare in the United States, these β-lactamase-negative ampicillin-resistant strains are common in Japan and are increasing in prevalence in Europe. Resistance to macrolides is also being observed with increasing frequency globally. Continued monitoring of the evolving antimicrobial susceptibility patterns of *H. influenzae* will be important.

PREVENTION

Vaccination (See also Chap. 129) Three monovalent conjugate vaccines that prevent invasive infections with Hib in infants and children are licensed in the United States. In addition to eliciting protective antibodies, these vaccines prevent disease by reducing rates of pharyngeal colonization with Hib. The widespread use of conjugate vaccines has dramatically reduced the incidence of Hib disease in developed countries. Even though the manufacture of Hib vaccines is costly, vaccination is cost-effective. The Global Alliance for Vaccines and Immunizations has recognized the underuse of Hib conjugate vaccines.

The disease burden has been reduced in developing countries that have implemented routine vaccination (e.g., The Gambia, Chile). An important obstacle to more widespread vaccination is the lack of data on the epidemiology and burden of Hib disease in many developing countries.

All children should be immunized with a Hib conjugate vaccine, receiving the first dose at ~2 months of age, the rest of the primary series at 2–6 months of age, and a booster dose at 12–15 months of age. Specific recommendations vary for the different conjugate vaccines. The reader is referred to the recommendations of the American Academy of Pediatrics (Chap. 129 and *https://www.aap.org/en/patient-care/immunizations/vaccination-recommendations-by-the-aap/*).

Currently, no vaccines are available specifically for the prevention of disease caused by nontypeable *H. influenzae*. However, a vaccine that contains protein D—a surface protein of *H. influenzae*—conjugated to pneumococcal polysaccharides is licensed in other countries and is used widely throughout the world. The vaccine has shown partial efficacy in preventing *H. influenzae* otitis media in clinical trials. Vaccine formulations that include surface protein antigens are currently in clinical trials, and additional progress in the development of vaccines against nontypeable *H. influenzae* is anticipated.

Chemoprophylaxis The risk of secondary disease is greater than normal among household contacts of patients with Hib disease. Therefore, all children and adults (except pregnant women) in households with an index case and at least one incompletely immunized contact <4 years of age should receive prophylaxis with oral rifampin. When two or more cases of invasive Hib disease have occurred within 60 days at a child-care facility attended by incompletely vaccinated children, administration of rifampin to all attendees and personnel is indicated, as it is for household contacts. Chemoprophylaxis is not indicated in nursery and child-care contacts of a single index case. The reader is referred to the recommendations of the American Academy of Pediatrics.

HAEMOPHILUS DUCREYI

Haemophilus ducreyi is the etiologic agent of chancroid (Chap. 141), a sexually transmitted disease characterized by genital ulceration and inguinal adenitis. In addition to being a cause of morbidity in itself, chancroid is associated with HIV infection because of the role played by genital ulceration in HIV transmission. Chancroid increases the efficiency of transmission of and the degree of susceptibility to HIV infection. *H. ducreyi* has also been recognized as an important cause of non–sexually transmitted cutaneous ulcers.

MICROBIOLOGY

H. ducreyi is a highly fastidious coccobacillary gram-negative bacterium whose growth requires X factor (hemin). Although in light of this requirement, the bacterium has been classified in the genus *Haemophilus*, DNA homology and chemotaxonomic studies have established substantial differences between *H. ducreyi* and other *Haemophilus*

species. Taxonomic reclassification of the organism is likely in the future but awaits further study. Ulcers contain predominantly T cells. The fact that patients who have had chancroid may have repeated infections indicates that infection does not confer protection.

EPIDEMIOLOGY AND PREVALENCE

The prevalence of chancroid has steadily declined in the United States and worldwide over the past decade and a half. The infection appears to be more common in developing countries. Transmission is predominantly heterosexual, and cases in males have outnumbered those in females by ratios of 3:1 to 25:1 during outbreaks. Contact with commercial sex workers and illicit drug use are strongly associated with chancroid. Most cases in developed countries are sporadic.

H. ducreyi has emerged as a major cause of cutaneous ulcers in children in developing countries, particularly in the South Pacific and Africa. Strains that cause cutaneous ulcers have genome sequences that are nearly identical to class I strains (of two related classes) of *H. ducreyi* that cause genital ulcers.

CLINICAL MANIFESTATIONS AND DIFFERENTIAL DIAGNOSIS

Infection is acquired as the result of a break in the epithelium during sexual contact with an infected individual. After an incubation period of 4–7 days, the initial lesion—a papule with surrounding erythema—appears. In 2 or 3 days, the papule evolves into a pustule, which spontaneously ruptures and forms a sharply circumscribed ulcer that generally is not indurated **(Fig. 162-3)**. The ulcers are painful and bleed easily; little or no inflammation of the surrounding skin is evident. Approximately half of patients develop enlarged, tender inguinal lymph nodes, which frequently become fluctuant and spontaneously rupture. Patients usually seek medical care after 1–3 weeks of painful symptoms.

The presentation of chancroid does not usually include all of the typical clinical features and is sometimes atypical. Multiple ulcers can coalesce to form giant ulcers. Ulcers can appear and then resolve, with inguinal adenitis (Fig. 162-3) and suppuration following 1–3 weeks later; this clinical picture can be confused with that of lymphogranuloma venereum **(Chap. 194)**. Multiple small ulcers can resemble folliculitis. Other differential diagnostic considerations include the various infections causing genital ulceration, such as primary syphilis, secondary syphilis (condyloma latum), genital herpes, and donovanosis. In rare cases, chancroid lesions become secondarily infected with bacteria; the result is extensive inflammation.

Non–sexually transmitted cutaneous ulcers caused by *H. ducreyi* resemble those of yaws caused by *Treponema pallidum* subspecies *pertenue*, which is endemic in regions where *H. ducreyi* cutaneous ulcers are seen. Ulcers caused by *H. ducreyi* are less likely than those of yaws to show central granulating tissue and less likely to have indurated edges, but substantial overlap in clinical characteristics exists.

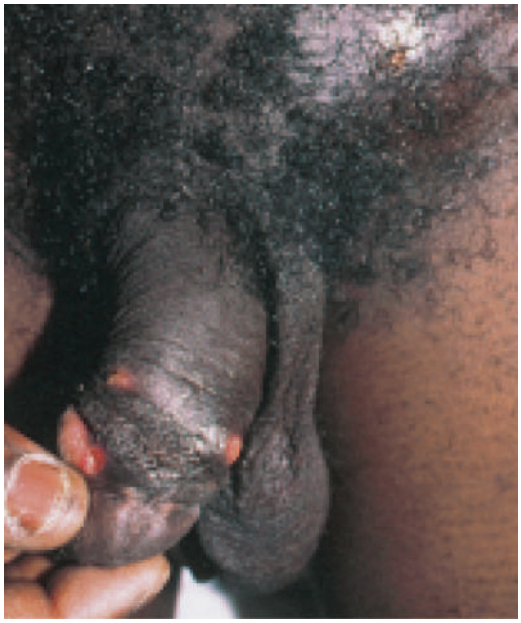

FIGURE 162-3 Chancroid with characteristic penile ulcers and associated left inguinal adenitis (bubo).

DIAGNOSIS

Clinical diagnosis of chancroid is often inaccurate, and laboratory confirmation should be attempted in suspected cases. An accurate diagnosis of chancroid relies on culture of *H. ducreyi* from the lesion or from an aspirate of suppurative lymph nodes. Since the organism can be difficult to grow, the use of selective and supplemented media is necessary. DNA detection by PCR is in use in larger clinical laboratories.

A probable diagnosis of sexually transmitted chancroid can be made when the following criteria are met: (1) one or more painful genital ulcers; (2) no evidence of *T. pallidum* infection by dark-field examination of ulcer exudate or by a negative serologic test for syphilis performed at least 7 days after ulcer onset; (3) a typical clinical presentation for chancroid; and (4) a negative test for herpes simplex virus in the ulcer exudate. A serologic test for syphilis does not distinguish cutaneous ulcers due to *H. ducreyi* from those due to yaws, but PCR should be performed.

TREATMENT

Haemophilus ducreyi

Treatment regimens for both genital and cutaneous infections include either (1) a single 1-g oral dose of azithromycin; (2) ceftriaxone (250 mg intramuscularly in a single dose); (3) ciprofloxacin (500 mg by mouth twice a day for 3 days); or (4) erythromycin base (500 mg by mouth three times a day for 7 days). Isolates from patients who do not respond promptly to treatment should be tested for antimicrobial resistance. In patients with HIV infection, healing may be slow and longer courses of treatment may be necessary. Clinical treatment failure in HIV-seropositive patients may reflect co-infection, especially with herpes simplex virus. Contacts of patients with chancroid should be identified and treated, whether or not symptoms are present, if they have had sexual contact with the patient during the 10 days preceding the patient's onset of symptoms.

MORAXELLA CATARRHALIS

MICROBIOLOGY

M. catarrhalis is an unencapsulated gram-negative diplococcus whose ecologic niche is the human respiratory tract. The organism was initially designated *Micrococcus catarrhalis*. Its name was changed to *Neisseria catarrhalis* in 1970 because of phenotypic similarities to commensal *Neisseria* species. On the basis of more rigorous analysis of genetic relatedness, *Moraxella catarrhalis* is now the widely accepted name for this species.

EPIDEMIOLOGY

Nasopharyngeal colonization by *M. catarrhalis* is common in infancy, with colonization rates ranging between 33 and 100% and depending on geographic location. Several factors probably account for this geographic variation, including living conditions, day-care attendance, hygiene, household smoking, and population genetics. The prevalence of colonization decreases steadily with age.

The widespread use of pneumococcal conjugate vaccines in some countries has resulted in alterations in patterns of nasopharyngeal colonization in resident populations. A relative increase in colonization by nonvaccine pneumococcal serotypes, nontypeable *H. influenzae*, and *M. catarrhalis* has occurred. These changes in colonization patterns may be altering the distribution of pathogens of both otitis media and sinusitis in children.

PATHOGENESIS

M. catarrhalis causes mucosal infections of the respiratory tract by contiguous spread from its colonizing site in the upper airway. A preceding

viral upper respiratory tract infection is a common inciting event for otitis media. In exacerbations of COPD, the acquisition of new strains is critical for pathogenesis. Strains exhibit substantial genetic diversity and differences in virulence properties.

The expression of several adhesin molecules with differing specificities for various host cell receptors reflects the importance of adherence to the respiratory epithelial surface in the pathogenesis of infection. *M. catarrhalis* invades multiple cell types. Its intracellular residence in lymphoid tissue provides a potential reservoir for persistence in the human respiratory tract. Like many gram-negative bacteria, *M. catarrhalis* sheds vesicles into the surrounding environment. The vesicles are internalized by host cells and mediate several virulence mechanisms, including induction of inflammation and delivery of β-lactamase, that can promote the survival of co-pathogens such as group A streptococci and *H. influenzae*.

CLINICAL MANIFESTATIONS

In children, *M. catarrhalis* causes predominantly mucosal infections when the bacterium migrates from the nasopharynx to the middle ear or the sinuses **(Chap. 37)**. The inciting event for both otitis media and sinusitis is often a preceding viral infection. It has, for example, been shown that rhinovirus promotes adhesion of *M. catarrhalis*. Overall, cultures of middle-ear fluid obtained by tympanocentesis indicate that *M. catarrhalis* causes 15–20% of cases of acute otitis media. More sensitive molecular analysis of middle ear fluid detects *M. catarrhalis* alone or with other pathogens in 30–50% of middle ear fluid samples from children with otitis media. Acute otitis media caused by *M. catarrhalis* or nontypeable *H. influenzae* is clinically milder than otitis media caused by *S. pneumoniae*, with less fever and a lower prevalence of a red bulging tympanic membrane. However, substantial overlap makes it impossible to predict etiology in an individual child on the basis of clinical features.

A small proportion of viral upper respiratory tract infections are complicated by bacterial sinusitis. Cultures of sinus puncture aspirates show that *M. catarrhalis* accounts for ~20% of cases of acute bacterial sinusitis in children and for a smaller proportion in adults.

M. catarrhalis is a common cause of exacerbations in adults with COPD. The bacterium used to be overlooked in this clinical setting because it had long been considered a commensal and because it was easily mistaken for commensal *Neisseria* species in cultures of respiratory secretions (see "Diagnosis," below). Several independent lines of evidence have established *M. catarrhalis* as a pathogen in COPD. These include (1) the demonstration of *M. catarrhalis* in the lower airways during exacerbations, (2) the association of exacerbation with acquisition of new strains, (3) elevations of inflammatory markers in association with *M. catarrhalis*, and (4) the development of specific immune responses following infection. *M. catarrhalis* is the second most common bacterial cause of COPD exacerbations (after *H. influenzae*), as shown in a 10-year prospective study; the distribution of exacerbations associated with new-strain acquisitions is shown in Fig. 162-2. Not included are culture-negative cases or cases from which a pathogen had been previously isolated. With the application of rigorous clinical criteria for defining the etiology of exacerbations (both culture-positive and culture-negative), ~10% of all exacerbations in the same study were caused by *M. catarrhalis*. The clinical features of an exacerbation due to *M. catarrhalis* are similar to those of exacerbations due to other bacterial pathogens, including *H. influenzae* and *S. pneumoniae*. The cardinal symptoms are cough with increased sputum production, sputum purulence, and dyspnea in comparison with baseline symptoms.

Pneumonia due to *M. catarrhalis* occurs in the elderly, particularly in the setting of underlying cardiopulmonary disease, but is infrequent. Invasive infections, such as bacteremia, endocarditis, neonatal meningitis, and septic arthritis, are rare.

DIAGNOSIS

Tympanocentesis is required for etiologic diagnosis of otitis media, but this procedure is not performed routinely. Therefore, treatment of otitis media is generally empirical. Similarly, an etiologic diagnosis of sinusitis requires an invasive procedure and thus is usually not available to the clinician. Isolation of *M. catarrhalis* from an expectorated sputum sample from an adult experiencing clinical symptoms of an exacerbation is suggestive, but not diagnostic, of *M. catarrhalis* as the cause.

Upon culture, colonies of *M. catarrhalis* resemble those of commensal neisseriae that are part of the normal upper airway flora. As mentioned above, the difficulty in distinguishing colonies of *M. catarrhalis* from neisserial colonies in cultures of respiratory secretions explains in part why *M. catarrhalis* has been overlooked as a pathogen. In contrast to these *Neisseria* species, *M. catarrhalis* colonies can be slid across the agar surface without disruption (the "hockey puck sign"). In addition, after 48 h of growth, *M. catarrhalis* colonies take on a pink color and tend to be larger than neisserial colonies.

TREATMENT

Moraxella catarrhalis

M. catarrhalis rapidly acquired β-lactamases during the 1970s and 1980s, the fastest documented spread of β-lactamases encoding plasmids. Antimicrobial susceptibility patterns have remained relatively stable since that time, with >90% of strains now producing β-lactamase and thus resistant to amoxicillin. Otitis media in children and exacerbations of COPD in adults are generally managed empirically with antimicrobial agents that are active against *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Most strains of *M. catarrhalis* are susceptible to amoxicillin/clavulanic acid, extended-spectrum cephalosporins, newer macrolides (azithromycin, clarithromycin), trimethoprim-sulfamethoxazole, and fluoroquinolones. However, recent reports from several centers in Asia show substantial resistance to macrolides and fluoroquinolones, indicating emerging resistance. Continued monitoring of global antimicrobial susceptibility patterns of *M. catarrhalis* will be critical.

163 Infections Due to the HACEK Group and Miscellaneous Gram-Negative Bacteria

Tamar F. Barlam

THE HACEK GROUP

HACEK organisms are a group of fastidious, slow-growing, gram-negative bacteria whose growth requires an atmosphere of carbon dioxide. These organisms do not grow on media routinely used for enteric bacteria (e.g., MacConkey agar). Species belonging to this group include several *Haemophilus* species, *Aggregatibacter* (formerly

Actinobacillus) species, *Cardiobacterium* species, *Eikenella corrodens*, and *Kingella kingae*. HACEK bacteria normally reside in the oral cavity and have been associated with local infections in the mouth. They are also known to cause severe systemic infections—such as bacteremia and bacterial endocarditis, which can develop on either native or prosthetic valves **(Chap. 133)**. In a nationwide survey in Denmark, HACEK bacteremias were most often due to *Haemophilus* species, followed by *Aggregatibacter* species. HACEK bacteremia is strongly predictive of underlying infective endocarditis (overall positive predictive value, 60%). However, this association varies significantly by organism. For example, infective endocarditis was diagnosed in 62–100% of patients with *Aggregatibacter actinomycetemcomitans* bacteremia, 17–55% with *Haemophilus parainfluenzae* bacteremia, 50% with *Cardiobacterium hominis* bacteremia, but only 0–6% of patients with *Eikenella* bacteremia.

In large series, 0.8–6% of cases of infective endocarditis are attributable to HACEK organisms, most often *Aggregatibacter* species, *Haemophilus* species, and *Cardiobacterium hominis*. Invasive infection typically occurs in patients with a history of cardiac valvular disease or prosthetic valves, often in the setting of a recent dental procedure or nasopharyngeal infection. The aortic and mitral valves are most commonly affected. The clinical course of HACEK endocarditis tends to be subacute, particularly with *Aggregatibacter* or *Cardiobacterium*. However, *K. kingae* endocarditis may have a more aggressive presentation. Compared with non-HACEK endocarditis, HACEK endocarditis occurs in younger patients and has been more frequently associated with embolic, vascular, and immunologic manifestations. Systemic embolization is common. The overall prevalence of major emboli associated with HACEK endocarditis ranges from 28 to 71% in different series. On echocardiography, valvular vegetations are seen in up to 85% of patients. *Aggregatibacter* and *Haemophilus* species cause mitral valve vegetations most often; *Cardiobacterium* is associated with aortic valve vegetations.

The microbiology laboratory should be alerted when a HACEK organism is being considered. Most cultures that ultimately yield a HACEK organism become positive within the first week, especially with improved culture systems such as BACTEC. Studies have not shown that prolonged incubation increases laboratory recovery of clinically significant HACEK isolates. Polymerase chain reaction (PCR) techniques, such as gene amplification of 16S rRNA, can facilitate the diagnosis of HACEK infection of blood or cardiac valves. Other tools, such as matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry performed directly on agar colonies, can increase the accuracy and speed of diagnosis of HACEK infections.

Because of HACEK organisms' slow growth, antimicrobial susceptibility testing may be difficult, and β-lactamase production may not be detected. Resistance is most commonly noted in *Haemophilus* and *Aggregatibacter* species. Etest methodology may increase the accuracy of susceptibility testing. In recent studies, ceftriaxone and levofloxacin have been active against all isolates. The overall prognosis in both native-valve and prosthetic-valve HACEK endocarditis is excellent and is significantly better than that in endocarditis caused by non-HACEK pathogens.

***Haemophilus* Species** *Haemophilus parainfluenzae* is the most common *Haemophilus* species isolated from cases of HACEK endocarditis. Of patients with HACEK endocarditis due to *Haemophilus* species, 60% have been ill for <2 months before presentation, and 19–50% develop congestive heart failure. The mitral valve is most frequently involved, and large vegetations resulting in septic emboli, including central nervous system emboli, are common. *H. parainfluenzae* has been isolated from other infections, such as pneumonia; meningitis; brain, dental, pelvic, and liver abscess; urinary tract infection; and septicemia that is often polymicrobial.

***Aggregatibacter* Species** *Aggregatibacter* species are the most common cause of HACEK endocarditis; the species most frequently involved are *A. actinomycetemcomitans*, *A.* (formerly *Haemophilus*) *aphrophilus*, and *A. paraphrophilus*. *Aggregatibacter* is associated with prosthetic-valve endocarditis more often than are *Haemophilus* species. *A. actinomycetemcomitans* can be isolated from soft tissue infections and abscesses in association with *Actinomyces israelii*. Typically, patients who develop *Aggregatibacter* endocarditis have periodontal disease or have recently undergone dental procedures in the setting of underlying cardiac valvular damage. The disease is insidious; patients may be sick for several months before diagnosis. Frequent complications include embolic phenomena, congestive heart failure, and renal failure.

A. actinomycetemcomitans has been isolated from patients with brain abscess, meningitis, endophthalmitis, parotitis, osteomyelitis, urinary tract infection, pneumonia, and empyema, among other infections. *A. aphrophilus* is often associated with bone and joint infection and is an important cause of brain abscess. In one series, *A. aphrophilus* was isolated from brain abscesses in 10% of cases—a rate that is disproportionate to its isolation from oral flora. This species has also been described as a cause of abscess in other organ systems.

***Cardiobacterium* Species** *Cardiobacterium* species, most often *C. hominis*, cause endocarditis primarily in patients with underlying valvular heart disease or with prosthetic valves. These organisms most frequently affect the aortic valve. Many patients have signs and symptoms of long-standing infection before diagnosis, with evidence of arterial embolization, vasculitis, cerebrovascular accidents, immune complex glomerulonephritis, or arthritis at presentation. Embolization, mycotic aneurysms, and congestive heart failure are common complications. A second species, *C. valvarum*, has been described in association with endocarditis.

Eikenella corrodens *E. corrodens* is most frequently recovered from sites of infection in conjunction with other bacterial species. Clinical sources of *E. corrodens* include sites of human bite wounds (clenched-fist injuries), endocarditis, soft tissue infections, osteomyelitis, head and neck infections, respiratory infections, chorioamnionitis, gynecologic infections associated with intrauterine devices, meningitis, brain abscesses, and visceral abscesses. This organism is the least common cause of HACEK endocarditis.

Kingella kingae More than half of cases of *K. kingae* infection are bone and joint infections; the majority of the remaining infections are infective endocarditis, bacteremia, and meningitis. Invasive *K. kingae* infections with bacteremia are associated with upper respiratory tract infections and stomatitis in 80% of cases. Rates of oropharyngeal colonization with *K. kingae* are highest in the first 3 years of life (detected in ~5–10% of children) and appear higher in children regularly attending daycare; colonization coincides with an increased incidence of skeletal infections and other invasive infections due to this organism from the age of 6 months to 4 years. *K. kingae* can be transmitted from child to child and has been the cause of outbreaks among young children. Isolates associated with outbreaks appear to be more virulent and transmissible compared with nonoutbreak strains. *K. kingae* bacteremia can present with a petechial rash similar to that seen in *Neisseria meningitidis* sepsis.

Because of improved microbiologic methodology and molecular methods such as real-time PCR, the isolation of *K. kingae* is increasingly common. Inoculation of clinical specimens (e.g., synovial fluid) into aerobic blood culture bottles enhances recovery of this organism. PCR studies of blood or joint fluid can identify *K. kingae* in culture-negative cases. Some studies have demonstrated that *K. kingae* has surpassed *Staphylococcus aureus* as the leading cause of septic arthritis and osteomyelitis in children.

Infective endocarditis, unlike other infections with *K. kingae*, occurs in older children and adults. The majority of patients have preexisting valvular disease. There is a high incidence of complications, including arterial emboli, cerebrovascular accidents, tricuspid insufficiency, and congestive heart failure with cardiovascular collapse.

TREATMENT

HACEK Endocarditis

(Table 163-1) Ceftriaxone (2 g/d) is first-line therapy for HACEK endocarditis, with a favorable outcome in 80–90% of cases. Data on the use of levofloxacin (750 mg/d) for HACEK endocarditis remain

TABLE 163-1 Treatment of Infections Caused by HACEK-Group and Other Fastidious Gram-Negative Organisms

ORGANISMS	PREFERRED THERAPY	ALTERNATIVE AGENTS	COMMENTS
Haemophilus spp. *Aggregatibacter* spp. *Cardiobacterium* spp. *Eikenella corrodens* *Kingella kingae*	Ceftriaxone (2 g/d)	Ampicillin/sulbactam (3 g of ampicillin q6h) Levofloxacin (750 mg/d)	Ampicillin/sulbactam resistance has been described in *Haemophilus* and *Aggregatibacter* spp. Data on use of levofloxacin for endocarditis therapy are limited. Fluoroquinolones are not recommended for treatment of patients <18 years of age. Penicillin (16–18 million units q4h) or ampicillin (2 g q4h) can be used if the organism is susceptible. However, because of the slow growth of HACEK bacteria, antimicrobial testing may be difficult, and β-lactamase production may not be detected.
Capnocytophaga spp.	Ampicillin/sulbactam (1.5–3 g of ampicillin q6h)	Ceftriaxone (2 g/d q12–24h)	Penicillin (12–18 million units q4h) should be used if the isolate is known to be susceptible.
Pasteurella multocida	Ampicillin/sulbactam (1.5–3 g of ampicillin q6h)	Ceftriaxone (1–2 g/d q12–24h)	Penicillin should be used if the isolate is known to be susceptible. *P. multocida* is also susceptible to tetracyclines and fluoroquinolones.

limited, but this drug can be considered an alternative for treatment of patients intolerant of β-lactam therapy. Of note, *Eikenella* is resistant to clindamycin, metronidazole, and aminoglycosides.

Native-valve endocarditis should be treated for 4 weeks with antibiotics, whereas prosthetic-valve endocarditis requires 6 weeks of therapy. The cure rates for HACEK prosthetic-valve endocarditis appear to be high. Unlike prosthetic-valve endocarditis caused by other gram-negative organisms, HACEK endocarditis is often cured with antibiotic treatment alone—i.e., without surgical intervention. In a recent case-control study, 1-year mortality was significantly lower than infective endocarditis caused by viridans group *Streptococcus*.

OTHER FASTIDIOUS GRAM-NEGATIVE BACTERIA

***Capnocytophaga* Species** Like HACEK organisms, this genus of fastidious, fusiform, gram-negative coccobacilli is facultatively anaerobic and requires an atmosphere enriched in carbon dioxide for optimal growth. *Capnocytophaga* species such as *C. ochracea*, *C. gingivalis*, *C. haemolytica*, and *C. sputigena* are part of the oral flora; most infections are contiguous with the oropharynx (e.g., periodontal disease, respiratory tract infections, cervical abscesses). These organisms have also been associated with sepsis in immunocompromised hosts, particularly neutropenic patients with oral ulcerations, meningitis, endocarditis, cellulitis, osteomyelitis, and septic arthritis. *Capnocytophaga* species have been isolated from many other sites as well, usually as part of a polymicrobial infection. There is a high prevalence of resistance to β-lactams and macrolides in *Capnocytophaga*.

C. canimorsus and *C. cynodegmi* are endogenous to the canine and feline mouth (Chap. 146). Patients infected with these species frequently have a history of dog or cat bites or of exposure without scratches or bites. Asplenia, glucocorticoid therapy, and alcohol abuse are predisposing conditions that can be associated with severe sepsis with shock and disseminated intravascular coagulation. Patients typically have a petechial rash that can progress from purpuric lesions to gangrene.

TREATMENT

Capnocytophaga Infections

(Table 163-1) Because of increasing β-lactamase production, a penicillin derivative plus a β-lactamase inhibitor—such as ampicillin/sulbactam (1.5–3.0 g of ampicillin every 6 h)—is currently recommended for empirical treatment of infections caused by *Capnocytophaga* species. If the isolate is known to be susceptible, infections with *C. canimorsus* should be treated with penicillin (12–18 million units every 4 h). *Capnocytophaga* is also susceptible to third-generation cephalosporins such as ceftriaxone (2 g every 12–24 h), doxycycline (100 mg every 12 h), and clindamycin (600–900 mg every 6–8 h). Antibiotics should be given prophylactically to asplenic patients who have sustained dog-bite injuries.

Pasteurella multocida *P. multocida* is a fastidious, bipolar-staining, gram-negative coccobacillus that colonizes the respiratory and gastrointestinal tracts of domestic animals; oropharyngeal colonization rates are 50–90% in cats and 50–70% in dogs. *P. multocida* can be transmitted to humans through bites or scratches, via the respiratory tract from contact with contaminated dust or infectious droplets, or via deposition of the organism on injured skin or mucosal surfaces during licking. Most human infections affect skin and soft tissue; almost two-thirds of these infections are caused by cats. Patients at the extremes of age or with serious underlying disorders (e.g., cirrhosis, diabetes, cancer) are at increased risk for invasive infection with systemic manifestations, including bacteremia, meningitis, peritonitis, osteomyelitis and septic arthritis, endocarditis, septic shock, ecthyma, necrotizing fasciitis, and purpura fulminans, and are more likely not to have evidence of an animal bite. However, cases have also occurred in healthy individuals of all ages. Mortality has been reported to be as high as 30% in invasive disease, despite active antimicrobial therapy. If inhaled, *P. multocida* can cause acute respiratory tract infection, particularly in patients with underlying sinus and pulmonary disease.

TREATMENT

Pasteurella multocida Infections

(Table 163-1) *P. multocida* is susceptible to penicillin, ampicillin, ampicillin/sulbactam, second- and third-generation cephalosporins, tetracyclines, and fluoroquinolones. β-Lactamase–producing strains have been reported.

OTHER GRAM-NEGATIVE BACTERIA

Achromobacter xylosoxidans *Achromobacter* (previously *Alcaligenes*) *xylosoxidans* is an aerobic nonfermenting gram-negative organism that is probably part of the endogenous intestinal flora. It has been isolated from a variety of water sources, including well water, IV fluids, and humidifiers. Immunocompromised hosts, including patients with cancer and postchemotherapy neutropenia, cirrhosis, chronic renal failure, and cystic fibrosis, are at increased risk for infection. Nosocomial outbreaks and pseudo-outbreaks of infection with *A. xylosoxidans,* and other *Achromobacter* species, have been attributed to contaminated fluids, and clinical illness has been associated with isolates from many sites, including blood (often in the setting of intravascular devices). Community-acquired *A. xylosoxidans* bacteremia usually occurs in the setting of pneumonia. Metastatic skin lesions are present in one-fifth of cases. The reported mortality rate is as high as 67%—a figure similar to rates for other bacteremic gram-negative pneumonias.

TREATMENT

Achromobacter xylosoxidans Infections

(Table 163-2) Treatment is based on in vitro susceptibility testing of all clinically relevant isolates; multidrug resistance is common.

TABLE 163-2 Treatment Options for Other Selected Gram-Negative Bacteria[a]

ORGANISM	TREATMENT OPTIONS
Achromobacter xylosoxidans	Carbapenems, piperacillin-tazobactam, ceftazidime, trimethoprim-sulfamethoxazole
Aeromonas spp.	Fluoroquinolones, third- and fourth-generation cephalosporins, carbapenems, minocycline, aminoglycosides
Elizabethkingia/ Chryseobacterium spp.	Fluoroquinolones, minocycline, trimethoprim-sulfamethoxazole, piperacillin/tazobactam
Rhizobium radiobacter	Fluoroquinolones, third- and fourth-generation cephalosporins, carbapenems
Shewanella spp.	Fluoroquinolones, third- and fourth-generation cephalosporins, β-lactam/β-lactamase inhibitors, carbapenems, aminoglycosides
Chromobacterium violaceum	Carbapenems, fluoroquinolones, trimethoprim-sulfamethoxazole

[a]Treatment should be based on in vitro susceptibility testing; multidrug resistance is common among these organisms.

Carbapenems, piperacillin-tazobactam, ceftazidime, trimethoprim-sulfamethoxazole, minocycline, and colistin are typically the most active agents.

***Aeromonas* Species** *Aeromonas* is a facultative anaerobic gram-negative bacterium. *Aeromonas* infections are most often caused by *A. hydrophila*, *A. caviae*, *A. veronii*, and *A. dhakensis*. *Aeromonas* proliferates in potable water, seawater, freshwater, raw seafood, and soil. It remains controversial whether *Aeromonas* is a cause of bacterial gastroenteritis; asymptomatic colonization of the intestinal tract with *Aeromonas* occurs frequently, and no clonally related diarrheal outbreak has been documented. However, rare cases of hemolytic-uremic syndrome following bloody diarrhea have been shown to be secondary to the presence of *Aeromonas*.

Aeromonas causes health care–associated sepsis and bacteremia in infants with multiple medical problems and in immunocompromised hosts, particularly those with cancer or hepatobiliary disease, including cirrhosis. *A. caviae* is associated with health care–related bacteremia. Community-acquired infections include bacteremia, spontaneous bacterial peritonitis, biliary tract infections, and skin and soft tissue infections. Severe soft tissue infections such as necrotizing fasciitis are more common in Taiwan than in Western countries; *Aeromonas* was the most common pathogen associated with skin and soft tissue infections after the tsunami in Thailand. Along with other gram-negative organisms such as *Shewanella* and *Chromobacterium*, *Aeromonas* infections are associated with floods and other hydrologic disasters. *Aeromonas* infection and sepsis can occur in patients with trauma (including severe trauma with myonecrosis), patients with seawater-contaminated wounds, and burn patients exposed to the organism by environmental (freshwater or soil) wound contamination. Reported mortality rates range from 25% among immunocompromised adults with sepsis to >90% among patients with myonecrosis. Patients with *A. dhakensis* bacteremia have higher 14-day mortality rates than do those whose bacteremia is attributable to other species. *Aeromonas* can produce ecthyma gangrenosum (hemorrhagic vesicles surrounded by a rim of erythema with central necrosis and ulceration; **see Fig. A1-34**) resembling the lesions seen in *Pseudomonas aeruginosa* infection. This organism causes nosocomial infections related to catheters, surgical incisions, or use of leeches. Other manifestations include meningitis, peritonitis, pneumonia, and ocular infections.

TREATMENT

Aeromonas Infections

(Table 163-2) *Aeromonas* species are generally susceptible to fluoroquinolones (e.g., ciprofloxacin at a dosage of 500 mg every 12 h PO or 400 mg every 12 h IV), third- and fourth-generation cephalosporins, carbapenems, minocycline, and aminoglycosides, but resistance to all those agents has been described. Because *Aeromonas* can produce various β-lactamases, including carbapenemases, susceptibility testing must be used to guide therapy. Antibiotic prophylaxis (e.g., with ciprofloxacin) is indicated when medicinal leeches are used.

***Elizabethkingia/Chryseobacterium* Species** *Elizabethkingia meningoseptica* (formerly *Chryseobacterium meningosepticum*) is a nonfastidious aerobic nonfermentative gram-negative bacillus, found in soil, water, and hospital environments. It is an important cause of nosocomial infections, including outbreaks due to contaminated fluids (e.g., contaminated sinks, disinfectants, and aerosolized antibiotics) and sporadic infections due to indwelling devices, feeding tubes, and other fluid-associated apparatuses. Outbreaks due to this organism have persisted until extensive cleaning of environmental surfaces and equipment has been performed. Nosocomial *E. meningoseptica* infection usually involves preterm neonates, patients with underlying immunosuppression (e.g., related to malignancy or diabetes), or patients exposed to antibiotics in intensive care. *E. meningoseptica* has been reported to cause meningitis (primarily in neonates), pneumonia, sepsis, endocarditis, bacteremia, eye infections, and soft tissue infections. Other species of *Elizabethkingia* are emerging, identified using MALDI-TOF and 16s rRNA sequencing. In a report of 86 clinical isolates, only 12 (19.8%) of the isolates were *E. meningoseptica;* the majority were *E. anophelis* (51 isolates; 59.3%). More than three-quarters of the isolates were from the lower respiratory tract, and 9.3% were from blood cultures. In a U.S. study of 11 patients with *E. anophelis* infection, all had bloodstream infections. In that series, the patients had underlying comorbidities and recent health care exposure; there was a mortality rate of 18.2%. *E. anophelis* has also been associated with sepsis and meningitis in neonates.

Chryseobacterium indologenes has caused bacteremia, sepsis, peritonitis, meningitis, and pneumonia, typically in immunocompromised patients with indwelling devices. Mortality rates have been as high as 50% in some reports; it is unclear whether a poor prognosis is related to underlying comorbidities or to the multidrug-resistant phenotype of the organism.

TREATMENT

Elizabethkingia/Chryseobacterium Infections

(Table 163-2) These organisms are often susceptible to fluoroquinolones, minocycline, and trimethoprim/sulfamethoxazole. They may be susceptible to β-lactam/β-lactamase inhibitor combinations such as piperacillin/tazobactam but are resistant to carbapenems. Multidrug-resistant isolates are increasing and can possess extended-spectrum β-lactamases and metallo-β-lactamases. Combination therapy may be needed for successful treatment. Susceptibility testing should be performed to guide the choice of optimal agents.

MISCELLANEOUS ORGANISMS

Rhizobium (formerly *Agrobacterium) radiobacter* has usually been associated with infection in the presence of medical devices, including intravascular catheter–related infections, prosthetic-joint and prosthetic-valve infections, peritonitis caused by dialysis catheters, and endophthalmitis after cataract surgery. Most *R. radiobacter* infections occur in immunocompromised hosts, especially individuals with malignancy or HIV infection. Elderly patients with septic shock, watery diarrhea, and acute renal failure also have been reported. Strains are usually susceptible to fluoroquinolones, third- and fourth-generation cephalosporins, and carbapenems (Table 163-2).

Shewanella species are ubiquitous nonfermentative gram-negative organisms found in seawater and marine environments. Human disease is caused primarily by *S. putrefaciens* and *S. algae*; *S. algae* may be the more virulent species. Most infections involve skin and soft tissue, ranging from impetigo to necrotizing fasciitis. Patients are exposed to the organism through contact of bites, open wounds, or devitalized tissue with seawater, marine animals, or through ingestion of seawater or of raw or undercooked seafood, especially shellfish. Nosocomial outbreaks

have been reported. *Shewanella* species also cause chronic ulcers of the lower extremities, bacteremia, osteomyelitis, biliary tract infections, pneumonia, sepsis, and potentially chronic otitis media. A fulminant course is associated with cirrhosis, hemochromatosis, diabetes mellitus, malignancy, or other severe underlying conditions. These organisms are often susceptible to fluoroquinolones, third- and fourth-generation cephalosporins, β-lactam/β-lactamase inhibitors, carbapenems, and aminoglycosides (Table 163-2), but multidrug resistance is increasing.

Chromobacterium violaceum is a facultative anaerobic organism found in soil and water in tropical or subtropical regions. After exposure, it can cause rare but serious—often fatal—skin and soft tissue infections of limbs, although several recent reports suggest a more benign course with lower mortality. Life-threatening infections with severe sepsis and metastatic abscesses occur most often in patients with underlying illness, particularly in children with defective neutrophil function (e.g., those with chronic granulomatous disease). *C. violaceum* is frequently resistant to multiple drugs; carbapenems are most often used empirically. Fluoroquinolones and trimethoprim-sulfamethoxazole also can be active (Table 163-2).

Organisms that can cause nosocomial infections of medical devices in compromised hosts, such as central venous catheters, include *Ochrobactrum anthropi*, *Pseudomonas* (formerly *Flavimonas*) *oryzihabitans*, and *Sphingobacterium*. *Alcaligenes faecalis* has been associated with hospital-acquired infections, such as bloodstream infections, due to contaminated hemodialysis and IV fluids or respirators. *Sphingomonas koreensis* was associated with a small cluster of nosocomial cases at one hospital and was traced to a reservoir in the plumbing system. *Ralstonia* species also can contaminate water supplies, including hospital water systems. Cases of bacteremia, osteomyelitis, pneumonia, and meningitis have been described. *Pandoraea commovens* primarily infects patients with cystic fibrosis. However, an outbreak described in Germany resulted in critical illness. Patients were more likely to be receiving mechanical ventilation and have had prior surgery or antimicrobial exposure. *Sphingomonas paucimobilis,* a rare cause of infection in both healthy and immunocompromised patients, can cause bloodstream infections, respiratory distress, and sepsis. It has a predilection for bone and soft tissue infection, osteomyelitis, and septic arthritis. Other organisms can cause rare human infections such as *Weeksella* species; *Bergeyella* species; various Centers for Disease Control and Prevention (CDC) groups; and *Oligella urethralis.* The reader is advised to consult subspecialty texts and references for further guidance on these and other organisms.

164 *Legionella* Infections

Steven A. Pergam, Thomas R. Hawn

Bacteria of *Legionella* species cause two primary human diseases: *Legionella* pneumonia (often referred to as Legionnaires' disease) and Pontiac fever; collectively, these diseases are referred to as *legionellosis*. Legionnaires' disease was first described in 1976 in an outbreak among members of the American Legion participating in a conference at a hotel in Philadelphia, Pennsylvania. Since their original description, *Legionella*-related infections have increased in frequency throughout the world as techniques to diagnose them have improved, clinical awareness has increased, cities have grown, and water systems have both aged and become more complex. Most cases of legionellosis are linked to waterborne exposures. These infections can be either sporadic or due to common-source community or nosocomial exposures. Outbreaks of legionellosis are well described. After exposure, legionellosis occurs primarily among persons with risk factors for disease, including older adults and those with primary organ dysfunction, immunocompromise, or other chronic illnesses. Clinical awareness is important, as the similarity of signs and symptoms of legionellosis to those of other respiratory illnesses can lead to delayed treatment. Despite appropriate therapy, *Legionella* pneumonia is associated with significant morbidity and mortality.

PATHOGEN AND PATHOGENICITY

Legionellae are aerobic gram-negative bacteria that are ubiquitous in aquatic environments, damp soil, and compost. Of the more than 60 *Legionella* species, approximately half have been documented to lead to clinical disease, but most clinical disease is driven by *Legionella pneumophila*, primarily serotype 1. The primary habitats for growth and replication of *Legionella* are amoebae and other free-living protozoa, in which these bacterial species can thrive intracellularly; humans are accidental hosts. Legionellae are reliant on host-derived amino acids and nutrients for intracellular replication. The organisms have a biphasic life cycle: a replicative phase in nutrient-rich conditions (e.g., in their protozoal hosts) and a noninfective transmissive phase under scarcity of resources. Therefore, they can persist in complex biofilms in both natural and engineered water systems (e.g., premise plumbing—a building's hot and cold water piping systems) and are phagocytized by waterborne protozoa. In premise plumbing systems, where temperature and nutrients support the protozoal hosts of legionellae, the bacteria can replicate to concentrations sufficient to cause human infection.

After exposure to *Legionella* through inhalation or aspiration of small aerosol particles, the organisms attach to immune cells and are phagocytized. After phagocytosis, they can evade intracellular defenses and replicate in human alveolar macrophages and monocytes. Pathogenic *Legionella* species have numerous virulence systems that they use to evade the human immune system, including the development of *Legionella*-containing vacuoles within immune cells, downregulation of cytokine receptors, inhibition of host protein synthesis, and avoidance of lysosomal degradation. Despite their ability to replicate and persist in an intracellular environment, innate immune components that target intracellular pathogens—specifically, pattern recognition receptors, including Toll-like receptors and nucleotide-binding oligomerization domain–like receptors—activate immune responses. Adaptive CD4 and CD8 cytotoxic T-cell involvement and these innate immune responses eventually lead to the production of interferon γ and tumor necrosis factor, the promotion of neutrophil recruitment into the lung, and other proinflammatory responses. This cascade can be beneficial and result in clearance of the pathogen. However, these inflammatory responses can also cause immunopathology and adverse outcomes. *L. pneumophila* is more cytopathogenic than most non-*pneumophila Legionella* species, a characteristic that may be partially responsible for its association with severe disease.

EPIDEMIOLOGY

Legionella species are responsible for >50% of all waterborne outbreaks and >10% of disease related to drinking water in the United States. A National Academies of Sciences, Engineering, and Medicine report estimates that 50,000–70,000 Americans develop Legionnaires' disease per year. Incidence rates of legionellosis in the United States are reportedly 2–3 cases per 100,000 persons, but higher rates have been reported in other parts of the world. Numerous global epidemiologic studies assessing legionellosis have shown an increasing prevalence over the past few decades; this increase has been hypothesized to be due to a variety of causes, including an aging population, improved diagnostics, global temperature changes, and an aging water infrastructure. Legionellosis is associated with substantial health care costs.

Legionella species are found throughout the world, but most epidemiologic data focus on legionellosis in large metropolitan areas in Australia/New Zealand, Europe, and North America. Rates of infection in other parts of the world are unknown, as surveillance systems and laboratory testing are less readily available in large portions of Africa and Asia. More than 80% of cases of Legionnaires' disease are linked to *L. pneumophila*—in particular to serotype 1, which is the most frequently isolated *Legionella* pathogen. Although *L. pneumophila* predominates as a cause of disease, species predilection varies regionally. In Australia and New Zealand, for example, the rate of disease due to *Legionella longbeachae* approaches or exceeds that for *L. pneumophila*.

As previously mentioned, most reported cases are due to *L. pneumophila* serotype 1—a reflection of its pathogenicity. However, this predominance is also due to the frequency and ease of use of urinary antigen testing that targets this pathogen and allows more effective diagnosis in the community. It is unclear how large a role non-*pneumophila* species and non–serotype 1 *L. pneumophila* play in disease. However, in studies in Europe, where respiratory cultures are more frequently collected, nearly 10% of Legionnaires' disease patients were infected with species other than *L. pneumophila*. In the United States, nearly 10% of culture-confirmed cases are due to non–serogroup 1 *L. pneumophila*. Immunosuppressed patients, such as cancer patients and transplant recipients, may be more likely to develop pneumonia caused by non-*pneumophila* species such as *Legionella micdadei, Legionella bozemanii,* and *L. longbeachae*.

Despite increases in cases in the United States **(Fig. 164-1)** and throughout the world, incident cases are still thought to be underreported. Many cohort studies of community-acquired pneumonia do not require routine testing for *Legionella* or assess only for *L. pneumophila* serotype 1 (by urinary antigen testing) and therefore may underestimate true prevalence. For example, a large administrative database of studies shows that, of patients with clinically proven community-acquired pneumonia, only 26% underwent *Legionella*-specific testing; even patients with documented risk factors for legionellosis are not always tested for *Legionella*. In studies that routinely assess for legionellosis, the prevalence of *Legionella* pneumonia ranges between 2 and 10% of all community-acquired pneumonia cases. In addition, extrapulmonary presentations and Pontiac fever are less likely to be identified or to result in presentation for health care, and this trend leads to further underestimation of the true burden of legionellosis.

Seasonality and Climate Geoclimatic changes, storms, and seasonality are thought to be important components of *Legionella*'s epidemiology. The incidence of *Legionella* disease increases in the summer and fall—specifically, in warmer weather and with increased rain and humidity. Studies that screen all respiratory samples for *Legionella* find that legionellosis is indeed diagnosed most frequently in the United States during warmer summer/fall months and periods of greater humidity. Furthermore, seasonal storms, which may disrupt water pipes or cause increased flooding, can result in contamination of water systems with soil and lead to *Legionella* exposures. There is concern that, with ongoing climate shifts and rising global temperatures, cases of legionellosis may continue to increase.

Community and Health Care–Associated Outbreaks Small and large clusters and point-source outbreaks of *Legionella* cases lead to public health investigations, but these situations account for only ~5–10% of all *Legionella* cases yearly. Outbreaks occur when two or more people become ill after shared exposures in a community. In health care systems, a single proven case should trigger a *Legionella* investigation. The Centers for Disease Control and Prevention (CDC) recommends an outbreak investigation if a single patient with *Legionella* is identified who did not leave the facility/campus for the 10 days prior to illness onset. Additionally, an outbreak investigation within a health care system is warranted if there are at least two possible *Legionella* patients who spent any time in the hospital/long-term care facility within 12 months of each other (see "Clinical Presentations" below).

Most common outbreaks are linked to water sources dispersing aerosol droplets that increase the area of particle spread (e.g., cooling towers or fountains) or to large building structural water systems that cause multiple prolonged exposures (e.g., those in hospitals, hotels, or apartments). The most commonly reported sources include not only cooling towers and fountains but also water misters; centralized heating, ventilation, and air-conditioning systems; hot tubs/spas; pools; ice machines; and showerheads and sinks in large premise plumbing structures **(Fig. 164-2)**. When used as primary sources of water, groundwater and wells have also been associated with *Legionella* exposures. The majority of exposures are related to engineered hot-water systems, which are often maintained at temperatures that limit scalding but are ideally suited for *Legionella*'s growth. *Legionella* can also be found in cold water, particularly in warmer summer months, as a consequence of the warming water temperature; engineering issues (e.g., heating lamps in fountains); or unexpected breaks in plumbing systems (e.g., malfunctioning thermostatic mixing valves), which can lead to hot-water contamination of cold-water systems.

Buildings with inconsistent use patterns, such as hotels in seasonal travel destinations, can be linked to outbreaks of legionellosis, as water stagnation leads to low chlorine/disinfectant levels and organism proliferation can reach high enough levels to cause disease. Outbreaks have also been linked to cruise ships and boats. Following stay-at-home orders during the SARS-CoV-2 pandemic, when buildings (e.g., hotels) were reopened, limited water movement and stagnation led to increases in cases of legionellosis. Modern buildings with water-saving devices, which aim to limit water and energy use, may increase the risk of legionellosis, as they can decrease water temperatures and limit water flow.

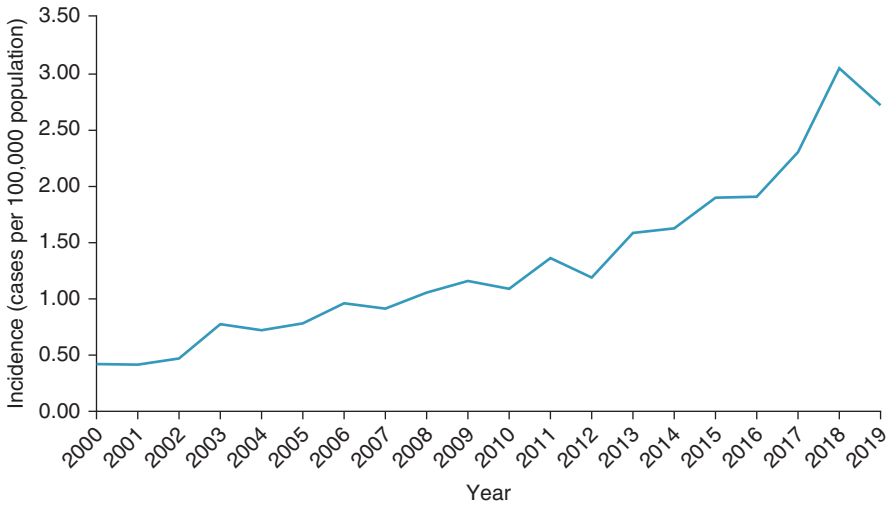

FIGURE 164-1 Increasing *Legionella* disease incidence in the United States over the past two decades (2000–2019). *(From https://www.cdc.gov/legionella/about/history.html.)*

Outbreaks in health care and long-term care facilities are identified more frequently than outbreaks in other facilities, as they often bring together at-risk patients, prolonged water exposures, accessible testing, elevated awareness, and regulations that help ensure that cases are more easily linked to common sources. The outbreak examples listed in **Table 164-1** demonstrate the wide variety of common sources and the number of cases associated with such factors. As previously mentioned, most large outbreaks involve cooling towers, which can spread aerosol droplets over a wide area. The largest outbreak reported to date involved a cooling tower in Spain that was linked to 449 documented cases of Legionnaires' disease. Outbreaks are increasingly discussed in the media, such as outbreaks linked to cooling towers in the Bronx neighborhood of New York City, a large hotel outbreak in Atlanta, and the outbreaks associated with the Flint, Michigan, water crisis that

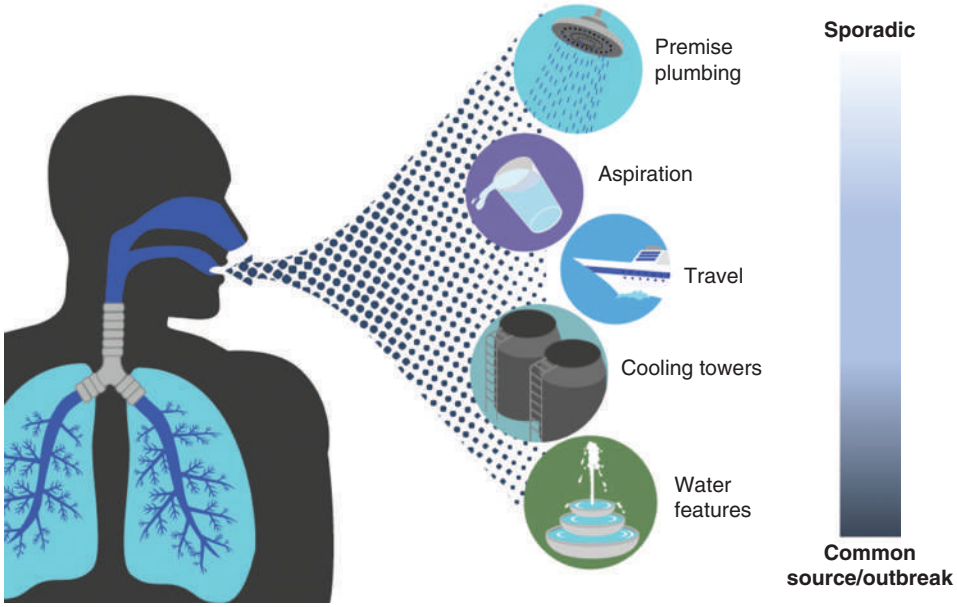

FIGURE 164-2 Sources of waterborne *Legionella* exposures and spectrum of presentation. The spectrum of sporadic to common-source outbreaks is a continuum. For example, premise plumbing in a large office building can lead to a large outbreak, and travel exposures can be related to large outbreaks. Most sporadic cases have no documented source of exposure, while outbreaks often involve mechanisms that spread water aerosol droplets over long distances (e.g., cooling towers), with a consequent ability to infect more individuals. *(Reproduced with permission from Kyoko Kurosawa.)*

led to numerous deaths. It is not uncommon for lawsuits to be initiated when deaths are linked to outbreaks.

Sporadic Cases The vast majority of cases of Legionnaires' disease occur sporadically in the community, manifesting as community-acquired pneumonia. Identification of the transmission source is more difficult in community-acquired cases than in nosocomial cases, despite reporting and review by local public health jurisdictions. In nearly 90% of all cases of legionellosis, a source of exposure is never identified. Since the spectrum of water exposures in the community is so broad and incubation periods can be long, identifying individual exposures often is not possible. Transient exposures to common sources, travel-related exposures, and exposures to less commonly linked sources (e.g., potting soil and compost) may also be hard to identify. Furthermore, studies of domestic hot water have demonstrated that 5–30% of households may have *Legionella* species detected, but the role that households play in clinical legionellosis is hard to determine, as home water testing is infrequently a part of usual contact investigations. Because of underdiagnosis, it is likely that diagnosed sporadic community-acquired cases represent only patients who are ill enough to present to health care for evaluation.

Risk Factors A number of epidemiologic and demographic risk factors are associated with legionellosis. Older age is a risk factor; most studies suggest that risk begins to increase at an age of ~40 years. Furthermore, elderly patients are at the highest risk for major complications. Males are at approximately three times greater risk for *Legionella* disease than are females in most large epidemiologic studies. Children are thought to be less likely to develop severe infections. However, since routine testing is less common among children, cases may be underreported.

Smoking has been strongly linked to legionellosis. Inhalation of smoke leads to anatomic changes in the airway epithelium, impairs neutrophil and monocyte phagocytosis, and has negative effects on airway ciliary clearance—all of which can increase the risk of pneumonia. Studies have shown that cigarette smoking is a dose-dependent risk factor. Smoking cannabis has also been associated with increased risk. Risk and severity of illness are further associated with smoking-related pulmonary diseases such as chronic obstructive pulmonary disease or emphysema, which in turn lead to increased risk for complications. Patients with other organ dysfunction/failure, such as those with renal disease (including those on dialysis), hepatic disease, nonsmoking pulmonary disease, and cardiac disease, are at increased risk for legionellosis, although it is unclear whether these factors are related to disease severity or to greater awareness and consequent recognition by health care providers.

Immunosuppressed patients are at increased risk for legionellosis and *Legionella*-related complications. Patients undergoing treatment for cancer (including recipients of hematopoietic cell transplantation) and solid organ transplant recipients are at high risk for legionellosis due to immunosuppression as well as disease- and treatment-related comorbidities. Use of prednisone and other glucocorticoids is strongly associated with legionellosis; however, in light of the heterogeneity of immunosuppressive agents and their use, it remains unclear whether

TABLE 164-1 Examples of *Legionella* Common Source Outbreaks, Indicating the Wide Variety of Sources and Cases[a]

SITE	YEAR	ORGANISM[a]	REPORTED SOURCE(S)	CASES
Hotel[b]	2012	*L. pneumophila* serotype 1	Potable water, fountain, spa	85 (29 suspect)
Hospital[c]	2012	*L. pneumophila*	Potable water	22 cases
Community[d]	2014	*L. pneumophila* serotype 1	Cooling tower	334 cases
Hospital/community[e]	2014-15	*L. pneumophila*	Potable water, household, cooling towers	86 cases
Long-term care facility[f]	2015	*L. pneumophila*	Potable water	74 cases
Community[g]	2015	*L. pneumophila*	Hotel cooling towers	128 cases
Hospital[h]	2018	*L. pneumophila* serotype 1	Potable water, showers	13 cases
Hotel[i]	2019	*L. pneumophila*	Fountain	13 LP (66 suspect)
Community[j]	2019	*L. pnuemophila*[k]	Hot-tub display	141 cases
Community[l]	2022	*L. pneumophila* serotype 1	Cooling tower	17 cases

most other single agents are as strongly associated with the disease. Combination immunosuppressive regimens increase risk. Patients treated with these regimens are more likely to develop non-*pneumophila* legionellosis and non–serotype 1 *L. pneumophila* infections that may be missed by routine urinary antigen testing. Patients with autoimmune diseases receiving tumor necrosis factor inhibitors, either with or without concomitant glucocorticoid use, are also at increased risk for legionellosis. Furthermore, studies suggest a possible association of legionellosis with genetic polymorphisms in components of the innate immune system that are important in recognizing and responding to intracellular pathogens (e.g., Toll-like receptors and interferon genes). There has also been transmission to lung transplant recipients from donor lungs.

Transmission The *Legionella* species involved in human disease are usually waterborne pathogens. However, disease development requires sufficient levels of the organism at the exposure site, the formation of small particles that can be inhaled or aspirated into pulmonary alveoli, and an at-risk host. *Legionella*-containing aerosol particles must be <10 μm in diameter for deposition into the alveoli. The infective dose during exposures is unknown but likely depends on the host: disease development in at-risk individuals may require a more limited exposure. Strain virulence is also thought to be important in disease development: *L. pneumophila* serotype 1 is more apt to lead to outbreaks and disease than, for example, *Legionella anisa*, which has only rarely been associated with disease in high-risk patients. Because of the necessity for these various factors, estimated attack rates during an exposure are only ~5% for pneumonic presentations. Attack rates for Pontiac fever (see below) are thought to be higher—up to 90% among those exposed.

Most exposures occur through the inhalation of contaminated aerosols from mists, sprays, or other mechanisms that produce small water droplets that can be inhaled into the distal alveoli. In homes, the most common sites of exposure are showerheads and sinks, which are especially apt to produce particles small enough for inhalation. The role played by aspiration or microaspiration in exposures is more controversial but is hypothesized to be a secondary route for developing pneumonia. Although human-to-human transmission is not a common pathway, a single presumptive case has been reported. After exposure, *L. pneumophila* has an incubation period of ~2–10 days; this period has been reported to be longer in immunosuppressed hosts. In contrast, symptoms of Pontiac fever occur within 24–48 h after exposure.

CLINICAL PRESENTATIONS

***Legionella* Pneumonia** *Legionella* pneumonia is the most common manifestation of legionellosis. In clinical practice, *Legionella* pneumonia is often referred to by clinicians as an "atypical pneumonia" (i.e., pneumonia that lacks the classic signs and symptoms of bronchopneumonia). Other bacterial pathogens, such as *Chlamydia pneumoniae* and *Mycoplasma pneumoniae*, are also considered as etiologic agents of atypical pneumonia. Initial symptoms of *Legionella* pneumonia are nonspecific and include fever, myalgias, headache, shortness of breath, and either a dry or a productive cough **(Table 164-2)**. Patients with pneumonia who present with neurologic or gastrointestinal symptoms such as anorexia, nausea, or vomiting may be more likely than others to have legionellosis. Immunosuppressed patients may present without typical symptoms such as fever. Patients who have recently traveled, who present during a known or possible *Legionella* outbreak, or who develop pneumonia while hospitalized should undergo testing for legionellosis. Patients with severe pneumonia presentations, including acute respiratory failure, and those with pneumonia and sepsis-like presentations should undergo testing for *Legionella* as per current community-acquired pneumonia guidelines.

Patients with *Legionella* pneumonia classically present with rales, rhonchi, and—when consolidation is present—egophony and dullness to percussion. Not all patients, particularly immunosuppressed patients, present with pulmonary findings on clinical examination. Initial laboratory findings in patients with *Legionella* pneumonia include leukocytosis or leukopenia, thrombocytopenia, and elevated liver enzyme levels; hyponatremia and/or renal dysfunction are frequent.

TABLE 164-2 Clinical and Epidemiologic Features of *Legionella* Pneumonia (Legionnaires' Disease) and Pontiac Fever

FEATURE	*LEGIONELLA* PNEUMONIA	PONTIAC FEVER
Incubation period	2–10 days[a]	24–72 h
Pathogenesis	*Legionella* infection	*Legionella* infection or exposure
Common symptoms	Abdominal or chest pain Anorexia Cough, sputum production Confusion[b] Diarrhea[b] Fatigue Fever/chills Headache Myalgias Nausea/vomiting[b] Shortness of breath	Cough Diarrhea Fatigue Fever/chills Headache Myalgias Nausea/vomiting Vertigo
Risk factors	Age >40 years Male Smoker Immunosuppressed host Neurologic disease Chronic lung disease Organ dysfunction/ chronic illness	Factors associated with increased exposure
Attack rate among exposed individuals	~5%[c]	~90%
Hospitalization rate	>90%	<1%
ICU admission rate	30–50%	Extremely low
Treatment	Antibiotics (macrolide or fluoroquinolone)	Supportive care
Case-fatality rate[d]	10%	Extremely low

[a]Incubation period in immunosuppressed hosts may be longer than 14 days. [b]This symptom is strongly associated with *Legionella* pneumonia. [c]Attack rates are highly dependent on method of exposure, level of the pathogen in source water, and host's level of risk. [d]Case-fatality rates are much higher among immunosuppressed patients and those with severe underlying lung disease, ranging from 30 to 50%.

Abbreviation: ICU, intensive care unit.

Source: Modified from *https://www.cdc.gov/legionella/clinicians/clinical-features.html*.

Levels of nonspecific laboratory markers of inflammation, such as C-reactive protein, can also be elevated; however, procalcitonin levels may not be as useful as a diagnostic tool. Although clinical symptoms and laboratory findings tend to be nonspecific, a number of clinical prediction tools, such as the Winthrop-University Hospital Criteria and the *Legionella* Score, have been developed to assist with the diagnosis of *Legionella* pneumonia. These scoring systems may be more useful for their negative than for their positive predictive value.

An important subset of *Legionella* pneumonia cases are those that are linked to health care systems—i.e., nosocomial cases. Although cases of hospital-acquired legionellosis are rare, their identification is necessary as they may be harbingers of contamination of water systems, devices, and/or potable water sources. Because of the rarity of nosocomial cases, outbreaks have sometimes occurred over years before the source is identified within the health care system. In this regard, the CDC offers the following definitions: (1) A *presumptive* health care–associated case of Legionnaires' disease is one developing in a patient with *Legionella* pneumonia after ≥10 days of continuous stay at a health care facility during the 14 days before onset of symptoms. (2) A *possible* case is one that develops in a patient with *Legionella* pneumonia who has spent a portion of the 14 days before symptom onset in one or more health care facilities but not enough time to meet the criteria for a presumptive case. To ensure that singular cases lead to

more system-wide evaluations, the CDC also recommends an investigation if a health care system detects one or more cases of presumptive health care–associated Legionnaires' disease at any time or two or more possible cases within 12 months of one another.

PONTIAC FEVER

Pontiac fever is an influenza-like illness whose primary symptoms are fever, headache, myalgias, chills, vertigo, nausea, vomiting, and diarrhea (Table 164-2). Compared with *Legionella* pneumonia, Pontiac fever is a milder, self-limited illness that is defined by the absence of pneumonia. Although studies have shown that Pontiac fever is associated with exposure to higher counts of colony-forming units in water sources, the role of the pathogen in the disease is not clear. Symptoms usually develop 24–48 h after exposure and can last for 2–5 days. Since many other illnesses resemble Pontiac fever, the diagnosis usually relies on the recognition of typical clinical features during an outbreak situation; therefore, sporadic cases are likely to be missed even when patients present for health care. Studies documenting specific *Legionella* species as the cause of Pontiac fever clusters find that most are due to *L. pneumophila* exposure; however, non-*pneumophila* species such as *L. anisa* have also been associated with this presentation.

Extrapulmonary Disease A number of rare presentations for legionellosis have been described. Skin and soft tissue infections that resemble cellulitis, including cases due to tap water contamination of postsurgical wounds, have been reported. Endocarditis, primarily culture-negative prosthetic valve endocarditis, and myocarditis and pericarditis have also been reported. Rarely, *Legionella* species have been associated with septic arthritis and sinusitis.

DIAGNOSIS

The diagnosis of legionellosis on the basis of clinical findings alone is difficult. Additional workup is needed to make a definitive diagnosis, even when cases are potentially linked to a possible outbreak. To make a diagnosis, laboratory confirmation is needed, and invasive procedures may be required—e.g., bronchoscopy, particularly for patients whose results on urinary antigen testing are negative and who cannot produce sufficient sputum for testing or for patients with severe disease requiring intensive care unit (ICU) admission. As current treatment guidelines for community-acquired pneumonia recommend empirical coverage that includes antibiotics active against *Legionella* species, diagnostic testing is not routine even among persons who meet the criteria for *Legionella*-specific testing. Furthermore, not all currently available diagnostic laboratory assays, including urinary antigen testing, are accessible or rapidly available in primary care clinics, urgent care facilities, and emergency rooms where patients may present with their initial symptoms.

Radiologic Findings On chest radiography, *Legionella* pneumonia presents as focal infiltrates or consolidations, most frequently in the lower lobes, that are indistinguishable from those due to other causes of pneumonia **(Fig. 164-3)**. On computed tomography (CT), air-space disease in one or more lobes is often with associated ground-glass opacities **(Fig. 164-4)**; pleural effusions and lymphadenopathy are less frequently seen. In immunocompromised patients, *Legionella* can present with similar lower-lobe consolidations or atypically as pulmonary nodules—with or without cavitation—that mimic fungal infections **(Fig. 164-5)** or even as lung abscesses. Progression during early therapy is not uncommon in immunosuppressed patients.

Laboratory Diagnostics • **CULTURE** Cultures—of sputum, bronchoalveolar lavage fluid, lung tissue, or extrapulmonary sites—are the gold standard for diagnosis of *Legionella* pneumonia because they are critical for epidemiologic investigations. *Legionella* species require special nutrients, such as cysteine, for growth and therefore require specialized media, such as buffered charcoal yeast extract (BCYE) agar. Legionellae grow slowly, usually over 3–5 days, with non-*pneumophila* species often requiring longer incubation times. Once growth is seen, *Legionella* can be stained with standard Gram stain, and colonies often fluoresce blue or white under ultraviolet light. *L. micdadei* is the only

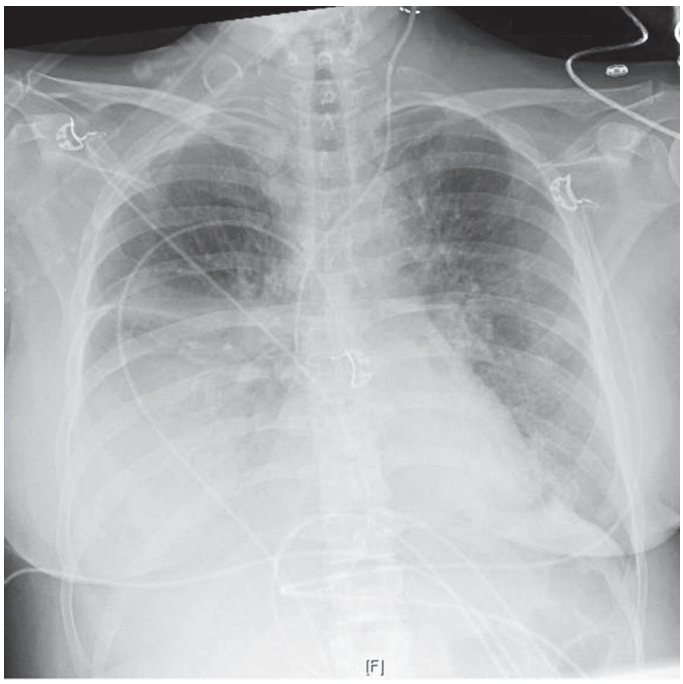

FIGURE 164-3 Chest x-ray of a patient with *Legionella* pneumonia and right-lower-lobe consolidation. A 64-year-old woman presented with fever, dry cough, and shortness of breath 7 days after returning from international travel. *Legionella* urinary antigen testing was positive for *L. pneumophila* serotype 1.

Legionella species that is also modified-acid-fast positive. Sensitivity varies with the sample but is highest among lower respiratory tract samples. At some referral centers, lower-tract samples from high-risk immunosuppressed patient populations are routinely sent for culture. Unfortunately, because of current community-acquired pneumonia guidelines, patients are often treated empirically, and many either never have samples sent for *Legionella*-specific cultures or have such samples collected only after antibiotic administration, which decreases sensitivity. Respiratory cultures from patients with legionellosis are crucial during outbreak investigations, as clinical and environmental cultures can be compared molecularly to help identify common-source outbreaks; cultures are also used for serotyping of *L. pneumophila*.

URINARY ANTIGEN TESTING *Legionella* urinary antigen tests are widely available at many hospitals and commercial laboratories and are characterized by ease of use, simple specimen collection, rapid turnaround time, high sensitivity, and the ability to detect the most prevalent *Legionella* species associated with clinical disease—*L. pneumophila* serotype 1. Urinary antigen testing has limitations, however: it detects only *L. pneumophila* serotype 1 and gives false-negative results in most cases caused by clinically important non–serotype 1 *L. pneumophila* and non-*pneumophila* species. Sensitivity for *L. pneumophila* serotype 1 is ~70% for most assays, but specificity is very high. The urinary antigen test can be negative very early in the disease and can remain positive for months after an infection, particularly in immunosuppressed patient populations; it cannot be used for patients who are anuric. Urinary antigen testing is not recommended for routine use in screening for exposures among asymptomatic patients in outbreak investigations.

SEROLOGY Acute- and convalescent-phase titers of antibody to *Legionella* have limited sensitivity in diagnosing acute Legionnaires' disease but can be useful during outbreak investigations. A case is *confirmed* by documenting a fourfold or greater rise in titer of specific serum antibody to *L. pneumophila* serogroup 1. A case is *suspected* in tests using pooled antigens by (1) a fourfold or greater rise in antibody titer to specific species (e.g., *L. longbeachae*) or non–serogroup 1 *L. pneumophila* or (2) a fourfold or greater rise in antibody titer to multiple species of *Legionella*. Some experts think that a single antibody level of ≥1:256 may be an adequate basis for diagnosing a presumptive case, but most prefer paired serology for confirmation. Serology is an imperfect tool; data suggest that as many as 20–30% of patients with

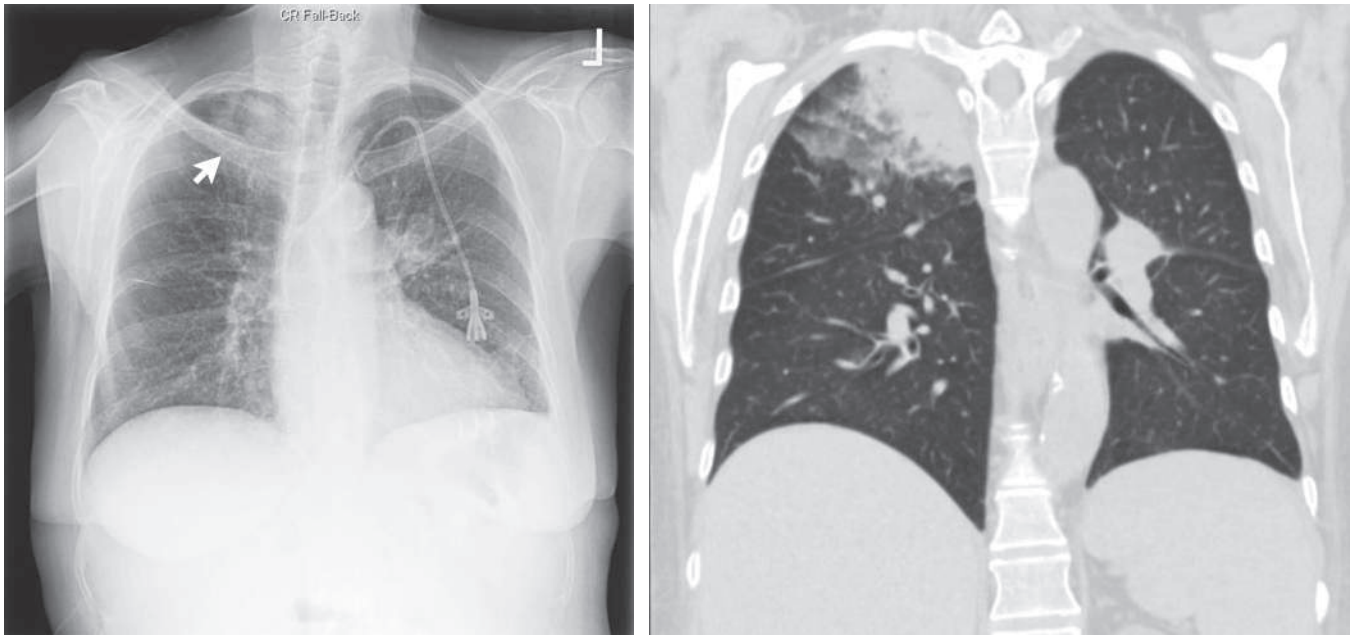

FIGURE 164-4 Right-upper-lobe infiltrate in a patient with *L. pneumophila* pneumonia on chest x-ray and computed tomography (CT). An immunosuppressed patient from a long-term care facility presented with cough, sputum production, fever, and chills. New renal insufficiency and hyponatremia were documented. A chest x-ray (***A***) was consistent with a small right-upper-lobe infiltrate (*white arrow*), which was confirmed by CT (***B***). Urinary antigen testing for *L. pneumophila* serotype 1 was negative, but polymerase chain reaction on bronchoalveolar lavage fluid was positive for *L. pneumophila*.

proven legionellosis may not mount an antibody response that is sufficient for diagnosis, and the sensitivity and specificity of seroconversion with regard to non-*pneumophila Legionella* species are unclear among patients with altered immunity. Serology can provide important information for epidemiologic investigations, helping to identify additional cases missed by other diagnostic methods. In addition, the use of serologic testing during outbreak studies allows the investigation of patients without severe disease (e.g., those with Pontiac fever).

DIRECT FLUORESCENT ANTIBODY TESTING The sensitivity of direct fluorescent antibody (DFA) testing of sputum is lower than that of other testing modalities, ranging from 20 to 70% depending on the assay used. Most available assays target specific species (e.g., *L. pneumophila*) or serotypes. DFA testing may have a higher positive predictive value in patients with severe pneumonia or symptoms consistent with Legionnaires' disease, but it is not recommended for screening of low-risk patients because of the frequency of false-positive results.

MOLECULAR TESTING Polymerase chain reaction (PCR), loop-mediated isothermal amplification (LAMP), and other nucleic acid amplification tests are highly sensitive for lower respiratory tract specimens

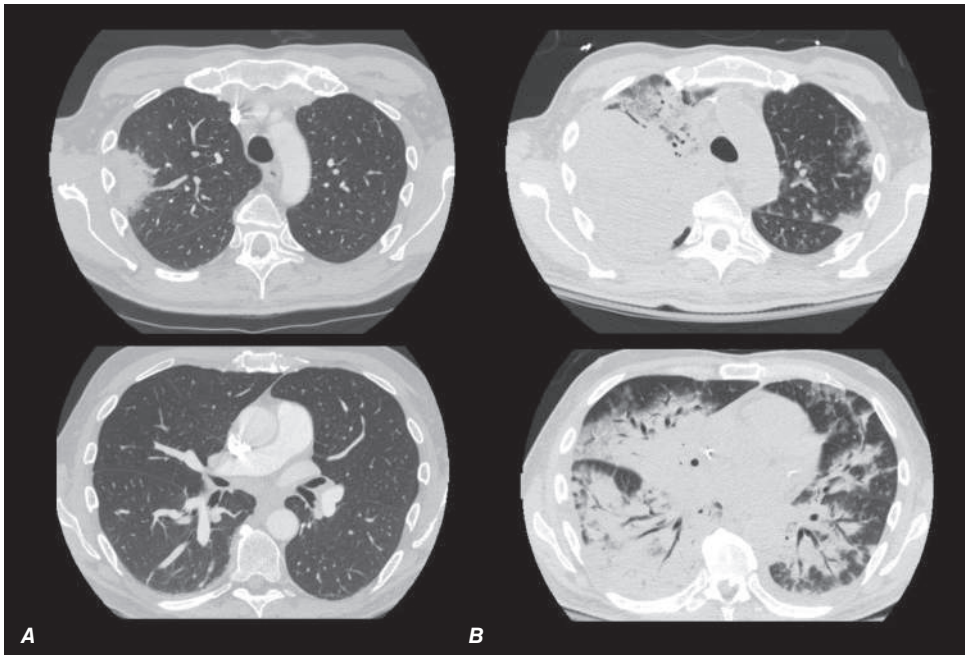

FIGURE 164-5 Nodular disease presentation on computed tomography (CT) in an immunosuppressed patient infected with *L. micdadei*. *A.* CT scan in a hematopoietic cell transplant recipient presenting with fever and cough. A pulmonary nodule was noted in the right upper lobe. Bronchoscopy was performed; cultures were positive on day 5 for small white colonies on buffered charcoal yeast extract plates, and these colonies were eventually identified as *L. micdadei*. ***B.*** Repeat CT scan at day 12 demonstrated an enlarging nodule, diffuse infiltrates, and possible cavitation. The patient required intensive care unit admission and intubation despite appropriate targeted antibiotic therapy.

(e.g., sputum) and are becoming more widely available. Molecular methods can detect *Legionella* from multiple sources but are most commonly used for respiratory specimens such as sputum and bronchoalveolar lavage fluid. PCR is more sensitive than culture; in some studies, up to two to four times as many cases of lower tract disease were detected only by molecular methods. Molecular techniques also are useful in diagnosing infection in patients during antibiotic therapy. However, PCR methods are not used to determine *L. pneumophila* serotypes—information that is needed for epidemiologic investigations—and most commercially available assays target only *L. pneumophila*. Multiplex PCR tests for pneumonia and other respiratory pathogens are increasingly available and may include *L. pneumophila*.

TREATMENT

Legionella Pneumonia

Treatment of *Legionella* pneumonia involves antibiotics that target intracellular pathogens, whereas patients with Pontiac fever do not require antibiotic therapy. Macrolides and fluoroquinolones are the first-line agents for *Legionella* pneumonia according to guidelines in the United States and Europe **(Table 164-3)**. Macrolides disrupt protein production critical for survival of the organism. Although erythromycin and clarithromycin are both effective, azithromycin is the preferred agent, as it is easier to tolerate and has fewer drug-drug interactions. Azithromycin and clarithromycin also reach higher intracellular concentrations than erythromycin.

Fluoroquinolones are potent agents against *Legionella* species. Data from both in vitro and in vivo models of infection suggest that fluoroquinolones may be more effective than macrolides, but no randomized clinical trials have yet compared the two drug classes for treatment of legionellosis. In nonrandomized observational studies, fluoroquinolones have been shown to be more effective than macrolides (erythromycin and clarithromycin) in terms of fever resolution and decreased duration of hospitalization; other such studies have shown no difference in outcome.

Both macrolides and fluoroquinolones are available as IV and oral formulations. Most experts prefer IV therapy during the first few days of treatment for patients with severe *Legionella* pneumonia. Secondary agents, such as rifampin, doxycycline, minocycline, and, less frequently, trimethoprim-sulfamethoxazole, have also been used, with mixed responses. Tigecycline, a third-generation glycylcycline related to tetracyclines, has been used for treatment of patients with significant antibiotic allergies. The novel aminomethylcycline antibiotic omadacycline appears to be efficacious in vitro, but its clinical efficacy has not been studied to date, and it is not currently recommended for routine use. Although data are limited, combination therapy does not appear to improve outcomes.

The optimal duration of treatment for Legionnaire's disease is unknown. For community-acquired pneumonia, guidelines recommend treatment until the patient achieves clinical stability and for a minimum of 5 days. In the absence of data, a similar duration of treatment for *Legionella* is a reasonable approach. For immunosuppressed patients and patients with severe disease, a more protracted course of therapy is recommended. The duration of therapy for extrapulmonary manifestations of *Legionella* infection is unknown and depends on the site involved and clinical improvement. Resistance to macrolides and fluoroquinolones has been reported only rarely. Susceptibility testing is not routinely performed but is available in specialized laboratories and public health departments.

TABLE 164-3 *Legionella* **Treatment Options**

	DISEASE SEVERITY	
DISEASE	**MILD**	**MODERATE/SEVERE[a,b]**
Pontiac fever	None	N/A
Legionella pneumonia	**A) Fluoroquinolone:** **Levofloxacin, 750 mg PO once daily** *or* Ciprofloxacin, 500 mg PO twice daily *or* Moxifloxacin, 400 mg PO once daily ***or*** **B) Macrolide:** **Azithromycin, 500 mg PO once daily (day 1), followed by 250 mg PO once daily (for minimum of 4 days)** *or* Clarithromycin, 400 mg PO daily	**A) Fluoroquinolone:[c]** **Levofloxacin, 750 mg IV once daily** *or* Ciprofloxacin, 500 mg IV twice daily *or* Moxifloxacin, 400 mg PO twice daily ***or*** **B) Macrolide:[c]** **Azithromycin, 500 mg IV daily** *or* Clarithromycin, 400 mg IV twice daily

Note: Agents in bold type are considered first-line treatment.

[a]All immunosuppressed patients should be considered to have moderate or severe disease and started on IV therapy if possible. [b]All patients requiring inpatient care should receive IV therapy until improving, when they can be switched to an oral agent. [c]Consider dual therapy, either with dual fluoroquinolone and macrolide therapy, or either agent with another secondary agent (e.g., rifampin). Secondary agents include doxycycline, minocycline, rifampin, and trimethoprim-sulfamethoxazole, all with varying efficacy for treatment.

Abbreviations: IV, intravenous; N/A, not applicable; PO, oral.

OUTCOMES

Legionella infections are associated with significant morbidity and mortality, leading to hospitalization and ICU admission of most patients who develop pneumonia. Case-fatality rates of *Legionella* pneumonia are reported to be ~10%, with death more likely among patients who are admitted to the ICU or have major comorbidities. Among patients in whom antibiotic treatment is delayed, mortality rates are approximately three times higher than among those treated earlier. Patients who develop nosocomial pneumonia attributable to health care–associated exposures, particularly those due to *L. pneumophila*, have case-fatality rates of ~25%. Death is a much more common outcome among immunocompromised hosts, whose mortality rates can reach ~30–50%. Assessment of long-term follow-up among patients who recover from severe *Legionella* pneumonia demonstrates that more than one-quarter have ongoing complications after recovery, including recurrent hospitalizations, acute renal failure, respiratory complications, and recurrent pneumonias. In contrast, recovery from Pontiac fever usually takes place within 3–5 days, as the disease is self-limiting; hospitalization, complications, and death related to Pontiac fever are extremely rare.

PREVENTION

Prevention of legionellosis starts with addressing water systems. Large municipal water systems provide water throughout the globe, but the quality of these systems varies regionally; many areas have limited access to potable water. Only limited regions have the resources to address *Legionella* water contamination; most water-monitoring agencies focus on control of enteric pathogens, such as *Escherichia coli* and other coliform bacteria, and do not have an adequate infrastructure to address *Legionella*. Even in countries and cities with more complex water systems, there is wide variation in how waterborne pathogens are addressed, and rules and regulations are often country dependent. In the Netherlands, for example, chlorination is not routine, whereas the United Kingdom and most countries in the European Union use chlorine routinely as the primary mode of disinfection for public water systems. Although regulated by the Environmental Protection Agency, management and treatment strategies in the United States vary by state and, in some instances, by city.

Prevention in the United States focuses on health care organizations and hospitals, where water-based exposures are more often linked to case fatalities. Federal requirements to reduce *Legionella* risk in the United States were first established in June 2017, when the Centers for Medicare and Medicaid Services required that all health care organizations develop and adhere to water management plans. These plans require the development of multidisciplinary teams, an understanding

of the organization's water system, identification of high-risk areas (e.g., transplant units, oncology floors), identification of at-risk structures for *Legionella* growth, implementation and monitoring of control measures, methods for intervention if control measures fail, and procedures to assure documentation that policies are followed. All medical centers are required to have an awareness of water quality and to have systems in place to help prevent nosocomial *Legionella* pneumonia. Such policies leave water quality assessment, including testing for *Legionella*, up to the individual facility. In addition to hospitals, an increasing number of cities, including New York City, require similar water-management plans for cooling towers, with registration, testing, and mitigation options.

Even if detected in regional water systems, *Legionella* becomes a human pathogen only after replication in premise plumbing systems. In buildings, *Legionella* finds the ideal environment for logarithmic growth, which leads to exposures and subsequent disease. An important first step in prevention within hospitals is a review of plumbing systems to identify areas of concern and a review of impact areas such as dental clinics, ICUs, rehabilitation units, and units that house high-risk patients. Specific water features, such as therapy pools, ice machines, and decorative fountains, need policies for cleaning and disinfection. Targeted approaches to management of cooling towers, such as high-efficiency drift eliminators and routine maintenance, are important considerations. In addition, areas that have undergone recent construction or renovation should be flagged, with prevention policies in place to address the associated risks. New construction or structural updates can lead to water stagnation, while modifications to plumbing can disrupt biofilms. Units with older premise plumbing are thought to be at higher risk, but even brand new facilities can become colonized during construction, with consequent outbreaks.

Testing for *Legionella* is an important step when presumptive or possible nosocomial pneumonia cases occur and can help address a facility's potential risks. There are a number of methods for environmental testing for *Legionella*, but environmental cultures are used in most hospitals because they quantify *Legionella* levels, allow species identification/serotyping, and can link environmental sources to nosocomial outbreaks. Testing usually focuses on locations where the index patient(s) may have had potential waterborne exposures (e.g., at showers and sinks). Other adjacent areas, along with those noted to be high-risk locations within the hospital, should be considered for additional testing; positive results should widen the testing area. Proactive testing is increasingly being used to preclude nosocomial cases; however, if testing is planned, it should be coupled with a management plan that addresses how *Legionella* will be dealt with if it is found in the water system and where and how frequently testing should be done; we recommend biannual or quarterly testing of select sites within hospital systems.

If a common-source outbreak is discovered, a number of approaches can be used to address *Legionella*. Regardless of source, immediate limitation of ongoing water exposures for patients in the affected room, unit, or floor is a crucial step in avoiding additional cases. Removing or replacing water features associated with exposures, such as decorative fountains and affected equipment or plumbing devices, may be needed. Immediate interventions such as heat shock (increasing water temperatures for a limited period) and hyperchlorination may also be useful as short-term steps in addressing an outbreak.

The addition of a disinfectant to the water system is one of the most common ways to address the presence of *Legionella*. Chemical disinfection with agents such as chlorine or monochloramine and copper and silver ionization are commonly used for secondary disinfection. Use of disinfectants requires routine maintenance and monitoring of chemical or ion levels to assure that they are sufficient for prevention. Lack of monitoring and system failures have led to breakthrough nosocomial *Legionella* cases. Another option is water filtration, which either can serve as a primary method for prevention or can be used in combination with secondary disinfection. Filters—either in-line with plumbing or at point-of-use sites—can be considered for either short- or long-term prevention during an outbreak. However, filters have a limited life span, can weaken water pressure, and are costly to maintain.

165 Pertussis and Other *Bordetella* Infections

May S. ElSherif, Scott A. Halperin

Pertussis is an acute infection of the respiratory tract caused by *Bordetella pertussis*. The word *pertussis* means "violent cough," which aptly describes the most consistent and prominent feature of the illness. The inspiratory sound made at the end of an episode of paroxysmal coughing gives rise to the common name for the illness, "whooping cough." However, this feature is variable: it is uncommon among infants ≤6 months of age and is frequently absent in older children and adults. The Chinese name for pertussis is "the 100-day cough," which describes the clinical course of the illness accurately. The identification of *B. pertussis* was first reported by Bordet and Gengou in 1906, and vaccines were produced over the following two decades.

MICROBIOLOGY

Of the 10 identified species in the genus *Bordetella*, only four are of major medical significance. *B. pertussis* infects only humans and is the most important *Bordetella* species causing human disease. *B. parapertussis* causes an illness in humans that is similar to pertussis but is typically milder; co-infections with *B. parapertussis* and *B. pertussis* have been documented. With improved polymerase chain reaction (PCR) diagnostic methodology, up to 20% of patients with a pertussis-like syndrome have been found to be infected with *B. holmesii*, formerly thought to be an unusual cause of bacteremia. *B. bronchiseptica* is an important pathogen of domestic animals that causes kennel cough in dogs, atrophic rhinitis and pneumonia in pigs, and pneumonia in cats. Both respiratory infection and opportunistic infection due to *B. bronchiseptica* are reported occasionally in humans. *B. petrii*, *B. hinzii*, and *B. ansorpii* have been isolated from patients who are immunocompromised.

Bordetella species are gram-negative pleomorphic aerobic bacilli that share common genotypic characteristics. *B. pertussis* and *B. parapertussis* are the most similar of the species, but *B. parapertussis* does not express the gene coding for pertussis toxin. *B. pertussis* is a slow-growing fastidious organism that requires selective medium and forms small, glistening, bifurcated colonies. Suspicious colonies are presumptively identified as *B. pertussis* by direct fluorescent antibody testing or by agglutination with species-specific antiserum. *B. pertussis*

is further differentiated from other *Bordetella* species by biochemical and motility characteristics.

B. pertussis produces a wide array of toxins and biologically active products that are important in its pathogenesis and in immunity. Most of these virulence factors are under the control of a single genetic locus that regulates their production, resulting in antigenic modulation and phase variation. Although these processes occur both in vitro and in vivo, their importance in the pathobiology of the organism is unknown; they may play a role in intracellular persistence and person-to-person spread. The organism's most important virulence factor is *pertussis toxin*, which is composed of a B oligomer–binding subunit and an enzymatically active A protomer that ADP-ribosylates a guanine nucleotide–binding regulatory protein (G protein) in target cells, producing a variety of biologic effects. Pertussis toxin has important mitogenic activity, affects the circulation of lymphocytes, and serves as an adhesin for bacterial binding to respiratory ciliated cells. Other important virulence factors and adhesins are *filamentous hemagglutinin*, a component of the cell wall, and *pertactin*, an outer-membrane protein. *Fimbriae*, bacterial appendages that play a role in bacterial attachment, are the major antigens against which agglutinating antibodies are directed. These agglutinating antibodies have historically been the primary means of serotyping *B. pertussis* strains. Other virulence factors include tracheal cytotoxin, a peptidoglycan fragment, which causes inflammatory respiratory epithelial damage; adenylate cyclase-hemolysin toxin, which impairs host phagocytic cell function; dermonecrotic toxin, which may contribute to respiratory mucosal damage; and lipooligosaccharide, which has properties similar to those of other gram-negative bacterial endotoxins. Since 2010, the emergence of pertactin-negative strains worldwide has been attributed to immune pressure resulting from the use of pertactin-containing acellular pertussis vaccines, reaching >80% dominance in some countries.

EPIDEMIOLOGY

Pertussis is a highly communicable disease, with attack rates of 80–100% among unimmunized household contacts and 20% within households in well-immunized populations. The infection has a worldwide distribution, with cyclical outbreaks every 3–5 years (a pattern that has persisted despite widespread immunization). Pertussis occurs in all months; however, in North America, its activity peaks in autumn and winter.

In developing countries, pertussis remains an important cause of infant morbidity and mortality despite the reported worldwide decrease in incidence following improved vaccine coverage **(Fig. 165-1)**. Monitored as a surrogate to evaluate immunization programs, 2022 DTP3 (diphtheria, tetanus, and pertussis) coverage rates are still <50% in many developing nations while globally recovering to 84% from 2021's 81%; the World Health Organization (WHO) estimates that 90% of the burden of pertussis is in developing regions. The overreporting of immunization coverage and underreporting of disease result in substantial underestimation of the global burden of pertussis. WHO estimates are 40 million cases globally each year, with 400,000 deaths, mostly among infants <3 months of age.

Before the institution of widespread immunization programs in the developed world, pertussis was one of the most common infectious causes of morbidity and death. In the United States before the 1940s, between 115,000 and 270,000 cases of pertussis were reported annually, with an average yearly rate of 150 cases per 100,000 population. With universal childhood immunization, the number of reported cases fell by >90%, and mortality rates decreased even more dramatically. Only 1010 cases of pertussis were reported in 1976 **(Fig. 165-2)**. After that historic low, rates of pertussis increased slowly. In recent years, pertussis epidemics have been reported with increasing frequency in high-income countries, including Australia, the United Kingdom, and the United States. The United States experienced widespread pertussis outbreaks in 2005, 2010, 2012, 2014, and 2015 at levels not seen in 40–50 years (48,000 reported cases in 2012).

Although thought of as a disease of childhood, pertussis can affect people of all ages and is a known cause of prolonged coughing illness in adolescents and adults. In unimmunized populations, pertussis incidence peaks during the preschool years, and well over half of children have the disease before reaching adulthood. In highly immunized populations such as those in North America, the peak incidence is among infants <1 year of age who have not completed the three-dose primary immunization series. An increase in pertussis incidence among adolescents and adults began in the late 1990s and led to the introduction of an adolescent booster dose across North America by 2006. While the disease burden among adolescents decreased initially, children 7–10 years of age emerged as a high-risk group during a major outbreak in 2010. Most of the affected children were fully immunized. Subsequent outbreaks in 2012, 2014, and 2015 showed a shift in epidemiology, with pertussis incidence increasing among adolescents while still remaining elevated among 10-year-olds. The most highly affected cohorts were those who received acellular pertussis vaccines in infancy. Although adults contribute a smaller proportion of reported cases of pertussis than do children and adolescents, this difference may be related to a greater degree of underrecognition and underreporting. Several studies of prolonged

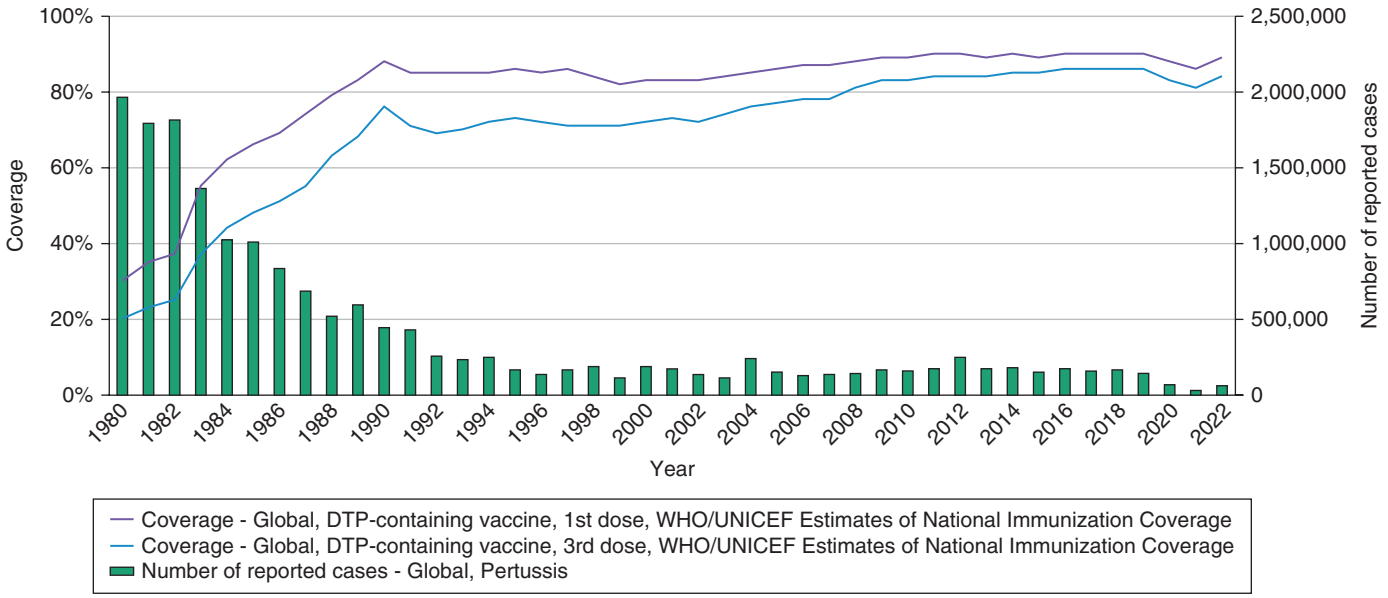

FIGURE 165-1 Global annual reported cases of pertussis and rate of coverage with DTP3 (diphtheria toxoid, tetanus toxoid, and pertussis vaccine; one and three doses), 1980–2022. *(Reproduced with permission from Diphtheria tetanus toxoid and pertussis (DTP) vaccination coverage (who.int). FIGURE 165-2 Reported cases of pertussis by year: United States, 1922–2021, marking the introduction of different vaccine types. *(From the Centers for Disease Control and Prevention, Pertussis Surveillance Trend Reporting and Case Defintion | CDC. Available at https://www.cdc.gov/pertussis/surv-reporting.html. Accessed December 26, 2023.)*

coughing illness suggest that *B. pertussis* may be the etiologic agent in 12–30% of adults with cough that does not improve within 2 weeks. In one study of the efficacy of an acellular pertussis vaccine in adolescents and adults, the incidence of pertussis in the placebo group was 3.7–4.5 cases per 1000 person-years. Although this prospective cohort study yielded a lower estimate than the studies of cough illness, its results still translate to ~1 million cases of pertussis annually among adults in the United States. In addition, asymptomatic pertussis infection, estimated at 56% by a systemic review of tested household contacts, is common and appears to contribute to disease transmission.

Severe morbidity and high mortality rates, however, are restricted almost entirely to infants. In the United States between 2000 and 2017, infants <2 months old accounted for 84% of pertussis deaths with annual mean number of cases, hospitalizations, and deaths at 2957 (range 1803–4994), 1122 (range 544–1938), and 15 (range 3–35), respectively. Although school-age children are the source of infection for most households, adults are often the source for cases in high-risk infants and may serve as the reservoir of infection between epidemic years.

PATHOGENESIS

Infection with *B. pertussis* is initiated by attachment of the organism to the ciliated epithelial cells of the nasopharynx. Attachment is mediated by surface adhesins (e.g., pertactin and filamentous hemagglutinin), which bind to the integrin family of cell-surface proteins, probably in conjunction with pertussis toxin. The role of fimbriae in adhesion and in maintenance of infection has not been fully delineated. Perhaps the result of redundancy of adhesins, no differences in virulence or clinical manifestations have been detected with the emergence of pertactin-negative strains. At the site of attachment, the organism multiplies, producing a variety of other toxins that cause local mucosal damage (tracheal cytotoxin, dermonecrotic toxin). Impairment of host defense by *B. pertussis* is mediated by pertussis toxin and adenylate cyclase-hemolysin toxin. There is local cellular invasion, with intracellular bacterial persistence; however, systemic dissemination does not occur. Systemic manifestations (lymphocytosis) result from the effects of the toxins.

The pathogenesis of the clinical manifestations of pertussis is poorly understood. It is not known what causes the hallmark paroxysmal cough. A pivotal role for pertussis toxin has been proposed but has not been confirmed. It is thought that neurologic events in pertussis, such as seizures and encephalopathy, are due to hypoxia from coughing paroxysms or apnea rather than to the effects of specific bacterial products. *B. pertussis* pneumonia, which occurs in up to 22% of infants with pertussis, is usually a diffuse bilateral primary infection. In older children and adults with pertussis, pneumonia is often due to secondary bacterial infection with streptococci or staphylococci. Deaths from pertussis among young infants are frequently associated with very high levels of leukocytosis and pulmonary hypertension.

IMMUNITY

Both humoral and cell-mediated immunity are thought to be important in pertussis. Although immunity after natural infection was thought to be lifelong, seroepidemiologic evidence demonstrates that it is not and that subsequent episodes of clinical pertussis are prevented by intermittent subclinical infection. Pertussis agglutinins were correlated with protection in early studies of whole-cell pertussis vaccines. Antibodies to pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae are all protective in animal models. Serologic correlates of protection conferred by acellular pertussis vaccines have not been established, although antibody to pertactin, fimbriae, and (to a lesser degree) pertussis toxin correlated best with protection in two efficacy trials. The duration of immunity after whole-cell pertussis vaccination is short-lived, with little protection remaining after 10–12 years. Waning of immunity is even more rapid in adolescents and children who have received all their immunizations with acellular vaccines—i.e., within 2–4 years after the fifth or sixth dose. The type of immune response elicited may affect duration of protection; natural infection and whole-cell pertussis vaccine elicit a TH1/TH17-predominant response, whereas acellular pertussis vaccines stimulate a TH2-biased response. Controlled Human Infection Models of pertussis are under development to facilitate better understanding of immunity after infection and after vaccination.

CLINICAL MANIFESTATIONS

Pertussis is a prolonged coughing illness with clinical manifestations that vary by age (Table 165-1). Although not uncommon among adolescents and adults, classic pertussis is most often seen in preschool and

TABLE 165-1 Clinical Features of Pertussis, by Age Group and Diagnostic Status

FEATURE	PERCENTAGE OF PATIENTS	
	ADOLESCENTS AND ADULTS	INFANTS AND CHILDREN
Cough		
Paroxysmal	70–99	89–93
Worse at night	61–87	41
Whoop	8–82	69–92
Post-tussive vomiting	17–65	48–60

school-age children. After an incubation period averaging 7–10 days, an illness develops that is indistinguishable from the common cold and is characterized by coryza, lacrimation, mild cough, low-grade fever, and malaise. After 1–2 weeks, this *catarrhal phase* evolves into the *paroxysmal phase*: the cough becomes more frequent and spasmodic with repetitive bursts of 5–10 coughs, often within a single expiration. Post-tussive vomiting is frequent, with a mucous plug occasionally expelled at the end of an episode. The episode may be terminated by an audible whoop, which occurs upon rapid inspiration against a closed glottis at the end of a paroxysm. During a spasm, there may be impressive neck-vein distension, bulging eyes, tongue protrusion, and cyanosis. Paroxysms may be precipitated by noise, eating, or physical contact. Between attacks, the patient's appearance is normal, but increasing fatigue is evident. The frequency of paroxysmal episodes varies widely, from several per hour to 5–10 per day. Episodes are often worse at night and interfere with sleep. Most complications occur during the paroxysmal stage. Fever is uncommon and suggests bacterial superinfection.

After 2–4 weeks, the coughing episodes become less frequent and less severe—changes heralding the onset of the *convalescent phase*. This phase can last 1–3 months and is characterized by gradual resolution of coughing episodes. For 6–12 months, intercurrent viral infections may be associated with a recrudescence of paroxysmal cough.

Not all individuals who develop pertussis have classic disease. The clinical manifestations in adolescents and adults are more often atypical. The cough is severe, prolonged, and often paroxysmal. Though uncommon, a whoop and vomiting with cough are more specific signs of pertussis in adults with prolonged cough. Other suggestive features are a cough at night, sweating episodes between paroxysms of coughing, and exposure to other individuals with a prolonged coughing illness.

COMPLICATIONS

Complications are frequently associated with pertussis and are more common among infants than among older children or adults. Subconjunctival hemorrhages, abdominal and inguinal hernias, pneumothoraces, and facial and truncal petechiae can result from increased intrathoracic pressure generated by severe fits of coughing. Weight loss can follow decreased caloric intake. Urinary incontinence, rib fracture, carotid artery aneurysm, and cough syncope have also been reported in adolescents and adults with pertussis. In a series of >1100 children <2 years of age who were hospitalized with pertussis, 27.1% had apnea, 9.4% had pneumonia, 2.6% had seizures, and 0.4% had encephalopathy; 10 children (0.9%) died. Pneumonia is reported in <5% of adolescents and adults and increases in frequency after 50 years of age. In contrast to the primary *B. pertussis* pneumonia that develops in infants, pneumonia in older children, adolescents, and adults with pertussis is usually caused by a secondary infection with encapsulated organisms such as *Streptococcus pneumoniae* or *Haemophilus influenzae*.

DIAGNOSIS

If the classic symptoms of pertussis are present, clinical diagnosis is not difficult. However, particularly in older children and adults, it is difficult to differentiate infections caused by *B. pertussis* and *B. parapertussis* from other respiratory tract infections on clinical grounds. Therefore, laboratory confirmation should be attempted in all cases. Lymphocytosis (absolute lymphocyte count $>10^8$–10^9/L) is common among young children, in whom it is unusual with other infections, but not among adolescents and adults. Culture of nasopharyngeal secretions remains the gold standard of diagnosis because of its 100% specificity, although DNA detection by PCR has replaced culture in most laboratories because of substantially increased sensitivity and quicker results. Multitarget real-time PCR methodology includes primers that differentiate between *B. pertussis*, *B. parapertussis*, and *B. holmesii*. The best specimen is collected by nasopharyngeal aspiration, in which a fine flexible plastic catheter attached to a 10-mL syringe is passed into the nasopharynx and withdrawn while gentle suction is applied. Since *B. pertussis* is highly sensitive to drying, secretions for culture should be inoculated without delay onto appropriate medium (Bordet-Gengou or Regan-Lowe), or the catheter should be flushed with a phosphate-buffered saline solution for culture and/or PCR. An alternative to the aspirate is a Dacron or rayon nasopharyngeal swab; again, inoculation of culture plates should be immediate or an appropriate transport medium (e.g., Regan-Lowe charcoal medium) should be used. Results of PCR can be available within hours; cultures become positive by day 5 of incubation.

Nasopharyngeal cultures in untreated pertussis remain positive for a mean of 3 weeks after the onset of illness; these cultures become negative within 5 days of the institution of appropriate antimicrobial therapy. The duration of a positive PCR in untreated pertussis or after therapy is not known but exceeds that of positive cultures. Since much of the period during which the organism can be recovered from the nasopharynx falls into the catarrhal phase, when the etiology of the infection is not suspected, there is only a small window of opportunity for culture- or PCR-proven diagnosis. Cultures and PCR from infants and young children are more frequently positive than those from older children and adults; this difference may reflect earlier presentation of the former age group for medical care.

As a result of the difficulties with laboratory diagnosis of pertussis in adolescents, adults, and patients who have been symptomatic for >4 weeks, increasing attention is being given to serologic diagnosis. Enzyme immunoassays detecting IgA and IgG antibodies to pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae have been developed and assessed for reproducibility. Two- or fourfold increases in antibody titer are suggestive of pertussis, although cross-reactivity of some antigens (such as filamentous hemagglutinin and pertactin) among *Bordetella* species makes it difficult to depend diagnostically on seroconversion involving a single type of antibody. Criteria for serologic diagnosis based on comparison of results for a single serum specimen with established population values are gaining acceptance, and serologic measurement of antibody to pertussis toxin is becoming more widely standardized and available for diagnostic purposes, particularly in outbreak settings and for surveillance.

DIFFERENTIAL DIAGNOSIS

A child presenting with paroxysmal cough, post-tussive vomiting, and whoop is likely to have an infection caused by *B. pertussis* or *B. parapertussis*; lymphocytosis increases the likelihood of a *B. pertussis* etiology. Viruses such as respiratory syncytial virus, rhinovirus, and adenovirus have been isolated from patients with clinical pertussis but probably represent co-infection, particularly in children <1 year of age.

In adolescents and adults, who often do not have paroxysmal cough or whoop, the differential diagnosis of a prolonged coughing illness is more extensive. Pertussis should be suspected when any patient has a cough that does not improve within 14 days, a paroxysmal cough of any duration, a cough followed by vomiting (adolescents and adults), or any respiratory symptoms after contact with a laboratory-confirmed case of pertussis. Other etiologies to consider include infections caused by *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, adenovirus, influenza virus, and other respiratory viruses. Use of angiotensin-converting enzyme (ACE) inhibitors, reactive airway disease, and gastroesophageal reflux disease are well-described noninfectious causes of prolonged cough in adults.

TREATMENT

Pertussis

ANTIBIOTICS

The purpose of antibiotic therapy for pertussis is to eradicate the infecting bacteria from the nasopharynx; therapy does not substantially alter the clinical course unless given early in the catarrhal phase. Macrolide antibiotics are the drugs of choice for treatment of pertussis **(Table 165-2)**; macrolide-resistant *B. pertussis* strains have been reported but are rare. Trimethoprim-sulfamethoxazole is recommended as an alternative for individuals allergic to macrolides.

SUPPORTIVE CARE

Young infants have the highest rates of complication and death from pertussis; therefore, most infants (and older children with

TABLE 165-2 Antimicrobial Therapy for Pertussis

PATIENT AGE GROUP	PRIMARY AGENTS			ALTERNATE AGENT
	AZITHROMYCIN (AZ)	ERYTHROMYCIN (ER)	CLARITHROMYCIN	TRIMETHOPRIM (TMP)-SULFAMETHOXAZOLE (SMZ)[a]
<1 month	AZ is the recommended agent for this age group, at 10 mg/kg per day in a single dose for 5 days	ER is not preferred, only use if AZ unavailable; 40–50 mg/kg per day in 4 divided doses for 14 days	Not recommended in this age group	Contraindicated in infants <2 months
1-5 months	10 mg/kg per day in a single dose for 5 days	40–50 mg/kg per day in 4 divided doses for 14 days	15 mg/kg per day in 2 divided doses for 7 days	Only for infants ≥2 months (otherwise contraindicated); TMP 8 mg/kg per day, SMZ 40 mg/kg per day in 2 divided doses for 14 days
Infants (≥6 months) and children	10 mg/kg on day 1, 5 mg/kg mg per day (maximum 500 mg) on days 2–5	40–50 mg/kg per day (maximum 2 g/d) in 4 divided doses for 14 days	15 mg/kg per day (maximum 1 g/d) in 2 divided doses for 7 days	TMP 8 mg/kg per day, SMZ 40 mg/kg per day in 2 divided doses for 14 days
Adults	500 mg on day 1, 250 mg/d on days 2–5	2 g/d in 4 divided doses for 14 days	1 g/d in 2 divided doses for 7 days	TMP 320 mg/d, SMZ 1600 mg/d in 2 divided doses for 14 days
Comments	Abdominal discomfort, prescribed with caution to cardiac patients	Frequent gastrointestinal side effects, hypersensitivity reactions	Epigastric distress and cramps	For patients allergic to macrolides, data on effectiveness are limited

[a]Trimethoprim-sulfamethoxazole (TMP-SMZ) replaces macrolides only in the event of a macrolide-resistant strain of *Bordetella pertussis* or when patients older than 2 months are allergic to or cannot tolerate macrolides.

Source: T Tiwari et al: Recommended antimicrobial agents for the treatment and postexposure prophylaxis of pertussis: 2005 CDC guidelines. MMWR Recomm Rep 54(RR-14):1, 2005.

severe disease) should be hospitalized. A quiet environment may decrease the stimulation that can trigger paroxysmal episodes. Use of β-adrenergic agonists and/or glucocorticoids has been advocated by some authorities but has not been proven to be effective. Cough suppressants are not effective and play no role in the management of pertussis.

INFECTION CONTROL MEASURES

Hospitalized patients with pertussis should be placed in respiratory isolation, with the use of precautions appropriate for pathogens spread by large respiratory droplets. Isolation should continue for 5 days after initiation of macrolide therapy or, in untreated patients, for 3 weeks (i.e., until nasopharyngeal cultures are consistently negative).

PREVENTION

Chemoprophylaxis Because the risk of transmission of *B. pertussis* within households is high, chemoprophylaxis is widely recommended for household contacts of pertussis cases regardless of their immunization status and should be initiated within 21 days of cough onset in the index case. The effectiveness of chemoprophylaxis is supported by several epidemiologic studies of institutional and community outbreaks. In the only randomized, placebo-controlled study, erythromycin estolate (50 mg/kg per day; maximum dose, 1 g/d) was effective in reducing the incidence of bacteriologically confirmed pertussis by 67%; however, there was no decrease in the incidence of clinical disease. Despite these results, authorities continue to recommend chemoprophylaxis, particularly in households with members at high risk of severe disease (children <1 year of age, pregnant women). Data on the use of the newer macrolides for chemoprophylaxis are not available, but these drugs are commonly used because of their increased tolerability and their effectiveness.

Immunization (See also Chap. 129) The mainstay of pertussis prevention is active immunization. Pertussis vaccine became widely used in North America after 1940; the reported number of pertussis cases subsequently fell by >90%. Whole-cell pertussis vaccines are prepared through the heating, chemical inactivation, and purification of whole *B. pertussis* organisms. Despite their efficacy (average estimate, 85%; range for different products, 30–100%), whole-cell pertussis vaccines are associated with adverse events—both common (fever; injection-site pain, erythema, and swelling; irritability) and uncommon (febrile seizures, hypotonic-hyporesponsive episodes). Alleged associations of whole-cell pertussis vaccine with encephalopathy, sudden infant death syndrome, and autism, although not substantiated, spawned an active anti-immunization lobby. The development of acellular pertussis vaccines, which are effective and less reactogenic, has greatly alleviated concerns about the inclusion of pertussis vaccine in the combined infant immunization series.

Although a wide variety of acellular pertussis vaccines were developed, only a few are still marketed widely; all contain pertussis toxoid and filamentous hemagglutinin. One acellular pertussis vaccine also contains pertactin, and another contains pertactin and two types of fimbriae. Adult formulations of acellular pertussis vaccines have been shown to be safe, immunogenic, and efficacious in clinical trials in adolescents and adults and are now recommended for routine immunization of these groups in several countries.

Although whole-cell vaccines are still used extensively in developing regions of the world, acellular pertussis vaccines are used exclusively for childhood immunization in much of the developed world. In light of evidence of early waning of immunity among children who received acellular pertussis vaccine in infancy, the WHO Strategic Advisory Group of Experts (SAGE) recommends that countries using whole-cell pertussis vaccine for the primary infant immunization series continue to do so. In countries using acellular pertussis vaccines in infancy, additional booster immunizations in older children, adolescents, and adults are recommended to prevent pertussis in high-risk infants. Pertussis immunization is also recommended during pregnancy to increase passive transfer of maternal antibodies to the fetus. Studies in high-income countries demonstrate that immunization of women during pregnancy is 90–93% effective at preventing pertussis in infants <2 months of age and is safe. In North America, acellular pertussis vaccines for children are given as a three-dose primary series at 2, 4, and 6 months of age, with a reinforcing dose at 15–18 months of age and a booster dose at 4–6 years of age. Adolescents (11–18 years of age) and all unvaccinated adults should receive a dose of the adult-formulation diphtheria–tetanus–acellular pertussis vaccine. Immunization is specifically recommended for health care providers, individuals in close contact with infants, and women at 27–36 weeks of every pregnancy, preferably in the earlier weeks of this range. Pertussis vaccine coverage among U.S. adolescents was 89.9% in 2022; among pregnant women, it was 55.4% during October 2022 to January 2023; and it was low among adults, at 30.1% in 2019. Further improvements in adult vaccine coverage may permit better control of pertussis across the age spectrum, with collateral protection of infants too young to be immunized. However, more effective vaccines with longer-lasting protection will ultimately be needed to control this disease.

166 Diseases Caused by Gram-Negative Enteric Bacilli

Thomas A. Russo, Yohei Doi

GENERAL FEATURES AND PRINCIPLES

The postantibiotic era has begun. For most patients, this is the first time in their lives when an effective treatment for a bacterial infection may not exist. Species in the order *Enterobacterales* are at the forefront of this evolving public health crisis. For example, the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) have designated carbapenem-resistant *Enterobacterales* (CRE) as representing a threat level of "urgent" and "priority one, critical." CRE are estimated to have caused more than 100,000 deaths in 2019 globally, and the disease burden is especially high in low- and middle-income countries (e.g., Indian Subcontinent). These pathogens cause a wide variety of infections involving diverse anatomic sites, mostly in compromised hosts but also in healthy individuals. Therefore, a thorough knowledge of clinical presentations and appropriate therapeutic choices is necessary for optimal outcomes. *Escherichia coli*, *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, *Citrobacter*, *Morganella*, *Providencia*, *Cronobacter*, and *Edwardsiella* are enteric gram-negative bacilli (GNB) within the order *Enterobacterales* that commonly cause extraintestinal infections. *Salmonella*, *Shigella*, and *Yersinia*, which also are in the order *Enterobacterales* but more commonly cause gastrointestinal infections, are discussed in **Chaps. 171, 172, and 176**, respectively.

EPIDEMIOLOGY

E. coli, *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, *Citrobacter*, *Morganella*, *Providencia*, *Cronobacter*, and *Edwardsiella* are components of the normal animal and human colonic microbiota and/or the microbiota in various environmental habitats, including long-term-care facilities (LTCFs) and hospitals. As a result, except for certain pathotypes of intestinal pathogenic *E. coli*, these genera are global pathogens. The incidence of infection due to these agents is increasing because of the combination of an aging population and increasing antimicrobial resistance. In healthy humans, *E. coli* is the predominant species of GNB in the colonic microbiota, followed by *Klebsiella* and *Enterobacter*. GNB can also colonize the oropharynx and intact skin but, in healthy individuals, tend to do so only transiently. By contrast, in LTCFs and hospital settings, a variety of GNB emerge as the dominant colonizers of both mucosal and skin epithelial surfaces, particularly in association with antimicrobial use, severe illness, and extended length of stay. LTCFs are emerging as an important reservoir for resistant GNB. Such colonization with GNB may lead to subsequent extraintestinal infection; for example, oropharyngeal colonization may lead to pneumonia, and colonic/perineal colonization may lead to urinary tract infection (UTI). The use of ampicillin or amoxicillin was associated with an increased risk of subsequent infection due to the hypervirulent pathotype of *Klebsiella pneumoniae* in Taiwan; this association suggests that changes in the quantity or prevalence of colonizing bacteria may significantly influence the risk of infection. *Serratia*, *Enterobacter*, and, less commonly, *Citrobacter* infection may be acquired directly through a variety of contaminated infusates (e.g., medications, blood products, non–U.S. Food and Drug Administration [FDA]-approved stem cell products). A multistate outbreak of highly resistant *Serratia* due to contaminated eyedrops has occurred. *Edwardsiella* infections are acquired through freshwater and marine environment exposures and are most common in Southeast Asia.

STRUCTURE AND FUNCTION

Enteric GNB possess an extracytoplasmic outer membrane consisting of a lipid bilayer with associated proteins, lipoproteins, and polysaccharides (capsule, lipopolysaccharide). The outer membrane interfaces with the external environment, including the human host. A variety of components of the outer membrane are critical determinants in pathogenesis (e.g., capsule, lipopolysaccharide) and antimicrobial resistance (e.g., permeability barrier, efflux pumps). In addition, secreted products play an important role in both host infection (e.g., iron acquisition molecules) and environmental niche survival and colonization (e.g., type VI secretion systems).

PATHOGENESIS

Multiple bacterial virulence factors are required for the pathogenesis of infections caused by GNB. Possession of specialized virulence genes defines pathogens and enables them to infect the host efficiently. Hosts and their cognate pathogens have been co-adapting throughout evolutionary history. During the host–pathogen "chess match" over time, various and redundant strategies have emerged in both the pathogens and their hosts **(Table 166-1)**.

Intestinal pathogenic (diarrheagenic) mechanisms are discussed below. The members of the order *Enterobacterales* that cause extraintestinal infections are primarily extracellular pathogens and therefore share certain pathogenic features. The two principal components of host defense against *Enterobacterales*, regardless of species, are innate immunity (including intact skin and mucosal barriers; the withholding of nutrients; and the activities of complement, antimicrobial peptides, and professional phagocytes) and humoral immunity. Both susceptibility to and severity of infection are increased with dysfunction or deficiencies of these host components. By contrast, the virulence traits of intestinal pathogenic *E. coli*—i.e., the distinctive strains that can cause diarrheal disease—are for the most part different from those of extraintestinal pathogenic *E. coli* (ExPEC) and other GNB that cause extraintestinal infections. This distinction reflects site-specific differences in host environments, defense mechanisms, and physiologic derangements that lead to disease.

A given enterobacterial strain usually possesses multiple adhesins for binding to a variety of host cells (e.g., in *E. coli*: type 1, S, and F1C fimbriae; P pili). Nutrient acquisition (e.g., of iron via

TABLE 166-1 Interactions of Extraintestinal Pathogenic *Escherichia coli* with the Human Host: A Paradigm for Extracellular, Extraintestinal, Gram-Negative Bacterial Pathogens

BACTERIAL GOAL	HOST OBSTACLE	BACTERIAL SOLUTION
Extraintestinal attachment	Flow of urine, mucociliary escalator	Multiple adhesins (e.g., type 1, S, and F1C fimbriae; P pili)
Nutrient acquisition for growth	Nutrient sequestration (e.g., iron via intracellular storage and extracellular scavenging via lactoferrin and transferrin)	Cellular lysis (e.g., hemolysin), multiple mechanisms for competing for iron (e.g., siderophores) and other nutrients
Initial avoidance of host bactericidal activity	Complement, phagocytic cells, antimicrobial peptides	Capsular polysaccharide, lipopolysaccharide
Dissemination (within host and between hosts)	Intact tissue barriers	Irritant tissue damage resulting in increased excretion (e.g., toxins such as hemolysin), invasion of brain endothelium
Late avoidance of host bactericidal activity	Acquired immunity (e.g., specific antibodies), treatment with antibiotics	Cell entry, acquisition of antimicrobial resistance

siderophores) requires many genes that are necessary but not sufficient for pathogenesis. The ability to resist the bactericidal activity of complement and phagocytes in the absence of antibody (e.g., as conferred by capsule or the O antigen component of lipopolysaccharide) is one of the defining traits of an extracellular pathogen. Tissue damage (e.g., as mediated by *E. coli* hemolysin) may facilitate nutrient acquisition and spread within the host. Without doubt, many important virulence genes await identification.

The ability to induce septic shock is another defining feature of these genera. GNB are the most common causes of this potentially lethal syndrome. Pathogen-associated molecular pattern molecules (PAMPs; e.g., the lipid A moiety of lipopolysaccharide) stimulate a proinflammatory host response via pattern recognition receptors (e.g., Toll-like or C-type lectin receptors) that activate host defense signaling pathways; if overly exuberant, this response results in shock **(Chap. 315)**. Direct bacterial damage of host tissue (e.g., by toxins) or collateral damage from the host response can result in the release of damage-associated molecular pattern molecules (DAMPs; e.g., HMGB1) that can propagate a detrimental proinflammatory host response.

Many antigenic variants (serotypes) exist in most genera of GNB. For example, *E. coli* has >150 O (somatic) antigens, 80 K (capsular) antigens, and 53 H (flagellar) antigens. This antigenic variability, which permits immune evasion and allows recurrent infection by different strains of the same species, has impeded vaccine development **(Chap. 129)**.

INFECTIOUS SYNDROMES

Depending on both the host and the pathogen, GNB can infect nearly every organ or body cavity. *E. coli* can cause either intestinal or extraintestinal infection, depending on the pathotype, and *Edwardsiella tarda* can cause both intestinal and extraintestinal infection. *Klebsiella* causes primarily extraintestinal infection, but a toxin-producing variant of *Klebsiella oxytoca* has been associated with hemorrhagic colitis, and *Providencia alcalifaciens* and *Escherichia albertii* have been associated with gastroenteritis.

E. coli and—to a lesser degree—*Klebsiella* account for most extraintestinal infections due to GNB. These species (for *K. pneumoniae*, primarily its hypervirulent pathotype) are the most virulent pathogens within this group, as demonstrated by their ability to cause severe infections in healthy, ambulatory hosts from the community. However, the other genera of GNB are also important extraintestinal pathogens, especially among LTCF residents and hospitalized patients, in large part because of the intrinsic or acquired antimicrobial resistance of these organisms and the increasing number of individuals with compromised host defenses. The mortality rate is substantial in many GNB infections and correlates with severity of illness, underlying host status, and in some cases the antimicrobial resistance of the infecting pathogen, which can result in suboptimal therapy. Especially problematic are pneumonia, sepsis, and septic shock (arising from any site of infection), for which the associated mortality rates are 20–60%.

DIAGNOSIS

Isolation of GNB from sterile sites almost always implies infection, whereas their isolation from nonsterile sites, particularly open wounds, the respiratory tract, and urine in the presence of an indwelling catheter, requires careful clinical correlation to differentiate colonization from infection. Clinical microbiology laboratories are increasingly replacing identification by biochemical tests with newer diagnostic methodologies such as matrix-assisted laser desorption–ionization–time-of-flight mass spectrometry (MALDI-TOF-MS), nucleic acid amplification tests (NAATs) and sequencing, and immunoassays to enhance the sensitivity, accuracy, and rapidity of reporting on pathogen identification and resistance genes. This information can be used to increase the timeliness of initiation and/or the accurate selection of empirical antimicrobial therapy, thereby improving outcomes. These new diagnostic modalities have also resulted in the identification from clinical specimens of unfamiliar species (e.g., *K. grimontii*, *Enterobacter hormaechei*). It is best to assume such isolates possess a similar pathogenic potential as their more familiar counterparts until more data become available.

TREATMENT

Principles Guiding Treatment in the Era of Increasing Antimicrobial Resistance

(See also Chap. 149) Initiation of appropriate empirical antimicrobial therapy early in the course of infections due to GNB (particularly the more serious ones) leads to improved outcomes. The ever-increasing prevalence of multidrug-resistant (MDR) and extensively drug-resistant (XDR) GNB; the lag between published and current resistance rates; and variations in antimicrobial susceptibility by species, geographic location, regional antimicrobial use, and hospital site (e.g., intensive care units [ICUs] vs wards) necessitate familiarity with evolving patterns of antimicrobial resistance for the selection of appropriate empirical therapy.

Patient factors predictive of resistance in a given isolate include recent antimicrobial use, a health care association (e.g., recent or ongoing hospitalization, dialysis, residence in an LTCF, transplant, hematologic malignancy), or international travel (e.g., to Asia, Latin America, Africa, Eastern Europe). Of concern are an increasing number of reports of resistant *Enterobacterales* causing infections in ambulatory patients without known risk factors.

In this era of increasing antimicrobial resistance, it is critical to culture the primary site of infection before initiating antimicrobial therapy and, for systemically ill patients, to obtain blood cultures. In vitro testing may not always detect antimicrobial resistance; therefore, it is important to assess the patient's clinical response to treatment. Moreover (see discussion of AmpC β-lactamases below), resistance may emerge during therapy. In addition, drainage of abscesses, resection of necrotic tissue, and removal of infected foreign bodies, sometimes referred to collectively as "source control," are often required for cure.

For appropriately selected patients, it may be prudent initially, pending antimicrobial susceptibility results, to use two potentially active agents to increase the likelihood that at least one agent will be active against the patient's organism. If broad-spectrum treatment has been initiated, it is important to switch to the most appropriate narrower-spectrum agent once antimicrobial susceptibility results become available. Such responsible antimicrobial stewardship should help disrupt the ever-escalating cycle of selection for increasingly resistant bacteria, plus decrease the likelihood of *Clostridioides difficile* infection, decrease costs, and maximize

the useful longevity of available antimicrobial agents. Likewise, it is important to avoid treatment of patients who are colonized but not infected (e.g., who have a positive sputum culture without evidence of pneumonia, or a positive urine culture without clinical manifestations of UTI).

At present, the most reliably and broadly active antimicrobial agents in vitro against *Enterobacterales* are the carbapenems (excepting imipenem, to which *Proteeae* [*Proteus*, *Morganella*, *Providencia*] are intrinsically resistant); the aminoglycoside amikacin (excepting the *Proteeae*); the fourth-generation cephalosporin cefepime; the β-lactamase inhibitor combination agents piperacillin-tazobactam, ceftolozane-tazobactam, ceftazidime-avibactam, meropenem-vaborbactam, and imipenem/cilastatin-relebactam; and the novel cephalosporin-siderophore cefiderocol. A limitation of imipenem/cilastatin-relebactam; the tetracycline derivatives tigecycline, omadacycline, and eravacycline; and the polymyxins B and E (colistin) (which are otherwise very active) is their poor activity against *Proteeae* and *Serratia*. Furthermore, the tetracycline derivatives achieve suboptimal concentrations at several anatomic sites (including urine and blood). Clinical data are limited for cefiderocol outside of UTIs and hospital-acquired ventilator-associated bacterial pneumonias; thus, caution is in order for serious infections at other sites.

The number of antimicrobial agents active against certain strains of *Enterobacterales* is shrinking, and truly pandrug-resistant GNB exist. Accordingly, the currently available antimicrobial drugs must be used judiciously. Extensive resistance to available agents may leave the clinician with few or no ideal therapeutic options. However, use of a regimen that considers the site of infection, achievable drug levels at that site (e.g., higher concentrations of many agents in urine), and pharmacodynamically guided administration strategies (e.g., prolonged infusion of β-lactam agents to maintain drug levels above the minimal inhibitory concentration [MIC]) may increase the chance for a successful outcome. Point-of-care, NAAT-based identification of resistance mechanisms in GNB is becoming available and will enable a strain-specific, patient-specific, precision medicine–based treatment approach that would be predicted to improve outcome.

GNB are commonly involved in polymicrobial infections, in which the role of each individual pathogen is uncertain **(Chap. 182)**. Although some GNB are more pathogenic than others, it is usually prudent, if possible, to design an antimicrobial regimen active against all the GNB identified, because each is typically capable of pathogenicity in its own right. For patients treated initially with a broad-spectrum empirical regimen, the regimen should be de-escalated as expeditiously as possible once susceptibility results are known and the patient has responded to therapy.

Treatment duration is best individualized based on underlying host status and site of infection. However, for selected non–critically ill patients with source control and a satisfactory clinical response to therapy, 7 days of treatment may suffice for many infections.

ANTIMICROBIAL TREATMENT AND RESISTANCE MECHANISMS

The most common resistance mechanisms possessed by *Enterobacterales* are summarized in **Table 166-2**. Enzymatic hydrolysis (e.g., β-lactamases, of which >3000 variants have been described) and modification of antimicrobials are the major mediators of resistance in GNB and will be discussed below. Importantly, it is becoming increasingly recognized that MDR and XDR GNB often possess multiple plasmids and genes that encode for multiple β-lactamases.

Broad-spectrum β-lactamases mediate resistance to many penicillins and first-generation cephalosporins and are frequently expressed in enteric GNB. These enzymes are inhibited by all available β-lactamase inhibitors (e.g., clavulanate, sulbactam, tazobactam, avibactam, relebactam, vaborbactam). In their wild-type form, they do not hydrolyze third- and fourth-generation cephalosporins or cephamycins (e.g., cefoxitin).

Extended-spectrum β-lactamases (ESBLs) are modified broad-spectrum enzymes that hydrolyze third-generation cephalosporins, aztreonam, and (in some instances) fourth-generation cephalosporins, in addition to the drugs hydrolyzed by broad-spectrum β-lactamases. GNB that produce ESBLs may also exhibit porin mutations that result in decreased uptake of relevant β-lactam agents (cephalosporins, β-lactam/β-lactamase inhibitor combinations, and carbapenems), further reducing susceptibility to these agents. The prevalence of acquired ESBL production, particularly of CTX-M-type enzymes, is increasing in GNB worldwide, largely due to the presence of the corresponding genes on transferable plasmids, which also variably confer or are associated with resistance to fluoroquinolones, trimethoprim-sulfamethoxazole (TMP-SMX), aminoglycosides, tetracyclines, and (more recently) fosfomycin. To date, ESBLs are most prevalent in *E. coli* (especially ST131), *K. pneumoniae*, and *K. oxytoca*, but these enzymes can occur in all species of *Enterobacterales*. The approximate regional prevalence of ESBL-producing GNB currently follows a descending gradient as follows: China > Eastern Europe > other parts of Asia (e.g., India) > Latin America and Africa > Western Europe, the United States, Canada, and Australia. Travel to high-prevalence regions increases the likelihood of colonization with these strains. The incidence of community-acquired infections due to ESBL-producing *Enterobacterales* has increased worldwide, including in the United States.

Carbapenems are the most reliably active β-lactam agents against ESBL-producing strains. Piperacillin-tazobactam, when active in vitro, has been used as a carbapenem-sparing alternative, but recent data from the MERINO trial do not support its use for bloodstream infections. Ceftazidime-avibactam, ceftolozane-tazobactam (less active against *Klebsiella*, *Enterobacter*, and *Citrobacter*) are also active against most ESBL-producing strains but have limited clinical data that support potential utility. The roles for tigecycline, eravacycline, and omadacycline are unclear despite these agents' excellent in vitro activity against most *Enterobacterales*; however, they are inactive against *Proteus*, *Morganella*, *Providencia*, and *Serratia*.

Oral options for the treatment of ESBL-producing strains are very limited. Fosfomycin, nitrofurantoin (for *E. coli*, 75–90% susceptible), pivmecillinam (recently approved in the United States), and omadacycline are the most reliably active agents. Older tetracyclines (e.g., doxycycline and minocycline) also are often active,

TABLE 166-2 Common Antimicrobial Resistance Mechanisms Possessed by the *Enterobacterales*

MECHANISM	ANTIMICROBIALS MOST SIGNIFICANTLY AFFECTED	COMMON MEDIATORS OF RESISTANCE
Efflux	Tetracyclines, fluoroquinolones (FQ)	Efflux pumps
Decreased permeability	Fosfomycin	Alterations in uptake system
Target site alteration or overproduction	FQ, trimethoprim-sulfamethoxazole (TMP-SMX), and polymyxins	DNA gyrase or topoisomerase IV for FQ; enzymes for folic acid synthesis for TMP-SMX Lipid A for polymyxins
Enzymatic hydrolysis of antimicrobials	Penicillins, cephalosporins, cephamycins, carbapenems	Broad-spectrum β-lactamases (e.g., TEM, SHV) ESBLs (e.g., CTX-M, modified TEM and SHV) AmpC β-lactamases Carbapenemases (e.g., serine-based KPC, OXA; metallo-based NDM, VIM, IMP)
Enzymatic modification of antimicrobials	Aminoglycosides	AAC, ANT, APH

Abbreviations: AAC, *N*-acetyltransferases; ANT, *O-adenylyltransferases*; APH, *O*-phosphotransferases; CTX, cefotaxime β-lactamase; ESBL, extended-spectrum β-lactamase; IMP, active on imipenem; KPC, *Klebsiella pneumoniae* carbapenemase; NDM, New Delhi metallo-β-lactamase; OXA, oxacillinase; SHV, sulfhydryl reagent variable β-lactamase; TEM, Temoniera β-lactamase; VIM, Verona integron-mediated metallo-β-lactamase.

although urine levels may be insufficient and clinical experience with gram-negative infections is limited.

AmpC β-*lactamases*, when induced or stably derepressed to high levels of expression, confer resistance to the same substrates as do ESBLs plus to the cephamycins (e.g., cefoxitin and cefotetan), except to the fourth-generation cephalosporins. The genes encoding these enzymes are primarily chromosomal and therefore may not exhibit the linked resistance to TMP-SMX, aminoglycosides, and tetracyclines that is common with ESBLs. These enzymes are problematic for the clinician: resistance may develop during therapy with third-generation cephalosporins and result in clinical failure, particularly in the setting of bacteremia. Although chromosomal AmpC β-lactamases are present in nearly all members of the order *Enterobacterales* (with the notable exceptions of *K. pneumoniae*, *K. oxytoca*, and *Proteus mirabilis*), the risk of clinically significant induction of high-level expression or selection of stably derepressed mutants with cephalosporin treatment is not uniform across species, being greatest with *Enterobacter cloacae*, *Klebsiella* (formerly *Enterobacter*) *aerogenes*, *Citrobacter freundii*, and *Hafnia alvei*, and less with *Serratia marcescens*, *Providencia*, and *Morganella morganii.* In addition, rare strains of *E. coli*, *K. pneumoniae*, and other *Enterobacterales* have acquired plasmids that contain AmpC β-lactamase genes.

For AmpC-producing strains, carbapenems are an appropriate treatment option, especially for severely ill patients. Meta-analyses support piperacillin-tazobactam as a possible option. The fourth-generation cephalosporin cefepime may be an appropriate option if the concomitant production of an ESBL can be excluded (a task that currently exceeds the capability of most clinical microbiology laboratories) and source control is achieved. Ceftazidime-avibactam and cefiderocol are active in vitro, but clinical data are limited. Other carbapenem-sparing alternatives to consider if isolates are susceptible in vitro include fluoroquinolones, TMP-SMX, and aminoglycosides. Tigecycline, eravacycline, and omadacycline are active in vitro (except against *Proteus*, *Morganella*, *Providencia*, and *Serratia*).

Carbapenemases of Ambler class A (serine-β-lactamases; e.g., *K. pneumoniae* carbapenemase [KPC]) and class B (metallo-β-lactamases [MBLs]; e.g., New Delhi metallo-β-lactamase [NDM], Verona integron-mediated metallo-β-lactamase [VIM], imipenemase [IMP]) confer resistance to the same drugs as do ESBLs, plus to cephamycins and carbapenems. By contrast, Ambler class D carbapenemases (serine-β-lactamases; e.g., oxacillinase-48 [OXA-48]) hydrolyze carbapenems and penicillins, but they have minimal activity against extended-spectrum cephalosporins. As with ESBLs, carbapenemase-encoding genes may be present on transferable plasmids, which often encode linked resistance to fluoroquinolones, TMP-SMX, tetracyclines, and aminoglycosides. Transposon-mediated spread (e.g., Tn*4401* for KPC) also is important. Although all major carbapenemases have been described around the globe, KPC is most common in the Americas, NDM in Asia, and OXA in Europe. Asymptomatic intestinal carriage of producing bacteria may facilitate spread.

Carbapenemase-producing *Enterobacterales* (CPE) are most prevalent in *K. pneumoniae*, followed by *Enterobacter* spp. and *E. coli*, but have been described in nearly all members of the order. *M. morganii*, *Proteus*, and *Providencia* exhibit intrinsic low-level imipenem resistance. A variety of genotypic and phenotypic methods can detect carbapenemase genes or activity, which could inform epidemiologic surveillance, infection control efforts, antimicrobial stewardship, and treatment decisions, especially if susceptibility data for selected agents are not available.

For the treatment of infections due to *Enterobacterales* that produce class A or D carbapenemases (serine-β-lactamases; KPC, OXA), ceftazidime-avibactam is emerging as a first-line agent particularly for bacteremia, but suboptimal efficacy has been observed with pneumonia and in patients on renal replacement therapy, and resistance has developed in up to 10% of cases. Clinical success against KPC-producing CRE has also been reported for meropenem-vaborbactam and, to a lesser extent, imipenem/cilastatin-relebactam; unlike ceftazidime-avibactam, however, neither of these agents is active against OXA-producing CRE. Ceftazidime, cefepime, and aztreonam are active against OXA-48-producing CRE, unless other enzymes such as ESBL an AmpC are co-produced.

Treatment of infections due to class B MBL–producing CRE is more challenging. The polymyxins B and E currently constitute one of the last lines of defense against strains that produce MBLs (e.g., NDM). However, these agents' nephrotoxicity and neurotoxicity potential, their limited clinical efficacy, and the recent emergence of the polymyxin resistance threaten their utility.

Aztreonam is stable against MBLs but is hydrolyzed by ESBLs and AmpC β-lactamases, which are often coproduced in XDR strains. Ongoing clinical trials are assessing aztreonam plus avibactam, a promising combination with in vitro activity against class A, B, and D enzymes, for the treatment of CRE strains that produce MBLs like NDM. A currently available workaround involving approved drugs is co-administration of ceftazidime-avibactam and aztreonam; avibactam protects aztreonam from hydrolysis from ESBLs and AmpC β-lactamases.

Cefiderocol is active in vitro against most strains producing KPC, MBLs, and OXA-48 (i.e., classes A, B, and D enzymes); clinical trials suggest that it may be as efficacious for serious CRE infections as the standard of care, but real-world data are limited. Although tigecycline, eravacycline, and omadacycline are active in vitro, pharmacokinetic-pharmacodynamic limitations exist, and along with the polymyxins, they exhibit poor activity against the tribe *Proteeae* and *Serratia*. Aminoglycosides, especially amikacin, may have some utility for combination therapy. Fosfomycin is often active in vitro, but clinical data in the treatment of serious infections due to CPE are limited and resistance may develop with monotherapy.

Carbapenem resistance in the absence of carbapenemases can occur in the presence of ESBLs or AmpC β-lactamase production in combination with porin mutations (non-CP-CRE); however, most laboratories will not be able to differentiate CPE from non-CP-CRE. The non-CP-CRE phenotype is most commonly seen in *E. coli* and *Enterobacter* spp. In general, resistance to noncarbapenem antimicrobial classes is less, but data are limited on the optimal management approach for non-CP-CRE.

Resistance to classic β-*Lactamase inhibitors* is an uncommon (4% of *E. coli*/*K. pneumoniae* blood isolates) but increasingly recognized phenotype that is characterized by resistance to β-lactamase inhibitors but not to third-generation cephalosporins. This mechanism of resistance is distinct from production of ESBLs, AmpC β-lactamases, and carbapenemases, and it is still being delineated. Limited evidence suggests that ceftriaxone is an appropriate treatment option for such strains. Resistance to newer β-lactamase inhibitors, especially avibactam, is increasingly reported in KPC-producing CPE and is due to mutations leading to structural modifications of the KPC enzyme. These strains remain susceptible to meropenem-vaborbactam.

Fluoroquinolone resistance is usually due to alterations in or protection of the target sites in DNA gyrase and topoisomerase IV, with or without decreased permeability and active efflux. Fluoroquinolone resistance is increasingly prevalent among GNB and is associated with resistance to other antimicrobial classes; for example, 20–80% of ESBL-producing enteric GNB are also resistant to fluoroquinolones. At present, fluoroquinolones should be considered unreliable as empirical therapy for GNB infections in critically ill patients.

Aminoglycoside resistance in *Enterobacterales* is conferred via enzymatic modification by *N*-acetyltransferases, *O*-adenylyltransferases, or *O*-phosphotransferases, which in turn affects ribosomal binding. Amikacin is less affected by these transferases than gentamicin and tobramycin and therefore is generally more active. A yet uncommon resistance mechanism involves acquired 16S ribosomal RNA methyltransferases, which prevent all parenterally

administered aminoglycosides from binding to their target ribosomes. To date, these methyltransferases are most common in strains that produce MBLs (e.g., NDM).

PREVENTION

(See also Chap. 147) Certain measures are broadly applicable for decreasing infection risk. Antimicrobial stewardship programs should be instituted to facilitate appropriate antimicrobial use, which will minimize the development of resistance. Diligent adherence to hand hygiene protocols by health care personnel and cleaning/disinfection or single-patient use of objects that come into contact with patients (e.g., stethoscopes and blood pressure cuffs) are essential. Indwelling devices (e.g., urinary and intravascular catheters) should be used only when necessary and inserted according to an appropriate protocol; protocols for daily-use evaluation and prompt removal should be implemented. Multiuse medication vials should be avoided if possible. Oral application of chlorhexidine decreases the incidence of pneumonia among patients on ventilators. Increasing data support the implementation of universal decolonization (e.g., chlorhexidine bathing) to prevent infection in ICU patients or nursing home residents. The public health threat from CRE has resulted in additional recommendations, especially for carbapenemase-producing CRE, which are an even greater concern. These recommendations include contact precautions for patients colonized or infected with CRE, notification to the receiving facility from facilities transferring such a patient, and daily environmental cleaning. Screening of contacts and active surveillance for these bacteria also may be appropriate.

ESCHERICHIA COLI INFECTIONS

All *E. coli* strains share a core genome of ~2,000 genes. In contrast, an *E. coli* strain's ability to cause infection and the nature of such infections are defined largely by accessory (i.e., noncore, nonessential) genes that encode various virulence factors. The composition of the *E. coli* accessory genome is continuously in flux, as demonstrated by the recent evolution of Shiga toxin–producing enteroaggregative *E. coli*.

COMMENSAL STRAINS

Commensal *E. coli* variants are an important constituent of the normal intestinal microbiota that confer benefits to the host (e.g., resistance to colonization with pathogenic organisms). Such strains generally lack the specialized virulence traits that enable extraintestinal and intestinal pathogenic *E. coli* strains to cause disease outside and within the gastrointestinal tract, respectively. However, even commensal *E. coli* strains can be involved in extraintestinal infections in the presence of an aggravating factor, such as a foreign body (e.g., a urinary catheter), host compromise (e.g., local anatomic or functional abnormalities [including urinary or biliary tract obstruction] or systemic immunocompromise), or an inoculum that is large or contains a mixture of bacterial species (e.g., fecal contamination of the peritoneal cavity).

EXTRAINTESTINAL PATHOGENIC STRAINS

ExPEC strains are the most common enteric GNB to cause community-acquired and health care–associated bacterial infections. The emerging propensity of these strains to acquire new mechanisms of antimicrobial resistance (e.g., FQ resistance mutations, ESBLs, carbapenemases) poses novel challenges in managing ExPEC infection. Several ExPEC clonal groups (e.g., sequence types [STs] ST131, ST95, ST69, ST73) are recognized to have undergone global dissemination. The mechanisms underlying the epidemiologic success of such disseminated lineages remain an area of active investigation. In the case of ST131, efficient human-to-human transmission followed by colonization and long-term persistence within the intestinal microbiota appears to be a critical factor. Although acquisition of ESBL-producing *E. coli* from the food chain has been described, this appears to occur relatively uncommonly.

Like commensal *E. coli* (but unlike intestinal pathogenic *E. coli*), ExPEC strains are often found in the intestinal microbiota of healthy individuals and, except for rare chimeric ExPEC/intestinal pathogenic *E. coli* strains, do not cause gastroenteritis in humans. Entry from their site of colonization (e.g., the colon, vagina, or oropharynx) into a normally sterile extraintestinal site (e.g., the urinary tract, peritoneal cavity, or lungs) is the rate-limiting step for infection. ExPEC strains have acquired accessory genes encoding diverse virulence factors that enable the bacteria to cause infections outside the gastrointestinal tract in both normal and compromised hosts (Table 166-1). These virulence genes define ExPEC and, for the most part, are distinct from the virulence genes that enable intestinal pathogenic strains to cause diarrheal disease **(Table 166-3)**. All age groups, all types of hosts, and nearly all organs and anatomic sites are susceptible to infection by ExPEC. Even previously healthy hosts can become severely ill or die when infected with ExPEC; however, adverse outcomes are more common among hosts with comorbid illnesses and host defense abnormalities. The diversity and the medical and economic impact of ExPEC infections are evident from consideration of the following specific syndromes.

Extraintestinal Infectious Syndromes • URINARY TRACT INFECTION The urinary tract is the site most frequently infected by ExPEC. UTI is an exceedingly common infection among ambulatory patients, accounting for 1% of ambulatory care visits in the United States and second only to lower respiratory tract infection among infections responsible for hospitalization. UTIs are best considered by clinical syndrome (e.g., cystitis, pyelonephritis, catheter-associated UTI) and within the context of specific hosts (e.g., premenopausal women, immunocompromised hosts; **Chap. 140**). *E. coli* is the single most common pathogen for all UTI syndrome/host group combinations.

TABLE 166-3 Intestinal Pathogenic *Escherichia coli*

PATHOTYPE	EPIDEMIOLOGY	CLINICAL SYNDROME[a]	DEFINING MOLECULAR TRAIT	RESPONSIBLE GENETIC ELEMENT[b]
STEC/EHEC/ ST-EAEC	Food, water, person-to-person; all ages, industrialized countries	Hemorrhagic colitis, hemolytic-uremic syndrome	Shiga toxin	Lambda-like Stx1- or Stx2-encoding bacteriophage
ETEC	Food, water; young children in and travelers to developing countries	Traveler's diarrhea	Heat-stable and labile enterotoxins, colonization factors	Virulence plasmid(s)
EPEC	Person-to-person; young children and neonates in developing countries	Watery diarrhea, persistent diarrhea	Localized adherence, attaching and effacing lesion on intestinal epithelium	EPEC adherence factor plasmid pathogenicity island (locus for enterocyte effacement [LEE])
EIEC	Food, water; children in and travelers to developing countries	Watery diarrhea, occasionally dysentery	Invasion of colonic epithelial cells, intracellular multiplication, cell-to-cell spread	Multiple genes contained primarily in a large virulence plasmid
EAEC	?Food, water; children in and travelers to developing countries; all ages, industrialized countries	Traveler's diarrhea, acute diarrhea, persistent diarrhea	Aggregative/diffuse adherence, virulence factors regulated by AggR	Chromosomal or plasmid-associated adherence and toxin genes

[a]Classic syndromes; see text for details on disease spectrum. [b]Pathogenesis involves multiple genes, including genes in addition to those listed.

Abbreviations: EAEC, enteroaggregative *E. coli*; EHEC, enterohemorrhagic *E. coli*; EIEC, enteroinvasive *E. coli*; EPEC, enteropathogenic *E. coli*; ETEC, enterotoxigenic *E. coli*; ST-EAEC, Shiga toxin–producing enteroaggregative *E. coli*; STEC, Shiga toxin–producing *E. coli*.

Each year in the United States, *E. coli* causes 80–90% of the estimated 6–8 million episodes of cystitis that occur in ambulatory, premenopausal women with an anatomically and functionally normal urinary tract (i.e., uncomplicated cystitis). Furthermore, 20% of women with an initial cystitis episode develop frequent recurrences.

Uncomplicated cystitis, the most common acute UTI syndrome, is characterized by dysuria, urinary frequency and urgency, and suprapubic pain. Progression to more severe infection is rare; the natural history is slow spontaneous symptom resolution, which antimicrobial therapy hastens. Fever and/or back pain suggest progression to pyelonephritis. Even when pyelonephritis is treated effectively, fever may take 5–7 days to resolve completely. Persistently elevated or increasing fever, flank pain, and neutrophil counts should prompt evaluation for intrarenal or perinephric abscess and/or obstruction. Pyelonephritis uncommonly causes renal parenchymal damage and loss of renal function, primarily in association with urinary obstruction, which can be preexisting or, rarely, occurs de novo in diabetic patients who develop renal papillary necrosis due to kidney infection. Pregnant women are at unusually high risk for developing pyelonephritis, which can adversely affect the outcome of pregnancy. As a result, prenatal screening for and treatment of asymptomatic bacteriuria during pregnancy are standard. Prostatic infection (prostatitis), a potential complication of UTI in men, can present either acutely (severe), which is rare, or in a chronic manner (recurrent cystitis), which is much more common. Acute pyelonephritis, acute prostatitis, and other systemic illnesses due to UTI can be designated collectively as *urosepsis*, *febrile UTI*, or *systemic UTI*, and may or may not be accompanied by bacteremia. The diagnosis and treatment of UTI, as detailed in **Chap. 140**, should be tailored to the individual host, the nature and site of infection, and local patterns of antimicrobial susceptibility.

ABDOMINAL AND PELVIC INFECTION The abdomen/pelvis is the second most common site of extraintestinal infection due to *E. coli*. A wide variety of clinical syndromes occur in this location, including acute peritonitis secondary to fecal contamination, spontaneous bacterial peritonitis, dialysis-associated peritonitis, diverticulitis, appendicitis, intraperitoneal or visceral abscesses (hepatic, pancreatic, splenic), infected pancreatic pseudocysts, and septic cholangitis and/or cholecystitis. In intraabdominal infections, *E. coli* can be isolated either alone or, as occurs more often, in combination with other facultative and/or anaerobic members of the intestinal microbiota **(Chap. 137)**.

PNEUMONIA *E. coli* is not usually considered an important cause of pneumonia **(Chap. 131)**. Indeed, enteric GNB account for only 1–3% of cases of community-acquired pneumonia, in part because these organisms colonize the oropharynx only transiently in a minority of healthy individuals. However, rates of oral colonization with *E. coli* and other GNB increase with severity of illness and antibiotic use. Consequently, GNB are a more common cause of pneumonia among residents of LTCFs and of hospital-acquired pneumonia **(Chap. 147)**, particularly among postoperative and ICU patients (e.g., ventilator-associated pneumonia).

Pulmonary infection is usually acquired by small-volume aspiration but occasionally occurs via hematogenous spread, in which case multifocal nodular infiltrates can be seen. Tissue necrosis, probably due in part to bacterial cytotoxins, is common. Despite significant institutional variation, *E. coli* is generally the third or fourth most commonly isolated type of GNB in hospital-acquired pneumonia, accounting for 5–8% of episodes in both U.S.-based and Europe-based studies. Regardless of the host, pneumonia due to ExPEC is a serious disease, with high crude and attributable mortality rates (20–60% and 10–20%, respectively).

MENINGITIS **(See also Chap. 143)** *E. coli* is one of the leading causes of neonatal meningitis, together with group B *Streptococcus*. Most *E. coli* strains that cause neonatal meningitis possess the K1 capsular antigen and derive from a limited number of meningitis-associated clonal groups (ST95, ST59, ST62). Ventriculomegaly occurs commonly. After the first month of life, *E. coli* meningitis is uncommon and usually accompanies surgical or traumatic disruption of the meninges or hepatic cirrhosis. In patients with cirrhosis who develop meningitis, the meninges are presumably seeded due to poor hepatic clearance of portal vein bacteremia.

CELLULITIS/MUSCULOSKELETAL INFECTION *E. coli* contributes frequently to infections of decubitus ulcers and occasionally to infections of lower-extremity ulcers and wounds in diabetic patients and other hosts with neurovascular compromise. Osteomyelitis secondary to contiguous spread can occur in these settings. *E. coli* also causes cellulitis or infections of burn sites and surgical wounds (accounting for ~10% of surgical site infections), particularly when the infection originates close to the perineum. *E. coli* causes hematogenously acquired osteomyelitis, especially of vertebral discs and bodies, accounting for up to 10% of cases in some series **(Chap. 136)**. *E. coli* occasionally causes orthopedic device–associated infection or septic arthritis and rarely causes hematogenous myositis. Myositis or fasciitis of the thigh due to *E. coli* should prompt an evaluation for an abdominal source with contiguous spread.

ENDOVASCULAR INFECTION Despite being one of the most common causes of bacteremia, *E. coli* rarely seeds native heart valves. When the organism does infect native valves, it usually does so in the setting of prior valvular disease. *E. coli* infections of aneurysms, the portal vein (*pylephlebitis*), and vascular grafts are uncommon.

MISCELLANEOUS INFECTIONS *E. coli* can cause infection in nearly every organ and anatomic site. It occasionally causes postoperative mediastinitis or complicated sinusitis and uncommonly causes endophthalmitis, ecthyma gangrenosum, or brain abscess.

BACTEREMIA *E. coli* bacteremia can arise from infection at any extraintestinal site. In addition, *E. coli* bacteremia can arise from percutaneous intravascular devices, transrectal prostate biopsy, and the increased intestinal mucosal permeability seen in neonates and patients with advanced cirrhosis, neutropenia, chemotherapy-induced mucositis, trauma, and extensive burns. *E. coli* bacteremia due to an ESBL-producing strain also has been reported after fecal microbiota transplant in patients with increased mucosal permeability. Roughly equal proportions of *E. coli* bacteremia cases originate in the community and in health care settings. Isolation of *E. coli* from the blood is almost always clinically significant and may be accompanied by the sepsis syndrome (dysfunction of at least one organ or system) or septic shock **(Chap. 315)**.

The urinary tract is the most common source for *E. coli* bacteremia, accounting for one-half to two-thirds of episodes. Bacteremia from a urinary tract source is particularly common among patients with pyelonephritis, urinary tract obstruction, or urinary instrumentation in the presence of infected urine. The abdomen is the second most common source, accounting for ~25% of episodes. Although many of these episodes result from biliary obstruction (stones, tumor) and overt bowel disruption, which typically are readily apparent, some abdominal sources (e.g., abscesses) are remarkably silent clinically and require identification via imaging studies (e.g., computed tomography). Therefore, especially given the high prevalence of asymptomatic bacteriuria among elderly and functionally compromised individuals, the physician should be cautious in attributing *E. coli* bacteremia to a urinary source in the absence of characteristic signs and symptoms of UTI. Soft tissue, bone, pulmonary infections, and intravascular catheter infections are other sources of *E. coli* bacteremia.

Diagnosis Strains of *E. coli* that cause extraintestinal infections usually grow both aerobically and anaerobically within 24 h on standard diagnostic media and are identified readily by the clinical microbiology laboratory according to routine biochemical criteria. More than 90% of ExPEC strains are rapid lactose fermenters and are indole-positive. However, MALDI-TOF MS is increasingly replacing biochemical methods.

TREATMENT

Extraintestinal *E. coli* Infections

E. coli does not possess clinically significant intrinsic resistance to antimicrobials; however, increasing acquired resistance is

making treatment problematic. Although geographic differences exist, in general, the prevalence of resistance is >20% for ampicillin, amoxicillin-clavulanate, ampicillin-sulbactam, cefazolin, TMP-SMX, and fluoroquinolones, even in community-acquired infections. This resistance precludes empirical use of these agents for serious infections. Travel outside of the United States, prior exposure to an antimicrobial agent, or exposure to a health care setting further increases the likelihood of resistance. Fortunately, >90% of isolates that cause uncomplicated cystitis remain susceptible to nitrofurantoin and fosfomycin.

From 2015 to 2017, the U.S. National Healthcare Safety Network (USNHSN) identified 24% of *E. coli* clinical isolates as ESBL-producers. Higher prevalences are reported from Asia, Eastern Europe, South America, and Africa; prevalence is also greater in isolates from health care settings, especially LTCFs. Unfortunately, community-acquired UTIs caused by *E. coli* strains that produce CTX-M ESBLs are increasingly common. Oral treatment options for ESBL-producers are limited. However, in vitro and limited clinical data indicate that fosfomycin, pivmecillinam, and nitrofurantoin are most active and can be used for cystitis (but not pyelonephritis); omadacycline is an option for pulmonary of soft-tissue infection.

For parenteral therapy of carbapenem-susceptible strains, the most predictably active agents (>90%) include carbapenems, amikacin, ceftazidime-avibactam, ceftolozane-tazobactam, piperacillin-tazobactam, polymyxins, cefiderocol, tigecycline, eravacycline, and omadacycline with the caveat that site-specific concentration and potential efficacy are agent dependent. Treatment of carbapenemase-producing strains is dependent on the class of enzyme produced (see "Carbapenemase" above). Uncertainty exists on the optimal treatment for non-CP-CR *E. coli*.

Empirical treatment decisions for critically ill patients should be dictated by local susceptibility patterns and patient-specific risk factors (1.2% prevalence from the USNHSN 2015–2017 data). Equally important as prompt institution of effective empirical therapy for seriously ill patients is use of appropriate narrower-spectrum agents for definitive therapy whenever possible and avoidance of treatment for patients who are colonized but not infected.

INTESTINAL PATHOGENIC STRAINS

Pathotypes Certain strains of *E. coli* are capable of causing diarrheal disease. **(Other important intestinal pathogens are discussed in Chaps. 138, 139, and 171–174.)** At least in the industrialized world, intestinal pathogenic *E. coli* strains are rarely encountered in the fecal flora of healthy persons, and instead appear to be essentially obligate pathogens. These strains have evolved a special ability to cause enteritis, enterocolitis, and colitis when ingested in sufficient quantities by a naïve host. At least five distinct pathotypes of intestinal pathogenic *E. coli* exist: (1) Shiga toxin–producing *E. coli* (STEC), which includes the subsets enterohemorrhagic *E. coli* (EHEC) and the recently evolved Shiga toxin–producing enteroaggregative *E. coli* (ST-EAEC); (2) enterotoxigenic *E. coli* (ETEC); (3) enteropathogenic *E. coli* (EPEC); (4) enteroinvasive *E. coli* (EIEC); and (5) enteroaggregative *E. coli* (EAEC). Diffusely adherent *E. coli* (DAEC) and cytodetaching *E. coli* are additional putative pathotypes. Lastly, a variant termed *adherent invasive E. coli* (AIEC) has been associated with Crohn disease (although a causal role remains unproven) but does not cause acute diarrheal disease.

Contaminated food and water are the primary transmission vehicles for ETEC, STEC/EHEC/ST-EAEC, EIEC, and EAEC, whereas person-to-person spread (direct or indirect) is the primary transmission route for EPEC and a secondary transmission route for STEC/EHEC/ST-EAEC. Gastric acidity confers some protection against infection; therefore, persons with decreased stomach acid levels are especially susceptible. Humans are the major reservoir for such strains (except for STEC/EHEC, for which bovines are the main carriers); host range appears to be dictated by species-specific attachment factors. Although some overlap exists, each pathotype possesses a distinctive combination of virulence traits that results in a pathotype-specific pathogenic mechanism (Table 166-3). With rare exceptions (e.g. DAEC), these strains are largely incapable of causing disease outside the intestinal tract. Whereas disease due to STEC/EHEC/ST-EAEC occurs primarily in high-income countries, disease due to ETEC, EPEC, and EIEC occurs primarily in low- and middle-income countries in Asia, Africa, and Latin America, and disease due to EAEC occurs globally.

SHIGA TOXIN–PRODUCING *E. COLI* STEC/EHEC/ST-EAEC strains are pathogens that can cause hemorrhagic colitis and the hemolytic-uremic syndrome (HUS). In contrast to other intestinal pathotypes, STEC/EHEC/ST-EAEC causes infections more frequently in high-income countries than in low and middle-income countries (LMICs). Several large outbreaks resulting from the consumption of fresh produce (e.g., lettuce, spinach, sprouts) and of undercooked ground beef have received significant media attention. In addition, a dramatic 2011 outbreak—mainly in Germany—involved an EAEC strain that acquired a Shiga toxin–encoding phage, resulting in a novel genotype, ST-EAEC (O104:H4). This strain was transmitted to the primary cases by sprouted fenugreek seeds, with subsequent human-to-human transmission, and resulted in >4000 cases and 54 deaths.

STEC strains are the fourth most commonly reported cause of bacterial diarrhea in the United States (after *Campylobacter*, *Salmonella*, and *Shigella*). O157:H7 is the most prominent serotype among STEC strains, but many other serogroups have been described, including O6, O26, O45, O55, O91, O103, O111, O113, O121, and O145. Domesticated ruminant animals, particularly cattle and young calves, serve as the major reservoir for STEC/EHEC. Ground or mechanically tenderized beef—the most common food source of STEC/EHEC strains—is often contaminated with intestinal bacteria from the source animals during processing. Furthermore, manure from cattle or other animals (including in the form of fertilizer) can contaminate produce (potatoes, lettuce, spinach, sprouts, fallen fruits, nuts, strawberries), and fecal runoff from manure can contaminate water systems. Dairy products and petting zoos are additional sources of infection.

It is estimated that $<10^2$ colony-forming units (CFU) of STEC/EHEC/ST-EAEC can cause disease. Therefore, not only can low levels of food or environmental contamination (e.g., in water swallowed while swimming) result in disease, but person-to-person transmission (e.g., at day-care centers and in institutions) is an important route for secondary spread. Laboratory-associated infections also occur. Illness due to this group of pathogens peaks in the summer months and occurs both as outbreaks and as sporadic cases.

For STEC/EHEC/ST-EAEC, production of Shiga toxin (Stx2a–g and/or Stx1a,c,d) is a critical factor for occurrence of clinical disease, as demonstrated by the 2011 ST-EAEC outbreak. The *stx* gene is present on chromosomally integrated prophages, and various combinations of *stx* types and subtypes can occur in a given strain. *Shigella dysenteriae* strains that produce the closely related Shiga toxin Stx can also cause hemorrhagic colitis and HUS. Stx2 (especially Stx2a,c,d) appears to be more important than Stx1 in the development of HUS. All Shiga toxins studied to date are multimers; they comprise one A subunit that is enzymatically active and five identical B subunits that mediate binding to globosyl ceramides, which are membrane-associated glycolipids expressed on certain host cells. As in ricin, the Stx A subunit cleaves an adenine from the host cell's 28S rRNA, thereby irreversibly inhibiting ribosomal function (i.e., protein synthesis) and potentially leading to apoptosis.

For full pathogenicity, STEC strains require additional properties such as acid tolerance and epithelial cell adherence. Most disease-causing isolates possess the chromosomal locus for enterocyte effacement (LEE). This pathogenicity island was first described in EPEC strains; it contains genes that mediate adherence to intestinal epithelial cells and a system that subverts host cells by the translocation of bacterial proteins (type III secretion system). EHEC strains make up the subgroup of STEC strains that possess stx_1 and/or stx_2, as well as LEE. By contrast, the 2011 ST-EAEC outbreak strain lacked LEE yet was associated with a higher proportion of patients developing HUS (22%) than the historic average for STEC/EHEC outbreaks (2–8%). Data support the essential role of the 2011 outbreak strain's EAEC-associated virulence

factors (e.g., AAF/I fimbriae, serine proteases SigA, SepA) in adherence, increased inflammation, and disruption of the intestinal epithelial barrier, which in turn increased the systemic translocation of Stx2a.

After exposure to STEC/EHEC/ST-EAEC and a 3- to 4-day incubation period, colonization of the colon and perhaps the ileum results in symptoms. Colonic edema and an initial nonbloody secretory diarrhea may progress to the hallmark syndrome of grossly bloody diarrhea (identified by history or examination). Significant abdominal pain and fecal leukocytes are common (70% of cases), whereas fever is not; absence of fever can incorrectly lead to consideration of noninfectious conditions (e.g., intussusception and inflammatory or ischemic bowel disease). Occasionally, infections caused by *C. difficile*, *K. oxytoca* (see "*Klebsiella* Infections," below), *Campylobacter*, and *Salmonella* present in a similar fashion. STEC/EHEC disease is usually self-limited, lasting 5–10 days.

A feared complication of infection with STEC/EHEC strains is HUS, which occurs 2–14 days after diarrhea, most often in young children (estimated to occur in 15% of infected children <10 years of age) or elderly patients. It is estimated that in the United States >50% of all HUS cases—and 90% of HUS cases in children, which is a leading cause of acute renal failure in this latter population—are caused by STEC/EHEC. By contrast, with ST-EAEC infection, HUS occurs more commonly among nonelderly adults, especially young women. HUS is mediated by the systemic translocation of Shiga toxins. Erythrocytes may serve as carriers of Stx to endothelial cells located in the small vessels of the kidney and brain. The subsequent development of thrombotic microangiopathy (perhaps with direct toxin-mediated effects on various nonendothelial cells) commonly produces some combination of fever, hemolytic anemia (hematocrit <30%), thrombocytopenia (<150,000/mm^3), renal failure, and encephalopathy. Stx-mediated complement activation also plays a role in the development of HUS. Although with dialysis support the mortality rate of HUS is <10%, survivors often have persisting renal and neurologic dysfunction.

ENTEROTOXIGENIC *E. COLI* ETEC is a major cause of endemic diarrhea in low- and middle-income countries and is responsible for an estimated 800 million cases annually. After weaning, children in these locales commonly experience several episodes of ETEC infection during the first 3 years of life. The incidence of disease diminishes with age, a pattern that correlates with the development of mucosal immunity to colonization factors (i.e., adhesins).

In industrialized countries, ETEC is the most common agent of traveler's diarrhea, causing 25–75% of cases. The incidence of infection may be decreased by prudent avoidance of potentially contaminated fluids and foods, particularly items that are raw, insufficiently cooked, peeled, or unrefrigerated **(Chap. 130)**. ETEC infection is uncommon in the United States, but outbreaks secondary to consumption of food products imported from endemic areas have occurred. A large inoculum (10^6–10^8 CFU) is needed to produce disease, which usually develops after an incubation period of 12–72 h.

After adherence of ETEC to enterocytes via colonization factors (e.g., CFA/I, CS), disease is mediated, primarily by a heat-labile toxin (LT) and/or a heat-stable toxin (ST), leading to diarrheal disease. Disease is less severe with strains that produce only LT. Both LT and ST cause net fluid secretion via activation of adenylate cyclase and/or guanylate cyclase C (ST) in the jejunum and ileum. The result is watery diarrhea accompanied by cramps.

LT consists of an A and a pentameric B subunit and is structurally and functionally similar to cholera toxin. Strong binding of the B subunit to the GM_1 ganglioside on intestinal epithelial cells leads to the intracellular translocation of the A subunit, which functions as an ADP-ribosyltransferase. Mature ST is an 18- or 19-amino-acid secreted peptide that leads to increased intracellular concentrations of cGMP. Characteristically absent in ETEC-mediated disease are histopathologic changes within the small bowel; mucus, blood, and inflammatory cells in stool; and fever.

The disease spectrum of ETEC infection ranges from mild illness to a life-threatening, cholera-like syndrome. Although symptoms are usually self-limited (typically lasting for 3–5 days), infection may result in significant morbidity and mortality (>250,000 deaths annually, mostly from profound volume depletion) when access to health care or suitable rehydration fluids is limited and when small and/or undernourished children are affected.

ENTEROPATHOGENIC *E. COLI* EPEC causes disease primarily in young children, including neonates. The first *E. coli* pathotype recognized as an agent of diarrheal disease, EPEC was responsible for outbreaks of infantile diarrhea (including in hospital nurseries) in industrialized countries in the 1940s and 1950s. At present, EPEC infection is uncommon in high-income countries, but among infants in low- and middle-income countries, it is an important cause of diarrhea (both sporadic and epidemic), often accompanied by vomiting and fever. Breast-feeding diminishes the incidence of EPEC infection. Rapid person-to-person spread may occur.

Symptoms develop after colonization of the small bowel and a brief incubation period (1 or 2 days). Initial localized adherence to enterocytes via type IV bundle-forming pili leads to a characteristic effacement of microvilli, with the formation of cuplike, actin-rich pedestals mediated by factors in the LEE. Diarrhea production is a complex and regulated process in which host cell modulation by a type III secretion system plays an important role. Strains lacking bundle-forming pili have been categorized as atypical EPEC (aEPEC); increasing data support a role for these strains as intestinal pathogens in all age groups and among HIV-infected individuals. Diarrheal stool often contains mucus but not blood. Although EPEC diarrhea is usually self-limited (lasting 5–15 days), it may persist for weeks.

ENTEROINVASIVE *E. COLI* EIEC, a relatively uncommon (or perhaps underrecognized) cause of diarrhea, is rarely identified in the United States, although a few food-related outbreaks have been described. In low- and middle-income countries, sporadic disease is recognized infrequently in children and travelers.

EIEC shares many genetic and clinical features, as well as a common ancestor, with *Shigella*. Both are intracellular pathogens for which virulence is mediated by the presence of specific factors and by the loss or inactivation of other factors (antivirulence genes), which presumably occurred during these organisms' transition from an extracellular to an intracellular lifestyle.

Colonization and invasion of the colonic mucosa, followed by replication therein and cell-to-cell spread (in part via a type III secretion system), result in the development of inflammatory colitis. However, unlike *Shigella*, EIEC produces disease only with a large inoculum (10^8–10^{10} CFU) and is less virulent, typically causing only mild, self-limited (7–10 days), watery diarrhea. Onset generally follows an incubation period of 1–3 days. Occasionally, EIEC can cause a shigellosis-like (dysentery) syndrome characterized by fever, abdominal pain, tenesmus, and scant stool containing mucus, blood, and inflammatory cells.

ENTEROAGGREGATIVE AND DIFFUSELY ADHERENT *E. COLI* EAEC has been described primarily in low- and middle-income countries and in young children. However, recent studies indicate that it may also be a relatively common cause of diarrhea in all age groups in industrialized countries. EAEC has been recognized increasingly as an important cause of traveler's diarrhea. It is highly adapted to humans—the probable reservoir. A large inoculum is required for infection, which usually manifests as watery and sometimes persistent diarrhea in healthy but also malnourished or HIV-infected hosts.

In vitro, EAEC cells exhibit a diffuse or "stacked-brick" pattern of adherence to small-intestine epithelial cells. Virulence factors that probably are necessary for disease are regulated in large part by the transcriptional activator AggR. The pathogenesis of EAEC disease begins with intestinal adherence, which results from stimulation of epithelial mucus production and bacterial biofilm formation, the latter mediated by fimbriae and possibly the mucinase Pic and dispersin. Inflammation ensues, resulting in epithelial cell exfoliation and intestinal secretion, which is mediated by the enterotoxins Pet, EAST-1, ShET1, and HlyE.

An additional enteric pathotype, DAEC, is a heterogenous group associated with diarrheal disease, primarily in children 2–6 years of age in some LMICs, and may cause traveler's diarrhea. DAEC can also cause UTI. Diffuse adherence is observed on epithelial cells. The Afa/Dr adhesins may contribute to the pathogenesis of such infections.

Diagnosis Acute infectious diarrhea can be classified as noninflammatory or inflammatory; the latter is suggested by grossly bloody or mucoid stools or a positive test for fecal leukocytes, lactoferrin, or calprotectin **(Chap. 138)**. ETEC, EPEC, DAEC, and EAEC cause noninflammatory diarrhea. Identification of these agents can be achieved with commercial multiplex molecular panels (e.g., the BioFire FilmArray Gastrointestinal Panel can detect STEC, ETEC, EPEC, EAEC, and EIEC). However, organism identification is rarely needed because the associated diseases are self-limited. ETEC causes the majority and EAEC a minority of cases of noninflammatory traveler's diarrhea; here again, however, definitive diagnosis generally is not necessary for management (as discussed below). If diarrhea persists for >10 days despite treatment, *Giardia* or *Cryptosporidium* (or, in immunocompromised hosts, certain opportunistic pathogens) should be sought.

Because of the considerable public-health importance of STEC/EHEC/ST-EAEC infections, including the threat of HUS, the CDC now recommends that all patients with community-acquired diarrhea, whether inflammatory or not, be evaluated for these pathogens by simultaneous culture (to provide an isolate for strain typing and for outbreak detection and control) and detection of Shiga toxin or the corresponding genes. The rationale for testing all cases of community-acquired diarrhea, regardless of clinical features, is that bloody stool and fecal white blood cells (or lactoferrin) are not reliably present with STEC/EHEC/ST-EAEC infection. In addition, the use of both tests increases diagnostic sensitivity over that with either test alone.

O157 STEC/EHEC may be identified via culture by screening for *E. coli* strains that do not ferment sorbitol, with subsequent serotyping and testing for Shiga toxin. Selective or screening media are not available for culture-based detection of non-O157 STEC/EHEC/ST-EAEC strains. Detection of Shiga toxins or toxin genes via DNA-based, enzyme-linked immunosorbent, and cytotoxicity assays offers the advantages of rapidity and detection of non-O157 STEC/EHEC/ST-EAEC strains. Specimens positive for toxin but culture-negative for O157 should be forwarded to the local or state public-health laboratory for specialized testing.

TREATMENT

Intestinal *E. coli* Infections

The mainstay of treatment for all diarrheal syndromes is replacement of water and electrolytes. This measure is especially important for STEC/EHEC/ST-EAEC infection because appropriate volume expansion may protect against renal injury and improve outcome.

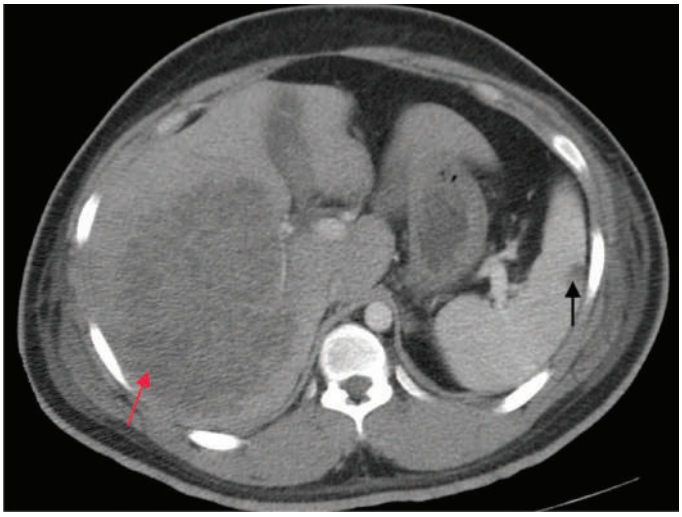
The use of prophylactic antibiotics to prevent traveler's diarrhea generally should be discouraged, especially in light of high rates of antimicrobial resistance. However, in selected patients (e.g., those who cannot afford a brief illness or are predisposed to infection), the use of rifaximin, which is nonabsorbable and is well tolerated, is reasonable.

When stools are free of mucus and blood, early patient-initiated treatment of traveler's diarrhea with a fluoroquinolone or azithromycin decreases the duration of illness, and the use of loperamide may halt symptoms within a few hours. Although dysentery caused by EIEC is self-limited, antimicrobial therapy hastens the resolution of symptoms, particularly in severe cases. By contrast, antimicrobial therapy for STEC/EHEC/ST-EAEC infection (the presence of which is suggested by grossly bloody diarrhea without fever) should be avoided because antibiotics may increase the incidence of HUS (possibly via increased production/release of Stx). In the treatment of HUS, plasmapheresis is not recommended and the use of eculizumab (inhibition of C5) should be limited to clinical trials.

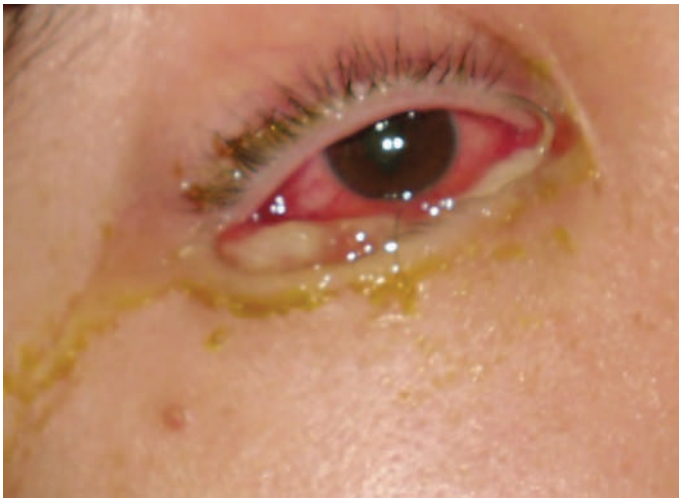
KLEBSIELLA INFECTIONS

K. pneumoniae is the most important *Klebsiella* species from a medical standpoint, causing community-acquired, LTCF-acquired, and nosocomial infections. *K. oxytoca* complex and *K.* (formerly *Enterobacter*) *aerogenes* are primarily pathogens in LTCFs and hospitals. *Klebsiella* species are broadly prevalent in the environment and colonize the mucosal surfaces of mammals. In healthy humans, the prevalence of *K. pneumoniae* colonization is 5–35% in the colon and 1–5% in the oropharynx; skin is usually colonized only transiently.

Most *Klebsiella* infections in Western countries are caused by "classic" *K. pneumoniae* (cKp) and occur in hospitals and LTCFs. The most common clinical syndromes due to cKp are pneumonia, UTI, abdominal infection, intravascular device infection, surgical site infection, soft tissue infection, and secondary bacteremia. cKp strains have gained notoriety because of their propensity for acquiring treatment-confounding antimicrobial resistance determinants and causing both localized and widespread outbreaks, such as with the global spread of cKp strains producing NDM-group MBLs. Clonal groups 11, 15, 101, 307, and 258, many members of which produce carbapenemases, are undergoing international dissemination. Transmission within or between institutions is common. *K. pneumoniae* is nearly fourfold more transmissible than *E. coli*, and, disconcertingly, carbapenemase-producing strains are associated with increased spread compared with carbapenem-susceptible strains.



In addition, hypervirulent *K. pneumoniae* (hvKp) strains that are phenotypically and clinically distinct from cKp have emerged recently, after their initial recognition in Taiwan in 1986. Although hvKp infections have occurred globally in all ethnic groups, most cases have been reported in individuals of Asian ethnicity residing in countries from the Asian Pacific Rim, but also in Asians living in other countries. Affected individuals often have diabetes mellitus. These demographics raise the possibility of a locale-specific distribution of the organism or an increased susceptibility of Asian hosts, especially those who are diabetic. In contrast to the usual health care–associated context for cKp infections in the West, hvKp can cause serious life- and organ-threatening infections in younger, healthy individuals from the community and can spread metastatically from the primary site of infection or present with multiple sites of infection. Of concern, recent reports from Asian countries have demonstrated that hvKp is responsible for an increasing number of health care–associated or hospital-acquired infections.



hvKp infection initially was characterized and distinguished from traditional infections caused by cKp strains by its (1) presentation as community-acquired monomicrobial pyogenic liver abscess **(Fig. 166-1, *top*)**, (2) occurrence in patients lacking a history of hepatobiliary disease, and (3) propensity for metastatic spread to distant sites. Subsequently, the hvKp pathotype has been recognized as the cause of extrahepatic abscesses and infections with or without liver involvement, including pneumonia; meningitis (in the absence of trauma or neurosurgery); endophthalmitis **(Fig. 166-1, *middle*)**; splenic, psoas, prostatic, epidural, and brain abscesses; and necrotizing fasciitis. Survivors often suffer catastrophic morbidity, such as vision loss and major neurologic sequelae. Most recently, clinicians are faced with an even greater challenge—the confluence of antimicrobial resistance determinants such as carbapenemase and ESBL genes possessed by cKp and the virulence factors possessed by hvKp on the same or coexisting plasmids. The result is the evolution of MDR and XDR hvKp.

K. pneumoniae subspecies *rhinoscleromatis* is the causative agent of rhinoscleroma, a granulomatous mucosal upper-respiratory infection that progresses slowly (over months or years) and causes necrosis and occasionally obstruction of the nasal passages. *K. pneumoniae* subspecies *ozaenae* has been implicated as a cause of chronic atrophic rhinitis and rarely of invasive disease in compromised hosts. *K.* (*Calymmatobacterium*) *granulomatis*, a sexually transmitted pathogen, is the causative agent of granuloma inguinale (donovanosis) that results in chronic genital ulcers **(Chap. 178)**. These *Klebsiella* pathotypes are usually isolated from patients in tropical climates and are genomically distinct from both cKp and hvKp.

INFECTIOUS SYNDROMES

Pneumonia Although cKp accounts for only a small proportion of cases of community-acquired pneumonia in Western countries

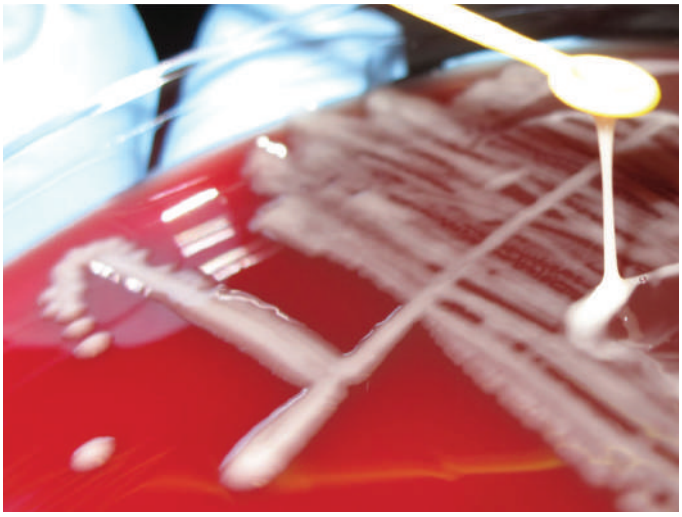


FIGURE 166-1 Hypervirulent pathotype of *K. pneumoniae* (hvKp). ***Top:*** Abdominal CT scan of a previously healthy 24-year-old Vietnamese man shows a primary liver abscess (*red arrow*) with metastatic spread to the spleen (*black arrow*). *(Courtesy of Drs. Chiu-Bin Hsaio and Diana Pomakova.)* ***Middle:*** A previously healthy 33-year-old Chinese man presented with endophthalmitis. *(AS Shon, RP Bajwa, TA Russo: Hypervirulent (hypermucoviscous) Klebsiella pneumoniae: A new and dangerous breed. Virulence 4:107, 2013.)* ***Bottom:*** A hypermucoviscous phenotype (which does not necessarily equate with a mucoid phenotype) has been associated with hvKp strains. A positive string test is shown. However, this test is not optimally sensitive or specific. Identification of all 5 of the biomarkers *iucA*, *iroB*, *peg-344*, *rmpA*, and *rmpA2* is presently the most accurate means to identify hvKp.

(Chap. 131), cKp and *K. oxytoca* are common causes of pneumonia among LTCF residents and hospitalized patients because of increased rates of oropharyngeal colonization with these organisms in such individuals. Mechanical ventilation is an important risk factor. In Asia and South Africa, community-acquired pneumonia due to hvKp is becoming increasingly common, rivaling *Streptococcus pneumoniae*, and may occur in younger patients with no underlying disease. *Klebsiella* is also a common cause of pneumonia in severely malnourished children in LMICs.

As in all pneumonias due to enteric GNB, typical manifestations include production of purulent sputum and evidence of airspace disease. Presentation with earlier, less extensive infection is now more common than is the classically described lobar infiltrate, bulging fissure, and currant-jelly sputum. Pulmonary infection due to hvKp that has spread metastatically (e.g., from a hepatic abscess) usually includes nodular bilateral densities, more commonly in the lower lobes. Pulmonary necrosis, pleural effusion, and empyema can occur with disease progression.

UTI cKp accounts for only 1–2% of UTI episodes among otherwise healthy adults but for 5–17% of episodes of UTI in patients with anatomic and functional abnormalities of the urinary tract, including indwelling urinary catheter use (complicated UTI). UTI due to hvKp presents more commonly as renal or prostatic abscess due to bacteremic spread than as ascending infection from the urethra and bladder.

Abdominal Infection cKp causes a spectrum of abdominal infections similar to that caused by *E. coli* but is less frequently isolated than *E. coli*. hvKp is a common cause of monomicrobial community-acquired pyogenic liver abscess; in the Asian Pacific Rim, it has been recovered with steadily increasing frequency over the past two decades, replacing *E. coli* as the most common pathogen causing this syndrome. hvKp also is increasingly described as a cause of spontaneous bacterial peritonitis and splenic abscess.

Other Infections When cKp and *K. oxytoca* cause cellulitis or soft tissue infection, the process most frequently involves devitalized tissue (e.g., decubitus and diabetic ulcers, burn wounds) and immunocompromised hosts. cKp and *K. oxytoca* cause some cases of surgical site infection and nosocomial sinusitis as well as occasional cases of osteomyelitis contiguous to soft tissue infection, nontropical myositis, and meningitis (during the neonatal period and after neurosurgery). By contrast, hvKp has become an important cause of community-acquired monomicrobial necrotizing fasciitis, meningitis, endophthalmitis (Fig. 166-1, *middle*), and abscesses within the brain, subdural space, and epidural space, particularly in the Asian Pacific Rim but also globally. Cytotoxin-producing strains of *K. oxytoca* have been implicated as a cause of non–*C. difficile* antibiotic-associated hemorrhagic colitis.

Bacteremia *Klebsiella* infection at any site can produce bacteremia. Infections of the urinary tract, respiratory tract, and abdomen (especially hepatic abscess) each account for 15–30% as the source of *Klebsiella* bacteremia. Intravascular device–related infections account for another 5–15% of episodes, and surgical site and miscellaneous infections account for the rest. *Klebsiella* is an occasional cause of sepsis in neonates and of bacteremia in neutropenic patients. However, like other enteric GNB, *Klebsiella* rarely causes endocarditis or other endovascular infections, although endocarditis can involve extensive valvular destruction when it occurs.

DIAGNOSIS

Klebsiellae are readily isolated and identified in the laboratory. These organisms usually ferment lactose, although the subspecies *rhinoscleromatis* and *ozaenae* are nonfermenters and are indole-negative. hvKp frequently possesses a hypermucoviscous phenotype (Fig. 166-1, ***bottom***), although the sensitivity and specificity of the string test are less than optimal. Identification of all 5 of the biomarkers *iucA*, *iroB*, *peg-344*, *rmpA*, and *rmpA2* is presently the most accurate means to identify hvKp in both antimicrobial sensitive and MDR isolates, although currently, this test is not routinely available.

TREATMENT

Klebsiella Infections

K. (formerly *Enterobacter*) *aerogenes* has a similar resistance profile to *E. cloacae*, the treatment of which is discussed below. *K. pneumoniae* and *K. oxytoca* have similar antibiotic resistance profiles; both are intrinsically resistant to ampicillin. The prevalence of acquired resistance in *K. pneumoniae* and *K. oxytoca* is generally >30% for amoxicillin-clavulanate, ampicillin-sulbactam, nitrofurantoin, and TMP-SMX and ~10–20% for fluoroquinolones, piperacillin-tazobactam, fosfomycin, and omadacycline.

USNHSN data from 2015–2017 identified 25% of *K. pneumoniae* as ESBL-producing strains; higher rates are reported from Asia, South America, and Africa. Although prevalence of ESBL-producing strains is greatest in LTCF, isolates of cKp that produce CTX-M ESBLs are increasingly described from the community. Oral treatment for infection due to ESBL-producing strains is more challenging with *Klebsiella* than with *E. coli* because of the comparatively poor activity of nitrofurantoin, the lesser activity of fosfomycin (~80%), and limited available data regarding pivmecillinam (>80%) and omadacycline (75–100% susceptible for ESBL-producing isolates, but 60% if resistant to tetracycline).

Predictably, the ESBL-driven use of carbapenems has selected for strains of cKp and *K. oxytoca* that produce carbapenemases (8–18% based on the study and locale, 8.6% prevalence from 2015–2017 USNHSN data). Treatment can be problematic for such organisms, especially those producing MBLs (e.g., NDM), for which the highest prevalences are in cKp and *K. oxytoca* isolates from Eastern Europe and Asia and among health care–associated isolates. Likewise, hvKp strains from Asia are also increasingly reported to produce ESBLs and carbapenemases.

Treatment options for carbapenem-resistant *Klebsiella* are similar to those described for *E. coli* and depend on the class of carbapenemase produced (see "Carbapenemase," above); consultation with infectious disease experts is advised. For carbapenem-susceptible strains, the most predictably active agents include carbapenems, amikacin, ceftazidime-avibactam, ceftolozane-tazobactam, polymyxins, cefiderocol, tigecycline, eravacycline, and omadacycline. Empirical treatment decisions for the critically ill patient should be dictated by local susceptibility patterns, patient-specific risk factors, and the site of infection.

PROTEUS INFECTIONS

Proteus species are part of the colonic flora of a wide variety of mammals, birds, fish, and reptiles. The ability of these GNB to generate histamine from contaminated fish has implicated them in the pathogenesis of scombroid (fish) poisoning (Chap. 471).

P. mirabilis causes 90% of *Proteus* infections, which occur in the community, LTCFs, and hospitals. By contrast, *Proteus vulgaris* and *Proteus penneri* are associated primarily with infections acquired in LTCFs or hospitals. Correspondingly, *P. mirabilis* colonizes healthy humans (up to 50%), whereas *P. vulgaris* and *P. penneri* are isolated primarily from individuals with underlying disease. By far the most common site of *Proteus* infection is the urinary tract, where the principal known urovirulence factors of *Proteus* include adhesins, flagella, IgA-IgG protease, iron acquisition systems, and urease. *Proteus* less commonly causes infection at a variety of other extraintestinal sites.

INFECTIOUS SYNDROMES

UTI *P. mirabilis* causes only 1–2% of UTIs in healthy women, and *Proteus* species collectively cause only 5% of hospital-acquired UTIs. However, *Proteus* is responsible for 10–15% of cases of complicated UTI, primarily those associated with catheterization; indeed, *Proteus* accounts for 20–45% of urine isolates from chronically catheterized patients. This high prevalence is due in part to bacterial production of urease, which hydrolyzes urea to ammonia and results in alkalization of the urine. In alkaline urine, organic and inorganic compounds precipitate, contributing to the formation of struvite and carbonate–apatite crystals, biofilms on catheters, and/or frank calculi. *Proteus* becomes associated with the stones and biofilms; thereafter, it usually cannot be eradicated without removal of the stones or catheter. Over time, staghorn calculi may form within the renal pelvis and lead to obstruction and renal failure. Although biologically plausible, clinical support is lacking for the concept that urine samples exhibiting unexplained alkalinity should be cultured, and that isolation of a *Proteus* species (or other urea-splitting organism) should prompt consideration of an evaluation for urolithiasis.

Other Infections *Proteus* occasionally causes pneumonia (primarily in LTCF residents or hospitalized patients), nosocomial sinusitis, intraabdominal abscesses, biliary tract infection, surgical site infection, soft tissue infection (especially decubitus and diabetic ulcers), and osteomyelitis (primarily contiguous); in rare cases, it causes nontropical myositis. In addition, *Proteus* uncommonly causes neonatal meningitis, with the umbilicus frequently implicated as the source; this disease is often complicated by development of a cerebral abscess. Otogenic brain abscess also occurs.

Bacteremia Most episodes of *Proteus* bacteremia originate from the urinary tract, although intravascular devices and any of the less common sites of *Proteus* infection also are potential sources. Endovascular infection is rare. *Proteus* species are occasional agents of sepsis in neonates and of bacteremia in neutropenic patients.

DIAGNOSIS

Proteus is readily isolated and identified in the laboratory. Most strains are lactose-negative, produce H_2S, and demonstrate characteristic swarming motility and distinct odor on agar plates. *P. mirabilis* and *P. penneri* are indole-negative, whereas *P. vulgaris* is indole-positive. The inability to produce ornithine decarboxylase differentiates *P. penneri* from *P. mirabilis*.

TREATMENT

Proteus Infections

Intrinsic resistance occurs in all *Proteus* spp. to nitrofurantoin, polymyxins, imipenem, and the tetracycline derivatives (e.g., tigecycline, eravacycline, omadacycline) and, in *P. vulgaris* and *P. penneri*, also to ampicillin and the first- and second-generation cephalosporins. Acquired resistance (% of isolates) occurs in *P. mirabilis* to ampicillin (15–65%), and in *Proteus* spp. to fluoroquinolones (10–55%), fosfomycin (7–22%), and TMP-SMX (20–50%). In *P. mirabilis*, ampicillin-sulbactam is more active than ampicillin, with resistance rates of 6–18%, but the prevalence of ESBL production (which confers ampicillin-sulbactam resistance) is increasing in the United States (5–10%) and Asia (up to 60%). Isolates of *P. mirabilis* that produce CTX-M ESBLs have been recovered from ambulatory patients with no recent health care contact (see the section on the treatment of extraintestinal *E. coli* infections for treatment considerations). Acquired carbapenem resistance remains relatively infrequent (<10%). However, production of MBLs (e.g., NDM) limits treatment options due to the inherent resistance of *Proteus* spp. to polymyxins and tetracycline derivatives (see "Carbapenemase," above). For critically ill patients, agents with excellent activity overall against *Proteus* spp. (90–100% of isolates susceptible) include carbapenems (excepting imipenem), amikacin, piperacillin-tazobactam, aztreonam, cefepime, ceftazidime-avibactam, ceftolozane-tazobactam.

ENTEROBACTER AND *CRONOBACTER* INFECTIONS

The *E. cloacae* complex is responsible for most *Enterobacter* infections, whereas *Cronobacter sakazakii* (formerly *Enterobacter sakazakii*), *Cronobacter malonaticus*, *E. cancerogenus*, E. *asburiae*, *E. hormaechei*, *E. kobei*, *E. ludwigii*, and *E. gergoviae* are less commonly isolated (<1% for each). *Enterobacter bugandensis* has been recently described as an agent of

sepsis in neonates and was isolated from the International Space Station. *Enterobacter* spp. cause primarily health care–related infections. The organisms are widely prevalent in foods, environmental sources (including equipment at health care facilities), and a variety of animals.

Colonization with these organisms is uncommon among healthy humans but increases significantly with LTCF residence or hospitalization. Although colonization is an important prelude to infection, direct introduction via IV lines (e.g., contaminated IV fluids or pressure monitors) or contaminated non-FDA-approved stem cell products also occurs. Extensive antibiotic resistance has developed in *Enterobacter* spp. and probably has contributed to these organisms' emergence as prominent nosocomial pathogens. Risk factors for *Enterobacter* infection include prior antibiotic treatment, comorbid disease, and ICU residency. *Enterobacter* spp. causes a spectrum of extraintestinal infections similar to those described for other GNB.

INFECTIOUS SYNDROMES

The most commonly encountered syndromes include pneumonia, UTI (particularly catheter-associated), intravascular device–related infection, surgical site infection, and abdominal infection (primarily postoperative or related to devices such as biliary stents). Nosocomial sinusitis, meningitis related to neurosurgical procedures (including use of intracranial pressure monitors), osteomyelitis, and endophthalmitis after eye surgery are less frequent. Neonates (particularly if low-birth-weight) are at risk for *C. sakazakii* infection, including neonatal bacteremia, necrotizing enterocolitis, and meningitis (which is often complicated by brain abscess or ventriculitis). Contaminated powdered infant formula has been implicated as a source for such neonatal infections. The WHO recommends that, to reduce the initial number of bacteria, powdered infant formula should be reconstituted with hot water (>70°C) and, to limit replication of residual bacteria, the reconstituted formula should be stored at <5°C or its storage time minimized.

Enterobacter bacteremia can result from primary infection at any anatomic site. In bacteremia of unclear origin, particularly in an outbreak setting, sources for consideration should include contaminated IV fluids or medications, blood components or plasma derivatives, catheter-flushing fluids, pressure monitors, and dialysis equipment. *Enterobacter* can also cause bacteremia in neutropenic patients. *Enterobacter* endocarditis is rare, occurring primarily in association with IV drug use or prosthetic valves.

DIAGNOSIS

Enterobacter is readily isolated and identified in the laboratory. Most strains are lactose-positive and indole-negative.

TREATMENT

Enterobacter Infections

E. cloacae is intrinsically resistant to ampicillin, ampicillin-sulbactam, ampicillin-clavulanate, the first-generation cephalosporins, and the cephamycins. The prevalence of acquired resistance has ranged from 15 to 40% for piperacillin-tazobactam, 5 to 23% for polymyxins, 15 to 17% for fosfomycin, 15 to 30% for TMP-SMX, and 5 to 20% for fluoroquinolones and is ~10% for omadacycline (53% if tetracycline resistant). USNHSN data from 2015–2017 identified at least 9% of *E. cloacae* isolates as presumptively ESBL-producing, based on cefepime resistance. The prevalence of ESBLs in *E. cloacae* outside of the United States is 20–50%. The use of third-generation cephalosporins can induce or select for stable derepression of AmpC β-lactamase. Because resistance may emerge during therapy (in one study, this phenomenon was documented in 20% of clinical isolates), these agents should be avoided in the treatment of severe *Enterobacter* infection.

Cefepime is stable to hydrolysis by AmpC β-lactamases; thus, it is a suitable option for treatment of *Enterobacter* infections so long as ESBL is not co-produced. Overall, resistance prevalence generally ranges from 10 to 25% for cefepime and 25 to 50% for aztreonam and the third-generation cephalosporins. Carbapenem resistance remains relatively uncommon (USNHSN data from 2015–2017 identified a 5% prevalence) and is more commonly associated with a combination of increased AmpC expression and decreased permeability due to porin mutations rather than carbapenemase production, although acquisition of carbapenemase genes is increasing (see "Carbapenemase," above). Uncertainty exists on the optimal treatment for non-CP-CR-*Enterobacter* spp. Fortunately, overall, the percentage of susceptibility is high (90–99%) for carbapenems, amikacin, ceftazidime-avibactam, cefiderocol, tigecycline, eravacycline, and omadacycline (the latter three for tetracycline-susceptible isolates). Once susceptibility data for a patient's isolate become available, de-escalation of the antimicrobial regimen is advisable whenever possible.

SERRATIA INFECTIONS

S. marcescens causes >90%, and *Serratia liquefaciens* complex <10%, of *Serratia* infections. Serratiae are found primarily in the environment (including in health care institutions), particularly in moist settings. Serratiae have been isolated from a variety of animals, insects, and plants, but only infrequently from healthy humans. In LTCFs and hospitals, reservoirs for the organisms include the hands and fingernails of health care personnel, food, milk (on neonatal units), sinks, medical equipment or devices, IV solutions or parenteral medications (particularly those generated by compounding pharmacies), prefilled syringes and multiple-access medication vials (e.g., for heparin, propofol, saline), blood products (e.g., platelets), hand soaps and lotions, irrigation solutions, and even disinfectants such as chlorhexidine.

Infection results from either direct inoculation (e.g., via contaminated injected substances [IV fluids, medications, or recreational drugs] or snake bite) or colonization (primarily of the respiratory tract). Sporadic infection is most common, but outbreaks (often involving MDR strains in adult and neonatal ICUs) also occur. Hygiene, medication-compounding standards, sterile technique, and infection control programs are critical measures to prevent infection.

The spectrum of extraintestinal infections caused by *Serratia* is similar to that for other GNB. *Serratia* species are usually considered to cause mainly health care–associated infections; they account for 1–3% of hospital-acquired infections. However, population-based laboratory surveillance studies in Canada and Australia have demonstrated that community-acquired *Serratia* infections occur more commonly than was previously appreciated, and case reports have documented serious infection in otherwise healthy hosts. *Serratia* also is one of the pathogens associated with chronic granulomatous disease.

INFECTIOUS SYNDROMES

The most common primary sites of *Serratia* infection are the respiratory and genitourinary tracts, intravascular devices, the eye (contact lens–associated keratitis and other ocular infections), surgical wounds, and the bloodstream (from contaminated infusions), although most episodes of *Serratia* bacteremia arise from one of the listed focal infections rather than contaminated infusate. Less common syndromes are soft tissue infections (including myositis, fasciitis, mastitis), osteomyelitis, abdominal and biliary tract infections (usually postprocedural), and septic arthritis (primarily from intraarticular injections). Serratiae are uncommon causes of neonatal meningitis; postsurgical meningitis, endophthalmitis, or breast implant infection; and bacteremia in neutropenic patients. Endocarditis is rare, occurring most commonly in IV drug users.

DIAGNOSIS

Serratiae are readily cultured and identified by the laboratory and are usually lactose- and indole-negative. The red pigmentation of some *S. marcescens* strains and *Serratia rubidaea* can produce distinctive clinical findings (e.g., pink breast milk or hypopyon; pseudohemoptysis).

TREATMENT

Serratia Infections

Most *Serratia* strains (>80%) are intrinsically resistant to ampicillin, amoxicillin-clavulanate, ampicillin-sulbactam, first- and

second-generation cephalosporins, cephamycins, nitrofurantoin, and polymyxins; likewise, tetracycline derivatives are poorly active. By contrast, fluoroquinolones, TMP-SMX, piperacillin-tazobactam, fosfomycin, and omadacycline are active against 85–95% of U.S. and European isolates, including those resistant to tetracycline. Both in the United States and globally, the prevalence of ESBL-producing isolates is generally low (<10%), but rates of 20–30% have been reported in Asia and Latin America. Induction or selection of variants with stable de-repression of chromosomal AmpC β-lactamases during therapy with third-generation cephalosporins is considered to be uncommon. Resistance prevalence generally ranges from 10 to 20% for aztreonam and the third-generation cephalosporins. Acquisition of carbapenemase-encoding genes is uncommon but increasing. Production of MBL (e.g., NDM) limits treatment options due to *Serratia*'s predictable resistance to polymyxins and tetracycline derivatives (see "Carbapenemase," above). For critically ill patients, the most active agents overall (>90% susceptible) are carbapenems, piperacillin-tazobactam, cefepime, amikacin, ceftazidime-avibactam, and ceftolozane-tazobactam.

CITROBACTER INFECTIONS

C. freundii and *Citrobacter koseri* cause most human *Citrobacter* infections, which are epidemiologically and clinically similar to *Enterobacter* infections. *Citrobacter* species are commonly present in water, food, soil, and certain animals. Colonization with these organisms is uncommon among healthy humans but increases significantly with LTCF residence or hospitalization. *Citrobacter* species account for 1–2% of nosocomial infections. The affected hosts are usually immunocompromised and/or have comorbid disease or disruption of skin or mucosal barriers. Infection from treatment with contaminated, non-FDA-approved stem cell products has been described. *Citrobacter* causes extraintestinal infections like those described for other GNB.

INFECTIOUS SYNDROMES

The urinary tract accounts for 40–50% of *Citrobacter* infections. Less commonly involved sites include the biliary tree (particularly with stones or obstruction), the respiratory tract, surgical sites, soft tissue (e.g., decubitus ulcers), the peritoneum, and intravascular devices. Osteomyelitis (usually from a contiguous focus), central nervous system infection in adults (from neurosurgical or other types of meningeal disruption), and myositis occur rarely. *Citrobacter* (primarily *C. koseri*) also causes 1–2% of neonatal meningitis cases, of which 50–80% are complicated by brain abscess. Further, case reports in adults suggest that *C. koseri* infection has a predilection for abscess formation. *Citrobacter* bacteremia is most often due to UTI, biliary/abdominal infection, or intravascular device infection, and occurs in some neutropenic patients. Endocarditis and other endovascular infections are rare.

DIAGNOSIS

Citrobacter species are readily isolated and identified; 35–50% of isolates are lactose-positive, and 100% are oxidase-negative. *C. freundii* is indole-negative, whereas *C. koseri* is indole-positive.

TREATMENT

Citrobacter Infections

C. freundii is more antibiotic-resistant than is *C. koseri*. Most *C. freundii* isolates are intrinsically resistant to ampicillin, ampicillin-sulbactam, amoxicillin-clavulanate, first-generation cephalosporins, and cephamycins. *C. koseri* exhibits intrinsic resistance to ampicillin and ampicillin-sulbactam. Overall, the prevalence of acquired resistance generally ranges from 15 to 35% for third-generation cephalosporins, piperacillin-tazobactam, fluoroquinolones, and TMP-SMX and is ~10% for nitrofurantoin and omadacycline (but 39% for omadacycline if tetracycline-resistant). The prevalence of ESBL production ranges from 5 to 30%. The use of third-generation cephalosporins may result in the induction or selection of variants with stable de-repression of chromosomal AmpC β-lactamases during therapy. Presently, <10% of isolates have acquired carbapenemases (see "Carbapenemase," above). Carbapenems, amikacin, fosfomycin, polymyxins, cefepime, ceftolozane-tazobactam, ceftazidime-avibactam, cefiderocol, tigecycline, eravacycline, and omadacycline (the latter three if tetracycline-susceptible) are the most active agents against *Citrobacter* isolates (>90% susceptible).

MORGANELLA AND *PROVIDENCIA* INFECTIONS

M. morganii, *Providencia stuartii*, and (less frequently) *Providencia rettgeri* are the members of their respective genera that cause systemic human infections. *P. alcalifaciens* has been implicated as a cause of food-borne gastroenteritis. These organisms' epidemiologic associations, pathogenic properties, and clinical manifestations resemble those of *Proteus* species. *Morganella* and *Providencia* occur more commonly among LTCF residents than among hospitalized patients, largely resulting from chronic urinary catheter use. Because of these organisms' intrinsic resistance to polymyxins and tigecycline, they may become more common in settings with extensive use of these agents.

INFECTIOUS SYNDROMES

These species are primarily urinary tract pathogens, causing UTIs that are most often associated with long-term (>30-day) catheterization. Such infections commonly lead to biofilm formation and catheter encrustation (sometimes causing catheter obstruction) or the development of struvite bladder or renal stones (sometimes causing renal obstruction, abscess, and extrarenal extension, and serving as foci for relapse). They can cause purple urine ("purple bag syndrome"), as can *P. mirabilis*, *K. pneumoniae*, *E. coli*, and *P. aeruginosa*. *Morganella* is also commonly isolated from snakebite infection.

Other, less common infectious syndromes due to *Morganella* and *Providencia* include surgical site infection, soft tissue infection (primarily involving decubitus and diabetic ulcers), burn site infection, pneumonia (particularly ventilator-associated), intravascular device infection, and intraabdominal infection. Rarely, the other extraintestinal infections described for GNB also occur. Bacteremia is uncommon; when it does occur, any infected site can serve as the source, but the urinary tract accounts for most cases, followed by surgical site, soft tissue, and hepatobiliary infections.

DIAGNOSIS

M. morganii and *Providencia* are readily isolated and identified. Nearly all isolates are lactose-negative and indole-positive.

TREATMENT

Morganella and *Providencia* Infections

Morganella and *Providencia* are intrinsically resistant to ampicillin, ampicillin-clavulanate, ampicillin-sulbactam, first-generation cephalosporins, nitrofurantoin, tetracyclines and derivatives (e.g., tigecycline), imipenem (but not the other carbapenems), and the polymyxins. *P. stuartii* additionally exhibits intrinsic resistance to gentamicin and tobramycin, as does *M. morganii* to second-generation cephalosporins. Fosfomycin is poorly active (>50% resistance). The prevalence of resistance generally ranges from 10 to 30% for the third-generation cephalosporins, from 10 to 40% for fluoroquinolones, and from 20 to 40% for TMP-SMX; the prevalence is more widely variable for piperacillin-tazobactam. The prevalence of ESBL production is generally <10%. The prevalence of acquired carbapenemase production is <10%. Production of MBL (e.g., NDM) limits treatment options due to the inherent resistance of *Proteeae* to polymyxins and tetracycline derivatives (see "Carbapenemase," above). Overall, the most active agents (>90% of isolates susceptible) are carbapenems (excepting imipenem), amikacin, cefepime, ceftazidime-avibactam, ceftolozane-tazobactam, and cefiderocol. Removal of a colonized urinary catheter or stone is critical for eradication of UTI.

EDWARDSIELLA INFECTIONS

E. tarda is the only member of the genus *Edwardsiella* that is associated with human disease. This organism is found predominantly in freshwater and marine environments and in the associated aquatic animal species. Human acquisition occurs primarily from interaction with these reservoirs or ingestion of raw or inadequately cooked aquatic animals. *E. tarda* infection is rare in the United States, where acquisition occurs mainly along the Gulf of Mexico; recently reported cases are mostly from Asia. This pathogen shares clinical features with *Salmonella* species (as an intestinal pathogen; **Chap. 171**), *Vibrio vulnificus* (as an extraintestinal pathogen; **Chap. 173**), and *Aeromonas hydrophila* (as both an intestinal and an extraintestinal pathogen; **Chap. 173**).

INFECTIOUS SYNDROMES

Gastroenteritis is the predominant *Edwardsiella*-associated infectious syndrome (50–80% of reported cases). Self-limiting watery diarrhea is most common, but severe colitis also occurs. The most common extraintestinal infection is wound infection due to direct inoculation, which is often associated with brackish or freshwater injuries, snakebites, or fish-related trauma. A case of pneumonia occurred after a near-drowning incident. Cholecystitis, cholangitis, and hepatic abscess may be due to ascending infection via the biliary tree. Other infectious syndromes result from invasion of the gastrointestinal tract and subsequent bacteremia. A primary bacteremic syndrome, sometimes complicated by meningitis, has a 40% case–fatality rate; hematogenous seeding may result in hepatic and intra- and extraperitoneal abscesses, endocarditis, mycotic aneurysm, septic arthritis, osteomyelitis, necrotizing fasciitis, and empyema. Most hosts who develop systemic *Edwardsiella* infection have significant comorbidities (e.g., hepatobiliary disease, iron overload, cancer, or diabetes mellitus).

DIAGNOSIS

Although *E. tarda* can readily be isolated and identified, most laboratories do not routinely screen for or identify it in stool samples. Production of hydrogen sulfide is a characteristic biochemical property.

TREATMENT

Edwardsiella Infections

E. tarda is susceptible to most antimicrobial agents appropriate for use against GNB. Gastroenteritis is generally self-limiting, but treatment with a fluoroquinolone may hasten resolution. In the setting of severe sepsis, fluoroquinolones, third- and fourth-generation cephalosporins, carbapenems, and amikacin—either alone or in combination—are the safest choices pending susceptibility data.

INFECTIONS CAUSED BY MISCELLANEOUS GENERA

Other gram-negative organisms such as *Hafnia*, *Kluyvera*, *Cedecea*, *Pantoea*, *Ewingella*, *Leclercia*, *Raoultella*, and *Photorhabdus* spp. are occasionally isolated from diverse clinical specimens, including blood, sputum, urine, cerebrospinal fluid, joint fluid, bile, and wounds. Such organisms cause infection predominantly in compromised hosts or in association with an invasive procedure or foreign body. Cephalosporinases from *Kluyvera* have been implicated as the progenitors of CTX-M ESBLs. *Kluyvera* and *Raoultella* may produce carbapenemases.

167 *Acinetobacter* Infections

Rossana Rosa, Christine A. Vu

DEFINITION

Acinetobacter species were first described in 1911 and named *Micrococcus calcoaceticus*. Thereafter, the genus was renamed multiple times; since 1950, it has been known as *Acinetobacter*. *Acinetobacter* species are gram-negative, oxidase-negative, nonmotile, nonfermenting coccobacilli that are easily recovered on standard culture media. Differentiation among *Acinetobacter* species on the basis of phenotypic characteristics alone is very difficult. Molecular-based methods such as matrix-assisted laser desorption–ionization–time-of-flight mass spectrometry (MALDI-TOF-MS) and quantitative real-time polymerase chain reaction (PCR) are usually necessary to identify *Acinetobacter baumannii*, the most clinically relevant species of the genus.

ETIOLOGY AND EPIDEMIOLOGY

Acinetobacter species are naturally encountered in water and soil and have also been recovered from fruits and vegetables. In humans, *Acinetobacter* can be found on the skin and in the respiratory and gastrointestinal tracts. *A. baumannii* is capable of surviving environmental desiccation for weeks; this characteristic is important from an infection-control perspective as it allows this organism to persist in the hospital environment and on equipment.

Acinetobacter was historically considered a pathogen of hot and humid climates. In recent years, however, hospital outbreaks caused by *A. baumannii* have been reported worldwide, even in temperate climates. In the United States, the Centers for Disease Control and Prevention (CDC) estimates that 12,000 *Acinetobacter* infections occur every year, 7300 of which are caused by multidrug-resistant strains, with 500 attributable deaths. The increase in the number of infections with *A. baumannii* is suspected to be due to the rapid spread of certain genetically distinct lineages; of the three international clonal lineages (ICLs), ICL I and ICL II are multidrug resistant. The predominance of these lineages remains unexplained, although it has been proposed that this population structure is the result of two waves of expansion.

The first wave followed a bottleneck (possibly linked to a restricted ecologic niche) that occurred in the distant past. The second wave is ongoing and is being driven by the rapid expansion of a limited number of multidrug-resistant clones. The COVID-19 pandemic resulted in a setback to the efforts to control the spread of multidrug-resistant organisms, with significant increases in the rates of infections with carbapenem-resistant *Acinetobacter* reported worldwide.

Analysis of the *A. baumannii* pangenome (the sum of the core and dispensable genomes) has shown that its organization is characterized by a small core genome and a large accessory or disposable genome. This organization reflects *A. baumannii's* high plasticity, which enables it to acquire exogenous genetic material. With few exceptions, gene functions associated with virulence are found in the core genome; this observation suggests a limited role for the acquisition of new virulence traits in the recent nosocomial expansion of *A. baumannii* clones. Genes associated with resistance to antimicrobial agents are found in both the species core genome and the accessory genome. In the accessory genome, these genes have been found in alien islands, often flanked by integrases, transposases, or insertion sequences. This pattern suggests possible acquisition by horizontal gene transfer from other *Acinetobacter* strains or even from different bacterial species present in the immediate environment. Acquisition of these antimicrobial resistance genes is hypothesized to have led to the recent rapid expansion of highly homogeneous clonal lineages, whose main difference from nonclonal *A. baumannii* appears to be their antimicrobial resistance.

Health Care–Associated Infections Infections caused by *A. baumannii* occur frequently among patients admitted to intensive care units (ICUs). Risk factors for colonization and infection with this pathogen include nursing home residence, prolonged ICU stay, central venous catheterization, tracheostomy, mechanical ventilation, enteral feedings, and treatment with third-generation cephalosporins, fluoroquinolones, and carbapenems. Acquisition of carbapenem-resistant *A. baumannii* is most common among patients exposed to carbapenems. Spread of *A. baumannii* across different regions is facilitated by the movement of patients between health care systems and throughout the continuum of health care. Within the hospital, environmental spread of *A. baumannii* occurs as a result of inappropriate hand hygiene among workers providing health care for infected or colonized patients and the contamination of hospital equipment, such as respiratory therapy and ventilation equipment. The air surrounding the patient may also play a role in environmental colonization with *A. baumannii*, especially in inpatient areas without physical barriers between patients and with an inadequate number of air exchanges.

A. baumannii strains identified during hospital outbreaks are typically resistant to more antibiotic classes than strains from the community. The prevalence of colonization with *A. baumannii* at the time of admission or during a stay in a long-term acute-care hospital (LTACH) or nursing home is variable and depends on regional flora. Outbreaks of *A. baumannii* in acute-care hospitals and LTACHs that "share" patients have been described in Ohio, Michigan, Illinois, and Indiana.

Community-Acquired Infections Community-acquired infections caused by *Acinetobacter* have been described in Australia and Asia. Few cases have been reported in regions with a temperate climate, and even those few cases have taken place during warm and humid months. Risk factors for community-acquired pneumonia due to this organism include a history of alcohol abuse, diabetes mellitus, smoking, and chronic lung disease.

War Zone–Associated Infections Infections caused by *Acinetobacter* in war zones include skin and soft tissue infections associated with traumatic injuries and bloodstream infections. Outbreak investigations of *A. baumannii* infections among military personnel returning from Iraq and Afghanistan suggested the acquisition of *A. baumannii* in field hospitals rather than colonization of the skin before an injury. This view is supported by the recovery of *A. baumannii* isolates with similar genetic characteristics from inanimate surfaces in field hospitals and from patients.

Disaster Medicine *A. baumannii* is linked to infections among victims of trauma during tsunamis, earthquakes, and terrorist attacks. The types of infections most frequently observed in these settings are soft tissue injuries, but bloodstream infections and pneumonia have also been reported. In addition, outbreaks of *A. baumannii* infection in ICUs caring for disaster victims have been described.

PATHOGENESIS

Mechanisms of pathogenesis and virulence in *Acinetobacter* species have not been fully elucidated. However, *A. baumannii* seems to have greater virulence potential than other *Acinetobacter* species, as evidenced by its ability to grow at 37°C and to resist uptake by macrophages.

Initial *A. baumannii* colonization of the host and the environment is facilitated by the organism's ability to adhere to surfaces and human cells and to create biofilms. The ability to form a biofilm is phenotypically associated with exopolysaccharide production and pilus formation. A quorum-sensing molecule encoded by the *abaI* autoinducer synthase gene has been implicated in *A. baumannii* biofilm formation on abiotic surfaces. Outer-membrane porins appear to mediate cell apoptosis. *A. baumannii* can survive in harsh environments within the host and on inanimate surfaces by modifying the structure of its lipid A, with a consequent decrease in susceptibility to antibiotics and antimicrobial peptides and an increase in survival upon desiccation.

Acinetobacter species produce an extracellular capsule that protects the bacteria from external threats, including complement-mediated killing. Studies of mouse models showed that *Acinetobacter* species can increase capsule production in the presence of subinhibitory levels of antibiotic—an ability that leads to increased resistance to complement-mediated killing and a hypervirulent phenotype.

Phospholipase C and phospholipase D have been identified as virulence factors in *A. baumannii*. These enzymes exert cytotoxic effects on epithelial cells and facilitate their invasion.

Iron-acquisition systems are also important virulence mechanisms in *A. baumannii*. Through secretion of siderophores (low-molecular-mass ferric-binding compounds), *A. baumannii* is able to grow despite iron deficiencies in the surrounding environment (e.g., in the human host).

Several protein-secretion systems have been identified in *A. baumannii*. The most recently described is a type II secretion system. The substrate for this system, the LipA lipase, is required for growth on medium containing lipids as a sole carbon source. Mutants lacking the genes for the type II secretion system or its substrate exhibit defective in vivo growth in a neutropenic murine model of bacteremia. *A. baumannii* also has a type VI secretion system whose primary function seems to be to secrete antibacterial toxins that kill competing bacteria, including other strains in the same species.

The type V autotransporter system has been characterized in *A. baumannii*. In a murine systemic model of *Acinetobacter* infection, the *Acinetobacter* trimeric autotransporter mediates biofilm formation and maintenance; adherence to extracellular matrix components such as collagen I, II, and IV; and virulence.

Outer-membrane vesicles (OMVs) play a special role in protein secretion. Many *A. baumannii* strains secrete OMVs containing various virulence factors, including outer-membrane protein A (OmpA), proteases, and phospholipases. The membrane proteins in OMVs are responsible for eliciting a potent innate immune response. Several studies have shown that *A. baumannii* OMVs could be used as an acellular vaccine to effectively control *A. baumannii* infections.

Nosocomial strains of *Acinetobacter* can deploy multiple mechanisms of resistance, including alterations in porins and efflux pumps and expression of β-lactamases. More specifically, *Acinetobacter* species can reduce the expression of porins, thus hindering the passage of β-lactam antibiotics into the periplasmic space. These species can overexpress bacterial efflux pumps and decrease the concentration of β-lactam antibiotics in the periplasmic space. Efflux pumps can also actively remove quinolones, tetracyclines, chloramphenicol, disinfectants, and tigecycline. *Acinetobacter* species possess chromosomally encoded cephalosporinases and are capable of acquiring β-lactamases,

including serine and metallo-β-lactamases. AmpC β-lactamases are class C β-lactamases intrinsic to all *A. baumannii* strains. Although these enzymes are expressed at low levels and are not inducible, the addition of the insertion sequence *ISAba1* next to the AmpC gene increases β-lactamase production, with resulting resistance to most cephalosporins.

Carbapenem resistance in *Acinetobacter* species is mostly tied to the emergence of Ambler class D oxacillinases of group 2d, some of which are intrinsic and chromosomal (e.g., OXA-51-like) while others are acquired and are found in plasmids or are chromosomally encoded (e.g., OXA-23-like, 24 [33-like, 40-like], 58-like, 143-like, and 235-like).

CLINICAL MANIFESTATIONS

Pneumonia *A. baumannii* is a notorious cause of nosocomial pneumonia, most frequently among patients requiring prolonged mechanical ventilation. The onset of disease tends to be later than that caused by other gram-negative bacilli; however, clinical symptoms of hospital-acquired or ventilator-associated pneumonia due to *A. baumannii* are similar to those of nosocomial or ventilator-associated pneumonia due to other nosocomial pathogens. Thus, the most common indicators of infection include fever and increased sputum production. The positivity of respiratory cultures in most cases may present a challenge for the clinician since airway colonization with *A. baumannii* may not always indicate a diagnosis of pneumonia, but it is a known risk factor for infection itself. In addition, radiologic findings are nonspecific and can include lobar consolidations and pleural effusions, with cavitations being rarely seen. The crude mortality rates associated with nosocomial pneumonia due to *A. baumannii* are reported as high as 65%. However, since these infections occur in debilitated patients, their attributable mortality has been difficult to establish.

Community-acquired pneumonia due to *A. baumannii* is relatively rare. Its clinical presentation is characterized by fever, severe respiratory symptoms, and multiple-organ dysfunction. Patients frequently have a cough productive of purulent sputum, shortness of breath, and chest pain. Imaging studies usually show lobar consolidation. Mortality rates associated with this process are >50%.

Bloodstream Infections Bloodstream infections due to *A. baumannii* are most frequent among ICU patients and usually occur in the presence of a central venous catheter or as a secondary complication of hospital-acquired or ventilator-associated pneumonia. Polymicrobial growth has been reported in 20–36% of bacteremia episodes. Fever is the most common sign of infection (developing in >95% of cases), and presentation with septic shock and disseminated intravascular coagulopathy has been described in as many as 25 to 30% of patients, respectively. *A. baumannii* bloodstream infections often result in higher hospitalization costs and longer ICU stays. Crude mortality rates from this infection are as high as 40%; however, rates can be as high as 70% from infections caused by carbapenem-resistant isolates. In patients with infections caused by extremely drug-resistant strains, poor outcomes are thought to be driven by delays in the initiation of adequate antimicrobial therapy.

Skin and Soft Tissue Infections *Acinetobacter* species have been described as part of the skin flora, yet the majority of the organisms from this genus that colonize the skin are not those associated with nosocomial infections. Discerning infection from wound colonization is challenging. Gunshot wounds and the presence of orthopedic external-fixation devices are common among patients with combat trauma–associated *A. baumannii* skin and soft tissue infections. The report on a case series of eight U.S. military patients described the clinical presentation of their infections as evolving from an edematous *peau d'orange* appearance to a sandpaper appearance with overlying vesicles and then to a necrotizing process with hemorrhagic bullae. Other case series have also included necrotizing fasciitis. *A. baumannii* is an important pathogen in burn units worldwide. Large burns provide ideal conditions for *A. baumannii* and facilitate patient-to-patient transmission. The presence of *A. baumannii* in wounds contributes to healing delays and graft loss. In addition, wound colonization is a risk factor for bloodstream infections among patients with extensive burn injuries.

A. baumannii infections resulting from trauma to soft tissues in the setting of natural disasters, such as tsunamis and earthquakes, have been reported. The implication is that *A. baumannii* should be considered in the differential diagnosis of soft tissue infections following exposure to tropical and subtropical environments.

Urinary Tract Infections *A. baumannii* is an infrequent cause of urinary tract infections. The majority of cases reported are catheter-associated infections, reflecting the ability of *A. baumannii* to form biofilms on these devices. A few reports have described community-acquired infections occurring in the setting of nephrolithiasis and after renal transplantation.

Meningitis Central nervous system infections with *A. baumannii* have been reported in the context of outbreaks, traumatic injuries, neurosurgical procedures, and external ventricular drains. One case series described a petechial rash in up to 30% of patients. *Acinetobacter* species may look similar to *Neisseria meningitidis* on a Gram stain of cerebrospinal fluid; both appear as gram-negative paired cocci. Eradication of *A. baumannii* from the cerebrospinal fluid can be challenging and requires careful selection of antibiotics that adequately penetrate the site of infection.

Other Miscellaneous Infections A few cases of *A. baumannii* keratitis associated with the use of contact lenses have been reported. Cases of native- and prosthetic-valve endocarditis have also been described.

TREATMENT

Acinetobacter Infections

Treatment of *Acinetobacter* infections is challenging due to difficulties in differentiating colonization versus infection and because *Acinetobacter* can develop resistance to most available antibiotics. Therefore, the choice of empirical therapy should be based on local epidemiology and, if available, the patient's colonization status with a carbapenem-resistant isolate. Definitive therapy should be determined by antimicrobial susceptibility testing. Antimicrobial options for the management of infections caused by *A. baumannii* are displayed in **Table 167-1**.

Acinetobacter species possess intrinsic β-lactamases that inactivate first- and second-generation cephalosporins. Through acquisition of extended-spectrum β-lactamases, these organisms can also become resistant to third- and fourth-generation cephalosporins, along with carbapenems. Nevertheless, when the isolate is susceptible, β-lactam agents should be used. Ampicillin-sulbactam (due to its sulbactam component) is the treatment of choice, with cefepime, meropenem, and imipenem as alternative options based on in vitro susceptibility testing.

Currently, there is no antibiotic regimen that has been proven superior for the treatment of carbapenem-resistant *A. baumannii*. The 2024 Infectious Diseases Society of America (IDSA) "Guidance on the Treatment of Antimicrobial Resistant Gram-Negative Infections" recommends sulbactam-durlobactam in combination with a carbapenem as their preferred regimen, and high-dose ampicillin-sulbactam in combination with either polymyxin B, minocycline, tigecycline, or cefiderocol is an alternative. Pairing of sulbactam with durlobactam makes a novel diazabicyclooctane non-β-lactam β-lactamase inhibitor with activity against the *Acinetobacter*-derived cephalosporinases and class D β-lactamases including carbapenemases of the OXA family. High-dose ampicillin-sulbactam is recommended in combination with either polymixn B, minocycline, tigecycline, or cefiderocol. The use of high-dose over standard dose ampicillin-sulbactam increases binding of sulbactam to its penicillin-binding proteins (PBP) targets (PBP2 and PBP3) in order to optimize inhibition of cell wall synthesis. This recommendation is based on two meta-analyses of small clinical trials and observational data. In a randomized clinical trial including 125 patients with carbapenem-resistant *A. baumannii*, patients treated

TABLE 167-1 Therapeutic Options for the Management of Multidrug-Resistant *Acinetobacter baumannii* Infections

ANTIBIOTIC	DOSING[a]	COMMENTS
Sulbactam	6–9 g/d	Unavailable as single drug in many countries (including the United States). Different dosing strategies proposed if administered with ampicillin.
Ampicillin-sulbactam	3 g q4h 9 g q8h 27 g q24h	Infuse over 30 min Infuse over 4 h Infuse as continuous infusion
Sulbactam-durlobactam	1 g/1 g q6h	Infuse over 3 h
Meropenem	2 g q8h	Carbapenem-susceptible isolates only; infuse over 3 h
Imipenem-cilastatin	500 mg q6h	Carbapenem-susceptible isolates only; infuse over 3 h
Cefiderocol	2g q8h	Use in combination therapy; infuse over 3 h
Colistin	Dosing per the international consensus guidelines on polymixins (Tsuji BT et al, Pharmacotherapy 39:10, 2019)	Colistin is preferred for urinary tract infections.
Polymyxin B	Dosing per the international consensus guidelines on polymixins (Tsuji BT et al, Pharmacotherapy 39:10, 2019)	Polymyxin B is preferred over colistin for bloodstream infections.
Tigecycline	200-mg loading dose followed by 100 mg q12h	Use in combination therapy
Minocycline	200 mg q12h	IV/PO. Use in combination therapy

[a]All drugs are given by the IV route unless otherwise stated.

with sulbactam-durlobactam had a 28-day all-cause mortality of 19% compared to 32% in patients treated with colistin, and with lower rates of nephrotoxicity in the sulbactam-durlobactam arm.

Cefiderocol is a siderophore cephalosporine with in vitro stability against the *Acinetobacter*-derived cephalosporinase and other extended-spectrum β-lactamases. However, *A. baumannii* isolates with reduced cefiderocol susceptibility have been described, and in a randomized clinical trial that included 54 critically ill patients with carbapenem-resistant *A. baumannii*, the end-of-study mortality was 50% in the cefiderocol arm, compared to 18% in the best available therapy arm (mostly consisting of colistin).

Polymyxins are cationic detergents that have become less popular as a result of nephrotoxicity and neurotoxicity. Additionally, polymyxins are difficult to dose, have a narrow therapeutic window, and do not reach optimal tissue concentration in the lungs, which is a common site of infection for *A. baumannii*. Despite its disadvantages, polymyxin B and polymyxin E (colistin) have been reintroduced in clinical practice as they retain in vitro activity against carbapenem-resistant *A. baumannii*. In a randomized study of patients with pneumonia due to carbapenem-resistant *Acinetobacter,* patients receiving colistin in combination with high-dose ampicillin-sulbactam had a higher rate of clinical improvement by day 5 compared to those receiving colistin monotherapy. The combination of colistin plus meropenem was long favored due to in vitro synergy; however, two randomized controlled trials showed this strategy had comparable outcomes to colistin monotherapy.

Several tetracycline derivatives have in vitro activity against *A. baumannii*. Of them, tigecycline and minocycline could be considered as part of a combination regimen, used at high doses when minimum inhibitory concentrations are low. Although doxycycline is a widely available agent with established breakpoints against *A. baumannii*, it is usually less active than minocycline. Eravacycline is a newer tetracycline with promising activity against *A. baumannii*; however its use has been limited; it is currently being marketed to treat more resistant strains.

Bacteriophage therapy against multidrug-resistant *A. baumannii* has been reported with varied success rates. Furthermore, dosing and duration of therapy vary by syndrome and resistance can also arise during treatment.

COMPLICATIONS AND PROGNOSIS

Infections caused by *A. baumannii* can be associated with high mortality rates. Factors contributing to higher mortality are thought to include severity of the patient's underlying illness and drug resistance in the infecting strain.

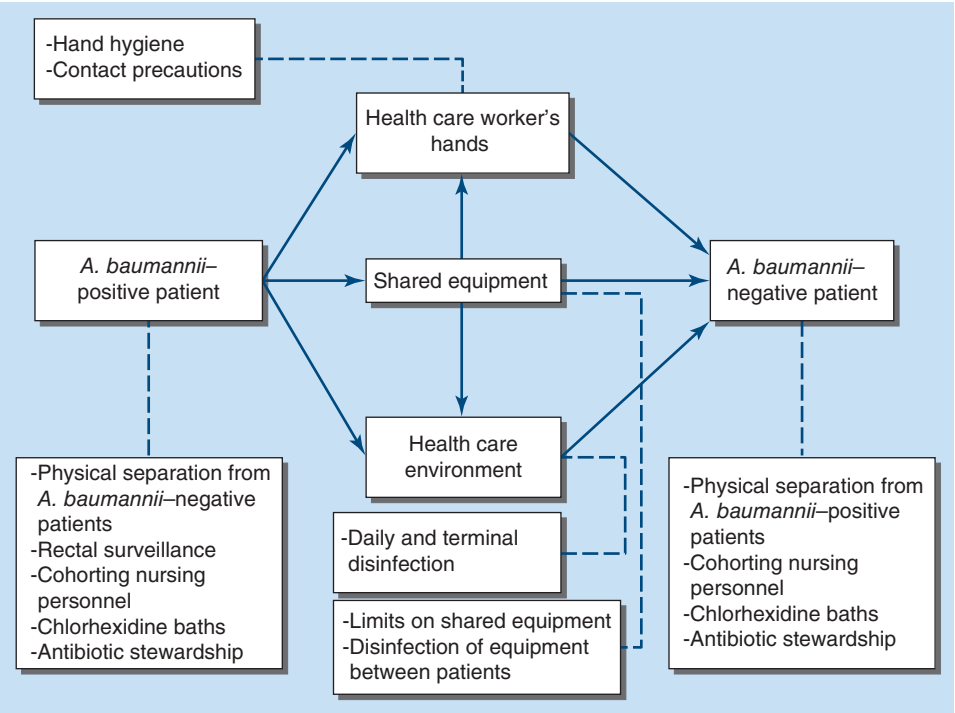

FIGURE 167-1 Strategies for the prevention of dissemination of *Acinetobacter baumannii* in health care facilities.

INFECTION CONTROL AND PREVENTION

Acinetobacter species are capable of surviving on hospital surfaces for prolonged periods. In the hospital environment, *A. baumannii* has been associated with establishment of a *fecal patina*; this term refers to a coating of enteric organisms that can cover the skin of colonized patients and extend to their surrounding environment. Concentrations of enteric organisms are highest in the colonized patient's rectum, with spread in a target-like concentric pattern covering the patient's body and the surrounding environment. High-frequency touch areas in rooms occupied by patients colonized with *A. baumannii* are more likely to be contaminated. The hands, gloves, and gowns of health care workers can be contaminated after entry into the room of a patient colonized with *A. baumannii* **(Fig. 167-1)**.

Outbreaks caused by *A. baumannii* are frequently mono- or oligoclonal. A common source of infection has been identified in ~50% of outbreaks. These sources include respiratory therapy equipment, the hands of health care workers, bedside humidifiers, warm bathwater, hospital-prepared distilled water, bedpans, urine jugs, heparinized saline solution, mattresses, reusable pressure transducers in arterial lines, and fluids used for pressure lavage of wounds.

Control of multidrug-resistant *Acinetobacter* outbreaks starts with early recognition, with subsequent halting of the spread of infection throughout a facility and prevention of the establishment of an endemic strain. It is important to identify the outbreak strain and differentiate it from nonoutbreak strains so that infection control activities can be better targeted. Traditionally, the strain was identified with phenotypic typing systems (biotyping) or by determination of antimicrobial susceptibility patterns. Whole genome sequencing (WGS) has been proven an effective tool during outbreak investigations, usually deployed in response to an increase in the number of patients infected or colonized with a multidrug-resistant organism. However, an emerging body of evidence supports the prospective use of WGS for infection prevention, as it leads to early detection of transmission pathways and the potential for halting spread sooner and limiting cluster sizes through targeted infection prevention interventions.

During outbreaks, the simultaneous introduction of multiple ("bundled") measures makes it difficult to assess the impact of each individual measure. These interventions include aggressive cleaning of the general environment, active surveillance, contact isolation of colonized or infected patients, cohorting of medical staff, reinforcement of compliance with hand hygiene by health care workers, and use of aseptic care devices.

Colonization with *A. baumannii* is a strong predictor of subsequent clinical infection by this organism. Exposure to carbapenems is a risk factor for initial acquisition of this pathogen; therefore, efforts to curtail unnecessary use of antibiotics are fundamental to the prevention of *A. baumannii* colonization of patients and the organism's establishment in health care facilities.

168 *Helicobacter pylori* Infections

Emad M. El-Omar, Martin J. Blaser

Helicobacter pylori colonizes the stomach in ~40% of the world's human population, essentially for life unless eradicated by antibiotic treatment. Colonization with this organism is the main risk factor for peptic ulceration **(Chap. 335)** as well as for gastric adenocarcinoma and gastric mucosa-associated lymphoid tissue (MALT) lymphoma **(Chap. 85)**. Treatment for *H. pylori* has revolutionized the management of peptic ulcer disease, providing a permanent cure in most cases. Such treatment also represents first-line therapy for patients with low-grade gastric MALT lymphoma. Treatment of *H. pylori* is of no benefit in the treatment of gastric adenocarcinoma, but prevention of *H. pylori* colonization or eradicative treatment could potentially prevent gastric malignancy and peptic ulceration. In contrast, increasing evidence indicates that lifelong *H. pylori* colonization may offer some protection against complications of gastroesophageal reflux disease (GERD), including esophageal adenocarcinoma, although this point is still uncertain. Recent research has focused on whether *H. pylori* colonization is also a risk factor for some extragastric diseases and whether it is protective against some recently emergent medical problems, such as childhood-onset asthma and other allergic and metabolic conditions.

ETIOLOGIC AGENT

Helicobacter pylori *H. pylori* is a gram-negative bacillus that has naturally colonized humans for at least 100,000 years, and probably throughout human evolution. It lives in gastric mucus, with a proportion of the bacteria adherent to the mucosa and possibly a very small number of the organisms entering cells or penetrating the mucosa; the organism's distribution is mucosal rather than systemic. Its spiral shape and flagella render *H. pylori* motile in the mucus environment. The organism has several acid-resistance mechanisms, most notably a highly expressed urease that catalyzes urea hydrolysis to produce buffering ammonia. *H. pylori* is microaerophilic (i.e., grows in low levels of oxygen), is slow-growing, and requires complex growth media in vitro.

Other *Helicobacter* Species A small proportion of gastric *Helicobacter* infections are due to species other than *H. pylori*, possibly acquired as zoonoses. These non-*pylori* gastric helicobacters are associated with low-level inflammation and occasionally with disease. In immunocompromised hosts, several nongastric (intestinal) *Helicobacter* species can cause disease with clinical features resembling those of *Campylobacter* infections; these species are covered in **Chap. 169**.

EPIDEMIOLOGY

Prevalence and Risk Factors The prevalence of *H. pylori* among adults is <30% in most parts of the United States, Europe, and Oceania as opposed to >60% in many parts of Africa, South America, and West Asia. In the United States, prevalence varies with age but has been dropping; an estimated 18% of adults and 14% of children and adolescents are positive. *H. pylori* is usually acquired in childhood. The age association is due mostly to a birth-cohort effect whereby current 60-year-olds were more commonly colonized as children than are current children. Spontaneous acquisition or loss of *H. pylori* in adulthood is uncommon. Childhood acquisition explains why the main risk factors for infection are markers of crowding and social deprivation in childhood. Longitudinal studies have shown declining prevalences over the past half-century, concomitant with socioeconomic development and widespread antibacterial treatments.

Transmission Humans are the only important reservoir of *H. pylori*. Children may acquire the organism from their parents (most often the primary caregiver) or from other children. The former is more common in developed countries and the latter in less developed countries. Whether transmission takes place more often by the fecal–oral or the oral–oral route is unknown, but *H. pylori* is easily cultured from vomitus and gastroesophageal refluxate and is much less easily cultured from stool. Most acquisition of *H. pylori* is during the early years of childhood.

PATHOLOGY AND PATHOGENESIS

Long-term *H. pylori* colonization induces *chronic superficial gastritis*, a tissue response in the stomach that includes infiltration of the mucosa by both mononuclear and polymorphonuclear cells. (The term *gastritis* should be used specifically to describe histologic features; it has also been used to describe endoscopic appearances and even symptoms, but only magnification endoscopy correlates with microscopic findings or even with the presence of *H. pylori*, and even this is insufficient for diagnosis.) Although *H. pylori* is capable of numerous adaptations that prevent excessive stimulation of the immune system, colonization is accompanied by a considerable persistent local and systemic immune response, including the production of antibodies and cell-mediated responses. However, these responses are ineffective in clearing the bacterium. This inefficient clearing appears to be due in part to *H. pylori*'s downregulation of the immune system, which fosters its own persistence.

Most *H. pylori*–colonized persons do not develop clinical sequelae. That some persons develop overt disease whereas others do not is related to a combination of factors: bacterial strain differences, host susceptibility to disease, and environmental factors.

Bacterial Virulence Factors Several *H. pylori* virulence factors are more common among strains that are associated with disease than among those that are not. The *cag* island is a group of genes that encodes a bacterial type IV secretion system. Through this system, an effector protein, CagA, is translocated into epithelial cells, where it may be activated by phosphorylation and induces host cell signal transduction; proliferative, cytoskeletal, and inflammatory changes in the cell result. The protein at the tip of the secretory apparatus, CagL, binds to integrins on the cell surface, transducing further signaling. Finally, soluble components of the peptidoglycan cell wall enter the cell, mediated by the same secretory system. These components are recognized by the intracellular bacterial receptor Nod1, which stimulates a proinflammatory cytokine response resulting in an enhanced tissue response. Carriage of *cag*-positive strains increases the risk of both peptic ulcer and gastric adenocarcinoma. A second major host-interaction factor is the vacuolating cytotoxin VacA, which forms pores in cell membranes. VacA is polymorphic, and carriage of more active forms also increases the risk of ulcer disease and gastric cancer. Other bacterial factors that are associated with increased disease risk include adhesins, such as BabA (which binds to blood group antigens on epithelial cells).

Host Genetic and Environmental Factors There are currently no host genetic factors that have been reproducibly associated with risk of acquisition of *H. pylori* infection. The best-characterized host determinants of disease are genetic polymorphisms leading to enhanced activation of the innate immune response, including polymorphisms in cytokine genes and in genes encoding bacterial recognition proteins such as Toll-like receptors. For example, colonized people with polymorphisms in the interleukin 1 gene that increase the production of this cytokine in response to *H. pylori* infection are at increased risk of gastric adenocarcinoma. Another host genetic factor that has been linked with increased risk of gastric cancer in multiple populations is a single-nucleotide polymorphism (SNP) in the prostate stem cell antigen (*PSCA*) rs2294008. In addition to host genetics, environmental cofactors are important in pathogenesis. Smoking increases the risks of duodenal ulcers and gastric cancer in *H. pylori*–positive individuals. Diets high in salt and preserved foods increase cancer risk, whereas diets high in antioxidants and vitamin C are modestly protective.

Distribution of Gastritis and Differential Disease Risk The pattern of gastric tissue response is associated with disease risk: antral-predominant gastritis is most closely linked with duodenal ulceration, whereas pan-gastritis and corpus-predominant gastritis are linked with gastric ulceration and adenocarcinoma. This difference probably explains why patients with duodenal ulceration are not at high risk of developing gastric adenocarcinoma later in life, despite being colonized by *H. pylori*.

PATHOGENESIS OF DUODENAL ULCERATION How gastric colonization causes duodenal ulceration is now becoming clearer. *H. pylori*–induced tissue responses in the gastric antrum diminish the number of somatostatin-producing D cells. Because somatostatin inhibits gastrin release, gastrin levels are higher than in *H. pylori*–negative persons, and these higher levels lead to increased meal-stimulated acid secretion from the relatively spared gastric corpus. How this situation increases duodenal ulcer risk remains controversial, but the increased acid secretion may contribute to the formation of potentially acid-protective gastric metaplasia in the duodenum. Gastric metaplasia in the duodenum may become colonized by *H. pylori* and subsequently inflamed and ulcerated.

PATHOGENESIS OF GASTRIC ULCERATION AND GASTRIC ADENOCARCINOMA The pathogenesis of these conditions is less well understood, although both arise in association with pan- or corpus-predominant gastritis. The hormonal changes described above still occur, but the tissue responses in the gastric corpus mean that it produces less acid (hypochlorhydria) despite hypergastrinemia. Gastric ulcers commonly occur at the junction of antral and corpus-type mucosa, an area that is often particularly inflamed. Gastric cancer usually arises in stomachs with extensive atrophic gastritis and hypo- or achlorhydria, and probably stems from progressive DNA damage and the survival of abnormal epithelial cell clones. The DNA damage is thought to be due principally to reactive oxygen and nitrogen species arising from inflammatory cells, perhaps in relation to other bacteria that survive in a hypochlorhydric stomach. Longitudinal analyses of gastric biopsy specimens taken years apart from the same patient show that the common *intestinal* type of gastric adenocarcinoma follows stepwise changes from simple gastritis to gastric atrophy, metaplasia, and dysplasia. A second, *diffuse* type of gastric adenocarcinoma found more commonly in younger adults may arise directly from chronic gastritis without atrophic changes. In recent years, there has been a progressive rise in gastric cancers centered on the gastric corpus and occurring in younger adults (<50 years old) and disproportionately in females; this appears to be in the absence of *H. pylori.*

PATHOGENESIS OF GASTRIC MALT LYMPHOMA Low-grade B-cell MALT lymphomas are rare malignancies, reported at a rate of ~1 per million population per year prior to the discovery of *H. pylori*. Since then, reported rates have increased substantially, possibly reflecting overdiagnosis. These tumors arise from the substrate of chronic stimulation of lymphocyte populations by the persistent *H. pylori* colonization. Importantly, there have been numerous reports of these low-grade tumors responding dramatically to *H. pylori* eradication therapies. However, the boundary between true malignancy and benign lymphoid

hypertrophy is uncertain. Among responders to *H. pylori* eradication, most do not have the characteristic t(11;18)(q21;q21) translocation of the malignancy and may not have true malignancies but rather benign polyclonal lymphoid proliferation. CagA-positive *H. pylori* strains have been significantly associated with the t(11;18)(q21;q21)–positive gastric MALT lymphoma compared with translocation-negative cases.

CLINICAL MANIFESTATIONS

Essentially all *H. pylori*–colonized persons have histologic gastritis, but only ~10–15% develop associated illnesses such as peptic ulceration, gastric adenocarcinoma, or gastric lymphoma **(Fig. 168-1)**. Despite similar rates of *H. pylori* colonization, rates of these diseases among women are less than half of those among men.

PEPTIC ULCER DISEASE

Worldwide, ~70% of duodenal ulcers and ~50% of gastric ulcers are related to *H. pylori* colonization **(Chap. 335)**. However, in particular, the proportion of gastric ulcers caused by aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) is increasing, and in many developed countries, these drugs have overtaken *H. pylori* as a cause of gastric ulceration. The main lines of evidence supporting an ulcer-promoting role for *H. pylori* are that (1) the presence of the organism is a risk factor for the development of ulcers, (2) non-NSAID-induced ulcers rarely develop in the absence of *H. pylori*, (3) eradication of *H. pylori* virtually abolishes long-term ulcer relapse, and (4) experimental *H. pylori* infection of gerbils can cause gastric ulceration. Thus, *H. pylori* is neither necessary nor sufficient for the development of peptic ulcer disease, but it is a very strong risk factor for its occurrence, and removal of *H. pylori* changes the natural history of ulcer disease.

Gastric Adenocarcinoma and Lymphoma Prospective nested case–control studies have shown that *H. pylori* colonization is a risk factor for adenocarcinomas of the distal (noncardia) stomach **(Chap. 85)**. Long-term experimental infection of gerbils also may result in gastric adenocarcinoma. Moreover, *H. pylori* may induce primary gastric lymphoma, although this condition is much less common, and the approaches to histopathologic and cytogenetic evaluations are not standardized. Many of the diagnosed low-grade gastric B-cell lymphomas are dependent on *H. pylori* for continuing growth and proliferation, and these tumors may regress either fully or partially after *H. pylori* eradication. However, they require careful short- and long-term monitoring; any that are not confined to the superficial mucosa (and, indeed, some that are) require additional treatment with chemotherapeutic agents or radiotherapy.

Functional Dyspepsia Many patients have upper gastrointestinal symptoms but have normal results on upper gastrointestinal endoscopy (so-called functional or nonulcer dyspepsia; **Chap. 335**). Because *H. pylori* is common, some of these patients will be colonized with the organism. *H. pylori* eradication leads to symptom resolution up to 15% more commonly than does placebo treatment. Whether such patients have peptic ulcers in remission at the time of endoscopy or whether a small subgroup of patients with "true" functional dyspepsia respond to *H. pylori* treatment is unclear. Either way, because functional dyspepsia is often persistent and difficult to treat, most consensus conference guidelines recommend *H. pylori* eradication in these patients. If this advice is followed, it is important to realize that only a small subgroup of patients who are treated will benefit.

Protection Against Peptic Esophageal Disease, Including Esophageal Adenocarcinoma Much interest has focused on a protective role for *H. pylori* against GERD **(Chap. 334)**, Barrett's esophagus **(Chap. 334)**, and adenocarcinoma of the esophagus and gastric cardia **(Chap. 85)**. The main lines of evidence for this role are (1) that there is a temporal relationship between a falling prevalence of gastric *H. pylori* colonization and a rising incidence of these conditions; (2) that, in most studies, the prevalence of *H. pylori* colonization (especially with proinflammatory *cagA*$^+$ strains) is significantly lower among patients with these esophageal diseases than among control participants; and (3) that, in prospective nested studies (see above), the presence of *H. pylori* is inversely related to these cancers. The mechanism underlying this protective effect is likely *H. pylori*–induced hypochlorhydria. Because, at the individual level, GERD severity may decrease, worsen, or remain unchanged after *H. pylori* treatment, concerns about GERD should not affect decisions about whether to treat *H. pylori* in an individual patient if a clear-cut indication exists; if there is no clear indication, clinicians should carefully balance considerations of benefit and harm.

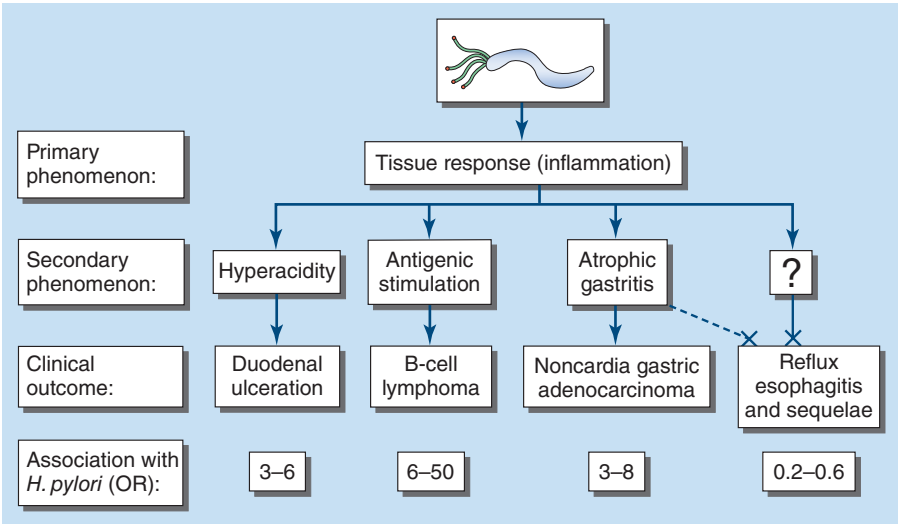

FIGURE 168-1 Schematic of the relationships between colonization with *Helicobacter pylori* and diseases of the upper gastrointestinal tract. Essentially all persons colonized with *H. pylori* develop a host response, which is generally termed *chronic gastritis*. The nature of the host's interaction with the particular bacterial population determines the clinical outcome. *H. pylori* colonization increases the lifetime risk of peptic ulcer disease, noncardia gastric cancer, and B-cell non-Hodgkin's gastric lymphoma (odds ratios [ORs] for all, >3). In contrast, a growing body of evidence indicates that *H. pylori* colonization (especially with *cagA*$^+$ strains) protects against adenocarcinoma of the esophagus (and the sometimes related gastric cardia) and premalignant lesions such as Barrett's esophagus (ORs, <1). Although the incidences of peptic ulcer disease (cases not due to nonsteroidal anti-inflammatory drugs) and noncardia gastric cancer are declining in developed countries, the incidence of adenocarcinoma of the esophagus is increasing. *(Reproduced with permission from MJ Blaser: Hypothesis: The changing relationships of Helicobacter pylori and humans: Implications for health and disease. J Inf Dis 179:1523, 1999.)*

Other Pathologies *H. pylori* has an increasingly recognized role in other gastric pathologies. It may predispose some patients to iron deficiency through occult blood loss and/or hypochlorhydria and reduced iron absorption. In addition, several extragastrointestinal pathologies have been linked with *H. pylori* colonization, although evidence of causality is less strong. Studies of *H. pylori* treatment in idiopathic thrombocytopenic purpura have consistently described improvement in or even normalization of platelet counts. Potentially important but even more controversial (protective) associations are with ischemic heart disease and cerebrovascular disease. However, the strength of the latter associations is reduced if confounding factors are taken into account, and our present knowledge is incomplete. Most authorities consider the associations to be noncausal. An increasing number of studies have shown an inverse association of *cagA*$^+$ *H. pylori* with childhood-onset asthma, hay fever, and atopic disorders. These associations have been shown to be causal in animal models, but the effect size in humans has not been established.

DIAGNOSIS

Tests for *H. pylori* fall into two groups: tests that require upper gastrointestinal endoscopy and simpler tests that can be performed in the clinic **(Table 168-1)**.

TABLE 168-1 Tests Commonly Used to Detect *Helicobacter pylori*

TEST	ADVANTAGES	DISADVANTAGES
Tests Based on Endoscopic Biopsy		
Biopsy urease test	Quick, simple	Some commercial tests not fully sensitive before 24 h
Histology	May give additional histologic information	Sensitivity dependent on experience and use of special stains
Culture	Permits determination of antibiotic susceptibility	Sensitivity dependent on experience
Noninvasive Tests		
Serology	Inexpensive and convenient; not affected by recent antibiotics or proton pump inhibitors to the same extent as breath and stool tests	Cannot be used to monitor treatment success; some commercial kits inaccurate, and most less accurate than urea breath test
^{13}C urea breath test	Inexpensive and simpler than endoscopy; useful for follow-up after treatment	Requires fasting; not as convenient as blood or stool tests
Stool antigen test	Inexpensive and convenient; useful for follow-up after treatment; may be particularly useful in children	Stool-based tests disliked by people from some cultures

Endoscopy-Based Tests Endoscopy is usually unnecessary in the initial management of young patients with simple dyspepsia but is commonly used to exclude malignancy and make a positive diagnosis in older patients or those with "alarm" symptoms. If endoscopy is performed, the most convenient biopsy-based test is the biopsy urease test, in which one large or two small gastric biopsy specimens are placed into a gel containing urea and an indicator. The *H. pylori* urease enzyme hydrolyses urea in gastric juice and generates ammonia. This leads to a rise in pH and therefore to a color change, which often occurs within minutes but can require up to 24 h. Histologic examination of biopsy specimens for *H. pylori* also is accurate, provided that a special stain (e.g., a modified Giemsa, silver, or immuno-stain) permitting optimal visualization of the organism is used. If biopsy specimens are obtained from both antrum and corpus, histologic study yields additional information, including the degree and pattern of inflammation and the presence of any atrophy, metaplasia, or dysplasia. Microbiologic culture is most specific but may be insensitive because of difficulty with *H. pylori* isolation. Once the organism is cultured, its identity as *H. pylori* can be confirmed by its typical appearance on Gram's stain and its positive reactions in oxidase, catalase, and urease tests. Moreover, the organism's susceptibility to antibiotics can be determined, and this information can be clinically useful in difficult cases. The occasional biopsy specimens containing the less common non-*pylori* gastric helicobacters give weakly positive results in the biopsy urease test. Positive identification of these bacteria requires visualization of the characteristic long, tight spirals in histologic sections; they cannot easily be cultured.

Noninvasive Tests Noninvasive *H. pylori* testing is the norm if gastric cancer does not need to be excluded by endoscopy. The longest-established test (and a very accurate one) is the *urea breath test*. In this simple test, the patient drinks a solution of urea labeled with the nonradioactive isotope ^{13}C and then blows into a tube. If *H. pylori* urease is present, the urea is hydrolyzed, and labeled carbon dioxide is detected in breath samples. The *stool antigen test*, a simple and accurate test using monoclonal antibodies specific for *H. pylori* antigens, is more convenient and less expensive than the urea breath test, but some patients dislike sampling stool. The simplest tests for ascertaining *H. pylori* status are *serologic assays* measuring specific IgG levels in serum by enzyme-linked immunosorbent assay or immunoblot. The best of these tests are nearly as accurate as other diagnostic methods, but many commercial tests—especially rapid office tests—do not perform well.

Use of Tests to Assess Treatment Success The urea breath test, the stool antigen test, and biopsy-based tests can all be used to assess the success of treatment (Fig. 168-2). However, because these tests are dependent on *H. pylori* load, their use <4 weeks after treatment may yield false-negative results. Early suppression of bacterial numbers may lead to false-negative results since regrowth of the organism can result in its detection weeks later. For the same reason, these tests are unreliable if performed within 4 weeks of intercurrent treatment with antibiotics or bismuth compounds or within 2 weeks of the discontinuation of proton pump inhibitor (PPI) treatment. In the assessment of treatment success, noninvasive tests are normally preferred. However, after gastric ulceration, endoscopy should be repeated to ensure healing and exclude gastric carcinoma by further histologic sampling; if PPIs have been stopped for at least 2 weeks and no antibiotics or bismuth compounds have been given for at least 6 weeks, there is an opportunity to assess treatment success with biopsy-based tests. Serologic tests are not used to monitor treatment success, as the gradual drop in titer of *H. pylori*–specific antibodies is too slow (requiring >14 weeks) to be of practical use.

TREATMENT

Helicobacter pylori Infection

INDICATIONS

The most clear-cut indications for treatment are *H. pylori*–related duodenal or gastric ulceration or low-grade gastric B-cell MALT lymphoma. Whether or not the ulcers are currently active, *H. pylori* should be eradicated in patients with documented ulcer disease to prevent relapse (Fig. 168-2). Guidelines have recommended *H. pylori* treatment for colonized patients with functional dyspepsia in case they are among the small percentage who will benefit from such therapy (beyond placebo effects). *H. pylori* eradication in the treatment of conditions not definitively known to respond has also been recommended but is not universally supported; such conditions include idiopathic thrombocytopenic purpura, vitamin B_{12} deficiency, and iron-deficiency anemia where other causes have been carefully excluded. For individuals with a strong family history of gastric cancer, treatment to eradicate *H. pylori* in the hope of reducing cancer risk is reasonable but of unproven value: it slightly reduces future cancer incidence, but there is no evidence it reduces all-cause mortality. For older dyspeptic patients in the community or those who have "alarm" symptoms (e.g., weight loss) associated with their dyspepsia, upper gastrointestinal endoscopy is indicated to seek a diagnosis and test for *H. pylori*; the decision regarding whether to eradicate the organism can then be based on indication. Endoscopy is usually considered unnecessary for young dyspeptic patients in the community who have no alarm symptoms (with the precise age cutoff dependent on local guidelines). If the community prevalence of *H. pylori* is below ~20%, such patients are treated with a short course of acid suppression using a PPI. If these patients do not respond or relapse when treatment is stopped, or if the *H. pylori* community prevalence is >20%, many national guidelines recommend a strategy of testing for *H. pylori* noninvasively and eradicating it if it is found. This strategy will benefit patients who have peptic ulcers and the ~5–10% of patients who have functional dyspepsia responsive to *H. pylori* eradication, but most patients will be treated unnecessarily. Currently, widespread community screening for and treatment of *H. pylori* as primary prophylaxis for gastric cancer and peptic ulcers are not recommended in most countries, mainly because the extent of the consequent reduction in cancer risk is not known. Several studies have found a modestly reduced cancer risk after treatment, but the period of follow-up is still fairly short, and the magnitude of the effect in different populations remains unclear. Other reasons not to treat *H. pylori* in asymptomatic populations at present include (1) the adverse side effects (which are common and can be severe in rare cases) of the multiple-antibiotic regimens used; (2) antibiotic resistance, which may emerge in *H. pylori* or other incidentally carried bacteria; (3) the anxiety that may arise in otherwise healthy people, especially if treatment is unsuccessful; and (4) the existence of a

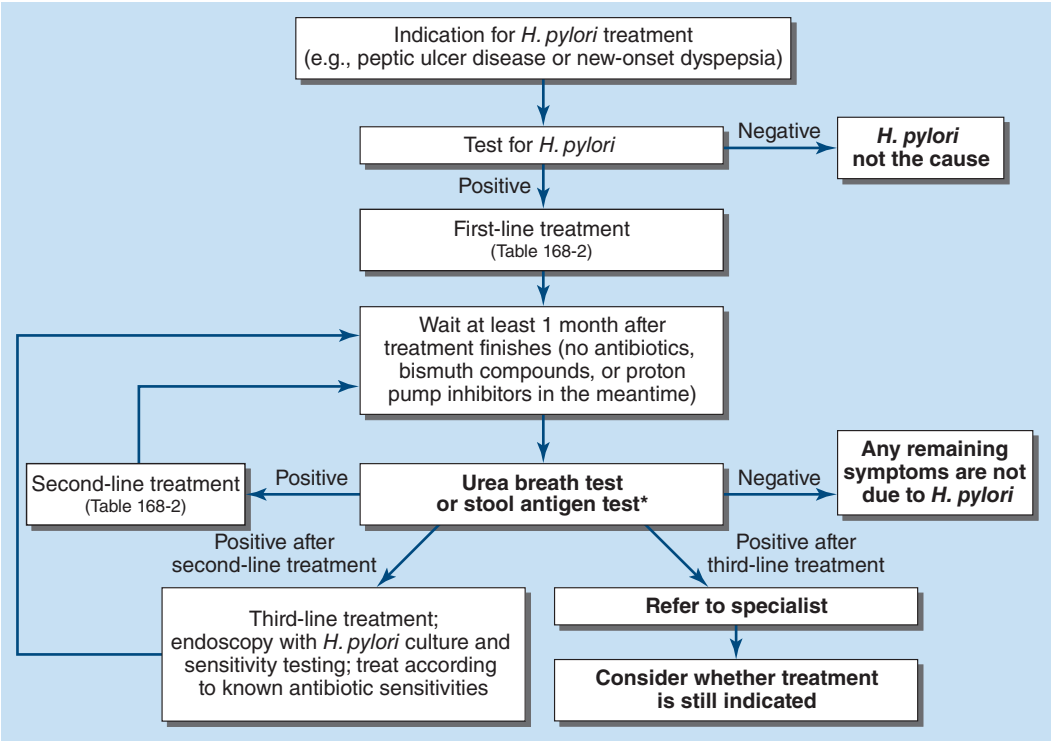

FIGURE 168-2 Algorithm for the management of *Helicobacter pylori* infection. *Note that either the urea breath test or the stool antigen test can be used in this algorithm. Occasionally, endoscopy and a biopsy-based test are used instead of either of these tests in follow-up after treatment. The main indication for these invasive tests is in follow-up after gastric ulceration; in this condition, as opposed to duodenal ulceration, it is important to check healing and exclude underlying gastric adenocarcinoma. However, even in this situation, patients undergoing endoscopy may still be receiving proton pump inhibitor therapy, which precludes *H. pylori* testing. Thus, a urea breath test or a stool antigen test is still required at a suitable interval after the end of therapy to determine whether treatment has been successful (see text). Some authorities use empirical third-line regimens, of which several have been described.

subset of people who will develop GERD symptoms after treatment. Despite the absence of screening strategies, many doctors treat *H. pylori* if it is known to be present (particularly in children and younger adults), even when the patient is asymptomatic. The rationale is that it reduces patient concern and may reduce future gastric cancer risk and that any reduction in risk is likely to be greater in younger patients. However, such practices do not factor in any potential benefits of *H. pylori* colonization. Overall, despite widespread clinical activity in this area, most treatment of persons with asymptomatic *H. pylori* carriage is given with no firm evidence base. Because a proportion of patients (up to 70%) of those diagnosed with gastric low-grade B-cell MALT lymphomas respond to *H. pylori* eradication, it should be used in all cases, regardless of whether *H. pylori* can be detected by the diagnostic modalities used since there may be falsely negative results. However, not all of these cases represent true malignancies, so the reported success rate may reflect the eradication of benign processes. Examination of tissues for the characteristic chromosomal translocations should be done to help distinguish benign and malignant processes and to guide further therapeutic approaches. These generally are slowly progressive tumors, so the time needed for *H. pylori* eradication and subsequent evaluation will not interfere with the use of subsequent chemotherapy and/or radiotherapy, if needed.

REGIMENS

Although *H. pylori* is susceptible to a wide range of antibiotics in vitro, monotherapy is not usually successful, probably because of inadequate active antibiotic delivery to the colonization niche. Clinical failure of monotherapy prompted the development of multidrug regimens. Current regimens consist of a PPI and two or three antimicrobial agents given for 10–14 days **(Table 168-2)**. The optimal regimens vary in different parts of the world, depending on the known

TABLE 168-2 Commonly Recommended Treatment Regimens for *Helicobacter pylori*

REGIMEN[a] (DURATION)	DRUG 1	DRUG 2	DRUG 3	DRUG 4
Regimen 1: OCM (14 days)[b]	Omeprazole (20 mg bid[c])	Clarithromycin (500 mg bid)	Metronidazole (500 mg bid)	—
Regimen 2: OCA (14 days)[b]	Omeprazole (20 mg bid[c])	Clarithromycin (500 mg bid)	Amoxicillin (1 g bid)	—
Regimen 3: OBTM (14 days)[d]	Omeprazole (20 mg bid[c])	Bismuth subsalicylate (2 tabs qid)	Tetracycline HCl (500 mg qid)	Metronidazole (500 mg tid)
Regimen 4: concomitant (14 days)[e]	Omeprazole (20 mg bid[c])	Amoxicillin (1 g bid)	Clarithromycin (500 mg bid)	Tinidazole (500 mg bid[f])
Regimen 5: OAL (10 days)[g]	Omeprazole (20 mg bid[c])	Amoxicillin (1 g bid)	Levofloxacin (500 mg bid or 200 mg bid)	—

[a]The recommended first-line regimens for most of the world are shown in **bold** type. [b]This regimen should be used only for populations in which the prevalence of clarithromycin-resistant strains is known to be <20%. In practice, this restriction limits the regimens' appropriate range mainly to northern Europe. [c]Many authorities and some guidelines recommend doubling this dose of omeprazole as trials show resultant increased efficacy with some antibiotic combinations. Omeprazole may be replaced with any proton pump inhibitor (PPI) at an equivalent dosage. Because extensive metabolizers of PPIs are prevalent among Caucasian populations, many authorities recommend esomeprazole (40 mg bid) or rabeprazole (20 mg bid), particularly for regimens 4 and 5. [d]Data supporting this regimen come mainly from Europe and are based on the use of bismuth subcitrate (1 tablet qid) and metronidazole (400 mg tid). This is a recommended first-line regimen in most countries and is the recommended second-line regimen in northern Europe. [e]This regimen may be used as an alternative to regimen 3. [f]Metronidazole (500 mg bid) may be used as an alternative. [g]These regimens are used as second-line treatment in many countries (particularly where quadruple or concomitant therapy is used as the first-line regimen) and as third-line treatment in others. They may be less effective where rates of fluoroquinolone use are high and are more likely to be ineffective if there is a personal history of fluoroquinolone use for previous treatment of other infections.

rates of primary antibiotic resistance in most *H. pylori* strains in a particular locale. For this reason, guidelines on optimal regimens for *H. pylori* eradication in individual countries are evolving, and physicians should refer to the most up-to-date local guideline.

The two most important factors in successful *H. pylori* treatment are the patient's close compliance with the regimen and the use of drugs to which the patient's strain of *H. pylori* has not acquired resistance. Treatment failure following minor lapses in compliance is common and often leads to acquired resistance. To stress the importance of compliance, written instructions should be given to the patient, and minor side effects of the regimen should be explained. Increasing levels of primary *H. pylori* resistance to macrolides (azithromycin and clarithromycin are primarily used), levofloxacin, and—to a lesser extent—metronidazole are of growing concern. In most parts of the world (the main exception being northwestern Europe), the rate of primary macrolide resistance is sufficiently high that regimens containing clarithromycin plus one other antibiotic often fail; regimens with clarithromycin and two other antibiotics remain an option as the other two antibiotics are likely to eradicate *H. pylori* even if the strain is macrolide -resistant. When a patient is known to have been exposed—even remotely in time—to clarithromycin or a fluoroquinolone, these antibiotics usually should be avoided. Resistance to amoxicillin or tetracycline is unusual, even if these antibiotics have been given previously, and resistance to metronidazole is only partial; thus, there is no need to avoid using these antibiotics whether or not they have been previously prescribed. Whichever antibiotic regimen is used, meta-analyses show that using high rather than moderate doses of acid-suppressive PPIs with the antibiotics increases the effectiveness of the regimen. Similarly, use of vonoprazan, a highly effective potassium-competitive acid blocker, originally licensed in Japan and now in several countries, including the United States, was associated with higher eradication rates in conjunction with amoxicillin and clarithromycin, than when a PPI was used for acid suppression.

Assessment of antibiotic susceptibilities before treatment would be optimal but is not usually undertaken because endoscopy and mucosal biopsy are necessary to obtain *H. pylori* for culture and because most microbiology laboratories are inexperienced in *H. pylori* culture. If initial *H. pylori* treatment fails, the usual approach is empirical re-treatment with another drug regimen (Table 168-2). The third-line approach ideally should be endoscopy, biopsy, and culture plus treatment based on documented antibiotic sensitivities. However, empirical third-line therapies are often used.

Non-*pylori* gastric helicobacters are treated in the same way as *H. pylori*. However, in the absence of trials, it is unclear whether a positive outcome always represents successful treatment or whether it is sometimes due to natural clearance of the bacteria.

PREVENTION

Carriage of *H. pylori* has considerable public health significance in economically richer countries, where it is associated with peptic ulcer disease and gastric adenocarcinoma, and in some, but not all, economically poorer countries, where gastric adenocarcinoma may be an even more common cause of cancer death late in life. If mass prevention were contemplated, vaccination would be the most obvious method: experimental immunization of animals has given promising results, but vaccines in humans have thus far not been successful. However, given that *H. pylori* has co-evolved with its human host over millennia, preventing colonization on a population basis may have biological and clinical costs. For example, lifelong absence of *H. pylori* may be a risk factor for GERD complications, including esophageal adenocarcinoma. We have speculated that the disappearance of *H. pylori* may also be associated with an increased risk of other emergent diseases reflecting aspects of the current Western lifestyle, such as childhood-onset asthma and allergy, as supported by both epidemiologic and animal model studies.

169 Infections Due to *Campylobacter* and Related Organisms

Martin J. Blaser

DEFINITION

Bacteria of the genus *Campylobacter* and of the related genera *Arcobacter* and *Helicobacter* **(Chap. 168)** cause a variety of inflammatory conditions. Although acute diarrheal illnesses are most common, these organisms may cause infections in virtually all parts of the body, especially in compromised hosts, and these infections may have late nonsuppurative sequelae. The designation *Campylobacter* comes from the Greek for "curved rod" and refers to the organism's vibrio-like morphology.

ETIOLOGY

Campylobacters are motile, non-spore-forming, curved, gram-negative rods. Originally known as *Vibrio fetus*, these bacilli were reclassified as a new genus in 1973 after their dissimilarity to other vibrios was recognized. More than 20 species have since been identified. These species are currently divided into three genera: *Campylobacter*, *Arcobacter*, and *Helicobacter*. Not all of the species are pathogens of humans. The human pathogens fall into two major groups: those that primarily cause diarrheal disease and those that cause extraintestinal infection. The principal diarrheal pathogen is *Campylobacter jejuni*, which accounts for 80–90% of all cases of recognized illness due to campylobacters and related genera. Other organisms that can cause diarrheal disease include *Campylobacter coli, Campylobacter upsaliensis, Campylobacter lari, Campylobacter hyointestinalis, Campylobacter fetus, Arcobacter butzleri, Arcobacter cryaerophilus, Helicobacter cinaedi*, and *Helicobacter fennelliae*. The two *Helicobacter* species causing diarrheal disease, *H. cinaedi* and *H. fennelliae*, are intestinal rather than gastric organisms; in terms of the clinical features of the illnesses they cause, these species most closely resemble *Campylobacter* rather than *Helicobacter pylori* **(Chap. 168)** and thus are considered in this chapter. The pathogenic roles of *Campylobacter concisus* (a member of the normal human oral microbiome), *Campylobacter ureolyticus*, and *Campylobacter troglodytis* are uncertain. A new subspecies—*C. fetus* subspecies *testudinum*—has been described, chiefly in Asian patients; the very close resemblance of human isolates to strains isolated from reptiles suggests a food source.

The major species causing extraintestinal illnesses is *C. fetus*. However, any of the diarrheal agents listed above may cause systemic or localized infection as well, especially in compromised hosts. Neither aerobes nor strict anaerobes, these microaerophilic organisms are adapted for survival in the gastrointestinal mucous layer. This chapter focuses on *C. jejuni* and *C. fetus* as the major pathogens and prototypes for their groups. The key features of infection are listed by species (excluding *C. jejuni*, described in detail in the text below) in **Table 169-1**.

EPIDEMIOLOGY

Campylobacters are found in the gastrointestinal tract of many animals used for food (including poultry, cattle, sheep, and swine) and many household pets (including birds, dogs, and cats). These microorganisms often do not cause illness in their animal hosts, but occasionally this can occur (especially in puppies); in such circumstances, puppy-to-human transmission may be detected. In most cases, campylobacters are transmitted to humans in raw or undercooked food products or through direct contact with infected animals. In the United States and other developed countries, ingestion of contaminated poultry that has not been sufficiently cooked is the most common mode of acquisition (30–70% of cases). Other modes include ingestion of raw (unpasteurized) milk or untreated water, contact with infected household pets, ingestion of contaminated seafood, travel to developing countries (campylobacters being a leading cause of traveler's diarrhea; **Chaps. 130 and 138**), oral–anal sexual contact, cross-contamination from any of these sources, and (occasionally) contact with an index case who is incontinent of stool.

Campylobacter infections are common. Active surveillance of foodborne infections in the United States estimates the incidence of diarrheal disease due to campylobacters at ~20 cases per 100,000 persons—similar in incidence to *Salmonella* and more common than *Shigella*. Infections occur throughout the year, but the incidence peaks during summer and early autumn. Persons of all ages are affected; however, attack rates for *C. jejuni* are highest among young children and young adults, whereas those for *C. fetus* are highest at the extremes of age. Systemic infections due to *C. fetus* (and to other *Campylobacter* and related species) are most common among compromised hosts. Persons at increased risk include those with AIDS, immunoglobulin deficiencies, neoplasia, liver disease, diabetes mellitus, and generalized atherosclerosis as well as neonates and pregnant women; proton pump inhibitor use also increases risk. However, apparently healthy nonpregnant persons occasionally develop transient *Campylobacter* bacteremia as part of a gastrointestinal illness (0.1–1% of cases).

In contrast, in many developing countries where sanitation is poor, *C. jejuni* infections are hyperendemic, with the highest rates among children <2 years old. According to large prospective cohort studies in low- to middle-income countries, *C. jejuni* infections—even when asymptomatic—are associated with short stature (stunting) and with a particular microbiome signature. Rates of clinically apparent infection fall with age, as does the illness-to-infection ratio, consistent with progressive development of immunity.

PATHOLOGY AND PATHOGENESIS

C. jejuni infections may be subclinical, especially in hosts in developing countries who have had multiple prior infections and may be partially

TABLE 169-1 Clinical Features Associated with Infection Due to "Atypical" *Campylobacter* and Related Species Implicated as Causes of Human Illness

SPECIES	COMMON CLINICAL FEATURES	LESS COMMON CLINICAL FEATURES	ADDITIONAL INFORMATION
Campylobacter coli	Fever, diarrhea, abdominal pain	Bacteremia[a]	Clinically indistinguishable from *C. jejuni*
Campylobacter fetus	Bacteremia[a], sepsis, meningitis, vascular infections	Diarrhea, relapsing fevers	Not usually isolated from media containing cephalothin or incubated at 42°C
Campylobacter upsaliensis	Watery diarrhea, low-grade fever, abdominal pain	Bacteremia[a], abscesses	Difficult to isolate because of cephalothin susceptibility
Campylobacter lari	Abdominal pain, diarrhea	Colitis, appendicitis	Seagulls frequently colonized; organism often transmitted to humans via contaminated water
Campylobacter hyointestinalis	Watery or bloody diarrhea, vomiting, abdominal pain	Bacteremia[a]	Causes proliferative enteritis in swine
Helicobacter fennelliae	Chronic mild diarrhea, abdominal cramps, proctitis	Bacteremia[a]	Best treated with fluoroquinolones
Helicobacter cinaedi	Chronic mild diarrhea, abdominal cramps, proctitis	Bacteremia[a]	Best treated with fluoroquinolones; identified in healthy hamsters
Campylobacter jejuni subspecies *doylei*	Diarrhea	Chronic gastritis, bacteremia[b]	Uncertain role as human pathogen
Arcobacter cryaerophilus	Diarrhea	Bacteremia[a]	Poultry, seafood sources. Cultured under aerobic conditions
Arcobacter butzleri	Fever, diarrhea, abdominal pain, nausea; or asymptomatic	Bacteremia[a], appendicitis	Cultured under aerobic conditions; enzootic in nonhuman primates
Campylobacter sputorum	Pulmonary, perianal, groin, and axillary abscesses; diarrhea	Bacteremia	Three clinically relevant biovars: *sputorum, faecalis,* and *paraureolyticus*

[a]In compromised hosts, especially including the elderly, and patients with immunodeficiencies, diabetes, and infection with HIV. [b]In children.

immune. Symptomatic infections mostly occur within 2–4 days (range, 1–7 days) of exposure to the organism. The sites of tissue injury include the jejunum, ileum, and colon. Biopsies show an acute nonspecific inflammatory reaction, with neutrophils, monocytes, and eosinophils in the lamina propria, as well as damage to the epithelium, including loss of mucus, glandular degeneration, and crypt abscesses. Biopsy findings may be consistent with Crohn's disease or ulcerative colitis, but these "idiopathic" chronic inflammatory diseases should not be diagnosed unless infectious colitis, *specifically including* that due to infection with *Campylobacter* species and related organisms, has been ruled out.

The components of protective immunity to *Campylobacter* in humans are poorly understood. The high frequency of *C. jejuni* infections and their severity and recurrence among immunoglobulin-deficient patients suggest that antibodies are important in protective immunity. Experience from field studies and human experimental infection models suggests that immune protection may be short-lived or incomplete in the absence of continuous exposure. Knowledge of the pathogenesis of infection is also incomplete. Both the motility of the strain and its capacity to adhere to host tissues appear to favor disease, but classic enterotoxins and cytotoxins (including cytolethal distending toxin) appear not to play substantial roles in tissue injury or disease production. The organisms have been visualized within the epithelium, albeit in low numbers. The documentation of a significant tissue response and occasionally of *C. jejuni* bacteremia further suggests that tissue invasion is clinically significant, and in vitro studies are consistent with this pathogenic feature.

The pathogenesis of *C. fetus* infections is better defined. Virtually all clinical isolates of *C. fetus* possess a proteinaceous capsule-like structure (an S-layer) that renders the organisms resistant to complement-mediated killing and opsonization. As a result, *C. fetus* can cause bacteremia and can seed sites beyond the intestinal tract. The ability of the organism to switch the S-layer proteins expressed—a phenomenon that results in antigenic variability—may contribute to the chronicity and high rate of recurrence of *C. fetus* infections in compromised hosts.

CLINICAL MANIFESTATIONS

The clinical features of infections due to *Campylobacter* and the related *Arcobacter* and intestinal *Helicobacter* species causing enteric disease appear to be highly similar. *C. jejuni* can be considered the prototype, in part because it is by far the most common enteric pathogen in the group. A prodrome of fever, headache, myalgia, and/or malaise often occurs 12–48 h before the onset of diarrheal symptoms. The most common signs and symptoms of the intestinal phase are diarrhea, abdominal pain, and fever. The degree of diarrhea varies from several loose watery stools to visibly bloody stools (~10% of cases in adults); most patients presenting for medical attention have ≥10 bowel movements on the worst day of illness. Abdominal pain usually consists of cramping and may be the most prominent symptom. Pain is usually generalized but may become localized; *C. jejuni* infection may cause pseudoappendicitis. Fever may be the only initial manifestation of *C. jejuni* infection, a situation mimicking the early stages of typhoid fever. Febrile young children may develop convulsions, and both myocarditis and pericarditis have been observed, especially in young men. *Campylobacter* enteritis is generally self-limited; however, symptoms persist for >1 week in 10–20% of patients seeking medical attention, and clinical relapses occur in 5–10% of untreated patients. Studies of common-source epidemics indicate that milder illnesses or asymptomatic infections may commonly occur.

C. fetus may cause a diarrheal illness similar to that due to *C. jejuni*, especially in immunocompetent hosts. This organism also may cause either intermittent diarrhea or nonspecific abdominal pain without localizing signs. Sequelae are uncommon, and the outcome is benign. *C. fetus* may also cause a prolonged relapsing systemic illness (with fever, chills, and myalgias) with bacteremia that has no obvious primary source; this manifestation is especially common among compromised hosts. Secondary seeding of an organ (e.g., meninges, brain, bone, urinary tract, or soft tissue) complicates the course, which may be fulminant. *C. fetus* infections have a tropism for vascular sites: endocarditis, mycotic aneurysm, and septic thrombophlebitis may all occur. Infection during pregnancy often leads to fetal death. A variety of *Campylobacter* species and *H. cinaedi* can cause recurrent cellulitis with fever and bacteremia in immunocompromised hosts.

COMPLICATIONS

About 90% of bacteremic infections are caused by *C. jejuni* and *C. fetus,* in roughly equal proportions, despite the manyfold greater incidence of *C. jejuni* infections. Overall, mortality has been reported at ~12%. Except in infection with *C. fetus*, bacteremia is uncommon, developing most often in compromised hosts—including those who are immunocompromised and diabetic—and at the extremes of age. Three patterns of extraintestinal infection have been noted: (1) transient bacteremia in a normal host with enteritis (benign course, no specific treatment needed); (2) sustained bacteremia or focal infection in a normal host (bacteremia originating from enteritis, with patients responding well to antimicrobial therapy); and (3) sustained bacteremia or focal infection in a compromised host. Enteritis may not be clinically apparent. Immediate antimicrobial therapy, possibly prolonged, is necessary for suppression or cure of these infections.

Campylobacter, Arcobacter, and intestinal *Helicobacter* infections in the elderly as well as in patients with AIDS or immunoglobulin-deficient patients (most often common variable immunodeficiency) may be severe, persistent, and extraintestinal; relapse after cessation of therapy is common. Immunoglobulin-deficient patients also may develop osteomyelitis and an erysipelas-like rash or cellulitis.

Local suppurative complications of infection include cholecystitis, pancreatitis, and cystitis; distant complications include meningitis, endocarditis, and endovasculitis (leading to mycotic aortic aneurysm), osteoarticular infection, peritonitis, cellulitis, and septic abortion. All these complications are rare, except in immunocompromised or elderly hosts. Hepatitis, interstitial nephritis, and the hemolytic-uremic syndrome occasionally complicate acute infection. The two most common postinfectious sequelae are reactive arthritis and Guillain-Barré syndrome. Reactive arthritis has been reported in up to 2.5% of cases, although nonspecific rheumatologic symptoms are more common (~10%). Reactive arthritis may develop several weeks after infection; population-based analysis shows that there is no association with the HLA-B27 phenotype. The knees are most frequently involved, but involvement of the ankles, wrists, and small joints of the hands is common, with an average of 3.2 joints affected. Guillain-Barré syndrome or its Miller Fisher (cranial polyneuropathy) variant follow either symptomatic or asymptomatic *Campylobacter* infections uncommonly—i.e., in 1 of every 1000–2000 cases or, for certain *C. jejuni* serotypes (such as O19), in 1 of every 100–200 cases. Despite the low frequency of this complication, it is estimated that *Campylobacter* infections, because of their high incidence, may trigger 20–40% of all cases of Guillain-Barré syndrome. The presence of sialylated lipopolysaccharides on *C. jejuni* strains prompts a form of molecular mimicry that promotes autoimmune recognition of sialylated cell-surface molecules on axons. Immunoproliferative small-intestinal disease (*alpha chain disease*), a form of lymphoma that originates in small-intestinal mucosa-associated lymphoid tissue (MALToma), has been associated with *C. jejuni*; antimicrobial therapy has led to marked clinical improvement.

DIAGNOSIS

In patients with *Campylobacter* enteritis, peripheral leukocyte counts reflect the severity of the inflammatory process. In addition, stools from nearly all *Campylobacter*-infected patients presenting for medical attention in the United States contain leukocytes or erythrocytes. Gram- or Wright-stained fecal smears should be examined in all suspected cases. When the diagnosis of *Campylobacter* enteritis is suspected on the basis of findings indicating inflammatory diarrhea (fever, fecal leukocytes), clinicians can ask the microbiology laboratory to attempt the visualization of organisms with characteristic vibrioid morphology by direct microscopic examination of stools with Gram's staining or to use phase-contrast or dark-field microscopy to identify the organisms' characteristic "darting" motility. Confirmation of the diagnosis of *Campylobacter* infection is based on identification of an

isolate from cultures of stool, blood, or another site; specific species can be identified by matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry. *Campylobacter*-specific media should be used to culture stools from all patients with inflammatory or bloody diarrhea. Because all *Campylobacter* species are fastidious, they will not be isolated unless selective media or other selective techniques are used. Failure to isolate campylobacters from stool by culture does not entirely rule out their presence. Although culture remains the diagnostic gold standard, species-specific real-time polymerase chain reaction (PCR) techniques appear more sensitive than culture. Although PCR and other culture-independent diagnostic test (CIDTs), including antigen detection tests, may detect nonviable bacteria and may be falsely positive, they are now used frequently to diagnose infection with *Campylobacter* and other enteric bacteria in clinical microbiology laboratories. The detection of the organisms in stool in the United States by culture almost always implies active or recent infection, but CIDT positivity is more questionable.

In any event, follow-up testing after the clinical resolution of an acute infection is rarely needed. *Campylobacter sputorum, C. concisus,* and related organisms ubiquitously found in the oral cavity are commensals that only rarely have pathogenic significance. In patients with microscopic colitis, *C. concisus* can be more frequently detected than in controls, but whether detection of this common oral organism is a marker for colonic disease or is involved in pathogenesis is uncertain. Because of the low levels of metabolic activity of *Campylobacter* species in standard blood culture media, *Campylobacter* bacteremia may be difficult to detect.

DIFFERENTIAL DIAGNOSIS

The symptoms of *Campylobacter* enteritis are not sufficiently unusual to distinguish this illness from that due to *Salmonella, Shigella, Yersinia*, enterohemorrhagic *Escherichia coli*, and other pathogens. The combination of fever and fecal leukocytes or erythrocytes is indicative of inflammatory diarrhea, and definitive diagnosis is based on culture, CIDTs, or demonstration of the characteristic organisms on stained fecal smears. Extraintestinal *Campylobacter* illness is diagnosed by culture. Infection due to *Campylobacter* should be suspected in the setting of septic abortion, and that due to *C. fetus* should be suspected specifically in the setting of septic thrombophlebitis. It is important to reiterate that (1) the presentation of *Campylobacter* enteritis may mimic that of ulcerative colitis or Crohn's disease, (2) *Campylobacter* enteritis is much more common than either of the latter (especially among young adults), and (3) biopsy may not distinguish among these entities. Thus, a diagnosis of inflammatory bowel disease should not be made until *Campylobacter* infection has been ruled out, especially in persons with a history of foreign travel, significant animal contact, immunodeficiency, or exposure incurring a high risk of transmission.

TREATMENT

Campylobacter Infection

Fluid and electrolyte replacement is central to the treatment of diarrheal illnesses **(Chap. 138)**. Even among patients presenting for medical attention with *Campylobacter* enteritis, not all clearly benefit from specific antimicrobial therapy. Indications for therapy include high fever, bloody diarrhea, severe diarrhea, persistence for >1 week, and worsening of symptoms. A 3-day course of azithromycin (500 mg once daily) is the regimen of choice. A 1-day regimen of azithromycin (1000 mg given as two 500-mg tablets) can also be used. Alternative regimens for adults consist of fluoroquinolones—ciprofloxacin (500 mg by mouth twice daily for 3 days) or levofloxacin (750 mg daily for 3 days)—but resistance to this class of agents as well as to tetracyclines is substantial; ~27% of U.S. human isolates of *Campylobacter* in 2014 were resistant to ciprofloxacin, and rates are higher in many other countries; thus, travel-related *Campylobacter* infections should be considered a priori to be fluoroquinolone-resistant. Because macrolide resistance usually is much less common (<10%), these drugs are the empirical agents of choice. Patients infected with antibiotic-resistant strains are at increased risk of adverse outcomes. Use of antimotility agents, which may prolong the duration of symptoms and have been associated with toxic megacolon and with death, is not recommended. Of note, *C. jejuni* and *C. coli* are resistant to trimethoprim and β-lactam antibiotics, including penicillin and most cephalosporins.

For patients with immunocompromising conditions and uncomplicated enteritis caused by *C. jejuni*, therapy duration should be extended to 7–14 days. Bacteremic infections should always be treated with appropriate antibiotics to reduce the high rate of mortality associated with these infections. For bacteremic or other systemic infections, treatment with a carbapenem (imipenem, 500 mg IV every 6 h; or meropenem, 1–2 g IV every 8 h) should be started empirically, and susceptibility testing should always be performed. For life-threatening illness, gentamicin (1.0–1.7 mg/kg IV every 8 h after a loading dose of 1.5–2 mg/kg) can be added. In the absence of endovascular involvement, therapy for systemic infections should be administered for 7–14 days. For immunocompromised patients with systemic infections due to *C. fetus* and for patients with endovascular infections due to any species, prolonged therapy (up to 4 weeks) is usually necessary. For recurrent infections in immunocompromised hosts, lifelong therapy/prophylaxis is sometimes necessary.

PROGNOSIS

Nearly all patients recover fully from *Campylobacter* enteritis, either spontaneously or after antimicrobial therapy. Volume depletion probably contributes to the few deaths that are reported. As stated above, occasional patients develop reactive arthritis or Guillain-Barré syndrome or its variants. Systemic infection with *C. fetus* is much more often fatal than that due to related species; this higher mortality rate reflects in part the population affected. Prognosis depends on the rapidity with which appropriate therapy is begun. Otherwise healthy hosts usually survive *C. fetus* infections without sequelae. Compromised hosts often have recurrent and/or life-threatening infections due to a variety of *Campylobacter* species.

170 Infections Due to *Pseudomonas*, *Burkholderia*, and *Stenotrophomonas* Species

Kartikeya Cherabuddi, Reuben Ramphal

The pseudomonads are a heterogeneous group of gram-negative bacteria that have in common an inability to ferment lactose. Formerly classified in the genus *Pseudomonas*, the members of this group have been assigned to three medically important genera—*Pseudomonas, Burkholderia*, and *Stenotrophomonas*—whose biologic behaviors encompass both similarities and marked differences and whose genetic repertoires differ in many respects. The pathogenicity of most pseudomonads is based on opportunism; the exceptions are *Burkholderia pseudomallei* and *Burkholderia mallei*, which are primary pathogens.

The genus *Pseudomonas* now contains >140 species. *Pseudomonas aeruginosa*, the major pathogen of the group, is a significant cause of infections in hospitalized patients and in patients with cystic fibrosis (CF; **Chap. 302**). Cytotoxic chemotherapy, mechanical ventilation, chronic lung diseases, and broad-spectrum antibiotic therapy set up conditions that predispose to colonization and infection of increasing numbers of hospitalized patients by this pathogen. Other significant members of the genus—*Pseudomonas putida, Pseudomonas fluorescens*, *Pseudomonas oryzihabitans*, and *Pseudomonas stutzeri*—infect humans infrequently and are generally opportunists that are always present in the environment.

The genus *Burkholderia* comprises >20 species, of which *Burkholderia cepacia* is most frequently encountered in Western countries. Similar to *P. aeruginosa, B. cepacia* (now referred to as the *B. cepacia* complex species) is both an opportunistic nosocomial pathogen and a cause of infection in CF. The other medically important members of this genus are *B. pseudomallei* and *B. mallei*, the etiologic agents of melioidosis and glanders, respectively.

The genus *Stenotrophomonas* contains one species of medical significance, *Stenotrophomonas maltophilia*. This organism is strictly an opportunist that "overgrows" in the setting of broad-spectrum antibiotic use.

PSEUDOMONAS AERUGINOSA

EPIDEMIOLOGY

P. aeruginosa is found in most moist environments. Soil, plants, vegetables, tap water, and countertops are all potential reservoirs for this microbe, as it has simple nutritional needs. Given the ubiquity of *P. aeruginosa*, it is clear that simple contact with the organism is not sufficient for colonization or infection. Clinical and experimental observations suggest that infection by *P. aeruginosa* occurs concomitantly with compromised host defenses, mucosal trauma, physiologic derangement, and antibiotic-mediated suppression of normal flora. Thus, it comes as no surprise that the majority of *P. aeruginosa* infections occur in intensive care units (ICUs), where these factors frequently converge. Although the organism is initially acquired from environmental sources, patient-to-patient spread occurs in CF clinics and may occur in closed hospital units.

In the past, patients with burns appeared to be unusually susceptible to *P. aeruginosa*. For example, in 1959–1963, *Pseudomonas* burn-wound sepsis was the principal cause of death in 60% of patients with burns dying at the U.S. Army Institute of Surgical Research. For reasons that are unclear, *P. aeruginosa* infection in burns is no longer the major problem that it was during the 1950s and 1960s. Similarly, in the 1960s, *P. aeruginosa* appeared as a common pathogen in patients receiving cytotoxic chemotherapy at many institutions in the United States, but it has subsequently diminished in importance. Despite this subsidence, *P. aeruginosa* remains one of the most feared pathogens in this population because of its high attributable mortality.

In some parts of Asia and Latin America, *P. aeruginosa* continues to be the most common cause of gram-negative bacteremia in neutropenic patients.

In contrast to the trends for patients with burns or neutropenia in the United States, the incidence of *P. aeruginosa* infections among patients with CF has not changed. *P. aeruginosa* remains the most common contributing factor to respiratory failure in CF and is responsible for the majority of deaths among CF patients.

LABORATORY FEATURES

P. aeruginosa is a nonfastidious, motile, gram-negative rod that grows on most common laboratory media, including blood and MacConkey agars. It is easily identified in the laboratory on primary-isolation agar plates by pigment production that confers a yellow to dark green or even bluish appearance. Colonies have a shiny "gun-metal" appearance and a characteristic fruity odor. Two of the identifying biochemical characteristics of *P. aeruginosa* are an inability to ferment lactose on MacConkey agar and a positive reaction in the oxidase test. Most strains are identified on the basis of these readily detectable laboratory features even before extensive biochemical testing is done. Some isolates from CF patients are easily identified by their mucoid appearance, which is due to the production of large amounts of the mucoid exopolysaccharide or alginate. Recently, there has been increasing use of molecular testing with multiplex polymerase chain reaction (PCR) platforms, which rapidly identify *P. aeruginosa* in respiratory and blood samples much earlier than the classical methods.

PATHOGENESIS

Unraveling the mechanisms that underlie disease caused by *P. aeruginosa* has proved challenging. Of the common gram-negative bacteria, no other species produces such a large number of putative virulence factors **(Table 170-1)**. Yet *P. aeruginosa* rarely initiates an infectious process in the absence of host injury or compromise, and few of its putative virulence factors have been shown definitively to be involved in disease in humans. Despite its metabolic versatility and possession of multiple colonizing factors, *P. aeruginosa* exhibits no competitive advantage over enteric bacteria in the human gut; it is not a normal inhabitant of the healthy human gastrointestinal tract, despite the host's continuous environmental exposure to the organism.

Virulence Attributes Involved in Acute *P. aeruginosa* Infections • **MOTILITY AND COLONIZATION** A general tenet of bacterial pathogenesis is that most bacteria must adhere to surfaces or colonize a host niche in order to initiate disease. Most gram-negative bacteria examined thus far possess adherence factors called *adhesins*. *P. aeruginosa* is no exception. Among its many adhesins are its pili, which demonstrate adhesive properties for a variety of cells and adhere best to injured cell surfaces. In the organism's flagellum, the flagellin molecule binds to cells, and the flagellar cap attaches to mucins through the recognition of glycan chains. Other *P. aeruginosa* adhesins

TABLE 170-1 Main Putative Virulence Factors of *Pseudomonas aeruginosa*

SUBSTANCE/ ORGANELLE	FUNCTION	VIRULENCE IN ANIMAL DISEASE
Pili	Adhesion to cells	?
Flagella	Adhesion, motility, inflammation	Yes
Lipopolysaccharide	Antiphagocytic activity, inflammation	Yes
Type III secretion system	Toxic activity (ExoU, ExoS)	Yes
Type II secretion system	Toxic activity	Yes
Proteases	Proteolytic activity	?
Phospholipases	Cytotoxicity	?
Exotoxin A	Cytotoxicity	?
Pyocyanin	Cytotoxicity	Yes

include the outer core of the lipopolysaccharide (LPS) molecule, which binds to the cystic fibrosis transmembrane conductance regulator (CFTR) and aids in internalization of the organism, and the alginate coat of mucoid strains, which enhances adhesion to cells and mucins. In addition, membrane proteins and lectins have been proposed as colonization factors. The deletion of any given adhesin by itself is not sufficient to abrogate the ability of *P. aeruginosa* to colonize surfaces probably because of the redundancy of adhesins. Motility is important in host invasion via mucosal surfaces or burned skin in animal models of infection; however, nonmotile strains are not uniformly avirulent. It has been well demonstrated that nonmotile strains of *P. aeruginosa* are poorly phagocytosed in vitro, possibly leading to enhancement of the virulence of this organism in vivo.

EVASION OF HOST DEFENSES The transition from bacterial colonization to disease requires the evasion of host defenses followed by invasion by the microorganism. *P. aeruginosa* appears to be well equipped for evasion. Attached bacteria inject four known toxins (ExoS or ExoU, ExoT, and ExoY) via a type III secretion system that allows the bacteria to evade phagocytic cells either by direct cytotoxicity or by inhibition of phagocytosis. Clinical studies suggest that the mortality rate is higher among patients infected by strains that secrete the ExoU toxin. Another secretion system—the type II system—secretes toxins that can kill animals, and some of its secreted toxins, such as exotoxin A, have the potential to kill phagocytic cells. Multiple proteases secreted by this system may degrade host effector molecules, such as cytokines and chemokines, that are released in response to infection and appear to play a role in corneal infections in mice.

TISSUE INJURY Among gram-negative bacteria, *P. aeruginosa* probably produces the largest number of substances that are toxic to cells and thus have the potential to injure tissues. The toxins secreted by the organism's type III secretion system are capable of injuring tissue. However, their delivery requires the adherence of the organism to cells. Thus, the effects of these toxins are likely to be local or to depend on the presence of large numbers of bacteria at the site of an infection or in the bloodstream. On the other hand, diffusible toxins, secreted by the organism's type II secretion system, can act freely wherever they come into contact with cells. Possible effectors of this system include exotoxin A, at least four different proteases, and at least two phospholipases. In addition to these secreted toxins, rhamnolipids, pyocyanins—the pigments that confer the characteristic color and odor of *P. aeruginosa* colonies—and hydrocyanic acid, are produced by *P. aeruginosa* and are all capable of causing host tissue injury and even neutrophil death.

INFLAMMATORY COMPONENTS The inflammatory responses to the lipid A component of *Pseudomonas* LPS and to its flagellin, mediated through the Toll-like receptor (TLR) system (principally TLR4 and TLR5, respectively), are thought to represent important factors in disease causation. Although these inflammatory responses are required for successful defense against *P. aeruginosa* (i.e., in their absence, animals are defenseless against *P. aeruginosa* infection), florid responses are likely to result in severe disease. Thus, when the sepsis syndrome and septic shock develop in *P. aeruginosa* infection, they are probably the result of the host response to one or both of these substances, but injury to the lung by *Pseudomonas* toxins may also result in sepsis syndromes, possibly by causing cell death and the release of cellular components (e.g., heat-shock proteins) that may activate the TLR or another proinflammatory system. Thus, the virulence of this bacterium in acute infections is likely to be multifactorial with a great redundancy of effector molecules being produced.

Chronic *P. aeruginosa* Infections Chronic infection due to *P. aeruginosa* occurs mainly in the lungs in the setting of structural pulmonary diseases. The classic example is CF; others include bronchiectasis and chronic relapsing panbronchiolitis, a disease seen in Japan and some Pacific Islands. A hallmark of these illnesses is severely defective mucociliary clearance leading to mucus stasis and mucus accumulation in the lungs. There is probably a common factor that selects for *P. aeruginosa* colonization in these lung diseases—perhaps the adhesiveness of *P. aeruginosa* for mucus, a phenomenon that is not noted for most other common gram-negative bacteria, and/or the ability of *P. aeruginosa* to evade host defenses in mucus. Furthermore, *P. aeruginosa* undergoes evolutionary adaptations and diversification in ways that allow its prolonged survival in the lung without an early fatal outcome for the host. The strains found in CF patients exhibit minimal production of virulence factors. Many strains lose the ability to produce pili and flagella, and most become complement-sensitive because of the loss of the O side chain of their LPS molecules. In addition, most strains found in CF patients overproduce a mucoid exopolysaccharide. These changes probably dampen the host response, allowing the organism to survive in CF mucus. *P. aeruginosa* is also believed to lose its ability to secrete many of its injectable toxins during growth in mucus. Although the alginate coat is thought to play a role in the organism's survival, alginate is not essential as nonmucoid strains may predominate for long periods. In short, virulence in chronic infections may be mediated by the chronic but attenuated host inflammatory response, which injures the lungs over decades.

CLINICAL MANIFESTATIONS

P. aeruginosa causes infections at almost all sites in the body but shows a rather marked predilection for the lungs. The infections encountered most commonly in hospitalized patients are described below.

Bacteremia Crude mortality rates exceeding 50% have been reported among patients with *P. aeruginosa* bacteremia. Consequently, this clinical entity has been much feared, and its management has been attempted with the use of multiple antibiotics. Recent publications report attributable mortality rates of 28–44%, with the precise figure depending on the adequacy and timing of treatment and the seriousness of the underlying disease. In the past, the patient with *P. aeruginosa* bacteremia classically was neutropenic or had a burn injury. Today, however, a minority of such patients have bacteremic *P. aeruginosa* infections. Rather, *P. aeruginosa* bacteremia is seen most often in patients in ICUs, with the lungs, the urinary tract, central venous lines, or wounds being the most important portals for systemic invasion.

The clinical presentation of *P. aeruginosa* bacteremia rarely differs from that of sepsis in general **(Chap. 315)**. Patients are usually febrile, but those who are most severely ill may be in shock or even hypothermic. The only point differentiating this entity from gram-negative sepsis due to other bacteria may be the distinctive skin lesions (ecthyma gangrenosum) of *Pseudomonas* infection, which occur almost exclusively in markedly neutropenic patients and patients with AIDS. These small or large, painful, reddish, maculopapular lesions have a geographic margin; they are initially pink, then darken to purple, and finally become black and necrotic **(Fig. 170-1)**. Histopathologic studies indicate that the lesions are due to vascular invasion and are teeming with bacteria. Although similar lesions may occur in aspergillosis, mucormycosis, and occasionally *Staphylococcus aureus* bacteremia, their presence in a neutropenic patient generally suggests *P. aeruginosa* bacteremia as the most likely cause.

TREATMENT

P. aeruginosa Bacteremia

(Table 170-2) Antimicrobial treatment of *P. aeruginosa* bacteremia has been controversial. Combination therapy with an

FIGURE 170-1 Ecthyma gangrenosum in a neutropenic patient 3 days after onset.

TABLE 170-2 Antibiotic Treatment of Infections Due to *Pseudomonas aeruginosa* and Related Species

INFECTION	ANTIBIOTICS AND DOSAGES	OTHER CONSIDERATIONS
Bacteremia		
Nonneutropenic host	Ceftazidime (2 g q8h IV) *or* cefepime (2 g q8h IV) *or* piperacillin/tazobactam (4.5 g q6h IV) *or* imipenem (500 mg q6h IV) *or* meropenem (1–2 g q8h IV) *or* doripenem (500 mg q8h IV) ***Optional:*** Amikacin (7.5 mg/kg q12h or 15 mg/kg q24h IV)	Add an aminoglycoside empirically for patients in shock and in regions or hospitals where rates of resistance to the primary β-lactam agents are high. Tobramycin may be used instead of amikacin (susceptibility permitting). A duration of 6–10 days of therapy can be used for uncomplicated bacteremia.
Neutropenic host	Cefepime (2 g q8h IV) *or* any of the other agents above (except doripenem) in the above dosages	Febrile neutropenic patients should be treated until no longer neutropenic.
Endocarditis	Antibiotic regimens as for bacteremia for 6–8 weeks	Resistance during therapy is common. Surgery is required for relapse.
Pneumonia	Drugs and dosages as for bacteremia, except that the available carbapenems should not be the sole primary drugs because of high rates of resistance during therapy.	Add aminoglycoside or ciprofloxacin, as for bacteremia, until sensitivities available. The duration of therapy is 7 days.
Bone infection, malignant otitis externa	Cefepime or ceftazidime at the same dosages as for bacteremia; aminoglycosides not a necessary component of therapy; ciprofloxacin (500–750 mg q12h PO) may be used	Duration of therapy varies with the drug used and type of infection (e.g., 6 weeks for a β-lactam agent; except in puncture-wound osteomyelitis, for which the duration should be 2–4 weeks; oral therapy can be used).
Central nervous system infection	Ceftazidime or cefepime (2 g q8h IV) *or* meropenem (2 g q8h IV)	Abscesses or other closed-space infections may require drainage. The duration of therapy is ≥2 weeks.
Eye infection		
Keratitis/ulcer	Topical therapy with tobramycin/ciprofloxacin/levofloxacin eyedrops	Use maximal strengths available or compounded by pharmacy. Therapy should be administered for 2 weeks or until the resolution of eye lesions, whichever is shorter.
Endophthalmitis	Ceftazidime or cefepime as for central nervous system infection ***plus*** Topical therapy	
Urinary tract infection (UTI)	Ciprofloxacin (500 mg q12h PO) *or* levofloxacin (750 mg q24h) *or* any aminoglycoside (total daily dose given once daily). Cefepime or ceftazidime (1g q8h) *or* piperacillin/tazobactam (3.375 g q6h)	Uncomplicated cystitis may be treated for 3 days with oral agents. Relapse may occur if an obstruction or a foreign body is present. The duration of therapy for complicated cystitis and uncomplicated pyelonephritis is 5–7 days.
Multidrug- and extreme drug-resistant *P. aeruginosa* infection	Ceftazidime/avibactam (2.5 g q8h, infused over 2 h) *or* ceftolozane/tazobactam (1.5–3 g q8h) *or* imipenem/relebactam (500 mg q6h) *or* cefiderocol (2 g q8h) *or* colistin (100 mg q12h IV for the shortest possible period to obtain a clinical response)	Use 3-g dose of ceftolozane/tazobactam for pneumonia. Meropenem-vaborbactam offers minimal benefit in carbapenem resistant strains. Alternatives to colistin are preferred, if available. Colistin dosing requires renal adjustment and expertise in its use. Inhaled colistin may be added for pneumonia (100 mg q12h).
Burkholderia cepacia complex infection	Meropenem (2 g q8h IV) *or* TMP-SMX (1600/320 mg q12h IV) for 14 days	Resistance to both agents is increasing. Do not use them in combination because of possible antagonism.
Melioidosis (*B. pseudomallei*), glanders (*B. mallei*)	Ceftazidime (2 g q6h) *or* meropenem (1 g q8h) *or* imipenem (500 mg q6h) for 2 weeks ***followed by*** TMP-SMX (1600/320 mg q12h PO) for 3 months	
Stenotrophomonas maltophilia infection	TMP-SMX (1600/320 mg q12h IV) *plus* either levofloxacin (750 mg q24h) *or* minocycline (100-200 mg q12h) or ticarcillin/clavulanate (3.1 g q4h IV) for 7 to 14 days	Broad-spectrum antibiotic therapy leads to respiratory tract colonization and often warrants no treatment. Ceftazidime-avibactam plus aztreonam, cefiderocol, or tigecycline are alternatives for XDR strains. Combination therapy should be used for bacteremia, especially in immunosuppressed patients.

Abbreviations: MIC, minimum inhibitory concentration; TMP-SMX, trimethoprim-sulfamethoxazole.

antipseudomonal β-lactam and an aminoglycoside became the standard of care because of the dismal outcome of single-drug therapy, mainly with aminoglycosides and polymixins, prior to 1971—first for *P. aeruginosa* bacteremia in febrile neutropenic patients and then extrapolated to all *P. aeruginosa* bacteremic infections in both neutropenic and nonneutropenic patients.

Following the introduction of new antipseudomonal drugs, a number of studies have revisited the choice between combination treatment and monotherapy for *Pseudomonas* bacteremia. Although some clinicians still favor combination therapy, most recent observational studies indicate that a single modern antipseudomonal β-lactam agent to which the isolate is sensitive is as efficacious as a combination. Even in patients at greatest risk of early death from *P. aeruginosa* bacteremia (i.e., those with fever and neutropenia), empirical antipseudomonal monotherapy is deemed to be as efficacious as empirical combination therapy by the practice guidelines of the Infectious Diseases Society of America (IDSA). One firm conclusion is that monotherapy with an aminoglycoside is not optimal.

There are, of course, institutions and countries where rates of susceptibility of *P. aeruginosa* to first-line antibiotics are <80%. Thus, when a septic patient with a high probability of *P. aeruginosa* infection is encountered in such settings, empirical combination therapy should be administered until the pathogen is identified and susceptibility data become available. Thereafter, whether one or two agents should be continued remains a matter of individual preference. Recent studies suggest that extended or continuous infusions of β-lactams such as cefepime, piperacillin-tazobactam, or meropenem may result in better outcomes of *Pseudomonas* bacteremia and possibly of *Pseudomonas* pneumonia. The duration of antibiotic therapy has now become an important consideration due to the increasing isolation of multiple drug-resistant (MDR) and extensively drug-resistant (XDR) *P. aeruginosa* strains. Recently published studies now strongly support the use of shorter courses of

therapy (7 days) rather than the longer duration (10–14 days) that is commonly recommended for many cases of *Pseudomonas* bacteremia. As in *S. aureus* bacteremia, catheter removal is important.

Acute Pneumonia Respiratory infections are the most common of all infections caused by *P. aeruginosa*. *P. aeruginosa* is common in both hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP). This organism appears first or second among the causes of VAP. However, much debate centers on the actual role of *P. aeruginosa* in VAP. Many of the relevant data are based on cultures of sputum or endotracheal tube aspirates and may represent nonpathogenic colonization of the tracheobronchial tree, biofilms on the endotracheal tube, or simple tracheobronchitis. The increasing use of PCR testing on endotracheal samples has further compounded this issue. PCR coupled with the widespread use of computed tomography with poor specificity for pneumonia, and overlap in appearance with fluid overload in patients with low to intermediate clinical suspicion, may contribute to the overdiagnosis of HAP and VAP. This scenario emphasizes the importance of clinical judgment in adjudicating *P. aeruginosa* colonization versus infection.

Older reports of *P. aeruginosa* pneumonia described patients with an acute clinical syndrome of fever, chills, cough, and necrotizing pneumonia indistinguishable from other gram-negative bacterial pneumonias. The traditional accounts described a fulminant infection. Chest radiographs demonstrated bilateral pneumonia, often with nodular densities with or without cavities. This picture is now remarkably rare. Today, the typical patient is on a ventilator, has a slowly progressive infiltrate, and has been colonized with *P. aeruginosa* for days. While some cases may progress rapidly over 48–72 h, they are the exceptions. Nodular densities are not commonly seen. However, infiltrates may go on to necrosis. Necrotizing pneumonia has also been seen in the community (e.g., after inhalation of hot-tub water contaminated with *P. aeruginosa*). The typical patient has fever, leukocytosis, tachypnea, hypoxemia, and purulent sputum, and the chest radiograph shows a new infiltrate or the expansion of a preexisting infiltrate. A sputum Gram's stain showing mainly polymorphonuclear leukocytes (PMNs) in conjunction with a culture positive for *P. aeruginosa* in this setting suggests a diagnosis of acute *P. aeruginosa* pneumonia.

There have been increasing reports of the occurrence of community-acquired *P. aeruginosa* pneumonia among patients with underlying lung diseases. While this undoubtedly occurs, it is difficult to make this diagnosis with a great degree of certainty with the use of sputum cultures in a population prone to airway colonization by multiple strains of bacteria. The patient population in whom the possibility of a community-acquired *P. aeruginosa* pneumonia should be considered is the neutropenic patient, given the pivotal role that neutrophils play in defense against this bacterium. Such a patient, whether hospitalized or admitted from the community with a pneumonia, should be treated empirically for *P. aeruginosa*.

TREATMENT

Acute Pneumonia

(Table 170-2) Therapy for *P. aeruginosa* pneumonia remains unsatisfactory. Reports suggest mortality rates of 40–80%, but how many of these deaths are attributable to underlying disease remains unknown. The drugs of choice for *P. aeruginosa* pneumonia are similar to those given for bacteremia. A potent antipseudomonal β-lactam drug is the mainstay of therapy. Failure rates were high when aminoglycosides were used as single agents, possibly because of their poor penetration into the airways and their binding to airway secretions. Nonetheless, for the treatment of patients at high risk of death, some experts suggest the combination of a β-lactam agent and an antipseudomonal fluoroquinolone or aminoglycoside. As for the duration of therapy, recent IDSA/American Thoracic Society (ATS) guidelines recommend 7 days of treatment for HAP or VAP, even when *P. aeruginosa* is the offending organism. However, the outcome in neutropenic patients is poor, especially if accompanied by bacteremia; thus, therapy needs to be extended until neutropenia resolves. In addition, therapy longer than 7 days should be used in patients with *P. aeruginosa* necrotizing pneumonia as, functionally, this entity is similar to a lung abscess.

Chronic Respiratory Tract Infections *P. aeruginosa* is responsible for chronic infections of the airways associated with a number of underlying or predisposing conditions—most commonly CF **(Chap. 302)**. A state of chronic colonization beginning early in childhood is seen in some Asian populations with chronic or diffuse panbronchiolitis, a disease of unknown etiology. *P. aeruginosa* is one of the organisms that colonizes damaged bronchi in bronchiectasis, a disease secondary to multiple causes in which profound structural abnormalities of the airways result in mucus stasis.

TREATMENT

Chronic Respiratory Tract Infections

Optimal management of chronic *P. aeruginosa* lung infection has not been determined. Patients respond clinically to antipseudomonal therapy, but the organism is rarely eradicated. Because eradication is unlikely, the aim of treatment for chronic infection is to quell exacerbations of inflammation. The regimens used are similar to those used for pneumonia, but an aminoglycoside is almost always added because resistance is common in chronic disease. However, it may be more appropriate to use an inhaled aminoglycoside preparation in order to maximize airway drug levels. MDR strains are now commonly found in such patients given their increased life span and the repeated courses of antibiotics they receive.

Endovascular Infections Infective endocarditis of native valves due to *P. aeruginosa* is most commonly seen in those who use IV drugs. This organism has also been reported to cause prosthetic-valve endocarditis. Sites of prior native-valve injury due to the injection of foreign material such as talc or fibers probably serve as niduses for bacterial attachment to the heart valve. The manifestations of *P. aeruginosa* endocarditis resemble those of other forms of endocarditis in those who use IV drugs except that the disease is more indolent than *S. aureus* endocarditis. While most disease involves the right side of the heart, left-sided involvement is not rare, and multivalvular disease is common. Fever is a common manifestation, as is pulmonary involvement (due to septic emboli to the lungs). Thus, patients may also experience chest pain and hemoptysis. Involvement of the left side of the heart may lead to signs of cardiac failure, systemic emboli, and local cardiac involvement with sinus of Valsalva abscesses and conduction defects. Skin manifestations other than injection site infections are rare in this disease, and ecthyma gangrenosum is not common. Vertebral osteomyelitis and sternoclavicular joint septic arthritis are uncommon but pathognomic complications of this disease. The diagnosis is based on positive blood cultures along with clinical signs of endocarditis.

TREATMENT

Endovascular Infections

(Table 170-2) It has been customary to use synergistic antibiotic combinations in treating *P. aeruginosa* endocarditis because of the development of resistance during therapy with a single antipseudomonal β-lactam agent. Which combination therapy is preferable is unclear, as all combinations have failed. Treatment is likely to more often be successful in cases of right-sided endocarditis. Cases of *P. aeruginosa* endocarditis that relapse during or fail to respond to therapy are often caused by resistant organisms and may require surgical therapy. Other considerations for valve replacement are similar to those in other forms of endocarditis **(Chap. 133)**.

Bone and Joint Infections *P. aeruginosa* is an infrequent cause of bone and joint infections. However, *Pseudomonas* bacteremia or

infective endocarditis caused by the injection of contaminated illicit drugs has been documented to result in vertebral osteomyelitis and sternoclavicular joint arthritis. The clinical presentation of vertebral *P. aeruginosa* osteomyelitis is more indolent than that of staphylococcal osteomyelitis. The duration of symptoms in IV drug users with vertebral osteomyelitis due to *P. aeruginosa* varies from weeks to months. Fever is not uniformly present; when present, it tends to be low grade. There may be mild tenderness at the site of involvement. Blood cultures are usually negative unless there is concomitant endocarditis. The erythrocyte sedimentation rate (ESR) is generally elevated. Vertebral osteomyelitis due to *P. aeruginosa* has also been reported in the elderly, in whom it originates from urinary tract infections (UTIs). The infection generally involves the lumbosacral area because of a shared venous drainage (Batson's plexus) between the lumbosacral spine and the pelvis. Sternoclavicular septic arthritis due to *P. aeruginosa* is seen almost exclusively in persons who use IV drugs. This disease may occur with or without endocarditis, and a primary site of infection often is not found. Plain radiographs show joint or bone involvement. Treatment of these forms of disease is generally successful.

Pseudomonas osteomyelitis of the foot most often follows puncture wounds through sneakers and mostly affects children. The main manifestation is pain in the foot, sometimes with superficial cellulitis around the puncture wound and tenderness on deep palpation of the wound. Multiple joints or bones of the foot may be involved. Systemic symptoms are generally absent, and blood cultures are usually negative. Radiographs may or may not be abnormal, but the bone scan is usually positive, as are magnetic resonance imaging (MRI) studies. Needle aspiration usually yields a diagnosis. Prompt surgery, with exploration of the nail puncture tract and debridement of the involved bones and cartilage, is generally recommended in addition to antibiotic therapy.

Osteomyelitis due to *P. aeruginosa* is also seen following trauma and with decubitus ulcers. In these settings, the cause of osteomyelitis is often polymicrobial, and the role of *P. aeruginosa* can be questioned. It is therefore critical that deep bone biopsies be requested to ascertain its significance prior to starting treatment that targets *P. aeruginosa*.

TREATMENT

Bone and Joint Infections

The treatment of bone and joint infections due to *P. aeruginosa* is often governed by the primary *Pseudomonas* infection. Since endocarditis is often the primary infection, the agents used for endocarditis will dictate treatment. In other situations, a 6-week course of therapy with an antipseudomonal β-lactam is recommended, and in case of puncture-wound osteomyelitis, oral ciprofloxacin may be used.

Central Nervous System (CNS) Infections CNS infections due to *P. aeruginosa* are relatively rare. Involvement of the CNS is almost always secondary to a surgical procedure, head trauma, implanted devices, temporary external ventricular drains, and rarely bacteremia. The entity seen most often is postoperative or posttraumatic meningitis. Subdural or epidural infection occasionally results from contamination of these areas. Embolic disease arising from endocarditis in users of IV drugs and leading to brain abscesses has also been described. The cerebrospinal fluid (CSF) profile of *P. aeruginosa* meningitis is no different from that of pyogenic meningitis of any other etiology.

TREATMENT

Central Nervous System Infections

(Table 170-2) Treatment of *Pseudomonas* meningitis is difficult; little information has been published. However, the general principles involved in the treatment of meningitis apply, including the need for high doses of bactericidal antibiotics to attain high drug levels in the CSF. The agent with which there is the most published experience in *P. aeruginosa* meningitis is ceftazidime, but other antipseudomonal β-lactam drugs that attain reasonable CSF concentrations, such as cefepime, piperacillin/tazobactam, and meropenem, have also been used successfully. Other forms of *P. aeruginosa* CNS infection, such as brain abscesses and epidural and subdural empyema, generally require surgical drainage and removal of devices, in addition to antibiotic therapy.

Eye Infections Eye infections due to *P. aeruginosa* occur mainly as a result of direct inoculation into the tissue during trauma or surface injury by contact lenses. Keratitis and corneal ulcers are the most common types of eye disease and are often associated with contact lenses (especially the extended-wear variety). Keratitis can be slowly or rapidly progressive, but the classic description is disease progressing over 48 h to involve the entire cornea, with opacification and sometimes perforation. *P. aeruginosa* keratitis should be considered a medical emergency because of the rapidity with which it can progress to loss of sight. *P. aeruginosa* endophthalmitis secondary to bacteremia is the most devastating of *P. aeruginosa* eye infections. The disease is fulminant, with severe pain, chemosis, decreased visual acuity, anterior uveitis, vitreous involvement, and panophthalmitis. It is also a rare complication of cataract removal with lens insertion. In the United States, a recent outbreak associated with artificial tears with carbapenem-resistant *P. aeruginosa* led to serious eye infections and, in some cases, vision loss, enucleation, or death.

TREATMENT

Eye Infections

(Table 170-2) The usual therapy for keratitis is the administration of topical antibiotics. Therapy for endophthalmitis includes the use of high-dose local and systemic antibiotics (to achieve higher drug concentrations in the eye) and vitrectomy.

Ear Infections *P. aeruginosa* infections of the ears vary from mild swimmer's ear to serious life-threatening infections with neurologic sequelae. Swimmer's ear is common among children and results from infection of moist macerated skin of the external ear canal. Most cases resolve with treatment, but some patients develop chronic drainage. Swimmer's ear is managed with topical antibiotic agents (otic solutions). The use of hearing aids may also predispose to this type of infection. The most serious form of *Pseudomonas* infection involving the ear has been given various names: two of these designations, *malignant otitis externa* and *necrotizing otitis externa*, are now used for the same entity. This disease was originally described in elderly patients with diabetes, in whom the majority of cases still occur. However, it has also been described in patients with AIDS and in elderly patients without underlying diabetes or immunocompromise. The usual presenting symptoms are decreased hearing and ear pain, which may be severe and lancinating. The pinna is usually painful, and the external canal may be tender. The ear canal almost always shows signs of inflammation, with granulation tissue and exudate. Tenderness anterior to the tragus may extend as far as the temporomandibular joint and mastoid process. A small minority of patients have systemic symptoms. Patients in whom the diagnosis is made late may present with cranial nerve palsies, most commonly cranial nerve VII, or even with cavernous venous sinus thrombosis. The ESR is invariably elevated (≥100 mm/h). The diagnosis is made on clinical grounds in severe cases; however, the "gold standard" is a positive technetium-99 bone scan in a patient with otitis externa due to *P. aeruginosa*. In diabetic patients, a positive bone scan constitutes presumptive evidence for this diagnosis and should prompt biopsy or empirical therapy. However, it should be kept in mind that *S. aureus* and *Aspergillus* spp. can also cause this entity.

TREATMENT

Ear Infections

(Table 170-2) Given the infection of the ear cartilage, sometimes with mastoid or petrous ridge involvement, patients with malignant (necrotizing) otitis externa are treated as for osteomyelitis.

Urinary Tract Infections UTIs due to *P. aeruginosa* generally occur as a complication of a catheter in the urinary tract, an obstruction or stone in the genitourinary system, urinary tract instrumentation, or surgery. A *P. aeruginosa* UTI occurring in the community often signals the presence of an abnormality in the urinary tract. It has been reported that the urinary tract is the second most important site of infection leading to *Pseudomonas* bacteremia.

TREATMENT

Urinary Tract Infections

(Table 170-2) Most *P. aeruginosa* UTIs are considered complicated infections that must be treated longer than uncomplicated cystitis. In general, a 7- to 10-day course of treatment suffices. Urinary catheters, stents, or stones should be removed to prevent relapse, which is common and may not be due to antibiotic resistance but rather to factors such as a foreign body that has been left in place or an ongoing obstruction. Removal of a urinary catheter will allow shorter courses of antibiotic therapy if that is the only predisposing factor.

Skin and Soft Tissue Infections Besides pyoderma (ecthyma) gangrenosum in neutropenic patients, folliculitis and other papular or vesicular lesions due to *P. aeruginosa* have been extensively described and are collectively referred to as *dermatitis*. Multiple outbreaks have been linked to whirlpools, spas, and swimming pools. To prevent such outbreaks, the growth of *P. aeruginosa* in the home and in recreational environments must be controlled by proper chlorination of water. Most cases of hot-tub folliculitis are self-limited, requiring only the avoidance of exposure to the contaminated source of water. Approximately one-third of reported outbreaks are associated with hotel facilities. Patients may also have ear pain, skin rashes, and eye irritation.

Toe-web infections occur especially often in the tropics, and the "green-nail syndrome" is caused by *P. aeruginosa* paronychia, which results from frequent submersion of the hands in water. In the latter entity, the green discoloration results from diffusion of pyocyanin into the nail bed. *P. aeruginosa* remains a prominent cause of burn wound infections in some parts of the world. The management of these infections is best left to specialists in burn wound care.

Infections in Febrile Neutropenic Patients In febrile neutropenia, *P. aeruginosa* has historically been the organism against which empirical coverage is always essential. Although in Western countries these infections are now less common, their importance has not diminished because of persistently high mortality rates. In other parts of the world, *P. aeruginosa* continues to be a significant problem in febrile neutropenia, causing a larger proportion of infections in febrile neutropenic patients than any other single organism. For example, *P. aeruginosa* was responsible for 28% of documented infections in 499 febrile neutropenic patients in one study from the Indian subcontinent and for 31% of such infections in another. In a large study of infections in leukemia patients from Japan, *P. aeruginosa* was the most frequently documented cause of bacterial infection. In studies performed in North America, northern Europe, and Australia, the incidence of *P. aeruginosa* bacteremia in febrile neutropenia was quite variable. In a review of 97 reports published between 1987 and 1994, the incidence was reported to be 1–2.5% among febrile neutropenic patients given empirical therapy and 5–12% among patients with microbiologically documented infections. The most common clinical syndromes encountered were bacteremia, pneumonia, and soft tissue infections manifesting mainly as ecthyma gangrenosum.

TREATMENT

Infections in Febrile Neutropenic Patients

(Table 170-2) Compared with rates three decades ago, improved rates of response to antibiotic therapy have been reported in many studies. A study of 127 patients demonstrated a reduction in the mortality rate from 71 to 25% with the introduction of ceftazidime and imipenem. Because neutrophils—the normal host defenses against this organism—are absent in febrile neutropenic patients, maximal doses of antipseudomonal β-lactam antibiotics should be used for the management of *P. aeruginosa* bacteremia in this setting.

Infections in Patients with AIDS *P. aeruginosa* infections were well documented in patients with AIDS before the advent of antiretroviral therapy. Since the introduction of protease inhibitors, *P. aeruginosa* infections in patients with AIDS have been seen less frequently but still occur, particularly in the form of sinusitis. While this entity is now uncommon in developed nations, there are still large numbers of patients with untreated HIV infection or poorly controlled disease in developing nations who are likely to suffer from *P. aeruginosa* infections. The clinical presentation of *Pseudomonas* infection (especially pneumonia and bacteremia) in patients with AIDS is remarkable in that, although the illness may appear not to be severe, the infection may nonetheless be fatal. Patients with bacteremia may have only a low-grade fever and may present with ecthyma gangrenosum. Pneumonia, with or without bacteremia, is perhaps the most common type of *P. aeruginosa* infection. Patients with *P. aeruginosa* pneumonia exhibit the classic clinical signs and symptoms of pneumonia, such as fever, productive cough, and chest pain. The infection may be lobar or multilobar and shows no predisposition for any particular location. The most striking feature is the high frequency of cavitary disease.

TREATMENT

Infections in Patients with AIDS

Therapy for any of these conditions in AIDS patients is no different from that in other patients. However, relapse is the rule unless the patient's CD4+ T-cell count rises to >50/μL or suppressive antibiotic therapy is given. In attempts to achieve cures and prevent relapses, therapy tends to be more prolonged.

Gastrointestinal Infections A poorly understood syndrome caused by *P. aeruginosa* has been described in the Far East and has been called *Shanghai fever* and *Pseudomonas enterocolitis*. This syndrome occurs in young children; its occurrence in adults appears to be rare. Shanghai fever manifests as severe enteric disease, sepsis with invasive disease, and complications, whereas *Pseudomonas* enterocolitis is characterized by prolonged fever with bloody or mucoid diarrhea mimicking bacterial enterocolitis. The mortality rate ranges between 23 and 89%, with ecthyma gangrenosum occurring in >50% of cases. Early recognition and treatment have led to a reduction in the mortality rate. There is an above-average occurrence of the *exoU* gene among *Pseudomonas* isolates from patients with this syndrome.

Multidrug-Resistant Infections (Table 170-2) *P. aeruginosa* has a notorious propensity to develop antibiotic resistance. Over three decades, the impact of resistance was minimized by the rapid development of several potent antipseudomonal β-lactams and fluoroquinolones. However, rates of resistance to these agents that revolutionized the treatment of *P. aeruginosa* have risen to the point where some are almost unusable empirically because of the worldwide emergence of strains carrying determinants that mediate resistance. Extremely high rates of MDR strains have been reported from eastern and southern Europe, Latin America, India, and China, especially in ICUs. Physicians have had to resort to drugs such as colistin and polymyxin B, which were discarded decades ago. This surge in resistance is mediated by multiple mechanisms sometimes converging in individual strains. Chief among these are chromosomal or plasmid-borne penicillinases, extended-spectrum β-lactamases, cephalosporinases, and carbapenemases. Any of these may be combined with permeability mutations and efflux pump overexpression. The greatest nemesis in this regard is the worldwide presence of carbapenemases in *P. aeruginosa* leading to resistance to most β-lactams except some of the newest agents recently developed. These new agents are generally combinations of a cephalosporin or a carbapenem most often with a novel β-lactamase inhibitor. Several have been approved for clinical use, and all are active against

MDR *P. aeruginosa* to varying degrees. Currently approved agents include ceftolozane-tazobactam, ceftazidime-avibactam, meropenem-vaborbactam, and imipenem-relebactam. A novel cephalosporin, cefiderocol, which uses the iron uptake pathway of *P. aeruginosa*, also demonstrates activity against MDR strains. Since MDR and XDR *P. aeruginosa* are unpredictable in regard to the underlying mechanisms of resistance, laboratory testing is absolutely required before the use of any of these agents. Most academic institutions restrict the use of these agents as there are increasing reports of resistance even to these agents, as well the cost implications of misuse.

BURKHOLDERIA SPECIES

BURKHOLDERIA CEPACIA COMPLEX

The *B. cepacia* complex (BCC) gained notoriety as the cause of a rapidly fatal syndrome of respiratory distress and septicemia (the "cepacia syndrome") in CF patients. Of the more than 20 species of this complex, the three most frequently seen in CF patients are *B. cenocepacia*, *B. multivorans*, and *B. stabilis.* In addition to their occurrence in CF, members of this complex were not uncommonly encountered in ICU patients (previously designated *Pseudomonas cepacia*) and patients with chronic granulomatous disease, in whom they caused lung disease. BCC organisms are environmental organisms that inhabit moist environments and are found in the rhizosphere. They possess multiple virulence factors that may play roles in disease as well as colonizing factors that are capable of binding to lung mucus—an ability that may explain the predilection of *B. cepacia* for the lungs in CF. *B. cenocepacia* is motile, secretes elastase, and possesses components of an injectable toxin-secretion system like that of *P. aeruginosa*; its LPS is among the most potent of all LPSs in stimulating an inflammatory response in the lungs. Inflammation may be the major cause of the lung disease seen in the "cepacia" syndrome. Besides infecting the lungs in CF, the BCC organisms appear as airway colonizers during broad-spectrum antibiotic therapy and are causes of VAP, catheter-associated infections, and wound infections. *B. cenocepacia* has emerged as a barrier to lung transplantation in CF, with relatively high mortality rates after a year compared to infection with other members of this complex.

TREATMENT

B. cepacia Complex Infections

BCC organisms are intrinsically resistant to many antibiotics, rendering empiric treatment difficult. Therefore, treatment must be tailored according to sensitivities. Trimethoprim-sulfamethoxazole (TMP-SMX), meropenem, and minocycline are the most active agents in vitro and may be started as first-line agents (Table 170-2). However, recent reports indicate that there has been increasing resistance to these agents especially in CF patients. Some strains are susceptible to third-generation ureidopenicillins, advanced cephalosporins, and fluoroquinolones, and these agents may be used against isolates known to be susceptible. Newer antibiotics such as ceftolozane-tazobactam and ceftazidime-avibactam show good activity against MDR strains in vitro. However, there is very limited clinical experience with these agents.

BURKHOLDERIA PSEUDOMALLEI

B. pseudomallei is the causative agent of melioidosis, a disease of humans and animals that is geographically restricted to Southeast Asia and northern Australia, with occasional cases in countries such as India and China. This organism may be isolated from individuals returning directly from these endemic regions and from military personnel who have served in endemic regions. Symptoms of this illness may develop only at a later date because of the organism's ability to cause latent infections, which has been attributed to its ability to survive within cells. *B. pseudomallei* is found in soil and water. Humans and animals are infected by inoculation, inhalation, or ingestion; only rarely is the organism transmitted from person to person. Humans are not colonized without being infected. Among the pseudomonads, *B. pseudomallei* is perhaps the most virulent species. Host compromise is not an essential prerequisite for disease, although many patients have common underlying medical diseases (e.g., diabetes, renal failure, or alcohol abuse). *B. pseudomallei* is a facultative intracellular organism whose replication in PMNs and macrophages may be aided by the possession of a polysaccharide capsule. The organism also possesses elements of a type III secretion system that plays a role in its intracellular survival. During infection, there is a florid inflammatory response whose role in disease is unclear.

B. pseudomallei causes a wide spectrum of conditions, ranging from asymptomatic infection to abscesses, pneumonia, and disseminated disease. It is a significant cause of fatal community-acquired pneumonia and septicemia in endemic areas, with mortality rates as high as 44% reported in Thailand. Acute pulmonary infection is the most commonly diagnosed form of melioidosis. Pneumonia may be asymptomatic (with routine chest radiographs showing mainly upper-lobe infiltrates) or may present as severe necrotizing disease. *B. pseudomallei* also causes chronic pulmonary infections with systemic manifestations that mimic those of tuberculosis, including chronic cough, fever, hemoptysis, night sweats, and cavitary lung disease. Besides pneumonia, the other principal form of *B. pseudomallei* disease is skin ulceration with associated lymphangitis and regional lymphadenopathy. Spread from the lungs or skin, which is most often documented in debilitated individuals, gives rise to septicemic forms of melioidosis that carry a high mortality rate.

TREATMENT

B. pseudomallei Infections

B. pseudomallei is susceptible to advanced penicillins, cephalosporins, and carbapenems (Table 170-2). Treatment is divided into two stages: an intensive 2-week phase of therapy with ceftazidime or a carbapenem followed by at least 12 weeks of oral TMP-SMX to eradicate the organism and prevent relapse. Australian guidelines for treating this condition recommend longer periods of intensive therapy—4–8 weeks for severe infections, osteomyelitis, and CNS infections. The recognition of this bacterium as a potential agent of biologic warfare has stimulated interest in the development of a vaccine.

BURKHOLDERIA MALLEI

B. mallei causes the equine disease glanders in Africa, Asia, and South America. The organism was eradicated from Europe and North America decades ago. The last case seen in the United States occurred in 2001 in a laboratory worker; before that, *B. mallei* had last been seen in this country in 1949. In contrast to the other organisms discussed in this chapter, *B. mallei* is not an environmental organism and does not persist outside its equine hosts. Consequently, *B. mallei* infection is an occupational risk for handlers of horses, equine butchers, and veterinarians in areas of the world where it still exists. Diabetics are thought to be especially susceptible to infection by this organism. The polysaccharide capsule is a critical virulence determinant. The organism is transmitted from animals to humans by inoculation into the skin, where it causes local infection with nodules and lymphadenitis. Regional lymphadenopathy is common. Respiratory secretions from infected horses are extremely infectious. Inhalation results in clinical signs of typical pneumonia but may also cause an acute febrile illness with ulceration of the trachea. The organism may disseminate from the skin or lungs to cause septicemia with signs of sepsis. The septicemic form is frequently associated with shock and a high mortality rate. The infection may also enter a chronic phase and present as disseminated abscesses. *B. mallei* infection may present as early as 1–2 days after inhalation or (in cutaneous disease) may not become evident for months.

TREATMENT

B. mallei Infections

The antibiotic susceptibility pattern of *B. mallei* is similar to that of *B. pseudomallei*; in addition, the organism is susceptible to the

macrolides azithromycin and clarithromycin. *B. mallei* infection should be treated with the same drugs and for the same duration as melioidosis.

STENOTROPHOMONAS MALTOPHILIA

S. maltophilia is the only potential human pathogen among a genus of ubiquitous organisms found in the rhizosphere (i.e., the soil that surrounds the roots of plants). The organism is an opportunist that is acquired from the environment but is even more limited than *P. aeruginosa* in its ability to colonize patients or cause infections. Immunocompromise is not sufficient to permit these events; rather, major perturbations of the human flora are usually necessary for the establishment of *S. maltophilia*. Accordingly, most cases of human infection occur in the setting of very broad-spectrum antibiotic therapy with agents such as advanced cephalosporins and carbapenems, which eradicate the normal flora and other pathogens. The remarkable ability of *S. maltophilia* to resist virtually all classes of antibiotics is attributable to the possession of antibiotic efflux pumps and of two β-lactamases (L1 and L2) that mediate β-lactam resistance, including that to carbapenems. It is fortunate that the virulence of *S. maltophilia* appears to be limited. Although a serine protease is present in some strains, virulence is probably a result of the host's inflammatory response to components of the organism such as LPS and flagellin. *S. maltophilia* is most commonly found in the respiratory tract of ventilated patients, where the distinction between its roles as a colonizer and as a pathogen is often difficult to make. However, *S. maltophilia* does cause pneumonia and bacteremia in such patients, and these infections have led to septic shock. A severe form of pneumonia with significant mortality has been reported in neutropenic patients. Also common is central venous line–associated infection (with or without bacteremia), which has been reported most often in patients with cancer. *S. maltophilia* is a rare cause of ecthyma gangrenosum in neutropenic patients. It has been isolated from ~5% of CF patients but is not believed to be a significant pathogen in this setting. There are also less common sites of infection such as the endocardium, meninges, urinary tract, and skin; however, the sites of major concern remain the blood and lungs.

TREATMENT

S. maltophilia Infections

The intrinsic resistance of *S. maltophilia* to most antibiotics renders infection difficult to treat. The antibiotics to which it is most often (although not uniformly) susceptible are TMP-SMX, ticarcillin-clavulanate, levofloxacin, minocycline, cefiderocol and tigecycline (Table 170-2). Ceftazidime is no longer recommended for treatment. A few retrospective studies show utility of minocycline, but relevant clinical outcomes have not been thoroughly evaluated. Consequently, combination therapy with TMP-SMX plus ticarcillin-clavulanate, levofloxacin, or high-dose minocycline is recommended for initial therapy pending susceptibility testing. Catheters must be removed early in the treatment of bacteremia. The treatment of proven, high-inoculum infections due to *S. maltophilia* is associated with frequent development of resistance during therapy. The newest β-lactam/β-lactamase inhibitor combinations show mixed results against this organism probably because of the presence of two different β-lactamases, a penicillinase and a cephalosporinase, compounded by the presence of efflux pumps. Resistance to one or the other of the newer agents has already been noted, including to cefiderocol. The most controversial aspect of therapy of *S. maltophilia* is whether pulmonary cultures in a nonneutropenic patient with lung consolidation require treatment or represent colonization. Many clinicians opt not to treat such patients given the fact that the development of resistance is quite common, compromising a serious subsequent infection such as a bacteremia.

171 Salmonellosis

David A. Pegues, Samuel I. Miller

Bacteria of the genus *Salmonella* are highly adapted for growth in both humans and animals and cause a wide spectrum of disease. The growth of serotypes *Salmonella* Typhi and *Salmonella* Paratyphi is restricted to human hosts, in whom these organisms cause enteric (typhoid) fever. The remaining serotypes (nontyphoidal *Salmonella*, or NTS) can colonize the gastrointestinal tracts of a broad range of animals, including mammals, reptiles, birds, and insects. More than 200 serotypes of *Salmonella* are pathogenic to humans, in whom they often cause gastroenteritis and can be associated with localized infections and/or bacteremia.

ETIOLOGY

This large genus of gram-negative bacilli within the family Enterobacteriaceae consists of two species: *Salmonella enterica*, which contains six subspecies, and *Salmonella bongori*. *S. enterica* subspecies I includes almost all the serotypes pathogenic for humans. Members of the seven *Salmonella* subspecies are classified into >2600 serotypes (serovars); for simplicity, *Salmonella* serotypes (most of which are named for the city where they were identified) are often used as the species designation. For example, the full taxonomic designation *S. enterica* subspecies *enterica* serotype Typhimurium can be shortened to *Salmonella* serotype Typhimurium or simply *S.* Typhimurium. Serotyping is based on antigenically diverse surface structures: the somatic O antigen (lipopolysaccharide cell-wall components), the surface Vi antigen (restricted to *S.* Typhi and *S.* Paratyphi C), and the flagellar H antigen.

Salmonellae are gram-negative, non-spore-forming, facultatively anaerobic bacilli that measure 2–3 μm by 0.4–0.6 μm. The initial

identification of salmonellae in the clinical microbiology laboratory is based on growth characteristics. Salmonellae, like other Enterobacteriaceae, produce acid on glucose fermentation, reduce nitrates, and do not produce cytochrome oxidase. In addition, all salmonellae except *Salmonella* Gallinarum-Pullorum are motile by means of peritrichous flagella, and all but *S.* Typhi produce gas (H_2S) on sugar fermentation. Notably, only 1% of clinical isolates ferment lactose; a high level of suspicion must be maintained to detect these rare clinical lactose-fermenting isolates.

Although serotyping of all surface antigens can be used for formal identification, most laboratories perform a few simple agglutination reactions that define specific O-antigen serogroups, designated A, B, C_1, C_2, D, and E. Strains in these six serogroups cause ~99% of *Salmonella* infections in humans and other warm-blooded animals. Whole-genome sequencing is used in epidemiologic investigations to identify the source of foodborne outbreaks and to explore the international transmission of multidrug-resistant *Salmonella* strains.

PATHOGENESIS

All *Salmonella* infections begin with ingestion of organisms, most commonly in contaminated food or water. The infectious dose ranges from 200 colony-forming units (CFU) to 10^6 CFU, and the ingested dose is an important determinant of incubation period and disease severity. Conditions that decrease either stomach acidity (an age of <1 year, acid suppression therapy, or achlorhydric disease) or intestinal integrity (inflammatory bowel disease, cytotoxic chemotherapy, prior gastrointestinal surgery, or alteration of the intestinal microbiome by antibiotic administration) increase susceptibility to *Salmonella* infection.

Once *S.* Typhi and *S.* Paratyphi reach the small intestine, they penetrate the mucus layer of the gut and traverse the intestinal layer through phagocytic microfold (M) cells that reside within Peyer's patches. Salmonellae can trigger the formation of membrane ruffles in normally nonphagocytic epithelial cells. These ruffles reach out and enclose adherent bacteria within large vesicles by *bacterium-mediated endocytosis*. This process is dependent on the direct delivery of *Salmonella* proteins into the cytoplasm of epithelial cells by the specialized bacterial type III secretion system. These bacterial proteins mediate alterations in the actin cytoskeleton that are required for *Salmonella* uptake.

After crossing the epithelial layer of the small intestine, *S.* Typhi and *S.* Paratyphi, which cause enteric (typhoid) fever, are phagocytosed by macrophages. These salmonellae survive the antimicrobial environment of the macrophage by sensing environmental signals that trigger alterations in regulatory systems of the phagocytosed bacteria. For example, PhoP/PhoQ (the best-characterized regulatory system) triggers the alteration of the outer membrane by increasing the synthesis and transport of different outer-membrane proteins, lipopolysaccharides, and glycerophospholipids, so that the altered bacterial surface can resist microbicidal activities and potentially alter host cell signaling. In addition, salmonellae encode a second type III secretion system that directly delivers bacterial proteins across the phagosome membrane into the macrophage cytoplasm. This secretion system functions to remodel the *Salmonella*-containing vacuole, promoting bacterial survival and replication.

Once phagocytosed, typhoidal salmonellae disseminate throughout the body in macrophages via the lymphatics and colonize reticuloendothelial tissues (liver, spleen, lymph nodes, and bone marrow). Patients have relatively few or no signs and symptoms during this initial incubation stage. Signs and symptoms, including fever and abdominal pain, probably result from secretion of cytokines by macrophages and epithelial cells in response to bacterial products that are recognized by innate immune receptors when a critical number of organisms have replicated. Over time, the development of hepatosplenomegaly is likely to be related to the recruitment of mononuclear cells and the development of a specific acquired cell-mediated immune response to *S.* Typhi colonization. The recruitment of additional mononuclear cells and lymphocytes to Peyer's patches during the several weeks after initial colonization/infection can result in marked enlargement and necrosis of the Peyer's patches, which may be mediated by bacterial products that promote cell death as well as the inflammatory response. In the case of *S.* Typhi and *S.* Paratyphi A, many strains produce a toxin when localized within host cells. This toxin is then transported extracellularly and probably contributes to systemic symptoms as well as the unusual neuropsychiatric states that can be seen in severe typhoidal illness.

In contrast to enteric fever, which is characterized by an infiltration of mononuclear cells into the small-bowel mucosa, NTS gastroenteritis is characterized by massive polymorphonuclear leukocyte infiltration into both the large- and small-bowel mucosa. This response appears to depend on the induction of interleukin 8, a strong neutrophil chemotactic factor, which is secreted by intestinal cells because of nontyphoidal *Salmonella* colonization and translocation of bacterial proteins and LPS into host cell cytoplasm with subsequent activation of inflammasomes. The degranulation and release of toxic substances by neutrophils may result in damage to the intestinal mucosa, causing the inflammatory diarrhea observed with nontyphoidal gastroenteritis. An additional important factor in the persistence of NTS in the intestinal tract and the organism's capacity to compete with endogenous flora is the ability to utilize the sulfur-containing compound tetrathionate for metabolism in a microaerophilic environment. In the presence of intestinal inflammation, tetrathionate is generated from thiosulfate produced by epithelial cells through inflammatory cell production of reactive oxygen species. In contrast to nontyphoidal Salmonellae, typhoidal Salmonellae do not effectively colonize the intestinal tract but have evolved as systemic pathogens, largely through gene loss and perhaps by the loss of the ability to utilize butyrate within the human intestine.

ENTERIC (TYPHOID) FEVER

Enteric (typhoid) fever is a systemic disease characterized by fever and abdominal pain and caused by dissemination of *S.* Typhi or *S.* Paratyphi. The disease was initially called *typhoid fever* because of its clinical similarity to typhus. In the early 1800s, typhoid fever was clearly defined pathologically as a unique illness based on its association with enlarged Peyer's patches and mesenteric lymph nodes. In 1869, given the anatomic site of infection, the term *enteric fever* was proposed as an alternative designation to distinguish typhoid fever from typhus. However, to this day, the two designations are used interchangeably.

EPIDEMIOLOGY

In contrast to other *Salmonella* serotypes, the etiologic agents of enteric fever—*S.* Typhi and *S.* Paratyphi serotypes A, B, and C—have no known hosts other than humans. Most commonly, food-borne or waterborne transmission results from fecal contamination by ill or asymptomatic chronic carriers. Sexual transmission between male partners has been described. Health care workers occasionally acquire enteric fever after exposure to infected patients or during processing of clinical specimens and cultures.

With improvements in food handling and water/sewage treatment, enteric fever has become rare in developed nations. An estimated 9.2–21 million cases of typhoid fever, 5 million cases of paratyphoid fever, and 110,000–280,000 deaths occur each year. The highest estimated annual incidence rates of typhoid fever are in the Indian subcontinent, including Pakistan, Bangladesh, Nepal, India, and Eastern Mediterranean and African regions, and exceed 1000 cases per 100,000 children in some urban areas **(Fig. 171-1)**. A high incidence of enteric fever correlates with mixing of drinking water with human sewage. In endemic regions, enteric fever is more common in poor neighborhoods in large cities than rural areas and among young children and adolescents than among other age groups. Risk factors include fecally contaminated drinking water or ice, flooding, food and drinks purchased from street vendors, raw fruits and vegetables grown in fields fertilized with sewage, ill household contacts, lack of hand washing and toilet access, and evidence of prior *Helicobacter pylori* infection (an association probably related to chronically reduced gastric acidity).

Multidrug-resistant (MDR) strains of *S.* Typhi emerged in the 1980s in China and Southeast Asia and have since disseminated widely. These strains contain plasmids encoding resistance to chloramphenicol,

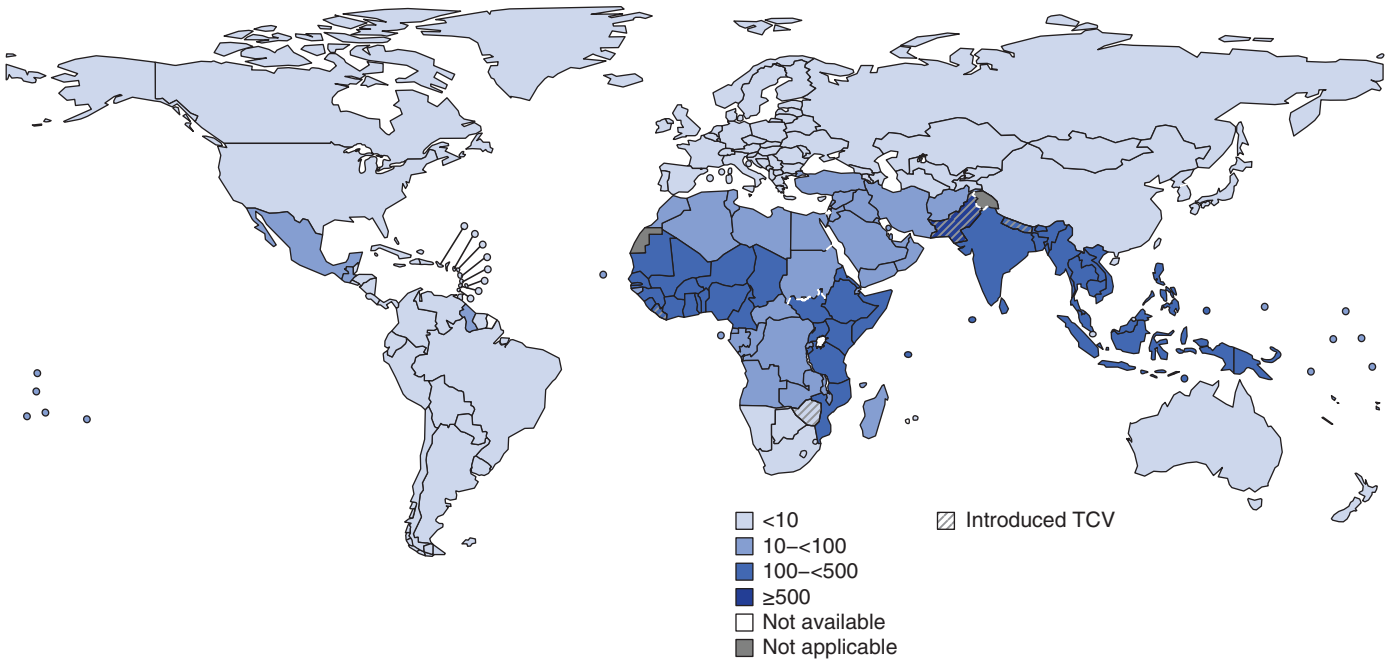

FIGURE 171-1 Estimated national typhoid fever incidence and worldwide typhoid conjugate vaccine introduction, 2019–2022. *(Reproduced from M Hancuh et al: Typhoid fever surveillance incidence estimates, and progress toward typhoid conjugate vaccine introduction – Worldwide, 2018–2022.* MMWR Morb Mortal Wkly Rep 72:171, 2023.)

ampicillin, and trimethoprim—antibiotics long used to treat enteric fever. With the increased use of fluoroquinolones to treat MDR enteric fever in the 1990s, MDR strains of *S.* Typhi and *S.* Paratyphi with decreased susceptibility to ciprofloxacin (DSC; minimal inhibitory concentration [MIC], ≥0.125 μg/mL) or ciprofloxacin resistance (MIC, ≥1 μg/mL) emerged on the Indian subcontinent and have spread with human migration first to Southern Asia and more recently to Eastern and Southern Africa. These strains represent clone H58, which is increasingly associated with clinical treatment failure of fluoroquinolones. Since emerging in 2016 in urban slums of Sindh province in Southeastern Pakistan, an extensively drug-resistant (XDR) *S.* Typhi H58 clone with plasmid-mediated extended-spectrum beta-lactamase (ESBL) resistance has now become the dominant cause of typhoid fever in Pakistan. Air travel from Pakistan has facilitated the international spread of this XDR strain. Azithromycin resistance has emerged in multiple countries where azithromycin is used for first-line treatment of enteric fever and for mass administration for trachoma.

In the United States, the Centers for Disease Control and Prevention (CDC) estimates that typhoid fever affects 5700 persons each year, a number far in excess of the ~350 cases of typhoid fever and ~90 cases of paratyphoid fever reported annually. In 2015, the median age of patients with typhoid fever was 23 years, and it was 29 years for paratyphoid fever. Most cases of enteric fever were associated with international travel (78%), predominantly to Indian, Pakistan, and Bangladesh, and visiting friends and family. Only 3% of travelers diagnosed with typhoid fever had received *S.* Typhi vaccine within the previous 5 years. In 2015, 66% of *S.* Typhi in the United States were DSC, and ~10% were resistant to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole (TMP-SMX). Infection with DSC *S.* Typhi was associated with travel to the Indian subcontinent. In the United States, domestically acquired cases of enteric fever are less often DSC or MDR compared with travel-associated cases and are most often sporadic, although outbreaks linked to contaminated food products and previously unrecognized chronic carriers continue to occur.

CLINICAL COURSE

Enteric fever is a misnomer, in that the hallmark features of this disease—fever and abdominal pain—are variable. While fever is documented at presentation in >75% of cases, abdominal pain is reported in only 30–40%. Thus, a high index of suspicion for this potentially fatal systemic illness is necessary when a person presents with fever and a history of recent travel to a developing country.

The mean incubation period for *S.* Typhi is 10–14 days but ranges from 5 to 21 days, depending on the inoculum size and the host's health and vaccination status. The most prominent symptom is prolonged fever (38.8°–40.5°C [101.8°–104.9°F]), which can continue for up to 4 weeks if untreated. *S.* Paratyphi A is thought to cause milder disease than *S.* Typhi, with predominantly gastrointestinal symptoms. However, a prospective study of 669 consecutive cases of enteric fever in Kathmandu, Nepal, found that the infections caused by these organisms were clinically indistinguishable. In this series, symptoms reported on initial medical evaluation included headache (80%), chills (35–45%), cough (30%), sweating (20–25%), myalgias (20%), malaise (10%), and arthralgia (2–4%). Gastrointestinal manifestations included anorexia (55%), abdominal pain (30–40%), nausea (18–24%), vomiting (18%), and diarrhea (22–28%) more commonly than constipation (13–16%). Physical findings included coated tongue (51–56%), splenomegaly (5–6%), and abdominal tenderness (4–5%).

Early physical findings of enteric fever include rash ("rose spots"; 30%), hepatosplenomegaly (3–6%), epistaxis, and relative bradycardia at the peak of high fever (<50%). Rose spots **(Fig. 171-2; see also Fig. A1-9)** make up a faint, salmon-colored, blanching, maculopapular rash located

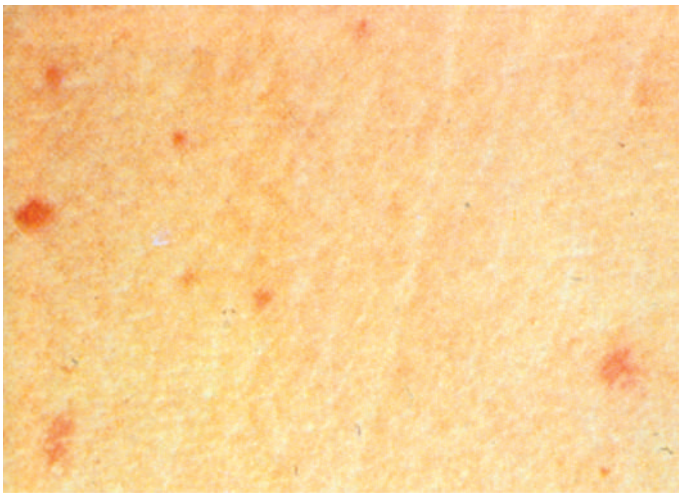

FIGURE 171-2 "Rose spots," the rash of enteric fever due to *Salmonella* Typhi or *Salmonella* Paratyphi.

primarily on the trunk and chest. The rash is evident in ~30% of patients at the end of the first week and resolves without a trace after 2–5 days. Patients can have two or three crops of lesions, and *Salmonella* can be cultured from punch biopsies of these lesions. The faintness of the rash makes it difficult to detect in highly pigmented patients.

Complications of typhoid fever are estimated to occur in ~27% of hospitalized patients and correlate with a longer duration of symptoms before hospitalization, host factors (host genetics, immunosuppression, acid suppression therapy, previous exposure, and vaccination status), strain virulence and inoculum, and choice of antibiotic therapy. Gastrointestinal bleeding (6%) and intestinal perforation (1%) most commonly occur in the third and fourth weeks of illness and result from hyperplasia, ulceration, and necrosis of the ileocecal Peyer's patches at the initial site of *Salmonella* infiltration **(Fig. 171-3)**. Both complications are life-threatening and require immediate fluid resuscitation and surgical intervention, with broadened antibiotic coverage for polymicrobial peritonitis **(Chap. 137)** and treatment of gastrointestinal hemorrhages, including bowel resection. Neurologic manifestations occur in 2–40% of patients and include meningitis, Guillain-Barré syndrome, neuritis, and neuropsychiatric symptoms (described as "muttering delirium" or "coma vigil"), with picking at bedclothes or imaginary objects.

Uncommon complications whose incidences are reduced by prompt antibiotic treatment include disseminated intravascular coagulation, hemophagocytic syndrome, pancreatitis, hepatitis, hepatic and splenic abscesses and granulomas, endocarditis, pericarditis, myocarditis, orchitis, glomerulonephritis, pyelonephritis and hemolytic-uremic syndrome, severe pneumonia, arthritis, osteomyelitis, endophthalmitis, and parotitis. Up to 10% of patients develop mild relapse, usually within 2–3 weeks of fever resolution and associated with the same strain and susceptibility profile.

Up to 10% of untreated patients with typhoid fever excrete *S.* Typhi in the feces for up to 3 months, and 2–5% develop chronic asymptomatic carriage, shedding *S.* Typhi in either urine or stool for >1 year. Chronic carriage is more common among women, infants, and persons who have biliary abnormalities or concurrent bladder infection with *Schistosoma haematobium*. *S.* Typhi and other salmonellae are adapted to survive in the gallbladder environment by forming biofilms on gallstones and invading gallbladder epithelial cells. Chronic carriage is associated with an increased risk of gallbladder cancer, which is much more common in locales where *S.* Typhi is common, such as the Indian subcontinent.

DIAGNOSIS

Because the clinical presentation of enteric fever is relatively nonspecific, the diagnosis needs to be considered in any febrile traveler returning from a developing region, especially the Indian subcontinent, and the Southeast Asian or African region. Other diagnoses that should be considered in these travelers include malaria, viral hepatitis, bacterial enteritis, dengue fever, rickettsial infections, leptospirosis, amebic liver abscesses, and acute HIV infection **(Chap. 130)**. Other than a positive culture, no specific laboratory test is diagnostic for enteric fever. In 15–25% of cases, leukopenia and neutropenia are detectable. Leukocytosis is more common among children, during the first 10 days of illness, and in cases complicated by intestinal perforation or secondary infection. Other nonspecific laboratory findings include moderately elevated values in liver function tests and muscle enzyme levels.

The definitive diagnosis of enteric fever requires the isolation of *S.* Typhi or *S.* Paratyphi from blood, bone marrow, other sterile sites, rose spots, stool, or intestinal secretions. The diagnostic sensitivity of blood culture is only ~40–60% and is lower with low blood sample volume and among patients with prior antimicrobial use or in the first week of illness, reflecting the small number of *S.* Typhi organisms (i.e., <15/mL) typically present in the blood. Because almost all *S.* Typhi organisms in blood are associated with the mononuclear cell/platelet fraction, centrifugation of blood and culture of the buffy coat can substantially reduce the time to isolation of the organism but do not increase sensitivity.

Bone marrow culture is ~80% sensitive for detection of *S.* Typhi or *S.* Paratyphi, and, unlike that of blood culture, its yield is not reduced by up to 5 days of prior antibiotic therapy. Culture of intestinal secretions (best obtained by a noninvasive duodenal string test) can be positive despite a negative bone marrow culture. If blood, bone marrow, and intestinal secretions are all cultured, the yield is >90%. Stool cultures, although negative in 60–70% of cases during the first week, can become positive during the third week of infection in untreated patients.

Rapid immunodiagnostic commercial tests, including Tubex and Typhidot, mainly focus on detection of IgM and IgG antibodies to O and H antigens and are widely used at point of care to diagnose typhoid and paratyphoid fever because they are simple and low cost. In a 2017 systematic review, these rapid diagnostic tests had sensitivities ranging from ~70% to 80% and specificities ranging from ~80% to 90% and thus are not sufficiently accurate to replace blood cultures as the main approach to diagnose enteric fever. PCR detection of *S.* Typhi and *S.* Paratyphi in the blood have sensitivities of ~40–100%, depending on the gene targets. Molecular-based test platforms were scarce in resource-limited settings, but advancements and investments in molecular diagnostics arising from the SARS-CoV-2 pandemic have made feasible the widespread use of molecular tests for diagnosis of enteric fever.

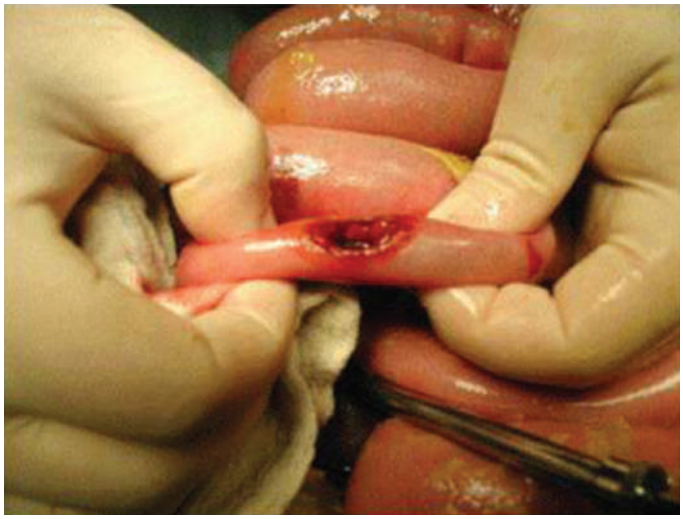

FIGURE 171-3 Typical ileal perforation associated with *Salmonella* Typhi infection. *(From JM Saxe, R Cropsey: Is operative management effective in treatment of perforated typhoid? Am J Surg 189:342, 2005.)*

TREATMENT

Enteric (Typhoid) Fever

Enteric fever is associated with an overall case-fatality rate of 2.5%, but mortality rates rise to 4.5% among hospitalized patients and to 10–30% if untreated. Prompt administration of appropriate antibiotic therapy prevents severe complications of enteric fever and reduces mortality to <1%. The initial choice of antibiotics depends on the susceptibility of the *S.* Typhi and *S.* Paratyphi strains in the area of residence or travel **(Table 171-1)**. A 2022 systematic review of 27 randomized clinical trials for the treatment of enteric fever found no difference between ceftriaxone, fluoroquinolone, or azithromycin in comparative risk of treatment failure, microbiologic failure, relapse, convalescent carriage, or adverse events. Oral cefixime also can be used to treat enteric fever but may increase the risk of clinical failure and time to defervescence compared with fluoroquinolones. Of note, most of the trials included in this review were small and conducted >20 years ago, and data on antimicrobial resistance could not be analyzed. Because of the high prevalence of strains of *S.* Typhi and *S.* Paratyphi with decreased susceptibility to ciprofloxacin (MIC >0.125 μg/mL) on the Indian subcontinent and in some locales in Africa, fluoroquinolones should no longer

TABLE 171-1 Antibiotic Therapy for Enteric Fever in Adults

INDICATION	AGENT	DOSAGE (ROUTE)	DURATION, DAYS
Empirical Treatment			
	Ceftriaxone[a]	2 g/d (IV)	10–14
	Ciprofloxacin[b]	500 mg bid (PO) or 400 mg q12h (IV)	5–7
	Azithromycin[c]	1 g/d (PO)	5
Fully Susceptible			
Optimal treatment	Ceftriaxone	2 g/d (IV)	10–14
	Ciprofloxacin	500 mg bid (PO) or 400 mg q12h (IV)	5–7
	Azithromycin	1 g/d (PO)	5
Alternative treatment	Amoxicillin	1 g tid (PO) or 2 g q6h (IV)	14
	Chloramphenicol	25 mg/kg tid (PO or IV)	14–21
	Trimethoprim-sulfamethoxazole	160/800 mg bid (PO)	7–14
Multidrug-Resistant, Depending on the Susceptibility Pattern			
Optimal treatment	Ceftriaxone	2 g/d (IV)	10–14
	Ciprofloxacin	500 mg bid (PO) or 400 mg q12h (IV)	5–7
	Azithromycin	1 g/d (PO)	5
Ceftriaxone-Resistant			
Optimal treatment	Meropenem[d]	1 g q8h (IV)	10–14
	Azithromycin	1 g/d (PO)	5
Eradication of Carriage			
Optimal treatment	Ciprofloxacin	500–750 mg bid (PO)	28
Alternative treatment	Azithromycin	500 mg (PO)	28

[a]Or another third-generation cephalosporin (e.g., cefotaxime, 2 g q8h IV; or cefixime, 400 mg bid PO). [b]Or 1 g on day 1 followed by 500 mg/d PO for 6 days. [c]Or ofloxacin, 400 mg bid PO for 2–5 days. [d]Or imipenem 500 mg q6h IV.

be used for empirical treatment of enteric fever in these regions. Patients with concern for ceftriaxone-resistant *S.* Typhi infection based on a history of travel to Pakistan should be treated empirically with a carbapenem or azithromycin.

Ceftriaxone, cefotaxime, and (oral) cefixime are effective for treatment of MDR enteric fever in adults and children, including that caused by DSC and fluoroquinolone-resistant strains. These agents clear fever in ~1 week, with failure rates of ~5–10%, fecal carriage rates of <3%, and relapse rates of 3–6%. Fluoroquinolones are effective against susceptible strains, with cure rates of ~98% and relapse and fecal carriage rates of <2%. Oral azithromycin is recommended for the treatment of uncomplicated enteric fever, including ESBL, DSC, and fluoroquinolone-resistant strains, and results in defervescence in 4–6 days, with rates of relapse and convalescent stool carriage of <3%. Against DSC strains, azithromycin is associated with lower rates of treatment failure and shorter durations of hospitalization than are fluoroquinolones. Carbapenems are increasingly being used to treat complicated XDR *S.* Typhi infections, but cost and IV route of administration are significant barriers.

Most patients with uncomplicated enteric fever can be managed at home with oral antibiotics and antipyretics. Patients with persistent vomiting, diarrhea, and/or abdominal distension should be hospitalized and given supportive therapy as well as a parenteral third-generation cephalosporin, a fluoroquinolone, or carbapenem, depending on the susceptibility profile. Therapy should be administered for at least 10 days or for 5 days after fever resolution.

In a randomized, prospective, double-blind study of critically ill patients with enteric fever (i.e., those with shock and obtundation) in Indonesia in the early 1980s, the administration of dexamethasone (an initial dose of 3 mg/kg followed by eight doses of 1 mg/kg every 6 h) with chloramphenicol was associated with a substantially lower mortality rate than was treatment with chloramphenicol alone (10% vs 55%). Although this study has not been repeated in the "post-chloramphenicol era," severe enteric fever remains one of the few indications for glucocorticoid treatment of an acute bacterial infection. Steroid treatment beyond 48 hours may increase the relapse rate.

The 2–5% of patients who develop chronic carriage of fluoroquinolone-susceptible *S.* Typhi can be treated for 4 weeks with oral ciprofloxacin or other fluoroquinolones, with an eradication rate of ~80%. A 4-week course of oral azithromycin can potentially be used to treat carriers with fluoroquinolone-resistant strains, but clinical experience is limited. Oral amoxicillin is associated with lower eradication rates than fluoroquinolones but can be considered in persons with fluoroquinolone-resistant strains that are susceptible to ampicillin. In cases of anatomic abnormality (e.g., biliary, kidney, or bladder stones), eradication often requires both antibiotic therapy and surgical correction.

PREVENTION AND CONTROL

Theoretically, it is possible to eliminate the salmonellae that cause enteric fever because they survive only in human hosts and are spread by contaminated food and water. However, given the high prevalence of the disease in developing countries that lack adequate sewage disposal and water treatment, this goal is currently unrealistic. Thus, travelers to developing countries should be advised to monitor their food and water intake carefully and to strongly consider immunization against *S.* Typhi.

Two unconjugated typhoid vaccines are commercially available in the United States: (1) Ty21a, an oral live attenuated *S.* Typhi vaccine (given on days 1, 3, 5, and 7, with revaccination with a full four-dose series every 5 years); and (2) Vi CPS, a parenteral vaccine consisting of purified Vi polysaccharide from the bacterial capsule (given in a single dose, with a booster every 2 years). The minimal age for vaccination is 6 years for Ty21a and 2 years for Vi CPS. In a 2018 meta-analysis of 18 randomized clinical trials of vaccines for preventing typhoid fever in populations in endemic areas, the cumulative efficacy was 50% for Ty21a at 2.5 to 3 years and 55% for Vi CPS at 3 years. Although data on typhoid vaccines in travelers are limited, recent evidence suggests that typhoid vaccines are moderately effective (80%) in U.S. travelers. Currently, there is no licensed vaccine for paratyphoid fever.

Unconjugated typhoid vaccines are poorly immunogenic in children <5 years of age because of limited ability to elicit T cell–dependent immune responses and immunologic memory. Compared with unconjugated vaccines, typhoid Vi polysaccharide conjugated vaccines are effective in children <2 years of age and elicit substantially longer duration of protection. The World Health Organization has recommended two typhoid conjugate vaccines (TCV) prioritized to prevent typhoid fever in countries with high incidence rates—Typbar TCV (manufactured by Bharat Biotech) in 2018 and TYPHIBEV (manufactured by Biological E) in 2020. A single intramuscular 0.5-mL dose of either TCV is safe and 79–95% effective, with antibody response persisting up to 7 years. As of 2023, TCV has been routinely introduced in national immunization programs in Pakistan, Nepal, Liberia, Zimbabwe, Malawi, and Samoa (Fig. 171-1).

Typhoid vaccine is not required for international travel, but it is recommended for travelers to areas where there is a moderate to high risk of exposure to *S.* Typhi, especially those who are traveling to southern Asia and other developing regions of Asia, Africa, the Caribbean, and Central and South America and who will be exposed to potentially contaminated food and drink. Typhoid vaccine should be considered even for persons planning <2 weeks of travel to high-risk areas. In addition, clinical microbiology or research laboratory staff at risk of occupational exposure to *S.* Typhi and household contacts of known *S.* Typhi carriers should be vaccinated. Because the protective efficacy of vaccine can be overcome by the high inocula that are commonly encountered in food-borne exposures, immunization is an adjunct and

not a substitute for the avoidance of high-risk foods and beverages. Immunization is not recommended for the management of persons who may have been exposed in a common-source outbreak.

Enteric fever is a notifiable disease in the United States. Individual health departments have their own guidelines for allowing ill or colonized food handlers or health care workers to return to their jobs. The reporting system enables public health departments to identify potential source patients and to treat chronic carriers in order to prevent further outbreaks. In addition, because 1–4% of patients with *S.* Typhi infection become chronic carriers, it is important to monitor patients (especially child-care providers and food handlers) for chronic carriage and to treat this condition if indicated.

NONTYPHOIDAL SALMONELLOSIS

EPIDEMIOLOGY

Worldwide, NTS causes ~93–150 million enteric infections and ~60,000–155,000 deaths annually. In the United States, the CDC estimates that NTS causes ~1.35 million illnesses, 26,500 hospitalizations, and 420 deaths each year. In 2022, the incidence of NTS infection in the United States was 14.5 cases per 100,000 persons—the second highest rate after *Campylobacter* (17.4 cases per 100,000 persons) among the 8 food-borne enteric pathogens under active surveillance. Although declining modestly since 2017, the incidence rate remains above the U.S. Healthy People 2030 goal of 11.5 cases per 100,000 persons. Globally, *S.* Typhimurium and *S.* Enteritidis are the most common serotypes causing human disease, with large differences in serotype distributions between regions but lesser differences between countries within the same region.

The incidence of NTS infection is highest during the rainy season in tropical climates and during the warmer months in temperate climates—a pattern coinciding with the peak in food-borne outbreaks. Rates of morbidity and mortality associated with NTS are highest among the elderly, infants, and immunocompromised individuals, including those with hemoglobinopathies, HIV infection, or infections that cause blockade of the reticuloendothelial system (e.g., bartonellosis, malaria, schistosomiasis, histoplasmosis).

Over the past three decades, bloodstream infection caused by invasive NTS, predominantly associated with closely related lineages of *S.* Typhimurium sequence type (ST) 313, as well as *S.* Enteritidis ST11, have emerged in sub-Saharan Africa and have spread to South Asia, the United Kingdom, and Brazil. These invasive NTS strains are adapted to person-to-person transmission through stepwise loss-of-function mutations and typically present with nonspecific febrile illness similar to enteric fever and uncommonly cause diarrhea. In 2017, there were ~535,000 invasive NTS cases and ~77,500 deaths, most of which (~80%) occurred in sub-Saharan Africa. Most (75%) *S.* Typhimurium ST313 isolates are MDR to ampicillin, trimethoprim-sulfamethoxazole, and chloramphenicol, and some are also resistant to ceftriaxone or ciprofloxacin, especially in South Asia. Recently, a sublineage of *S.* Typhimurium ST313 combining MDR with *both* ceftriaxone and azithromycin resistance has emerged in the Democratic Republic of the Congo. The incidence of invasive NTS infection is highest in children <5 years of age, exceeding 100 per 100,000 person-years in several West African countries, and risk is associated with malaria, HIV, malnutrition, and unclean drinking water sources. Transmission from asymptomatic stool carriers in the household and food or water sources has been proposed, but the sources of invasive NTS infection remain uncertain.

Unlike *S.* Typhi and *S.* Paratyphi, whose only reservoir is humans, NTS can be acquired from multiple animal and plant reservoirs that are part of the typical food supply. Transmission is most commonly associated with food products of animal origin (especially eggs, poultry, undercooked ground meat, and dairy products), fresh produce contaminated with animal waste, and contact with animals or their environments. In the United States, NTS are the second most common cause of food-borne outbreaks after norovirus, causing 30% of outbreaks and 35% of outbreak-associated illnesses.

S. Enteritidis infection associated with chicken eggs emerged as a major cause of food-borne disease during the 1980s and 1990s. *S.* Enteritidis infection of the ovaries and upper oviduct tissue of hens results in contamination of egg contents before shell deposition. Infection is spread to egg-laying hens from breeding flocks and through contact with rodents and manure. The number of *S.* Enteritidis outbreaks and the proportion attributable to egg-containing foods have continued to decline since the mid-1990s; these declines have coincided with interventions in the egg-producing and food service industries. Despite these control efforts, outbreaks of *S.* Enteritidis infection associated with shell eggs continue to occur. Transmission via contaminated eggs can be prevented by cooking eggs until the yolk is solidified and pasteurizing egg products. Increasingly, outbreaks of *S.* Enteritidis infection are associated with other foods, including meat, chicken, vegetables, dairy, and baked goods.

Salmonella serotype 4,[5],12:i:–, an antigenic variant of *S.* Typhimurium that lacks the second-stage flagellar antigen, has emerged since the 1990s as a foodborne pathogen primarily associated with pigs and pork products. This serotype is the second most common NTS in Europe and the fifth most common in the United States. These strains are MDR, with resistance to ampicillin, streptomycin, sulfonamides, and tetracycline. Increasing reports of plasmid-mediated colistin resistance in these strains have been linked to international travel to Thailand and swine farm isolates.

Centralization of food processing and widespread food distribution have contributed to the increased incidence of NTS in developed countries. NTS accounts for a significant majority of illnesses and hospitalizations associated with multistate foodborne outbreaks and retail food establishment outbreaks in the United States. Manufactured foods to which recent multistate *Salmonella* outbreaks have been traced include peanut butter; milk products, including powdered infant formula; and various processed foods, including packaged breakfast cereal, salsa, frozen prepared meals, and snack foods. Large outbreaks have also been linked to fresh produce, including alfalfa sprouts, nuts/seeds, cantaloupe, mangoes, papayas, tomatoes, and the herbal substance kratom consumed for its stimulant effect; these items become contaminated by manure or water at a single site and then are widely distributed.

In the United States, NTS infection associated with exotic pets is an ongoing clinical and public health problem, especially from contact with reptiles or amphibians, including iguanas, snakes, turtles, and lizards. Other pets, including hedgehogs, rodents, birds, baby chicks, ducklings, dogs, and cats, also are potential sources of NTS. Compared to foodborne outbreaks, outbreaks of NTS linked to animal contact more commonly affect young children (<1–4 years of age), result in hospitalization, and are more sustained.

Increasing antibiotic resistance in NTS species is a global problem and has been linked to the widespread use of antimicrobial agents in food animals and especially in animal feed. In the United States, clinically important resistant NTS infections, defined as resistance to ampicillin or ceftriaxone or nonsusceptibility to ciprofloxacin, increased an estimated 40% during 2015–2016 (annual incidence ~220,000) compared with 2004–2008 (~159,000 infections). The incidence (51.0 per 100,000 persons per year) and proportion of invasive NTS infections that are multidrug-resistant (75% with co-resistance to ampicillin, trimethoprim-sulfamethoxazole, and chloramphenicol) is dramatically higher across all sub-Saharan African regions. In the United States, infections caused by NTS with any antimicrobial resistance compared to NTS with no resistance are less likely to be associated with an outbreak and more likely to be associated with international travel, an increased risk of hospitalization, hospital length of stay, and death.

Outbreaks and sporadic cases of NTS resistant to third-generation cephalosporins have been reported, and international travel and adoption may have contributed to the global spread. Resistance is most commonly mediated by a transferable plasmid containing the *ampC* (bla_{CMY}) gene and has been linked to the widespread use of the veterinary cephalosporin ceftiofur. In 2021, 3.0% of NTS isolates from humans in the United States were ceftriaxone resistant (MIC, ≥4 μg/mL). Ceftriaxone resistance is more common among invasive NTS isolates from sub-Saharan Africa (>5%). Carbapenem-producing NTS have been reported sporadically in Europe, North Africa, and South Asia but remain extremely rare in the United States.

Since the early 2000s, strains of DSC NTS (MIC, ≥0.125 μg/mL) have emerged and have been associated with delayed response and treatment failure. In 2021, 10.6% of NTS isolates in the United States were DSC but only 0.5% of isolates were resistant to ciprofloxacin. These strains have diverse resistance mechanisms, including single and multiple mutations in the DNA gyrase genes *gyr*A and *gyr*B, mutations in the chromosomally encoded quinolone resistance–determining region, and plasmid-encoded quinolone resistance genes that are not reliably detected by nalidixic acid susceptibility testing or standard ciprofloxacin disk diffusion. In 2012, the U.S. Clinical Laboratory Standards Institute proposed a lower ciprofloxacin susceptibility breakpoint (≥0.06 μg/mL) for all *Salmonella* species to address this issue. Because some commercial test systems do not contain ciprofloxacin concentrations as low as the revised ≥0.06 μg/mL susceptibility breakpoint, laboratories can also determine the ciprofloxacin MIC by Etest or another alternative method.

In the United States, azithromycin-resistant NTS strains (MIC, ≥32 μg/mL) remain uncommon (1.1% in 2021), but most such isolates were also MDR. Azithromycin resistance is conferred by plasmid-encoded macrolide resistance genes, and their emergence may be related to international travel, especially to Thailand, and azithromycin overuse. Sporadic cases of carbapenemase-resistant NTS have been reported in Europe, North Africa, and southern Asia.

CLINICAL MANIFESTATIONS

Gastroenteritis Infection with NTS most often results in gastroenteritis indistinguishable from that caused by other enteric pathogens. Nausea, vomiting, and diarrhea occur 6–48 h after the ingestion of contaminated food or water. Patients often experience abdominal cramping and fever (38–39°C [100.5–102.2°F]). Diarrheal stools are usually loose, nonbloody, and of moderate volume. However, large-volume watery stools, bloody stools, or symptoms of dysentery may occur. Rarely, NTS causes pseudoappendicitis or an illness that mimics inflammatory bowel disease.

Gastroenteritis caused by NTS is usually self-limited. Diarrhea resolves within 3–7 days and fever within 72 h. Stool cultures remain positive for 4–5 weeks after infection—and in rare cases of chronic carriage (<1%) for >1 year. Persistent NTS infection and relapsing diarrhea have been described in a small fraction of Israeli patients and were associated with in-host single-nucleotide mutations in key virulence regulators. For acute NTS gastroenteritis, antibiotic treatment usually is not recommended and may prolong fecal carriage. Neonates, the elderly, and immunosuppressed patients (e.g., transplant recipients, HIV-infected persons) with NTS gastroenteritis are especially susceptible to dehydration and invasive infection and may require hospitalization and antibiotic therapy. Acute NTS gastroenteritis was associated with a threefold increased risk of dyspepsia and irritable bowel syndrome at 1 year in a study from Spain.

Bacteremia and Endovascular Infections Up to 8% of patients with NTS gastroenteritis develop bacteremia; of these, 5–10% develop localized infections. Bacteremia and metastatic infection are most common with *Salmonella* Choleraesuis and *Salmonella* Dublin and among infants, the elderly, and immunocompromised patients, especially those with HIV infection. NTS endovascular infection should be suspected in high-grade or persistent bacteremia, especially with preexisting valvular heart disease, atherosclerotic vascular disease, prosthetic vascular graft, or aortic aneurysm. Arteritis should be suspected in elderly patients with prolonged fever and back, chest, or abdominal pain developing after an episode of gastroenteritis. Endocarditis and arteritis are rare (<1% of cases) but are associated with serious and potentially fatal complications, including valve perforation, endomyocardial abscess, infected mural thrombus, pericarditis, mycotic aneurysms, aneurysm rupture, aortoenteric fistula, and vertebral osteomyelitis.

Invasive NTS disease is among the most common causes of bacteremia in children and in HIV-infected adults in sub-Saharan Africa and Southeast Asia, causing 39% of community-acquired bloodstream infection in one study. NTS bacteremia among these children is not associated with diarrhea and has been associated with poor nutritional status, malaria, sickle cell disease, and HIV infection. *S.* Typhimurium ST 131, the most common cause of invasive NTS disease in sub-Saharan Africa, forms a specific clade that is associated with genome reduction and loss of traits required for environmental stress resistance, likely contributing to making this strain more human adapted.

Localized Infections • **INTRAABDOMINAL INFECTIONS** Intraabdominal infections due to NTS are rare and usually manifest as hepatic or splenic abscesses or as cholecystitis. Risk factors include hepatobiliary anatomic abnormalities (e.g., gallstones), abdominal malignancy, and sickle cell disease (especially with splenic abscesses). Eradication of the infection often requires surgical correction of abnormalities and percutaneous drainage of abscesses.

CENTRAL NERVOUS SYSTEM INFECTIONS NTS meningitis most commonly develops in infants 1–4 months of age and in adults with HIV infection. It often results in severe sequelae (including seizures, hydrocephalus, brain infarction, and mental retardation), with death in up to 60% of cases. Other rare central nervous system infections include ventriculitis, subdural empyema, and brain abscesses.

PULMONARY INFECTIONS NTS pulmonary infections usually present as lobar pneumonia, and complications include lung abscess, empyema, and bronchopleural fistula formation. The majority of cases occur in patients with lung cancer, structural lung disease, sickle cell disease, or glucocorticoid use.

URINARY AND GENITAL TRACT INFECTIONS Urinary tract infections caused by NTS present as either cystitis or pyelonephritis. Risk factors include malignancy, urolithiasis, structural abnormalities, HIV infection, and renal transplantation. NTS genital infections are rare and include ovarian and testicular abscesses, prostatitis, and epididymitis. Like other focal infections, both genital and urinary tract infections can be complicated by abscess formation.

BONE, JOINT, AND SOFT TISSUE INFECTIONS *Salmonella* osteomyelitis most commonly affects the femur, tibia, humerus, or lumbar vertebrae and is most often seen in association with sickle cell disease, hemoglobinopathies, or preexisting bone disease (e.g., fractures). Prolonged antibiotic treatment is recommended to decrease the risk of relapse and chronic osteomyelitis. Septic arthritis occurs in the same patient population as osteomyelitis and usually involves the knee, hip, or shoulder joints. Reactive arthritis can follow NTS gastroenteritis and is seen most frequently in persons with the HLA-B27 histocompatibility antigen. NTS rarely can cause soft tissue infections, usually at sites of local trauma in immunosuppressed patients.

DIAGNOSIS

The diagnosis of NTS infection is based on isolation of the organism from freshly passed stool or from blood or another ordinarily sterile body fluid. *Salmonella* is increasingly identified by culture-independent molecular diagnostic tests due to increased sensitivity, rapid turnaround, and ability to detect multiple enteric pathogens in one test. Culture-independent positive specimens should have primary isolation performed to replicate results and recover NTS isolates. All NTS isolates should be referred to local public health departments for serotyping. Blood cultures should be obtained whenever a patient has prolonged or recurrent fever. Endovascular infection should be suspected if there is high-grade bacteremia (>50% of three or more sets of blood cultures positive). Echocardiography, CT, and indium-labeled white cell scanning are used to identify localized infection. When a localized infection is suspected, joint fluid aspiration, bone biopsy, abscess drainage, or cerebrospinal fluid should be cultured, as clinically indicated.

TREATMENT

Nontyphoidal Salmonellosis

Antibiotics should not be used routinely to treat uncomplicated NTS gastroenteritis. The symptoms are usually self-limited, and the duration of fever and diarrhea is not significantly decreased by

TABLE 171-2 Antibiotic Therapy for Nontyphoidal *Salmonella* Infection in Adults

INDICATION	AGENT	DOSAGE (ROUTE)	DURATION, DAYS
Preemptive Treatment[a]			
	Ciprofloxacin[b]	500 mg bid (PO)	2–3
Severe Gastroenteritis[c]			
	Ciprofloxacin	500 mg bid (PO) or 400 mg q12h (IV)	7
	Azithromycin	500 mg once daily	5
	Trimethoprim-sulfamethoxazole	160/800 mg bid (PO)	7
	Amoxicillin	1 g tid (PO)	7
	Ceftriaxone	1–2 g/d (IV)	7
Bacteremia			
	Ceftriaxone[d]	2 g/d (IV)	7–14
	Ciprofloxacin	400 mg q12h (IV), then 500 mg bid (PO)	
Endocarditis or Arteritis			
	Ceftriaxone	2 g/d (IV)	42
	Ciprofloxacin	400 mg q8h (IV), then 750 mg bid (PO)	
	Ampicillin	2 g q4h (IV)	
Meningitis			
	Ceftriaxone	2 g q12h (IV)	14–21
	Ampicillin	2 g q4h (IV)	
Other Localized Infection			
	Ceftriaxone	2 g/d (IV)	14–28
	Ciprofloxacin	500 mg bid (PO) or 400 mg q12h (IV)	
	Ampicillin	2 g q6h (IV)	

[a]Consider for neonates; persons >50 years of age with possible atherosclerotic vascular disease; and patients with immunosuppression, endovascular graft, or joint prosthesis. [b]Or ofloxacin, 400 mg bid (PO). [c]Consider on an individualized basis for patients with severe diarrhea and high fever who require hospitalization.
[d]Or cefotaxime, 2 g q8h (IV).

antibiotic therapy. In addition, antibiotic treatment has been associated with increased rates of relapse, prolonged gastrointestinal carriage, and adverse drug reactions. Dehydration secondary to diarrhea should be treated with fluid and electrolyte replacement.

Preemptive antibiotic treatment (Table 171-2) should be considered for patients at increased risk for invasive NTS infection, including neonates (probably up to 3 months of age); persons >50 years of age with known or suspected atherosclerosis; and patients with immunosuppression, cardiac valvular or endovascular abnormalities, or significant joint disease. Treatment should consist of an oral or IV antibiotic administered for 48–72 h or until the patient becomes afebrile. Immunocompromised persons may require up to 7–14 days of therapy. The <1% of persons who develop chronic carriage of NTS should receive a prolonged antibiotic course, as described above for chronic carriage of *S.* Typhi.

Because of the increasing prevalence of antibiotic resistance, empirical therapy for life-threatening NTS bacteremia or focal NTS infection should include a third-generation cephalosporin or a fluoroquinolone (Table 171-2). If the bacteremia is low-grade (<50% of blood cultures positive), the patient should be treated for 7–14 days. Patients with HIV/AIDS and NTS bacteremia should receive 1–2 weeks of IV antibiotic therapy followed by 4 weeks of oral therapy with a fluoroquinolone. Patients whose infections relapse after this regimen should receive long-term suppressive therapy with a fluoroquinolone, azithromycin, or TMP-SMX, as indicated by bacterial sensitivities.

If the patient has endocarditis or arteritis, treatment for 6 weeks with an IV β-lactam antibiotic (such as ceftriaxone or ampicillin) is indicated. IV ciprofloxacin followed by prolonged oral therapy is an option. Early surgical resection of infected aneurysms or other infected endovascular sites is recommended. Patients with infected prosthetic vascular grafts that cannot be resected have been maintained successfully on chronic suppressive oral therapy. For extraintestinal nonvascular infections, a 2- to 4-week course of antibiotic therapy (depending on the infection site) is usually recommended. In chronic osteomyelitis, abscess, or urinary or hepatobiliary infection associated with anatomic abnormalities, surgical resection or drainage may be required in addition to prolonged antibiotic therapy for eradication of infection.

PREVENTION AND CONTROL

Immunization against Invasive NTS Despite an urgent need for safe and effective vaccines, there is no available vaccine to protect against invasive NTS disease, and few candidate vaccines have progressed into early clinical trials. Candidate human NTS vaccines are O-antigen based and contain *S.* Typhimurium and *S.* Enteritidis bivalent components. NTS vaccines will need to target young children and protect those in at-risk groups, including persons with HIV infection and with malaria and those with sickle cell disease. In addition, rapid, point-of-care diagnostics are critically needed to reduce the morbidity and mortality associated with invasive NTS infection.

Despite widespread efforts to prevent or reduce bacterial contamination of animal-derived food products and to improve food-safety education and training, recent declines in the incidence of NTS in the United States have been modest compared with those of other food-borne pathogens. This observation probably reflects the complex epidemiology of NTS. Identifying effective risk-reduction strategies requires monitoring of every step of the food supply chain, including farm sources, slaughter and processing of raw animal or plant products, storage and transport, and preparation of finished foods. Contaminated food can be made safe for consumption by pasteurization, irradiation, or proper cooking. All cases of NTS infection should be reported to local public health departments because tracking and monitoring of these cases can identify the source(s) of infection and help authorities anticipate large outbreaks. Prudent use of antimicrobial agents in both humans and animals is needed to limit the emergence of MDR and XDR *Salmonella*.

172 Shigellosis

Philippe J. Sansonetti, Jean Bergounioux

The discovery of *Shigella* as the etiologic agent of dysentery—a clinical syndrome of fever, intestinal cramps, and frequent passage of small, bloody, mucopurulent stools—is attributed to the Japanese microbiologist Kiyoshi Shiga, who isolated the Shiga bacillus (now known as *Shigella dysenteriae* type 1) from patients' stools in 1897 during a large and devastating dysentery epidemic. *Shigella* cannot be distinguished from *Escherichia coli* by genome comparison and remains a separate species only on historical and clinical grounds.

ETIOLOGIC AGENT

Shigella is a non-spore-forming, gram-negative bacterium that, unlike *E. coli*, is nonmotile and does not produce gas from sugars, decarboxylate lysine, or hydrolyze arginine. Some serovars produce indole, and occasional strains utilize sodium acetate. *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei* (serogroups A, B, C, and D, respectively) can be differentiated on the basis of biochemical and serologic characteristics.

Genome sequencing of *E. coli* K12, *S. flexneri* 2a, *S. sonnei*, *S. dysenteriae* type 1, and *S. boydii* has revealed that these species have ~93% of genes in common. The three major genomic "signatures" of *Shigella* are (1) a 215-kb virulence plasmid that carries most of the genes required for pathogenicity (particularly invasive capacity); (2) the lack or alteration of genetic sequences encoding products (e.g., lysine decarboxylase) that, if expressed, would attenuate pathogenicity; and (3) in *S. dysenteriae* type 1, the presence of genes encoding Shiga toxin, a potent cytotoxin.

EPIDEMIOLOGY

The human intestinal tract is the major reservoir of *Shigella*, which is also found (albeit rarely) in the higher primates. Because excretion of shigellae is greatest in the acute phase of disease, the bacteria are transmitted most efficiently by the fecal–oral route via hand carriage; however, some outbreaks reflect foodborne or waterborne transmission. In impoverished areas, *Shigella* can be transmitted by flies. The high-level infectivity of *Shigella* is reflected by the very small inoculum required for experimental infection of volunteers (100 colony-forming units [CFU]), by the very high attack rates during outbreaks in day-care centers (33–73%), and by the high rates of secondary cases among family members of sick children (26–33%). Shigellosis can also be transmitted sexually.

Throughout history, bacillary dysentery epidemics have often occurred in settings of human crowding under conditions of poor hygiene—e.g., among soldiers in campaigning armies, inhabitants of besieged cities, groups on pilgrimages, and refugees in camps. Epidemics followed a cyclical pattern in areas such as the Indian subcontinent and sub-Saharan Africa. These patterns of devastating epidemics, which were most often caused by *S. dysenteriae* type 1, were characterized by high attack and mortality rates. In Bangladesh, for instance, an epidemic caused by *S. dysenteriae* type 1 was associated with a 42% increase in mortality rate among children 1–4 years of age. This pattern of severe cyclic disease has steeply declined over the last few decades. Along with the increasingly rare isolation of *S. dysenteriae 1*, the current epidemiology of shigellosis is generally attributed to a significant global reduction of extreme poverty; this coincides with the tremendous decrease in child mortality.

Nevertheless, apart from these severe epidemics of the past, shigellosis remains an endemic disease, with 99% of cases occurring in developing countries, with the highest prevalence in the most impoverished areas, where personal and general hygiene is below standard. *S. flexneri* isolates predominate in the least developed areas, whereas *S. sonnei* is more prevalent in economically emerging countries and in the industrialized world.

Prevalence in the Developing World In a review published under the auspices of the World Health Organization (WHO), the total annual number of cases in 1966–1997 was estimated at 165 million, and 69% of these cases occurred in children <5 years of age. In this review, the annual number of deaths was calculated to range between 500,000 and 1.1 million. Data (2000–2004) from six Asian countries indicate that, even though the incidence of shigellosis remains stable, mortality rates associated with this disease may have decreased significantly, possibly as a result of improved nutritional status. However, extensive and essentially uncontrolled use of antibiotics, which may also account for declining mortality rates, has increased the emergence of multidrug-resistant *Shigella* strains.

A 2013 prospective, matched, case-control study of children <5 years of age emphasized the importance of *Shigella* in the burden and etiology of diarrheal diseases in developing countries. *Shigella* was one of the top four pathogens associated with moderate to severe diarrhea and ranked first among children 12–59 months of age. These moderate to severe cases accounted for an 8.5-fold increase in mortality incidence over the average diarrheal disease-related mortality. The study concluded that *Shigella* remained a major pathogen to be targeted by health care programs.

Global reevaluation of the *Shigella* disease burden is warranted because an often-overlooked complication of shigellosis is the short- and long-term impairment of the nutritional status of infected children in endemic areas. Combined with anorexia, the exudative enteropathy resulting from mucosal abrasions contributes to rapid deterioration of the patient's nutritional status. Shigellosis thus now appears as a major contributor to stunted growth among children in endemic regions.

Peaking in incidence in the pediatric population, endemic shigellosis is rare among young and middle-aged adults, probably because of naturally acquired immunity. Incidence then increases again in the elderly population.

Prevalence in the Industrialized World In pediatric populations, local outbreaks occur when proper and adapted hygiene policies are not implemented in group facilities such as day-care centers and institutions for the developmentally disabled. In adults, as in children, sporadic cases occur among travelers returning from endemic areas, and rare outbreaks of varying size can follow waterborne or foodborne infections.

PATHOGENESIS AND PATHOLOGY

Shigella infection occurs essentially through oral contamination via direct fecal–oral transmission, the organism being poorly adapted to survive in the environment. Resistance to low-pH conditions allows *Shigella* to survive passage through the gastric barrier.

The watery diarrhea that usually precedes dysenteric symptoms is attributable to active secretion and abnormal water reabsorption in the jejunum, as described in experimentally infected rhesus monkeys. This initial purge is possibly due to the combined action of an enterotoxin (ShET-1) and mucosal inflammation. The dysenteric syndrome, manifested by bloody and mucopurulent stools, reflects invasion of the colonic mucosa.

The pathogenesis of *Shigella* is essentially determined by a large virulence plasmid of 214 kb comprising ~100 genes, of which 25 encode a type III secretion system that inserts into the membrane of the host cell to allow effectors to transit from the bacterial cytoplasm to the host cell cytoplasm **(Fig. 172-1)**. Bacteria are thereby able to invade intestinal epithelial cells by inducing their own uptake either directly at the opening of colonic crypts or following the initial crossing of the epithelial barrier through M cells (the specialized translocating epithelial cells in the follicle-associated epithelium that covers mucosal lymphoid nodules). *Shigella* induces apoptosis of subepithelial resident macrophages. Once inside the cytoplasm of intestinal epithelial cells, *Shigella* effectors trigger the cytoskeletal rearrangements necessary to direct uptake of the organism into the epithelial cell. The *Shigella*-containing vacuole is then quickly lysed, releasing bacteria into the cytosol.

Intracellular shigellae next use cytoskeletal components to propel themselves inside the infected cell; when the moving organism and the host cell membrane come into contact, cellular protrusions form and

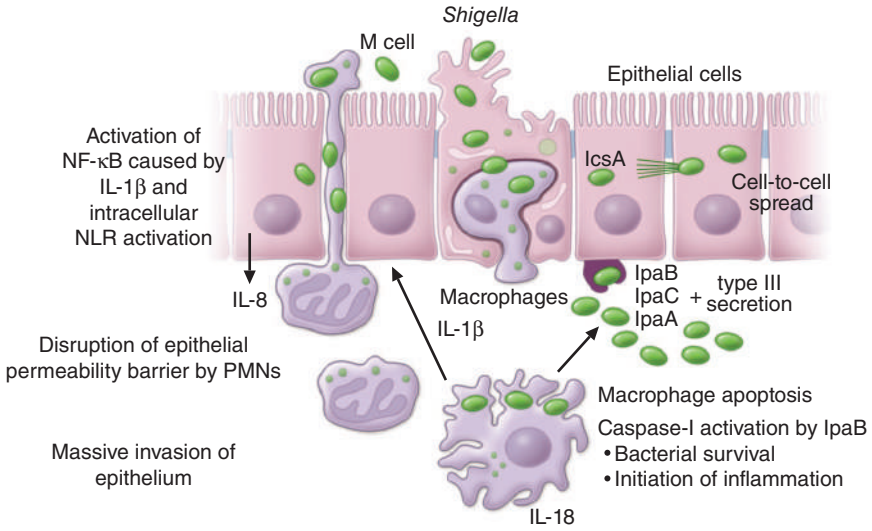

FIGURE 172-1 Invasive strategy of *Shigella flexneri.* IL, interleukin; NF-κB, nuclear factor κB; NLR, NOD-like receptor; PMN, polymorphonuclear leukocyte.

are engulfed by neighboring cells. This series of events permits bacterial cell-to-cell spread.

Cytokines released by a growing number of infected intestinal epithelial cells massively attract immune cells—particularly polymorphonuclear leukocytes [PMNs]—to the infected site, thus further destabilizing the epithelial barrier, exacerbating inflammation, and leading to the acute colitis that characterizes shigellosis. Evidence indicates that some type III secretion system–injected effectors can control the extent of inflammation, thus facilitating bacterial survival.

Shiga toxin produced by *S. dysenteriae* type 1 increases disease severity. This toxin belongs to a group of A1-B5 protein toxins whose B subunit binds to the receptor globotriaosylceramide on the target cell surface and whose catalytic A subunit is internalized by receptor-mediated endocytosis and interacts with the subcellular machinery to inhibit protein synthesis by expressing RNA *N*-glycosidase activity on 28S ribosomal RNA. This process leads to inhibition of binding of the amino-acyl-tRNA to the 60S ribosomal subunit and thus to a general shutoff of cell protein biosynthesis. Shiga toxins are translocated from the bowel into the circulation. After binding of the toxins to target cells in the kidney, pathophysiologic alterations may result in hemolytic-uremic syndrome (HUS; see below).

CLINICAL MANIFESTATIONS

The presentation and severity of shigellosis depend to some extent on the infecting serotype but even more on the age and the immunologic and nutritional status of the host. Poverty and poor standards of hygiene are strongly related to the number and severity of diarrheal episodes, especially in children <5 years following weaning.

Shigellosis typically evolves through four phases: incubation, watery diarrhea, dysentery, and the postinfectious phase. The incubation period usually lasts 1–4 days but may be as long as 8 days. Typical initial manifestations are transient fever, limited watery diarrhea, malaise, and anorexia. Signs and symptoms may range from mild abdominal discomfort to severe cramps, diarrhea, fever, vomiting, and tenesmus. The manifestations are usually exacerbated in children, with temperatures up to 40°–41°C (104.0°–105.8°F) and more severe anorexia and watery diarrhea. This initial phase may represent the only clinical manifestation of shigellosis, especially in developed countries. Otherwise, dysentery follows within hours or days and is characterized by uninterrupted excretion of small volumes of bloody mucopurulent stools with increased tenesmus and abdominal cramps. At this stage, *Shigella* produces acute colitis involving mainly the distal colon and the rectum. Unlike most diarrheal syndromes, dysenteric syndromes rarely present with dehydration as a major feature. Endoscopy, if performed, shows an edematous and hemorrhagic mucosa, with ulcerations and possibly overlying exudates resembling pseudomembranes. The extent of the lesions correlates with the number and frequency of stools and with the degree of protein loss by exudative mechanisms. Most episodes are self-limited and resolve without treatment in 1 week. With appropriate treatment, recovery takes place within a few days to a week, with no sequelae.

Acute life-threatening complications are seen most often in children <5 years (particularly those who are malnourished) and in elderly patients. Risk factors for death in a clinically severe case include nonbloody diarrhea, moderate to severe dehydration, bacteremia, absence of fever, abdominal tenderness, and rectal prolapse. Major complications are predominantly intestinal (e.g., toxic megacolon, intestinal perforations, rectal prolapse) or metabolic (e.g., hypoglycemia, hyponatremia, dehydration). Bacteremia is rare and is reported most frequently in severely malnourished and HIV-infected patients. Alterations of consciousness, including seizures, delirium, and coma, may occur, especially in children <5 years, and are associated with a poor prognosis; fever and severe metabolic alterations are more often the major causes of altered consciousness than is meningitis or the Ekiri syndrome (toxic encephalopathy associated with bizarre posturing, cerebral edema, and fatty visceral degeneration), which has been reported mostly in Japanese children. Pneumonia, vaginitis, and keratoconjunctivitis due to *Shigella* are rarely reported. In the absence of serious malnutrition, severe and very unusual clinical manifestations, such as meningitis, may be linked to genetic defects in innate immune functions (i.e., deficiency in interleukin 1 receptor–associated kinase 4 [IRAK-4]) and may require genetic investigation.

Two complications of particular importance are toxic megacolon and HUS. Toxic megacolon is a consequence of severe inflammation extending to the colonic smooth-muscle layer and causing paralysis and dilation. The patient presents with abdominal distention and tenderness, with or without signs of localized or generalized peritonitis. The abdominal x-ray characteristically shows marked dilation of the transverse colon (with the greatest distention in the ascending and descending segments); thumbprinting caused by mucosal inflammatory edema; and loss of the normal haustral pattern associated with pseudopolyps, often extending into the lumen. Pneumatosis coli is an occasional finding. If perforation occurs, radiographic signs of pneumoperitoneum may be apparent. Predisposing factors (e.g., hypokalemia and use of opioids, anticholinergics, loperamide, psyllium seeds, and antidepressants) should be investigated.

Shiga toxin produced by *S. dysenteriae* type 1 has been linked to HUS in developing countries but rarely in industrialized countries, where enterohemorrhagic *E. coli* (EHEC) predominates as the etiologic agent of this syndrome. HUS is an early complication that most often develops after several days of diarrhea. Clinical examination shows pallor, asthenia, and irritability and, in some cases, bleeding of the nose and gums, oliguria, and increasing edema. HUS is a nonimmune (Coombs-negative) hemolytic anemia defined by a diagnostic triad: microangiopathic hemolytic anemia (hemoglobin level typically <80 g/L [<8 g/dL]), thrombocytopenia (mild to moderate in severity; typically <60,000 platelets/μL), and acute renal failure due to thrombosis of the glomerular capillaries (with markedly elevated creatinine levels). Anemia is severe, with fragmented red blood cells (*schizocytes*) in the peripheral smear, high serum concentrations of lactate dehydrogenase and free circulating hemoglobin, and elevated reticulocyte counts. Acute renal failure occurs in 55–70% of cases; however, renal function recovers in most of these cases (up to 70% in various series). Leukemoid reactions, with leukocyte counts of 50,000/μL, are sometimes present in association with HUS.

The postinfectious immunologic complication known as *reactive arthritis* can develop weeks or months after shigellosis, especially in patients expressing the histocompatibility antigen HLA-B27. About 3% of patients infected with *S. flexneri* later develop this syndrome, with arthritis, ocular inflammation, and urethritis—a condition that can

last for months or years and can progress to difficult-to-treat chronic arthritis. Postinfectious arthritis occurs only after infection with *S. flexneri* and not after infection with the other *Shigella* serotypes.

LABORATORY DIAGNOSIS

The differential diagnosis in patients with a dysenteric syndrome depends on the clinical and environmental context. In developing areas, infectious diarrhea caused by other invasive pathogenic bacteria (*Salmonella*, *Campylobacter jejuni*, *Clostridium difficile*, *Yersinia enterocolitica*) or parasites (*Entamoeba histolytica*) should be considered. Only bacteriologic and parasitologic examinations of stool can truly differentiate among these pathogens. A first flare of inflammatory bowel disease, such as Crohn's disease or ulcerative colitis **(Chap. 337)**, should be considered in patients in industrialized countries. Despite the similarity in symptoms, anamnesis discriminates between shigellosis, which usually follows recent travel in an endemic zone, and these other conditions.

Microscopic examination of stool smears shows erythrophagocytic trophozoites with very few PMNs in *E. histolytica* infection, whereas bacterial enteroinvasive infections (particularly shigellosis) are characterized by high PMN counts in each microscopic field. However, because shigellosis often manifests only as watery diarrhea, systematic attempts to isolate *Shigella* are necessary.

The "gold standard" diagnosis of *Shigella* infection remains the isolation and identification of the pathogen from fecal material. One major difficulty, particularly in endemic areas where laboratory facilities are not immediately available, is the fragility of *Shigella* and its common disappearance during transport, especially with rapid changes in temperature and pH. In the absence of a reliable enrichment medium, buffered glycerol saline or Cary-Blair medium can be used as a holding medium, but prompt inoculation onto isolation medium is essential. The probability of isolation is higher if the portion of stools that contains bloody and/or mucopurulent material is directly sampled. Rectal swabs can be used, as they offer the highest rate of successful isolation during the acute phase of disease. Blood cultures are positive in fewer than 5% of cases but should be done when a patient presents with a clinical picture of severe sepsis.

In addition to quick processing, the use of several media increases the likelihood of successful isolation: a nonselective medium such as bromocresol-purple agar lactose; a low-selectivity medium such as MacConkey or eosin-methylene blue; and a high-selectivity medium such as Hektoen, *Salmonella-Shigella*, or xylose-lysine-deoxycholate agar. After incubation on these media for 12–18 h at 37°C (98.6°F), shigellae appear as non-lactose-fermenting colonies that measure 0.5–1 mm in diameter and have a convex, translucent, smooth surface. Suspected colonies on nonselective or low-selectivity medium can be subcultured on a high-selectivity medium before being specifically identified or can be identified directly by standard commercial systems on the basis of four major characteristics: glucose positivity (usually without production of gas), lactose negativity, H_2S negativity, and lack of motility. The four *Shigella* serogroups (A–D) can then be differentiated by additional characteristics. This approach adds time and difficulty to the identification process; however, after presumptive diagnosis, the use of serologic methods (e.g., slide agglutination, with group- and then type-specific antisera) should be considered. Group-specific antisera are widely available; in contrast, because of the large number of serotypes and subserotypes, type-specific antisera are rare and more expensive and thus are often restricted to reference laboratories.

Molecular methods of diagnostics, including polymerase chain reaction based on *Shigella*-specific virulence gene sequences or mass spectrometry, are not yet standardized for global use. However, serotyping may soon be replaced by genome-based techniques.

TREATMENT

Shigellosis

ANTIBIOTIC SUSCEPTIBILITY OF *SHIGELLA*

As an enteroinvasive disease, shigellosis requires antibiotic treatment. Since the mid-1960s, however, increasing resistance to multiple drugs has been a dominant factor in treatment decisions. Resistance rates are highly dependent on the geographic area. Clonal spread of particular strains and horizontal transfer of resistance determinants, particularly via plasmids and transposons, contribute to multidrug resistance. The current global status—i.e., high rates of resistance to classic first-line antibiotics such as amoxicillin—has led to a rapid switch to quinolones such as nalidixic acid. However, resistance to such early-generation quinolones has also emerged and spread quickly as a result of chromosomal mutations affecting DNA gyrase and topoisomerase IV; this resistance has necessitated the use of later-generation quinolones as first-line antibiotics in many areas. For instance, a review of the antibiotic resistance history of *Shigella* in India found that, after their introduction in the late 1980s, the second-generation quinolones norfloxacin, ciprofloxacin, and ofloxacin were highly effective in the treatment of shigellosis, including cases caused by multidrug-resistant strains of *S. dysenteriae* type 1. However, investigations of subsequent outbreaks in India and Bangladesh detected resistance to norfloxacin, ciprofloxacin, and ofloxacin in 5% of isolates. In the United States, the resistance rate of *Shigella* to fluoroquinolones reached 87% during 2014–2015. The incidence of multidrug resistance parallels the widespread, uncontrolled use of antibiotics and calls for the rational use of effective drugs. Despite the alarming proportion of resistant *Shigella*, there is a lack of studies assessing the resistance of community-acquired strains.

ANTIBIOTIC TREATMENT OF SHIGELLOSIS (TABLE 172-1)

With effective antibiotic therapy, clinical improvement occurs within 48 h, resulting in a decreased risk of complications and death, shorter duration of symptoms, and elimination of *Shigella* from the stools. Because of the transmissibility of *Shigella*, current public health recommendations in the United States are that every case be treated with antibiotics. The use of fluoroquinolones (first-line, preferably ciprofloxacin) and cephalosporins and β-lactams (second-line) for 7–10 days is recommended for the treatment of shigellosis. Whereas infections caused by non-*dysenteriae Shigella* in immunocompetent individuals are routinely treated with a 3-day course of antibiotics, it is recommended that *S. dysenteriae* type 1 infections be treated for 5 days and that *Shigella* infections in immunocompromised patients be treated for 7–10 days.

TABLE 172-1 Recommended Antimicrobial Therapy for Shigellosis

ANTIMICROBIAL AGENT	TREATMENT SCHEDULE		LIMITATIONS
	CHILDREN	ADULTS	
First-Line			
Ciprofloxacin	15 mg/kg	500 mg	
	2 times per day for 3 days, PO		
Second-Line			
Pivmecillinam	20 mg/kg	100 mg	Cost
	4 times per day for 5 days PO		No pediatric formulation Frequent administration Emerging resistance
Ceftriaxone	50–100 mg/kg	—	Efficacy not validated Must be injected
	Once a day IM for 2–5 days		
Azithromycin	6–20 mg/kg	1–1.5 g	Cost
	Once a day for 1–5 days PO		Efficacy not validated Minimum inhibitory concentration near serum concentration Rapid emergence of resistance and spread to other bacteria

Source: Reproduced with permission from World Health Organization: Guidelines for the control of shigellosis, including epidemics due to *Shigella dysenteriae* type 1. *https://www.who.int/publications/i/item/9241592330*.

Treatment for shigellosis must be adapted to the clinical context, with the recognition that the most fragile patients are children <5 years, who represent two-thirds of all cases worldwide and are the group most at risk of severe complications. There are few data on the use of quinolones in children, but *Shigella* dysentery is an accepted indication. The half-life of ciprofloxacin is longer in infants than in older individuals. The ciprofloxacin dose generally recommended for children is 30 mg/kg per day in two divided doses. Adults living in areas with high standards of hygiene are likely to develop milder, shorter-duration disease, whereas infants in endemic areas can develop severe, sometimes fatal, dysentery. In the former setting, treatment will remain minimal and bacteriologic proof of infection will often come after symptoms have resolved; in the latter setting, antibiotic treatment and more aggressive measures, possibly including resuscitation, are often required.

REHYDRATION AND NUTRITION

Shigella infection rarely causes significant dehydration, particularly in industrialized countries. It is recommended that rehydration should be oral unless the patient is comatose or in shock. Because of the improved effectiveness of reduced-osmolarity oral rehydration solutions, WHO and UNICEF now recommend a standard solution of 245 mOsm/L (sodium, 75 mmol/L; chloride, 65 mmol/L; glucose [anhydrous], 75 mmol/L; potassium, 20 mmol/L; citrate, 10 mmol/L). In shigellosis, the coupled transport of sodium and glucose may be variably affected, but oral rehydration therapy remains the easiest and most efficient form of rehydration, especially in severe cases.

Nutrition should be started as soon as possible, keeping in mind that in developing countries, malnutrition remains the primary indicator of the risk of diarrhea-related death. Early refeeding is safe, well tolerated, and clinically beneficial. Because breast-feeding reduces diarrheal losses and the need for oral rehydration in infants, it should be maintained in the absence of contraindications (e.g., maternal HIV infection).

NONSPECIFIC, SYMPTOM-BASED THERAPY

Antimotility agents have been implicated in prolonged fever in volunteers with shigellosis. These agents are suspected of increasing the risk of toxic megacolon and are thought to have been responsible for HUS in children infected by EHEC strains. For safety reasons, it is better to avoid antimotility agents in bloody diarrhea.

TREATMENT OF COMPLICATIONS

There is no consensus regarding the best treatment for toxic megacolon. The patient should be assessed frequently by both medical and surgical teams. Anemia, dehydration, and electrolyte deficits (particularly hypokalemia) may aggravate colonic atony and should be actively treated. Nasogastric aspiration helps to deflate the colon. Parenteral nutrition has not been proven to be beneficial. Fever persisting beyond 48–72 h raises the possibility of local perforation or abscess. Most studies recommend colectomy if, after 48–72 h, colonic distention persists. However, some physicians recommend continuation of medical therapy for up to 7 days if the patient seems to be improving clinically despite persistent megacolon without perforation. Intestinal perforation, either isolated or complicating toxic megacolon, requires surgical treatment and intensive medical support.

Rectal prolapse must be treated as soon as possible. With the health care provider using surgical gloves or a soft warm wet cloth and the patient in the knee-chest position, the prolapsed rectum is gently pushed back into place. If edema of the rectal mucosa is evident, making reduction difficult, it can be osmotically reduced by application of gauze impregnated with a warm solution of saturated magnesium sulfate. Rectal prolapse often relapses but usually resolves along with the resolution of dysentery.

HUS must be treated by water restriction, including discontinuation of oral rehydration solutions and potassium-rich nutrition. Hemofiltration or peritoneal dialysis is often required.

PREVENTION

Hand washing after defecation or handling of children's feces and before handling of food is recommended. Stool decontamination (e.g., with sodium hypochlorite), together with a cleaning protocol for medical staff as well as for patients, has proven useful in limiting the spread of infection during *Shigella* outbreaks. Ideally, patients should have a negative stool culture before their infection is considered cured. Recurrences are rare if therapeutic and preventive measures are correctly implemented. Protection against fly intrusion in commonly infested sites such as kitchens and latrines is strongly advised in endemic areas.

Although several live attenuated oral and subunit parenteral vaccine candidates have been produced and are undergoing clinical trials, no vaccine against shigellosis is currently available. Especially given the rapid progression of antibiotic resistance in *Shigella* and its increasing recognition as a cause of child stunting, a vaccine is urgently needed. Most recent evidence indicates that synthetic polysaccharide conjugate vaccines (based on chemically synthesized, concatenated lipopolysaccharide O-side chain mimics) elicit high levels of protective IgG antibodies, hence promising protection. Protection would be particularly important for children <3 years, the population most susceptible to severe forms of shigellosis.

173 Cholera and Other Vibrioses

Matthew K. Waldor, Edward T. Ryan

Members of the genus *Vibrio* cause several important infectious syndromes. Classic among them is cholera, a devastating diarrheal disease caused by *Vibrio cholerae* that has been responsible for seven global pandemics and much suffering over the past two centuries. Epidemic cholera remains a significant public-health concern in the

developing world today. Other vibrioses caused by other *Vibrio* species include syndromes of diarrhea, soft tissue infection, or primary sepsis. All *Vibrio* species are highly motile, facultatively anaerobic, curved, gram-negative rods with one or more flagella. In nature, vibrios most commonly reside in tidal rivers and bays under conditions of moderate salinity. They proliferate in the summer months when water temperatures exceed 20°C, and the illnesses they cause also increase in frequency during the warm months.

CHOLERA

DEFINITION

Cholera is an acute diarrheal disease that can, in a matter of hours, result in profound, rapidly progressive dehydration and death. Accordingly, *cholera gravis* (the severe form) is a much-feared disease, particularly in its epidemic presentation. Fortunately, prompt aggressive fluid repletion and supportive care can obviate the high mortality that is historically associated with cholera. Although the term *cholera* has occasionally been applied to any severely dehydrating secretory diarrheal illness, whether infectious in etiology or not, it now refers to disease caused by *V. cholerae* serogroup O1 or O139—i.e., the serogroups with epidemic potential.

MICROBIOLOGY AND EPIDEMIOLOGY

The species *V. cholerae* is classified into >200 serogroups based on the carbohydrate constituents of their lipopolysaccharide (LPS) O antigens. Although some non-O1 *V. cholerae* serogroups (strains that do not agglutinate in antisera to the O1 group antigen) have occasionally caused sporadic outbreaks of diarrhea, serogroup O1 was, until the emergence of serogroup O139 in 1992 (see below), the exclusive cause of epidemic cholera. The O1 serogroup is further subdivided into two serotypes, termed *Inaba* and *Ogawa*. Two biotypes of *V. cholerae* O1, classic and El Tor, have been described, but the former is thought to be extinct.

The natural habitat of *V. cholerae* is coastal salt water and brackish estuaries, where the organism lives in close relation to plankton. *V. cholerae* can also exist in freshwater in the presence of adequate nutrients and warmth. Humans become infected incidentally but, once infected, can act as vehicles for spread. Ingestion of water contaminated by human feces is thought to be the most common means of acquisition of *V. cholerae*. However, consumption of contaminated food and human-to-human transmission also contribute to spread. There is no known animal reservoir. Although the infectious dose is relatively high, it is markedly reduced in hypochlorhydric persons, in those using antacids, and when gastric acidity is buffered by a meal. Cholera is predominantly a pediatric disease in endemic areas, but it affects adults and children equally when newly introduced into a population. In endemic areas, the burden of disease is often greatest during "cholera seasons" associated with high temperatures, heavy rainfall, and flooding, but cholera can occur year-round.

Cholera is native to the Ganges delta on the Indian subcontinent. Since 1817, seven global pandemics have occurred. The current (seventh) pandemic—the first due to the El Tor biotype—began in Indonesia in 1961 and spread in serial waves throughout Asia as *V. cholerae* El Tor displaced the endemic classic biotype, which is thought to have caused the previous six pandemics. In the early 1970s, El Tor cholera erupted in Africa, causing major epidemics before becoming a persistent endemic problem. Currently, >95% of cholera cases reported annually to the World Health Organization (WHO) are from Africa and Asia **(Fig. 173-1)**, but the true burden and distribution of cholera are unknown because the diagnosis is often syndromic and many countries with endemic cholera do not report cholera to the WHO. In 2022 and 2023, large outbreaks involving more than 10,000 cases per country were being reported every few weeks to the World Health Organization. It is possible that >1–4 million cases of cholera occur yearly (of which only ~400,000 are reported to the WHO) and that these cases result in >20,000–140,000 deaths annually (of which <2000 are reported to the WHO).

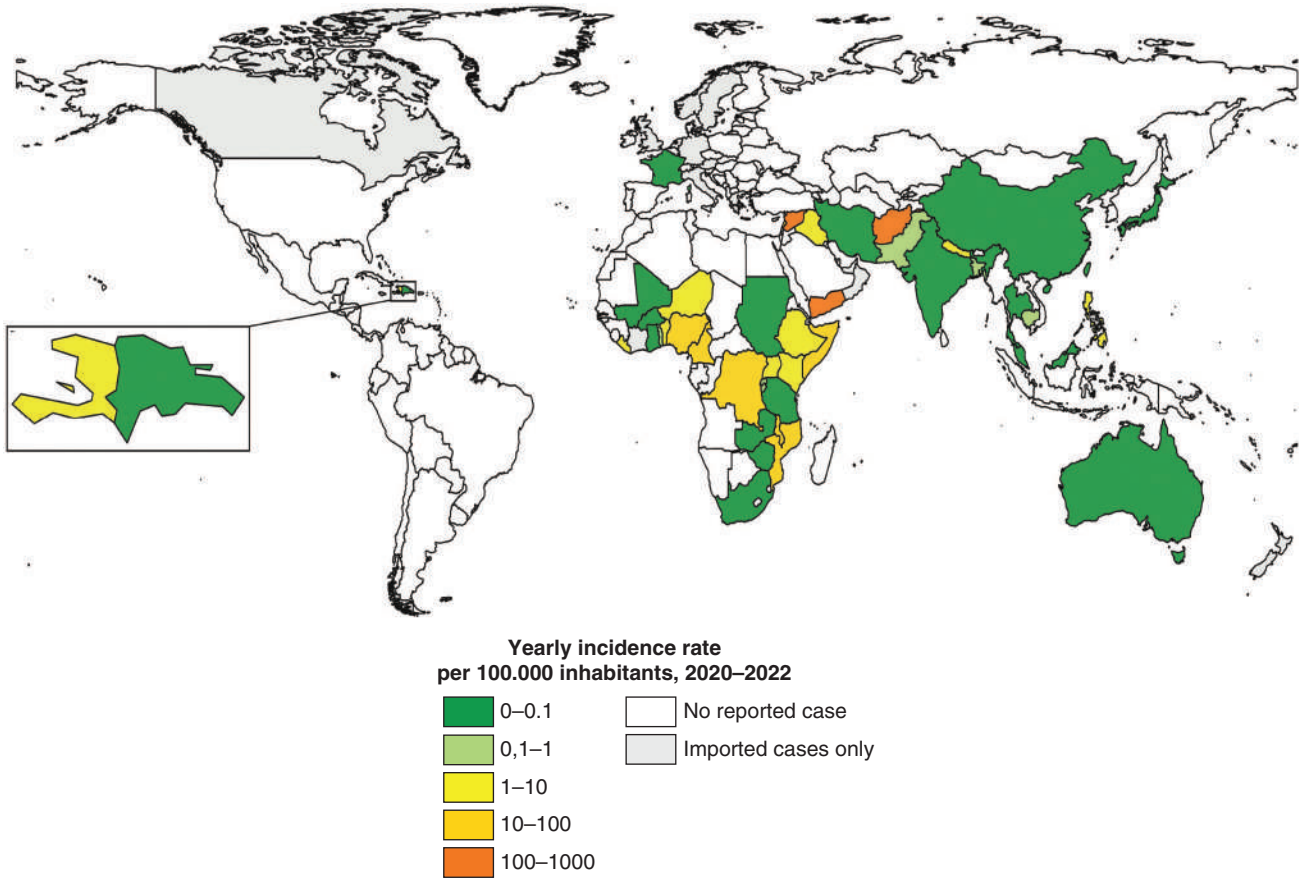

FIGURE 173-1 World distribution of cholera in 2020–2022. WHO, World Health Organization. *(Reproduced with permission from Dr. M. Piarroux, Université de la Méditerranée, France.)*

After a century without cholera in Latin America, the current cholera pandemic reached Central and South America in 1991. Following an initial explosive spread that affected millions, the burden of disease has markedly decreased in Latin America. In 2010, a severe cholera outbreak began in Haiti, a country with no recorded history of this disease. Several lines of evidence indicate that cholera was likely introduced into Haiti by United Nations security forces from Asia, raising the possibility that asymptomatic carriers of *V. cholerae* play an important role in transmitting cholera over long distances. In 2016, an outbreak of cholera began in Yemen in the setting of a civil war and population displacement and the breakdown of health infrastructure. The recent history of cholera has been punctuated by such severe outbreaks, especially among impoverished or displaced persons. These outbreaks are often precipitated by war or other circumstances that lead to the breakdown of public-health measures. Such was the case in the camps for Rwandan refugees set up in 1994 around Goma, Zaire; in 2008–2009 in Zimbabwe; in 2015 in South Sudan and the Democratic Republic of the Congo; and in 2022 in Lebanon and the Syrian Arab Republic.

Sporadic endemic infections due to *V. cholerae* O1 strains related to the seventh-pandemic strain have been recognized along the U.S. Gulf Coast of Louisiana and Texas. These infections are typically associated with the consumption of contaminated, locally harvested shellfish. Occasionally, cases in U.S. locations remote from the Gulf Coast have been linked to shipped-in Gulf Coast seafood.

In October 1992, a large-scale outbreak of clinical cholera caused by a new serogroup, O139, occurred in southeastern India. The organism appears to be a derivative of El Tor O1 but has a distinct LPS and an immunologically related O-antigen polysaccharide capsule. (O1 organisms are not encapsulated.) After an initial spread across 11 Asian countries, *V. cholerae* O139 has once again been almost entirely replaced by O1 strains. The clinical manifestations of disease caused by *V. cholerae* O139 are indistinguishable from those of O1 cholera. Immunity to one, however, is not protective against the other.

PATHOGENESIS

In the final analysis, cholera is a toxin-mediated disease. The watery diarrhea characteristic of cholera is due to the action of cholera toxin, a potent protein enterotoxin elaborated by the organism in the small intestine. The toxin-coregulated pilus (TCP), so named because its synthesis is regulated in parallel with that of cholera toxin, is essential for *V. cholerae* to survive and multiply in (colonize) the small intestine. Production of cholera toxin, TCP, and several other virulence factors are coordinately regulated by ToxR. This protein modulates the expression of genes coding for virulence factors in response to environmental signals via a cascade of regulatory proteins. Additional regulatory processes, including bacterial responses to the density of the bacterial population (in a phenomenon known as *quorum sensing*), modulate the virulence of *V. cholerae*.

Once established in the human small bowel, the organism produces cholera toxin, which consists of a monomeric enzymatic moiety (the A subunit) and a pentameric binding moiety (the B subunit). The B pentamer binds to GM_1 ganglioside, a glycolipid on the surface of epithelial cells that serves as the toxin receptor and makes possible the delivery of the A subunit to its cytosolic target. The activated A subunit (A_1) irreversibly transfers ADP-ribose from nicotinamide adenine dinucleotide to its specific target protein, the GTP-binding regulatory component of adenylate cyclase. The ADP-ribosylated G protein upregulates the activity of adenylate cyclase; the result is the intracellular accumulation of high levels of cyclic adenosine monophosphate (AMP). In intestinal epithelial cells, cyclic AMP inhibits the absorptive sodium-transport system in villus cells and activates the secretory chloride-transport system in crypt cells, and these events lead to the accumulation of sodium chloride in the intestinal lumen. Because water moves passively to maintain osmolality, isotonic fluid accumulates in the lumen. When the volume of that fluid exceeds the capacity of the rest of the gut to resorb it, watery diarrhea results. Unless the wasted fluid and electrolytes are adequately replaced, shock (due to profound dehydration) and acidosis (due to loss of bicarbonate) follow. Although perturbation of the adenylate cyclase pathway is the primary mechanism by which cholera toxin causes excess fluid secretion, cholera toxin also enhances intestinal secretion via prostaglandins and/or neural histamine receptors.

The *V. cholerae* genome is composed of two circular chromosomes. Lateral gene transfer has played a key role in the evolution of epidemic *V. cholerae*. The genes encoding cholera toxin (*ctxAB*) are part of the genome of a bacteriophage, CTXΦ. The receptor for this phage on the *V. cholerae* surface is the intestinal colonization factor TCP. Because *ctxAB* is part of a mobile genetic element (CTXΦ), horizontal transfer of this bacteriophage may account for the emergence of new toxigenic *V. cholerae* strains. Many of the other genes important for *V. cholerae* pathogenicity, including the genes encoding the biosynthesis of TCP, accessory colonization factors, and virulence regulators, are clustered together in the *V. cholerae* pathogenicity island. Similar clustering of virulence genes is found in other bacterial pathogens. It is believed that pathogenicity islands are acquired by horizontal gene transfer. *V. cholerae* O139 is probably derived from an El Tor O1 strain that acquired the genes for O139 O-antigen synthesis by horizontal gene transfer.

CLINICAL MANIFESTATIONS

Individuals infected with *V. cholerae* O1 or O139 exhibit a range of clinical manifestations. Some individuals are asymptomatic or have only mild diarrhea; others present with the sudden onset of explosive and life-threatening diarrhea (*cholera gravis*). The reasons for the range in signs and symptoms of disease are incompletely understood but include the level of preexisting immunity, blood type (persons with type O blood are at greatest risk of severe disease if infected, whereas those with type AB are at least risk), and nutritional status. In a nonimmune individual, after a 24- to 48-h incubation period, cholera characteristically begins with the sudden onset of painless watery diarrhea that may quickly become voluminous. Patients often vomit. In severe cases, volume loss can exceed 250 mL/kg in the first 24 h. If fluids and electrolytes are not replaced, hypovolemic shock and death may ensue. Fever is usually absent. Muscle cramps due to electrolyte disturbances are common. The stool has a characteristic appearance: a nonbilious, gray, slightly cloudy fluid with flecks of mucus, no blood, and a somewhat fishy, inoffensive odor. It has been called "rice-water" stool because of its resemblance to the water in which rice has been washed **(Fig. 173-2)**. Clinical symptoms parallel volume contraction:

FIGURE 173-2 Rice-water cholera stool. Note floating mucus and gray watery appearance. *(Courtesy of Dr. A. S. G. Faruque, International Centre for Diarrhoeal Disease Research, Dhaka; with permission.)*

at losses of <5% of normal body weight, thirst develops; at 5–10%, postural hypotension, weakness, tachycardia, and decreased skin turgor are documented; and at >10%, oliguria, weak or absent pulses, sunken eyes (and, in infants, sunken fontanelles), wrinkled ("washerwoman") skin, somnolence, and coma are characteristic. Complications derive exclusively from the effects of volume and electrolyte depletion and include renal failure due to acute tubular necrosis. Thus, if the patient is adequately treated with fluid and electrolytes, complications are averted and the process is self-limited, resolving in a few days.

Laboratory data usually reveal an elevated hematocrit (due to hemoconcentration) in nonanemic patients; mild neutrophilic leukocytosis; elevated levels of blood urea nitrogen and creatinine consistent with prerenal azotemia; normal sodium, potassium, and chloride levels; a markedly reduced bicarbonate level (<15 mmol/L); and an elevated anion gap (due to increases in serum lactate, protein, and phosphate). Arterial pH is usually low (~7.2).

DIAGNOSIS

Cholera should be suspected when a patient ≥5 years of age develops acute watery diarrhea in an area known to have cholera or develops severe dehydration or dies from acute watery diarrhea, even in an area where cholera is not known to be present. The clinical suspicion of cholera can be confirmed by the identification of *V. cholerae* in stool; however, the organism must be specifically sought. With experience, it can be detected directly by dark-field microscopy on a wet mount of fresh stool, and its serotype can be discerned by immobilization with specific antisera. Laboratory isolation of the organism requires the use of a selective medium such as taurocholate–tellurite–gelatin (TTG) agar or thiosulfate–citrate–bile salts–sucrose (TCBS) agar. If a delay in sample processing is expected, Cary-Blair transport medium and/or alkaline-peptone water-enrichment medium may be used as well. In endemic areas, there is little need for biochemical confirmation and characterization, although these tasks may be worthwhile in places where *V. cholerae* is an uncommon isolate. Standard microbiologic biochemical testing for Enterobacteriaceae will suffice for identification of *V. cholerae*. All vibrios are oxidase-positive. Point-of-care antigen-detection cholera dipstick assays are commercially available for use in the field or where laboratory facilities are lacking.

TREATMENT

Cholera

Death from cholera is due to hypovolemic shock; thus, treatment of individuals with cholera first and foremost requires fluid resuscitation and management. In light of the level of dehydration (Table 173-1) and the patient's age and weight, euvolemia should first be rapidly restored, and adequate hydration should then be maintained to replace ongoing fluid losses (Table 173-2). Administration of oral rehydration solution (ORS) takes advantage of the hexose-Na^+ co-transport mechanism to move Na^+ across the gut mucosa together with an actively transported molecule such as glucose (or galactose); Cl^- and water follow. This transport mechanism remains intact even when cholera toxin is active. ORS may be made by adding safe water to prepackaged sachets containing salts and sugar or by adding 0.5 teaspoon (i.e., half a small spoonful) of table salt and 6 level teaspoons (i.e., 6 small spoonfuls) of table sugar to 1 L of safe water. Potassium intake in bananas or green coconut water should be encouraged. A number of ORS formulations are available, and the WHO now recommends "low-osmolarity" ORS for treatment of individuals with dehydrating diarrhea of any cause (Table 173-3). If available, rice-based ORS is considered superior to standard ORS in the treatment of cholera. ORS can be administered via a nasogastric tube to individuals who cannot ingest fluid; however, optimal management of individuals with severe dehydration includes the administration of IV fluid and electrolytes. Because profound acidosis (pH <7.2) is common in this group, Ringer's lactate is the best choice among commercial products (Table 173-4); it must be used with additional potassium supplements, preferably given by mouth. The total fluid deficit in severely dehydrated patients (>10% of body weight) can be replaced safely within the first 3–4 h of therapy, half within the first hour. Transient muscle cramps and tetany are common. Thereafter, oral therapy can usually

TABLE 173-1 Assessing the Degree of Dehydration in Patients with Cholera

DEGREE OF DEHYDRATION	CLINICAL FINDINGS
None or mild, but diarrhea	Thirst in some cases; <5% loss of total body weight
Moderate	Thirst, postural hypotension, weakness, tachycardia, decreased skin turgor, dry mouth/tongue, no tears; 5–10% loss of total body weight
Severe	Unconsciousness, lethargy, or "floppiness"; weak or absent pulse; inability to drink; sunken eyes (and, in infants, sunken fontanelles); >10% loss of total body weight

TABLE 173-2 Treatment of Cholera, Based on Degree of Dehydration[a]

DEGREE OF DEHYDRATION, PATIENT'S AGE (WEIGHT)	TREATMENT[b]
None or Mild, but Diarrhea[c]	
<2 years	1/4–1/2 cup (50–100 mL) of ORS, to a maximum of 0.5 L/d
2–9 years	1/2–1 cup (100–200 mL) of ORS, to a maximum of 1 L/d
≥10 years	As much ORS as desired, to a maximum of 2 L/d
Moderate[c,d]	
<4 months (<5 kg)	200–400 mL of ORS
4–11 months (5–<8 kg)	400–600 mL of ORS
12–23 months (8–<11 kg)	600–800 mL of ORS
2–4 years (11–<16 kg)	800–1200 mL of ORS
5–14 years (16–<30 kg)	1200–2200 mL of ORS
≥15 years (≥30 kg)	2200–4000 mL of ORS
Severe[c]	
All ages and weights	Undertake IV fluid replacement with Ringer's lactate (or, if not available, normal saline). Give 100 mL/kg in the first 3-h period (or the first 6-h period for children <12 months old); start rapidly, then slow down. Give a total of 200 mL/kg in the first 24 h. Continue until the patient is awake, can ingest ORS, and no longer has a weak pulse.

[a]Adapted from World Health Organization: Outbreak Response Field Manual, Global Task on Cholera Control; *https://www.gtfcc.org/wp-content/uploads/2020/05/gtfcc-cholera-outbreak-response-field-manual-2024.pdf.* [b]Continue normal feeding during treatment. [c]Reassess regularly; monitor stool and vomit output. [d]Volumes of ORS listed should be given within the first 4 h.

Abbreviation: ORS, oral rehydration solution.

TABLE 173-3 Composition of World Health Organization Reduced-Osmolarity Oral Rehydration Solution (ORS)[a,b]

CONSTITUENT	CONCENTRATION, mmol/L
Na^+	75
K^+	20
Cl^-	65
Citrate[c]	10
Glucose	75
Total osmolarity	245

[a]Contains (per package, to be added to 1 L of drinking water): NaCl, 2.6 g; $Na_3C_6H_5O_7 \cdot 2H_2O$, 2.9 g; KCl, 1.5 g; and glucose (anhydrous), 13.5 g. [b]If prepackaged ORS is unavailable, a simple homemade alternative can be prepared by combining 3.5 g (~1/2 teaspoon) of NaCl with either 50 g of precooked rice cereal or 6 teaspoons of table sugar (sucrose) in 1 L of drinking water. In that case, potassium must be supplied separately (e.g., in orange juice or coconut water). [c]10 mmol of citrate per liter, which supplies 30 mmol of HCO_3/L.

TABLE 173-4 Electrolyte Composition of Cholera Stool and of Intravenous Rehydration Solution

	CONCENTRATION, mmol/L			
SUBSTANCE	NA^+	K^+	CL^-	BASE
Stool				
Adult	135	15	100	45
Child	100	25	90	30
Ringer's lactate	130	4[a]	109	28

[a]Potassium supplements, preferably administered by mouth, are required to replace the usual potassium losses from stool.

be initiated, with the goal of maintaining fluid intake equal to fluid output. However, patients with continued large-volume diarrhea may require prolonged IV treatment to match gastrointestinal fluid losses. Severe hypokalemia can develop but will respond to potassium given either IV or orally. In the absence of adequate staff to monitor the patient's progress, the oral route of rehydration and potassium replacement is safer than the IV route.

Although not necessary for cure, the use of an antibiotic to which the organism is susceptible diminishes the duration and volume of fluid loss and hastens clearance of the organism from the stool. Adjunctive antibiotics should therefore be administered to patients with moderate or severe dehydration due to cholera. In many areas, macrolides such as erythromycin (adults, 250 mg orally four times a day for 3 days; children, 12.5 mg/kg per dose four times a day for 3 days) or azithromycin (adults, a single 1-g dose; children, a single 20-mg/kg dose) are the agents of choice. Increasing resistance to tetracyclines is widespread; however, in areas with confirmed susceptibility, tetracycline (nonpregnant adults, 500 mg orally four times a day for 3 days; children >8 years old, 12.5 mg/kg per dose four times a day for 3 days) or doxycycline (nonpregnant adults, a 300-mg single dose; children >8 years old, a single dose of 4–6 mg/kg) may be used. Similarly, increasing resistance to fluoroquinolones is being reported, but in areas with confirmed susceptibility, a fluoroquinolone such as ciprofloxacin may be used (adults, 500 mg twice a day for 3 days; children, 15 mg/kg twice a day for 3 days). Oral administration of supplemental zinc is associated with decreased volume and severity of diarrhea in young children, including in those with cholera. Children <6 months of age with cholera should be treated with 10 mg of zinc daily for 10 days; children from 6 to <60 months of age should be treated with 20 mg of oral zinc daily for 10 days.

PREVENTION

Provision of safe water and of facilities for sanitary disposal of feces, improved nutrition, and attention to food preparation and storage in the household can significantly reduce the incidence of cholera. In addition, precautions should be taken to prevent the spread of cholera via infected and potentially asymptomatic persons from endemic to nonendemic regions of the world (as was probably the case in the outbreak in Haiti; see "Microbiology and Epidemiology," above).

Much effort has been devoted to the development of an effective cholera vaccine over the past few decades, with a particular focus on oral vaccine strains. In an attempt to maximize mucosal responses, two types of oral cholera vaccine have been developed: oral killed vaccines and live attenuated vaccines. Currently, three oral killed cholera vaccines have been prequalified by the WHO. BivWC (Shanchol™; Shantha Biotechnics, Hyderabad, India) contains both biotypes and serotypes of *V. cholerae* O1 and *V. cholerae* O139 without supplemental cholera toxin B subunit, but its manufacture is being terminated. A related vaccine is produced in South Korea (Euvichol™, Euvichol-Plus™; Eubiologics, Seoul) and currently accounts for the vast majority of cholera vaccine available to global health control programs. WC-rBS (Dukoral®; Valneva, Sweden AB, Stockholm,) contains both biotypes and serotypes of *V. cholerae* O1 supplemented with 1 mg of recombinant cholera toxin B subunit per dose. The vaccines are administered as a two- or three-dose regimen, with doses usually separated by 14 days. They provide ~60–85% protection for the first few months. Booster immunizations of WC-rBS are recommended after 2 years for individuals ≥6 years of age and after 6 months for children 2–5 years of age. For BivWC, no formal recommendation regarding booster immunizations exists. However, BivWC was associated with ~60% protection over 5 years among recipients of all ages in a study in Kolkata, India; the rate of protection among children ≤5 years of age approximated 40%. In outbreak situations, even a single dose of BivWC can provide some protection: 40% and 63% adjusted protection for 6 months for all and severely dehydrating cholera, respectively—although there was no evidence of protection in children younger than 5 years of age. Models predict significant herd immunity when vaccination coverage rates exceed 50%. The killed vaccines have been safely administered among populations with high rates of HIV infection.

Oral live attenuated vaccines for *V. cholerae* O1 also are in development. These strains have in common their lack of the genes encoding cholera toxin. One such vaccine, CVD 103-HgR (Vaxchora™; Emergent BioSolutions, Washington, DC), is derived from a classic strain of *V. cholerae* and has been approved by the U.S. Food and Drug Administration for use in travelers to cholera-endemic regions but is not prequalified by the WHO. The vaccine was 90% and 80% efficacious against severe cholera after experimental infection of North American volunteers 10 days and 90 days after vaccination, respectively. Vaxchora is approved for use in individuals 2–64 years of age; no recommendations concerning the timing or need for booster vaccinations are currently available. Other live attenuated vaccine candidate strains have been prepared from El Tor and O139 *V. cholerae* and have been tested in studies of volunteers. An advantage of live attenuated cholera vaccines is that they may induce more potent protection after a single oral dose. Conjugate and subunit cholera vaccines also are being developed.

Recognizing that it may be decades before safe water and adequate sanitation become a reality for those most at risk of cholera, the WHO has recommended incorporation of cholera vaccination into comprehensive control strategies and has established an international stockpile of oral killed cholera vaccine to assist in outbreak responses. A global strategy on cholera control was launched in 2017 with the WHO hosting the secretariat of the Global Task Force on Cholera Control (GTFCC). This country-by-country approach aims to reduce cholera deaths by 90% and to eliminate cholera in as many as 20 countries by 2030. Integral components of this strategy are advancing water, sanitation, and hygiene (WASH) programs, as well as use of cholera vaccine. From 2016 to 2023, almost 300 million doses of cholera vaccine have been requested from the Global Vaccine Stockpile, and approximately 150 million doses have been shipped to requesting countries for use in control programs. Due to vaccine shortages, cholera vaccines have most recently been almost solely used in reactive and not preventative campaigns, and are often given as single doses.

OTHER *VIBRIO* SPECIES

The genus *Vibrio* includes several human pathogens that do not cause cholera. Abundant in coastal waters throughout the world, noncholera vibrios can reach high concentrations in the tissues of filter-feeding mollusks. As a result, human infection commonly follows the ingestion of seawater or of raw or undercooked shellfish **(Table 173-5)**. Most noncholera vibrios can be cultured on blood or MacConkey agar, which contains enough salt to support the growth of these halophilic species. In the microbiology laboratory, the species of noncholera vibrios are distinguished by standard biochemical tests. The most important of these organisms are *Vibrio parahaemolyticus* and *Vibrio vulnificus*. Vibriosis causes an estimated 80,000 illnesses and 100 deaths in the United States every year.

The two major types of syndromes for which these noncholera vibrios are responsible are gastrointestinal illness (due to *V. parahaemolyticus*, non-O1/O139 *V. cholerae*, *V. mimicus*, *V. fluvialis*, *V. hollisae*, and *V. furnissii*) and soft tissue infections (due to *V. vulnificus*, *V. alginolyticus*, and *V. damselae*). *V. vulnificus* is also a cause of primary sepsis in some immunocompromised individuals.

TABLE 173-5 Features of Selected Noncholera Vibrioses

ORGANISM	VEHICLE OR ACTIVITY	HOST AT RISK	SYNDROME
Vibrio parahaemolyticus	Shellfish, seawater	Normal	Gastroenteritis
	Seawater	Normal	Wound infection
Non-O1/O139 *Vibrio cholerae*	Shellfish, travel	Normal	Gastroenteritis
	Seawater	Normal	Wound infection, otitis media
Vibrio vulnificus	Shellfish	Immunosuppressed[a]	Sepsis, secondary cellulitis
	Seawater	Normal, immunosuppressed[a]	Wound infection, cellulitis
Vibrio alginolyticus	Seawater	Normal	Wound infection, cellulitis, otitis
	Seawater	Burned, other immunosuppressed	Sepsis

[a]Especially with liver disease or hemochromatosis.

Source: Table 161-3 in *Harrison's Principles of Internal Medicine,* 14th edition.

SPECIES ASSOCIATED PRIMARILY WITH GASTROINTESTINAL ILLNESS

V. parahaemolyticus Widespread in marine environments, the halophilic *V. parahaemolyticus* is the leading seafood-borne bacterial cause of enteritis worldwide. This species was originally implicated in enteritis in Japan in 1953, accounting for 24% of reported cases in one study—a rate that presumably was due to the common practice of eating raw seafood in that country. In the United States, common-source outbreaks of diarrhea caused by this organism have been linked to the consumption of undercooked or improperly handled seafood or of other foods contaminated by seawater. Since the mid-1990s, the incidence of *V. parahaemolyticus* infections has increased in several countries, including the United States. Serotypes O3:K6, O4:K68, and O1:K-untypable, which are genetically related to one another, account in part for this increase. Recent reports from China and Thailand suggest that serotype O10:K4 may be an emerging serotype. The enteropathogenicity of *V. parahaemolyticus* is associated with its ability to cause hemolysis via a thermostable direct hemolysin (Vp-TDH). Although the mechanisms by which the organism causes diarrhea are not fully defined, most *V. parahaemolyticus* genomes encode two type III secretion systems, which directly inject toxic bacterial proteins into host cells. The activity of one of these secretion systems is required for intestinal colonization and virulence in animal models. *V. parahaemolyticus* should be considered a possible etiologic agent in all cases of diarrhea that can be linked epidemiologically to seafood consumption or to the sea itself. The incidence of *V. parahaemolyticus* infection in the United States has increased from 0.06 per 100,000 persons in 1996 to 0.9 cases per 100,000 in 2019.

Infections with *V. parahaemolyticus* can result in two distinct gastrointestinal presentations. The more common of the two presentations (including nearly all cases in North America) is characterized by watery diarrhea, usually occurring in conjunction with abdominal cramps, nausea, and vomiting and accompanied in ~25% of cases by fever and chills. After an incubation period of 4 h to 4 days, symptoms develop and persist for a median of 3 days. Dysentery, the less common presentation, is characterized by severe abdominal cramps, nausea, vomiting, and bloody or mucoid stools. *V. parahaemolyticus* also causes rare cases of wound infection and otitis and very rare cases of sepsis.

Most cases of *V. parahaemolyticus*–associated gastrointestinal illness, regardless of the presentation, are self-limited. Fluid replacement should be stressed. Antimicrobial agents may be of benefit in moderate or severe disease. Doxycycline, fluoroquinolones, macrolides, or third-generation cephalosporins are usually used. Deaths are extremely rare among immunocompetent individuals. Severe infections are associated with underlying diseases, including diabetes, preexisting liver disease, iron-overload states, or immunosuppression.

Non-O1/O139 (Noncholera) *V. cholerae* The heterogeneous non-O1/O139 *V. cholerae* organisms cannot be distinguished from *V. cholerae* O1 or O139 by routine biochemical tests but do not agglutinate in O1 or O139 antiserum. Non-O1/O139 strains have caused several well-studied food-borne outbreaks of gastroenteritis and have also been responsible for sporadic cases of otitis media, wound infection, and bacteremia. Generally, non-O1/O139 *V. cholerae* strains do not produce cholera toxin and do not cause large epidemics of diarrheal disease. Like other vibrios, non-O1/O139 *V. cholerae* organisms are widely distributed in marine environments. In most instances, recognized cases in the United States have been associated with the consumption of raw oysters or with recent travel. The broad clinical spectrum of diarrheal illness caused by these organisms is probably due to the group's heterogeneous virulence attributes.

The typical incubation period for gastroenteritis due to these organisms is <2 days, and the illness lasts for ~2–7 days. Patients' stools may be copious and watery or may be partly formed, less voluminous, and bloody or mucoid. Diarrhea can result in severe dehydration. Many cases include abdominal cramps, nausea, vomiting, and fever. Like those with cholera, patients who are seriously dehydrated should receive oral or IV fluids; the value of antibiotics is not clear.

Extraintestinal infections due to non-O1/O139 *V. cholerae* commonly follow occupational or recreational exposure to seawater. Around 10% of non-O1/O139 *V. cholerae* isolates come from cases of wound infection, 10% from cases of otitis media, 20% from cases of bacteremia (which is particularly likely to develop in patients with liver disease), and approximately 40% from stool. Extraintestinal infections should be treated with antibiotics. Information to guide antibiotic selection and dosing is limited, but most strains are sensitive in vitro to tetracycline, ciprofloxacin, and third-generation cephalosporins.

SPECIES ASSOCIATED PRIMARILY WITH SOFT TISSUE INFECTION OR BACTEREMIA

(See also Chap. 134)

V. vulnificus Infection with *V. vulnificus* is rare, but this organism is the most common cause of severe *Vibrio* infections in the United States. Like most vibrios, *V. vulnificus* proliferates in the warm summer months and requires a saline environment for growth. In the United States, infections in humans typically occur in coastal states between May and October and most commonly affect men >40 years of age. *V. vulnificus* has been linked to two distinct syndromes: primary sepsis, which usually occurs in patients with underlying liver disease, and primary wound infection, which generally affects people without underlying disease. (*Vulnificus* is Latin for "wound maker.") Some authors have suggested that *V. vulnificus* also causes gastroenteritis independent of other clinical manifestations. *V. vulnificus* is endowed with a number of virulence attributes, including a capsule that confers resistance to phagocytosis and to the bactericidal activity of human serum as well as a cytolysin. Measured as the 50% lethal dose in mice, the organism's virulence is considerably increased under conditions of iron overload; this observation is consistent with the propensity of *V. vulnificus* to infect patients who have hemochromatosis.

Primary sepsis most often develops in patients who have cirrhosis or hemochromatosis. However, *V. vulnificus* bacteremia can also affect individuals who have hematopoietic disorders or chronic renal insufficiency, those who are using immunosuppressive medications or alcohol, or (in rare instances) those who have no known underlying disease. After a median incubation period of 16 h, the patient develops malaise, chills, fever, and prostration. One-third of patients

develop hypotension, which is often apparent at admission. Cutaneous manifestations develop in most cases (usually within 36 h of onset) and characteristically involve the extremities (the lower more often than the upper). In a common sequence, erythematous patches are followed by ecchymoses, vesicles, and bullae. In fact, sepsis and hemorrhagic bullous skin lesions suggest the diagnosis in appropriate settings. Necrosis and sloughing also may be evident. Laboratory studies reveal leukopenia more often than leukocytosis, thrombocytopenia, or elevated levels of fibrin-split products. *V. vulnificus* can be cultured from blood or cutaneous lesions. The mortality rate approaches 50%, with most deaths due to uncontrolled sepsis **(Chap. 315)**. Accordingly, prompt treatment is critical and should include empirical antibiotic administration, aggressive debridement, and general supportive care. *V. vulnificus* is sensitive in vitro to a number of antibiotics, including tetracycline, fluoroquinolones, and third-generation cephalosporins. Optimal treatment usually involves administration of a third-generation cephalosporin such as ceftazidime with doxycycline or a fluoroquinolone and wound debridement.

V. vulnificus–associated soft tissue infection can complicate either a fresh or an old wound that comes into contact with seawater; the patient may or may not have underlying disease. After a short incubation period (4 h to 4 days; mean, 12 h), the disease begins with swelling, erythema, and (in many cases) intense pain around the wound. These signs and symptoms are followed by cellulitis, which spreads rapidly and is sometimes accompanied by vesicular, bullous, or necrotic lesions. Metastatic events are uncommon. Most patients have fever and leukocytosis. *V. vulnificus* can be cultured from skin lesions and occasionally from the blood. Prompt antibiotic therapy and debridement are usually curative.

V. alginolyticus First identified as a pathogen of humans in 1973, *V. alginolyticus* occasionally causes eye, ear, and wound infections. This species is the most salt-tolerant of the vibrios and can grow in salt concentrations of >10%. Most clinical isolates come from superinfected wounds that presumably become contaminated at the beach. Although its severity varies, *V. alginolyticus* infection tends not to be serious and generally responds well to antibiotic therapy and drainage. Cases of otitis externa, otitis media, and conjunctivitis due to this pathogen have been described. Tetracycline treatment usually results in cure. *V. alginolyticus* is a rare cause of bacteremia in immunocompromised hosts.

174 Brucellosis

Nicholas J. Beeching

DEFINITION

Brucellosis is a bacterial zoonosis transmitted directly or indirectly to humans from infected animals, predominantly domesticated ruminants and swine. The disease is known colloquially as *undulant fever* because of its remittent character. Although brucellosis commonly presents as an acute febrile illness, its clinical manifestations vary widely, and definitive signs indicative of the diagnosis may be lacking. Thus, the clinical diagnosis usually must be supported by the results of bacteriologic and/or serologic tests.

ETIOLOGIC AGENTS

Human brucellosis is caused by strains of the genus *Brucella*, with several species groups defined by differences in chromosomal structure, host preference, and epidemiologic patterns of infection. *Brucella melitensis* is the most common cause of symptomatic disease in humans, for which the main sources are sheep, goats, and camels; *B. abortus* is usually acquired from cattle or buffalo; *B. suis* is generally acquired from swine but has one variant that is enzootic in reindeer and caribou and another in rodents; *B. canis* is acquired from dogs. *B. ovis* causes reproductive disease in sheep but has not been clearly implicated in human disease. Rare human infections have been reported with *B. neotomae*, which is found in desert rodents. Two species, *B. ceti* and *B. pinnipedialis*, have been identified in marine mammals, including seals and dolphins. At least one case of laboratory-acquired human disease due to one of these species has been described, and several cases of natural human infection have been reported. As infections in marine mammals appear to be widespread, more cases of zoonotic infection in humans may be identified. Other reported species include *B. microti* (isolated from field voles), *B. papionis* (from baboons), *B. vulpis* (from foxes), and *B. inopinata* (from a patient with a breast implant). Additional novel strains have been described in diverse species, including frogs, bats, and various rodents, and the genus likely will expand further in forthcoming years. The genus *Brucella* is closely related to the genus *Ochrobactrum*, which includes free-living environmental bacteria that can occasionally cause opportunistic infections. Recent changes in taxonomy now place *Ochrobactrum* spp. as subspecies of *Brucella* on genetic grounds, although the ecology, physiology, clinical niche, and antimicrobial sensitivity of these organisms are completely different.

All brucellae are small, gram-negative, unencapsulated, nonsporulating rods or coccobacilli. They grow aerobically on peptone-based medium incubated at 37°C; the growth of some types is improved by supplementary CO_2. In vivo, brucellae behave as facultative intracellular parasites. The organisms are sensitive to sunlight, ionizing radiation, and moderate heat; they are killed by boiling and pasteurization but are resistant to freezing and drying. Their resistance to drying renders brucellae stable in aerosol form, facilitating airborne transmission. The organisms can survive for up to 2 months in soft cheeses made from goat's or sheep's milk; for at least 6 weeks in dry soil contaminated with infected urine, vaginal discharge, or placental or fetal tissues; and for at least 6 months in damp soil or liquid manure kept in cool dark conditions. Brucellae are easily killed by a wide range of common disinfectants used under optimal conditions but are likely to be much more resistant at low temperatures or in the presence of heavy organic contamination.

EPIDEMIOLOGY

Brucellosis is a zoonosis whose occurrence and control are closely related to its prevalence in domesticated animals. Its distribution is worldwide apart from the few countries where it has been eradicated from the animal reservoir. The true global prevalence of human brucellosis is unknown because of the imprecision of diagnosis and the inadequacy of reporting and surveillance systems in many countries.

Recent estimates suggest there may be more than 2 million cases of human infection a year worldwide. There has been increased recognition of brucellosis in India, Pakistan, Sri Lanka, and China, and of importations to countries in Oceania, such as Fiji, and in Asia, such as Thailand and Vietnam. In Europe, the incidence of brucellosis in a country is inversely related to gross domestic product, and in both developed and less well-resourced settings, human brucellosis is related to rural poverty and inadequate access to medical care. Failure of veterinary control programs due to conflicts or for economic reasons contributes further to the emergence and re-emergence of disease, as seen currently in some eastern Mediterranean countries.

Even in well-resourced settings, the true incidence of brucellosis in domesticated animals may be 10–20 times higher than the reported figures. Bovine brucellosis has been the target of control programs in many parts of the world and has been eradicated from the cattle populations of much of northern Europe, Australia, New Zealand, and Canada, among other nations. Its incidence has been reduced to a low level in the United States and most western European countries, with a varied picture in other parts of the world. Efforts to eradicate *B. melitensis* infection from sheep and goat populations have been much less successful. These efforts have relied heavily on vaccination programs, which have tended to fluctuate with changing economic and political conditions. In some countries (e.g., Israel), *B. melitensis* has caused serious outbreaks in cattle. Infections with *B. melitensis* still pose a major public health problem in Mediterranean countries; in western, central, and southern Asia; and in parts of Africa and South and Central America. Infections with *B. abortus* are common in cattle-rearing communities in African countries such as Kenya and Uganda. Canine infection with *B. canis* is present on most continents—the incidence appears to be increasing in North America and in several European countries, often associated with importation of dogs from an endemic area.

Human brucellosis is usually associated with occupational or domestic exposure to infected animals or their products. Farmers, shepherds, goatherds, veterinarians, and employees in slaughterhouses and meat-processing plants in endemic areas are occupationally exposed to infection. Feral pig hunters are at risk of infection with *B. suis* in several countries, including Australia. Family members of individuals involved in animal husbandry may be at risk, although it is often difficult to differentiate food-borne infection from environmental contamination under these circumstances. Laboratory workers who handle cultures or infected samples also are at risk. Travelers and urban residents usually acquire the infection through consumption of contaminated foods. In countries that have eradicated the disease, new cases are most commonly acquired abroad. Dairy products, especially soft cheeses, unpasteurized milk, and ice cream, are the most frequently implicated sources of infection; raw meat and bone marrow may be sources under exceptional circumstances. Infections acquired through cosmetic treatments using materials of fetal origin have been reported. Person-to-person transmission is extremely rare, as is transfer of infection by blood or tissue donation. Although brucellosis is a chronic intracellular infection, there is no evidence for increased prevalence or severity among individuals with HIV infection or with immunodeficiency or immunosuppression of other etiologies.

Brucellosis may be acquired by ingestion, inhalation, or mucosal or percutaneous exposure. Accidental injection or ingestion of the live vaccine strains of *B. abortus* (S19 and RB51) and *B. melitensis* (Rev 1) can cause disease. *B. melitensis* and *B. suis* have historically been developed as biological weapons by several countries and could be exploited for bioterrorism **(Chap. S4)**. This possibility should be borne in mind in the event of sudden unexplained outbreaks.

IMMUNITY AND PATHOGENESIS

Exposure to brucellosis elicits both humoral and cell-mediated immune responses. The mechanisms of protective immunity against human brucellosis are presumed to be similar to those documented in laboratory animals, but such generalizations must be interpreted with caution. The response to infection and its outcome are influenced by the virulence, phase, and species of the infecting strain. Differences have been reported between *B. abortus* and *B. suis* in modes of cellular entry and subsequent compartmentalization and processing. Antibodies promote clearance of extracellular brucellae by bactericidal action and by facilitation of phagocytosis by polymorphonuclear and mononuclear phagocytes; however, antibodies alone cannot eradicate infection. Organisms taken up by macrophages and other cells can establish persistent intracellular infections. The key target cell is the macrophage, and bacterial mechanisms for suppressing intracellular killing and apoptosis result in very large intracellular populations. Opsonized bacteria are actively phagocytosed by neutrophilic granulocytes and by monocytes. In these and other cells, initial attachment takes place via specific receptors, including Fc, C3, fibronectin, and mannose-binding proteins. Opsonized—but not unopsonized—bacteria trigger an oxidative burst inside phagocytes. Unopsonized bacteria are internalized via similar receptors but at much lower efficiency. Smooth strains enter host cells via lipid rafts. Smooth lipopolysaccharide (LPS), β-cyclic glucan, and possibly an invasion–attachment protein (Alb) are involved in this process. Tumor necrosis factor α (TNF-α) produced early in the course of infection stimulates cytotoxic lymphocytes and activates macrophages, which can kill intracellular brucellae (probably mainly through production of reactive oxygen and nitrogen intermediates) and may clear infection. However, virulent *Brucella* cells can suppress the TNF-α response, and control of infection in this situation depends on macrophage activation and interferon γ (IFN-γ) responses. Cytokines such as interleukin (IL) 12 promote production of IFN-γ, which drives T_H1-type responses and stimulates macrophage activation. Inflammatory cytokines, including IL-4, IL-6, and IL-10, downregulate the protective response. As in other types of intracellular infection, it is assumed that initial replication of brucellae takes place within cells of the lymph nodes draining the point of entry. Subsequent hematogenous spread may result in chronic localizing infection at almost any site, although the reticuloendothelial system, musculoskeletal tissues, and genitourinary system are most frequently targeted. Both acute and chronic inflammatory responses develop in brucellosis, and the local tissue response may include granuloma formation with or without necrosis and caseation. Abscesses may also develop, especially in chronic localized infection.

The determinants of pathogenicity of *Brucella* have not been fully characterized, and the mechanisms underlying the manifestations of brucellosis are incompletely understood. The organism is a "stealth" pathogen whose survival strategy is centered on several processes that avoid triggering innate immune responses and that permit survival within monocytic cells. These processes include evasion of intracellular destruction by restricting the fusion of type IV secretion system–dependent *Brucella*-containing vacuoles with lysosomal compartments, inhibition of apoptosis of infected mononuclear cells, and prevention of dendritic cell maturation, antigen presentation, and activation of naïve T cells. The smooth *Brucella* LPS, which has an unusual O-chain and core-lipid composition, has relatively low endotoxin activity and plays a key role in pyrogenicity and in resistance to phagocytosis and serum killing in the nonimmune host. In addition, LPS is believed to play a role in suppressing phagosome–lysosome fusion and diverting the internalized bacteria into vacuoles located in endoplasmic reticulum, where intracellular replication takes place. Specific exotoxins have not been isolated, but a type IV secretion system (Vir) that regulates intracellular survival and trafficking has been identified. In *B. abortus*, this system can be activated extracellularly, but in *B. suis*, it is activated (by low pH) only during intracellular growth. Brucellae then produce acid-stable proteins that facilitate the organisms' survival in phagosomes and may enhance their resistance to reactive oxygen intermediates. A type III secretion system based on modified flagellar structures also has been inferred, although not yet confirmed. Virulent brucellae are resistant to defensins and produce a Cu-Zn superoxide dismutase that increases their resistance to reactive oxygen intermediates. A hemolysin-like protein may trigger the release of brucellae from infected cells.

CLINICAL FEATURES

Brucellosis almost invariably causes fever, which may be associated with profuse sweats, especially at night. In endemic areas, brucellosis may be

difficult to distinguish from other causes of fever. However, two features recognized in the nineteenth century distinguish brucellosis from other tropical fevers, such as typhoid and malaria: (1) Left untreated, the fever of brucellosis shows an undulating pattern that persists for weeks before the commencement of an afebrile period that may be followed by relapse. (2) The fever of brucellosis is associated with musculoskeletal symptoms and signs in about one-half of all patients.

The clinical syndromes caused by the different species are similar, although *B. melitensis* tends to be associated with a more acute and aggressive presentation and *B. suis* with focal abscess induction. *B. abortus* infections may have a more insidious onset and are more likely to become chronic. *B. canis* infections are generally regarded as less severe but, like other species, can cause serious disease such as endocarditis.

The incubation period varies from 1 week to several months, and the onset of fever and other symptoms may be abrupt or insidious. In addition to experiencing fever and sweats, patients become increasingly apathetic and fatigued; lose appetite and weight; and have nonspecific myalgia, headache, and chills. Overall, the presentation of brucellosis often fits one of three patterns: febrile illness that resembles typhoid but is less severe; fever and acute monoarthritis, typically of the hip or knee, in a young child; and long-lasting fever, misery, and low-back or hip pain in an older person (especially men). In an endemic area (e.g., much of the Middle East), a patient with fever and difficulty walking into the clinic would be suspected to have brucellosis until it was proven otherwise.

Diagnostic clues in the patient's history include travel to an endemic area, employment in a diagnostic microbiology laboratory, consumption of unpasteurized milk products (including soft cheeses), contact with animals, accidental inoculation with veterinary *Brucella* vaccines, and—in an endemic setting—a history of similar illness in the family (documented in almost 50% of cases). Focal features are present in the majority of patients. The most common are musculoskeletal pain and physical findings in the peripheral and axial skeleton (~40% of cases). Osteomyelitis more commonly involves the lumbar and low thoracic vertebrae than the cervical and high thoracic spine. Individual joints that are most commonly affected by septic arthritis are the knee, hip, sacroiliac, shoulder, and sternoclavicular joints; the pattern may be one of monoarthritis or polyarthritis. Osteomyelitis may also accompany septic arthritis.

In addition to the usual causes of vertebral osteomyelitis or septic arthritis, the most important disease in the differential diagnosis is tuberculosis. This point influences the therapeutic approach as well as the prognosis, given that several antimicrobial agents used to treat brucellosis are also used to treat tuberculosis. Septic arthritis in brucellosis progresses slowly, starting with small pericapsular erosions. In the vertebrae, anterior erosions of the superior end plate are typically the first features to become evident, with eventual involvement and sclerosis of the whole vertebra. Anterior osteophytes eventually develop, but vertebral destruction or impingement on the spinal cord is rare and usually suggests tuberculosis **(Table 174-1)**.

Other systems may be involved in a manner that resembles typhoid. About one-quarter of patients have a dry cough, usually with few changes visible on the chest x-ray, although pneumonia, empyema, intrathoracic adenopathy, or lung abscess can occur. Sputum or pleural effusion cultures are rarely positive in such cases, which respond well to standard brucellosis treatment. One-quarter of patients have hepatosplenomegaly, and 10–20% have significant lymphadenopathy; the differential diagnosis includes glandular fever–like illness such as that caused by Epstein-Barr virus, *Toxoplasma*, cytomegalovirus, HIV, or *Mycobacterium tuberculosis*. Up to 10% of men have acute epididymo-orchitis, which must be distinguished from mumps and from surgical problems such as torsion. Prostatitis, inflammation of the seminal vesicles, salpingitis, and pyelonephritis all occur. There is an increased incidence of fetal loss among infected pregnant women, although teratogenicity has not been described and the tendency toward abortion is much less pronounced in humans than in animals.

Neurologic involvement is common, with depression and lethargy whose severity may not be fully appreciated by either the patient or the physician until after treatment. A small proportion of patients develop lymphocytic meningoencephalitis that mimics mild neurotuberculosis, atypical leptospirosis, or noninfectious conditions. Rare manifestations include intracerebral abscess, a variety of cranial nerve deficits, or ruptured mycotic aneurysms.

Endocarditis occurs in ~1% of cases, most often affecting the aortic valve (natural or prosthetic). Any site in the body may be involved in metastatic abscess formation or inflammation; the female breast and the thyroid gland are affected particularly often. Nonspecific maculopapular rashes and other skin manifestations are uncommon and are rarely noticed by the patient even if they develop.

TABLE 174-1 Radiology of the Spine: Differentiation of Brucellosis from Tuberculosis

	BRUCELLOSIS	TUBERCULOSIS
Site	Lumbar and others	Dorsolumbar
Vertebrae	Multiple or contiguous	Contiguous
Diskitis	Late	Early
Body	Intact until late	Morphology lost early
Canal compression	Rare	Common
Epiphysitis	Anterosuperior	General: upper and lower disk regions, central, subperiosteal
Osteophyte	Anterolateral (parrot beak)	Unusual
Deformity	Wedging uncommon	Anterior wedge, gibbus
Recovery	Sclerosis, whole-body	Variable
Paravertebral abscess	Small, well-localized	Common and discrete loss, transverse process
Psoas abscess	Rare	More likely

DIAGNOSIS

Because the clinical picture of brucellosis is not distinctive, the diagnosis must be based on a history of potential exposure, a presentation consistent with the disease, and supporting laboratory findings. Results of routine biochemical assays are usually within normal limits, although serum levels of hepatic enzymes and bilirubin may be elevated. Peripheral leukocyte counts are usually normal or low, with relative lymphocytosis. Mild anemia may be documented. Thrombocytopenia and disseminated intravascular coagulation with raised levels of fibrinogen degradation products can develop. The erythrocyte sedimentation rate and C-reactive protein levels are often normal but may be raised.

In body fluids such as cerebrospinal fluid (CSF) or joint fluid, lymphocytosis and low glucose levels are the norm. Elevated CSF levels of adenosine deaminase cannot be used to distinguish tubercular meningitis, as they may also be found in brucellosis. Biopsied samples of tissues such as lymph node or liver may show noncaseating granulomas without acid-fast bacilli. The radiologic features of bony disease develop late and are much more subtle than those of tuberculosis or septic arthritis of other etiologies, with less bone and joint destruction. Isotope scanning is more sensitive than plain x-ray and continues to give positive results long after successful treatment.

Isolation of brucellae from blood, CSF, bone marrow, or joint fluid or from a tissue aspirate or biopsy sample is definitive, and attempts at isolation are usually successful in 50–70% of cases. Blood culture using modern nonradiometric or similar signaling systems (e.g., Bactec) usually become positive within 7 days. Clinicians should alert the laboratory to the possibility of brucellosis if suspected, as all cultures should be handled under containment conditions appropriate for dangerous pathogens. *Brucella* species may be misidentified as *Agrobacterium*, *Ochrobactrum*, or *Psychrobacter (Moraxella) phenylpyruvicus* by the gallery identification strips that may still be used in the diagnostic laboratory. In recent years, matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) has emerged as a powerful tool for bacterial identification in well-resourced laboratories. Earlier implementations of MALDI-TOF often failed to identify *Brucella* species correctly as a genus or at species level. Following recent changes in taxonomy, *Ochrobactrum* isolates may now be reported as a

subspecies of *Brucella*. This can lead to confusion and have important clinical and public health consequences, as management differs completely. Clinicians should confirm the meaning of any culture report suggestive of brucellosis with laboratory colleagues before making therapeutic decisions.

The peripheral blood–based polymerase chain reaction (PCR) has enormous potential to detect bacteremia, to predict relapse, and to exclude "chronic brucellosis." This method is more sensitive and quicker than blood culture, and it does not carry the attendant biohazard risk posed by culture. However, it is not perfect, and false-negative results are sometimes observed in patients with positive blood cultures. Nucleic acid amplification techniques are now quite widely used, although no single standardized procedure has been adopted. Primers for the spacer region between the genes encoding the 16S and 23S ribosomal RNAs (*rrs-rrl*), various outer-membrane protein–encoding genes, the insertion sequence *IS711*, and the protein BCSP31 are sensitive and specific. Blood and other tissues are the most suitable samples for analysis. The clinical significance of prolonged PCR positivity, commonly seen in blood after successful treatment, remains controversial.

Serologic examination often provides the only positive laboratory findings in brucellosis. In acute infection, IgM antibodies appear early and are followed by IgG and IgA. All these antibodies are active in agglutination tests, whether performed by tube, plate, or microagglutination methods. The majority of patients have detectable agglutinins at this stage. As the disease progresses, IgM levels decline, and the avidity and subclass distribution of IgG and IgA change. The result is reduced or undetectable agglutinin titers. However, the antibodies are detectable by alternative tests, including the complement fixation test, Coomb's antiglobulin test, and enzyme-linked immunosorbent assays. There is no clear cutoff value for a diagnostic titer. Rather, serology results must be interpreted in the context of exposure history and clinical presentation. In endemic areas or in settings of potential occupational exposure, agglutinin titers of 1:320–1:640 or higher are considered diagnostic; in nonendemic areas, a titer of ≥1:160 is considered significant. Repetition of tests after 2–4 weeks may demonstrate a rising titer.

In most centers, the standard agglutination test (or a derivative such as the microagglutination test) is still the mainstay of serologic diagnosis. In an endemic setting, >90% of patients with acute bacteremia have standard agglutination titers of at least 1:320 at the time of clinical presentation. Some centers rely on the Rose Bengal test, particularly for screening, but it has been only partially validated for human diagnostic use. A variety of near-patient or point-of-care tests are still in developmental stages.

Antibody to the *Brucella* LPS O chain—the dominant antigen—is detected by all the conventional tests that employ smooth *B. abortus* cells as antigen. Because *B. abortus* cross-reacts with *B. melitensis* and *B. suis*, there is no advantage in replicating the tests with these antigens. Cross-reactions also occur with the O chains of some other gram-negative bacteria, including *Yersinia enterocolitica* O:9, *Escherichia coli* O157, *Francisella tularensis*, *Salmonella enterica* group N, *Stenotrophomonas maltophilia*, and *Vibrio cholerae*. The cell-surface antigens of rough *Brucella* strains such as *B. canis* or *B. ovis* do not react in these serologic tests, which will give false-negative results. Specific antigen-based tests used in veterinary practice to detect *B. canis* and *B. ovis* produce inconsistent results in human diagnosis and are not validated for this purpose. Clinicians should consult with the laboratory about test selection if *B. canis* infection is suspected. Similarly, live *B. abortus* vaccine strain RB51 does not elicit antibody responses in serologic tests that use smooth antigens, and this fact must be taken into account if serologic tests are employed in attempts to identify or follow the course of infections in persons accidentally exposed to the vaccine.

TREATMENT

Brucellosis

The broad aims of antimicrobial therapy are to treat and relieve the symptoms of current infection and to prevent relapse. Focal disease presentations may require specific intervention in addition to more prolonged and tailored antibiotic therapy. In addition, tuberculosis must always be excluded, or—to prevent the emergence of resistance—therapy should be tailored to specifically exclude drugs active against tuberculosis (e.g., rifampin used alone) or to include a full antituberculous regimen.

Early experience with streptomycin or tetracycline monotherapy showed that relapse was common; thus dual therapy with both agents became the norm. This is still the most effective combination, but alternatives may be used, with the options depending on local or national policy about the use of rifampin for the treatment of nonmycobacterial infection. For the several antimicrobial agents that are active in vivo, efficacy can usually be predicted by in vitro testing. However, numerous *Brucella* strains show in vitro sensitivity to a whole range of antimicrobials that are therapeutically ineffective, including assorted β-lactams. The use of fluoroquinolones remains controversial despite the good in vitro activity and white-cell penetration of most agents of this class. Low intravacuolar pH is probably a factor in the poor performance of these drugs.

For adults with acute nonfocal brucellosis (duration <1–2 months), a 6-week course of therapy incorporating at least two antimicrobial agents is required. Complex or focal disease may necessitate ≥3 months of therapy. Adherence to the therapeutic regimen is very important, and poor adherence underlies almost all cases of apparent treatment failure; such failure is rarely due to the emergence of drug resistance, although increasing resistance to trimethoprim-sulfamethoxazole (TMP-SMX) is being reported.

The gold standard for the treatment of brucellosis in adults is IM streptomycin (0.75–1 g daily for 14–21 days) together with doxycycline (100 mg twice daily for 6 weeks). In both clinical trials and observational studies, relapse follows such treatment in 5–10% of cases. The usual alternative regimen favored by the World Health Organization and many national guidelines consists of rifampin (600–900 mg/d) plus doxycycline (100 mg twice daily) for 6 weeks. This is easier for the patient and health care provider but requires sustained treatment adherence. The relapse/failure rate of this regimen is ~10% in trial conditions but can rise to >20% in many nontrial situations, possibly because doxycycline levels are reduced and clearance rates increased by concomitant rifampin administration. Patients who cannot tolerate or receive tetracyclines (children, pregnant women) can be given high-dose TMP-SMX instead (two or three standard-strength tablets twice daily for adults, depending on weight).

Good evidence supports the use of an aminoglycoside such as gentamicin (5–6 mg/kg per day for 1–2 weeks) instead of streptomycin, and this is recommended in U.S. and U.K. guidelines. Shorter courses of gentamicin have been associated with high failure rates in adults. Early experience with fluoroquinolone monotherapy was disappointing, but it has been suggested that ofloxacin or ciprofloxacin, given together with rifampin for 6 weeks, might be an acceptable alternative to the other 6-week regimens for adults. A substantial meta-analysis did not support the use of fluoroquinolones in first-line treatment regimens, and these drugs were not recommended by an expert consensus group (the Ioannina Recommendations) except in the context of well-designed clinical trials. However, a more recent meta-analysis is more supportive of the efficacy of these drugs, and adequately powered prospective studies will be needed to resolve their role in standard combination therapy. Although triple-drug regimens are superior to double-drug regimens in meta-analyses, they are not indicated for uncomplicated brucellosis. A triple-drug regimen such as doxycycline and rifampin, enhanced by initial aminoglycoside, should be considered for all patients with complicated disease and for those for whom treatment adherence is likely to be a problem.

Focal neurologic disease due to *Brucella* species requires prolonged treatment (i.e., for 3–6 months), usually with ceftriaxone supplementation of a standard regimen. *Brucella* endocarditis is treated with at least three drugs (an aminoglycoside, a tetracycline, and rifampin), and many experts add ceftriaxone and/or a

fluoroquinolone to reduce the need for valve replacement. Treatment is usually given for at least 4–6 months, and clinical endpoints for its discontinuation are often difficult to define. Surgery is still required for the majority of cases of infection of prosthetic heart valves and prosthetic joints.

There is good evidence for the benefit of antimicrobial prophylaxis to reduce the risk of infection after occupational or other exposure to *Brucella* organisms, inadvertent immunization with live vaccine intended for use in animals, or exposure to deliberately released brucellae. However, there is little evidence to inform the duration of prophylaxis or preference for dual or single therapy. Based on historical practices, many national guidelines recommend the administration of rifampin plus doxycycline for 3 weeks. However, such regimens are poorly tolerated, and doxycycline monotherapy of the same duration may be used instead. Monotherapy is the standard recommendation in the United Kingdom but not in the United States. Rifampin should be omitted after exposure to vaccine strain RB51, which is resistant to rifampin, and replaced by another agent such as TMP-SMX in combination with doxycycline. After significant brucellosis exposure, expert consultation is advised for women who are (or may be) pregnant.

PROGNOSIS AND FOLLOW-UP

Relapse occurs in up to 30% of poorly compliant patients. Thus, patients should ideally be followed clinically for up to 2 years to detect relapse, which responds to a prolonged course of the same therapy used originally. The general well-being and the body weight of the patient are more useful guides than serology to lack of relapse. IgG antibody levels detected by the standard agglutination test and its variants can remain in the diagnostic range for >2 years after successful treatment. Complement fixation titers usually fall to normal within 1 year of cure. Immunity is not solid; patients can be reinfected after repeated exposures. Fewer than 1% of patients die of brucellosis. When the outcome is fatal, death is usually a consequence of cardiac involvement; more rarely, it results from severe neurologic disease. Despite the low mortality rate, recovery from brucellosis is slow, and the illness can cause prolonged inactivity, with domestic and economic consequences.

The existence of a prolonged chronic brucellosis state after successful treatment remains controversial. Evaluation of patients in whom this state is considered (often those with work-related exposure to brucellae) includes careful exclusion of malingering, nonspecific chronic fatigue syndromes, and other causes of excessive sweating, such as alcohol abuse and obesity. In the future, the availability of more sensitive assays to detect *Brucella* antigen or DNA may help to identify patients with ongoing infection.

PREVENTION

Vaccines based on live attenuated *Brucella* strains, such as *B. abortus* strain 19BA or 104M, have been used in some countries to protect high-risk populations but have displayed only short-term efficacy and high reactogenicity. Subunit vaccines have been developed but are of uncertain value and cannot be recommended at present. Research in this area has been stimulated by interest in biodefense **(Chap. S4)** and may eventually yield new products. The mainstay of veterinary prevention is a national commitment to testing and slaughter of infected herds/flocks (with compensation for owners), control of animal movement, and active immunization of animals. These measures are usually sufficient to control human disease as well. In their absence, pasteurization of all milk products before consumption is sufficient to prevent nonoccupational animal-to-human transmission. All cases of brucellosis in animals and humans should be reported to the appropriate public health authorities.

175 Tularemia

Anders F. Johansson

DEFINITION

Tularemia is a zoonotic disease that can naturally be transmitted from vertebrate animals to humans, causing a febrile illness. Synonyms include deer-fly fever, rabbit fever, market men's disease, water-rat trappers' disease, wild hare disease (yato-byo), Francis' disease, and Ohara's disease.

ETIOLOGY

Tularemia is caused by *Francisella tularensis*, a small (0.2–0.7 × 0.2 μm), facultatively intracellular, aerobic, gram-negative, pleomorphic bacterium. *F. tularensis* is highly virulent for humans and numerous mammals, including rodents, hares, and rabbits. It is known to cause airborne laboratory-acquired infection; therefore, laboratory work, including culturing of the bacterium, must be performed by trained staff in biologic safety cabinets under biosafety level 3 conditions. The disease tularemia was described by the American researchers McCoy and Chapin as a "plague-like disease of rodents" in California in 1911, 1 year after they cultivated and described the causative bacterium as "Bacterium tularense." *Francisella* was later named after Edward Francis, an American bacteriologist who extensively studied the etiologic agent and the pathogenesis of tularemia over several decades. There are two *F. tularensis* subspecies of high clinical importance: *F. tularensis* subspecies *tularensis* (aka Jellison type A) with human disease documentation exclusively from the North American continent, and subspecies *holarctica* (Jellison type B) with human disease documentation both from North America and from other parts of the world. A third subspecies, *F. tularensis* subspecies *mediasiatica*, has been isolated from vertebrate animals in Central Asia and Russia, but there is no documented disease in humans. The division into type A and type B strains of *F. tularensis* is based on minor biochemical test differences, with type A strains being significantly more lethal in experimentally infected rabbits. Type A but not type B cultures can ferment glycerol and are positive in a citrulline ureidase assay. Microbial genome sequencing has revealed an average nucleotide identity >99% between type A and type B strains of *F. tularensis,* but current and historic epidemiologic studies mirror the experimental findings in rabbits—tularemia mortality among humans is higher with type A in the United States. However, recent research using high-resolution genetic subtyping, combined with analyses of disease outcomes, shows there is heterogeneity in mortality risks among different type A genetic varieties, with some being less virulent for humans than the type B varieties.

Genetic neighbors of *F. tularensis*, including *Francisella novicida* (sometimes referred to as a fourth subspecies of *F. tularensis* with a genomic average nucleotide identity of ~97% with other subspecies) and the genetically more distant *Francisella philomiragia*, are opportunistic pathogens that may cause disease in humans with symptoms varying according to the immune status of the patient. Moreover, modern microbiology methods and intense research efforts have resulted in the identification of additional *Francisella* bacteria, including

pathogens of fish, endosymbiont bacteria of ticks, soil bacteria, and bacteria isolated from sea and freshwater, some of which may be opportunistic human pathogens. Taxonomists now recognize at least nine distinct *Francisella* species, including *Francisella tularensis*, the causative agent of tularemia.

EPIDEMIOLOGY

F. tularensis infects humans through bites of arthropods functioning as disease vectors (e.g., mosquitoes, ticks, tabanid flies), inhaling infectious aerosols, handling infected animals, or ingesting contaminated water. The reported human cases represent bridging between endemic *F. tularensis* maintenance in nature, or spillover events from massive amplification in infected rodents, hares, or rabbits during disease outbreaks among animals (epizootics). The disease is endemic to the Northern Hemisphere but has a patchy and geographically uneven distribution, which is believed to be the result of *F. tularensis* being maintained long-term in smaller geographic areas experiencing repeated outbreaks, often at intervals of several years. In the United States, reported human cases have dropped sharply from several thousand annual cases before 1950 to 200–300 cases annually from 2010–2020, with most of these cases being associated with tick bites in Arkansas, Kansas, Missouri, and Oklahoma according to Centers for Disease Control and Prevention (CDC) statistics. Surveillance data from 2006–2021 with available *F. tularensis* culture data showed 66% type A and 34% type B cases in humans. In some parts of Europe and Asia where type B only causes human disease, tularemia was relatively more common in 2010–2022, with several hundred to >2000 cases in peak years in Finland, Sweden, and Turkey, respectively. In the Northern Boreal Forest regions of Sweden, Finland, and Russia, tularemia is primarily associated with mosquito bites, while tick bites are more common in Western and Eastern Europe. Most cases in the United States, as well as in Finland and Sweden, occur during summer, likely reflecting increased human exposure to blood-feeding arthropods, infected wildlife mammals, or aerosols from carcasses of infected animals during outdoor activities. In contrast to this seasonal pattern, most cases occur in the winter months in Turkey, where the predominant infection route to humans in some rural areas is nonchlorinated drinking water from natural springs that may be contaminated by infected rodents. Colder temperatures enhance the survival of the bacterium in water during winter. In the Southern Hemisphere, rare human and animal infections have been documented from Australia. It is uncertain whether the lack of reporting from other areas of the Southern Hemisphere is due to lack of disease or from underreporting.

Based on extensive historic field studies performed in the United States and the former Soviet Union during the 1950s–1970s, it is believed that distinct disease ecologies characterize *F. tularensis* subspecies *tularensis* (type A) and *F. tularensis* subspecies *holarctica* (type B), respectively. This concept recognizes the association of type A tularemia with rabbits, ticks, domestic cats, and sheep in comparatively dry environments, in contrast to the association of type B tularemia with streams, ponds, lakes, rivers, and semiaquatic animals such as muskrats and beavers **(Fig. 175–1)**.

It remains unknown exactly how the bacterium is maintained in nature. *F. tularensis* is a generalist eukaryotic host-associated microbe that can infect many animals and cell types, including amphibians, birds, rodents, rabbits, carnivores, and ruminant mammals. Most of these animals are accidental hosts or rapidly die from septic disease. It is unclear if any can maintain the bacterium for a long duration. However, when an animal dies from a tularemia infection with a high level of bacteria in their bodies, this can potentially help temporarily maintain the bacteria in the environment. Over the long term, decaying infectious tissues might also contribute to the bacteria's persistence

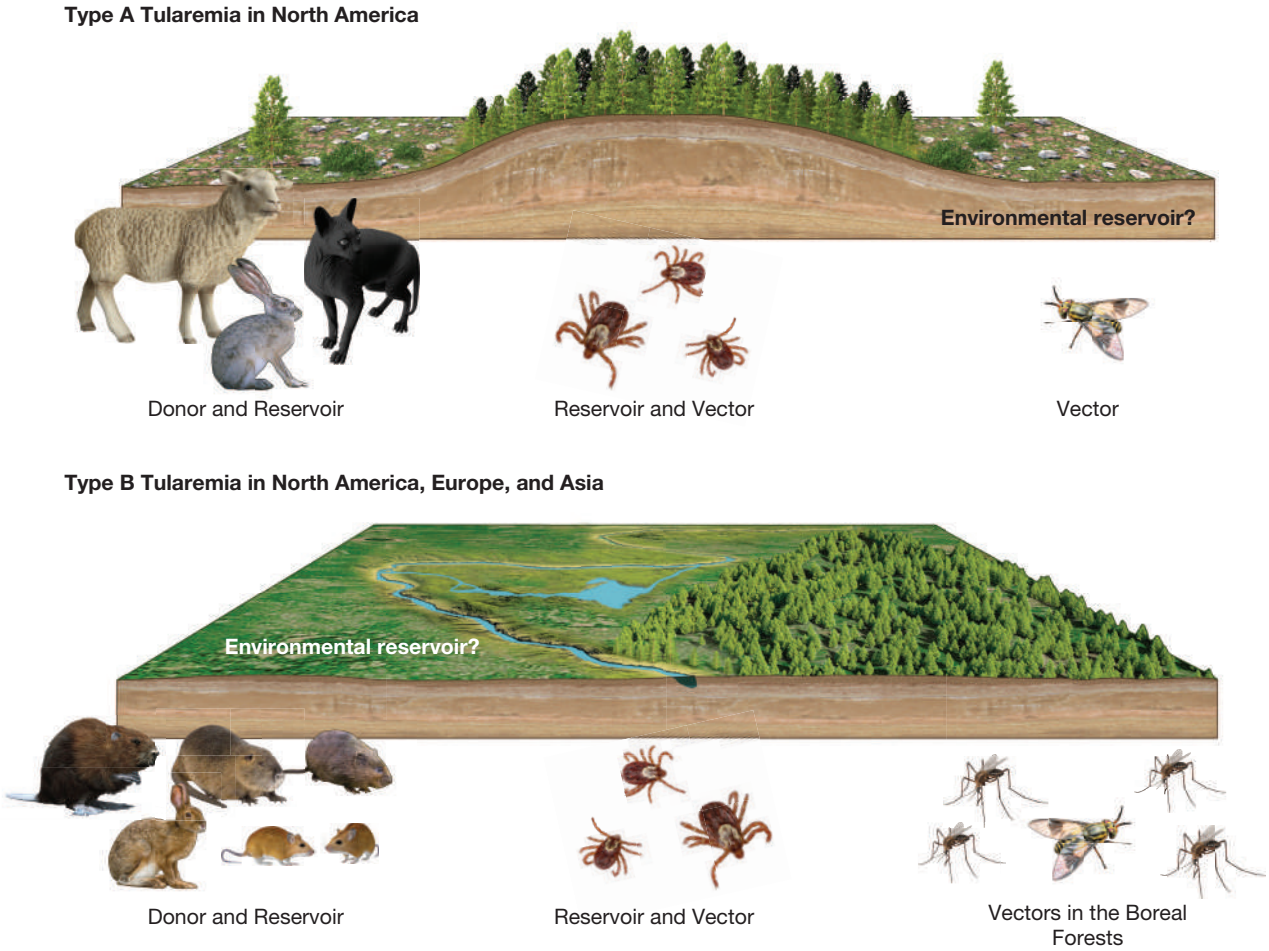

FIGURE 175–1 Schematic illustration of the type A and type B disease ecology concepts. *(Adapted from P. Keim et al: Molecular epidemiology, evolution, and ecology of Francisella. Ann N Y Acad Sci 1105:30, 2007, Figure 11.)*

under certain conditions. Another hypothesis for maintenance of *F. tularensis* is persistence in water with protozoa such as amoeba serving as host cells.

Since the 1940s, research has shown that *F. tularensis* can infect multiple species of soft and hard ticks, supporting the idea of tularemia as an obligate vector-borne disease with ticks as reservoirs. In North America, tularemia in humans is mainly tick-borne, but the role of ticks in maintaining and spreading the disease geographically is more debated compared with other pathogens like *Babesia* and *Borrelia*; these latter pathogens are better adapted for transmission between the different life stages of a tick. Contemporary well-designed experiments involving mice and American dog ticks have tested *F. tularensis* type A strains from three main genetic clades and a type B strain. They demonstrated rapid *F. tularensis* acquisition by adult ticks from bacteremic mice, an interrupted blood-feeding behavior, and high transmission efficiency to uninfected mice (58–89%), indicating that adult ticks can serve as highly effective disease vectors to humans during outbreaks. However, ticks of the more immature nymph life stage showed low survival after *F. tularensis* ingestion and low transmission efficiency (0–13.5%), indicating that these are ineffective disease vectors. Overall, both older and newer studies suggest that *F. tularensis* infection poses a high burden for immature tick stages, and the literature is conflicted on the presence of transovarial transmission in ticks. It has been suggested that ticks, like other blood-feeding arthropods including tabanid flies in North America and mosquitoes in the Boreal Forest regions of Northern Europe, are important for transmitting disease to humans during tularemia epizootics but may not be obligate for maintaining *F. tularensis*. To better understand the zoonotic potential and the epidemiology seen in humans, a better understanding of how *F. tularensis* is maintained between outbreaks will be required.

PATHOGENESIS

Natural transmission to humans usually occurs through the skin or by inhalation of aerosols containing *F. tularensis*, but ingesting infected food or water also may cause infection. An extremely low dose of 10–50 bacteria inoculated through microtrauma of the skin or inhaled into the lungs suffices to cause disease in humans. In contrast, a dose in the range of 10^6–10^8 bacteria is required to infect humans and other primates by the oral route. Tissue-resident macrophages, including alveolar macrophages in the lung and Langerhans cells in the skin, are believed to be important in the transport of *F. tularensis* by blood or lymph vessels to lymph nodes, spleen, and bone marrow. In the skin, *F. tularensis* undergoes phagocytosis by neutrophils at initial stage of infection. After the bacteria have been taken up by tissue-resident macrophages and other local phagocytic cells, *F. tularensis* escapes from the phagosome into the cell cytosol, replicates, leaves the cell, and disseminates throughout the host. *F. tularensis* is a "stealth pathogen," implying that the bacterium is able to manipulate host-cell signaling, thus rendering itself a safe milieu inside the host cell suitable for its replication. In experimental oral infection of mice, there is minimal local gastrointestinal pathology despite the large infection dose required. It remains unknown what cell types mediate *F. tularensis* to cross the intestinal epithelium to cause fatal systemic infection.

Gross and histopathology findings in nonhuman primates experimentally infected by the inhalation route have shown 0.5- to 1-mm necrotic lesions with live bacteria in the spleen at day 4 after the infection, and subsequent larger foci in liver and lymph nodes at days 5–7, which likely mirror disease events and progression in more severe human tularemia cases. At day 6 after infection of nonhuman primates, randomly scattered subacute abscesses and pyogranulomas 6–20 mm in diameter have been observed on the lung surfaces. From day 7 and onward, granuloma formation and necrotic lesions in tissues surrounded by layers of macrophages, lymphocytes, and giant cells are typical reaction patterns in lymph nodes, lungs, spleen, kidney, and liver, corroborated by historic reports of similar autopsy findings in fatal human tularemia.

The immune invasion strategy of *F. tularensis*—delaying the immune response and permitting rapid systemic distribution—has made studies of early immune responses challenging. The mechanisms behind cell-mediated responses against *F. tularensis* after a primary infection or vaccination by the live vaccine strain of *F. tularensis*, however, are well described and require both B and T cells, resulting in antigen-specific recall T cell responses persisting 25–30 years after infection or vaccination. Nevertheless, although the bacterium can manipulate and delay them, effective early immune responses occur and involve complement, antibodies, neutrophils, inducible NO synthase, phagocyte oxidase, and cytokines such as interferon γ, tumor necrosis factor α, and interleukin 12.

APPROACH TO THE PATIENT

Clinical recognition of tularemia may be challenging, especially if the patient does not spontaneously report fever. Sporadic cases of patients seeking health care can easily be misdiagnosed with a diversity of other conditions, including lung cancer, head and neck cancer, lymphoma, tuberculosis, or another disease with lymphoid tissue engagement or a suspected tumor. Tularemia may not be suspected before extensive and costly medical investigations have already been performed. Awareness of the disease and a high index of suspicion is critical. Even in high-endemic areas, patients with tularemia often initially are mistakenly managed and treated for other conditions, including unspecified viral infection, common skin and soft tissue infection, common community-acquired pneumonia, or undifferentiated fever or sepsis. A careful disease history of a patient with tularemia typically reveals an acute fever onset episode with influenza-like illness. If the patient seeks care immediately, an acute fever onset can be easily recollected; if care is sought several weeks after initial symptoms, acute onset of fever may not be mentioned spontaneously. The acute illness may be described as "a severe virus" with high fever, muscle pain, headache, and other constitutional symptoms. Fever may be persistent or intermittent. A tularemia-focused disease history should include risk factors for exposure to *F. tularensis* and epidemiologic information (e.g., household member or friend having similar symptoms and sharing the same exposure). Exposure risk factors or activities include wild animal contact (e.g., rodents, rabbits, hares), contact with or inhalation of dust contaminated with their urine or feces, recent arthropod bites (tick, fly, or mosquitoes), performing brush cutting or grass trimming, handling of wood, handling of hay, and walking or hunting in the forest or other natural habitats of wildlife species.

When tularemia is suspected it is important to define patient factors with relevance for coping with infection, to define the infection syndrome, and to decide on an appropriate level for patient management:

- Consider factors that may increase the risk of severe infection (e.g., geriatric frailty, immunosuppression, severe lung and/or heart function impairment, other significant comorbidities).
- By physical examination, determine any anatomic location and extent of inflammation (e.g., presence of pneumonitis, lymph node inflammation, skin inflammation including minute ulcers or pustules, pharyngitis). Collect information on the rate of progression and judge the severity of infection.
- Determine an appropriate level of care (e.g., localized symptoms likely suitable for outpatient care, multiorgan involvement/hemodynamic instability suggesting inpatient care).

CLINICAL MANIFESTATIONS

The most common initial manifestation of tularemia is an influenza-like illness with high fever. The incubation period is usually 3–5 days but may range from 1 to 21 days. Inflamed swollen lymphoid tissue is typical for tularemia. The initial infection route determines what lymphoid tissue is engaged **(Fig. 175–2)**. If bacteria are acquired through skin or oral mucous membranes of the pharynx, palpable enlarged tender regional lymph node(s) can result. If bacteria are inhaled, the result will be lymph node enlargement in the mediastinum. Different recognized clinical forms of tularemia are the same for type A and type B tularemia and depend on the initial *F. tularensis* infection route as outlined in **Table 175-1**.

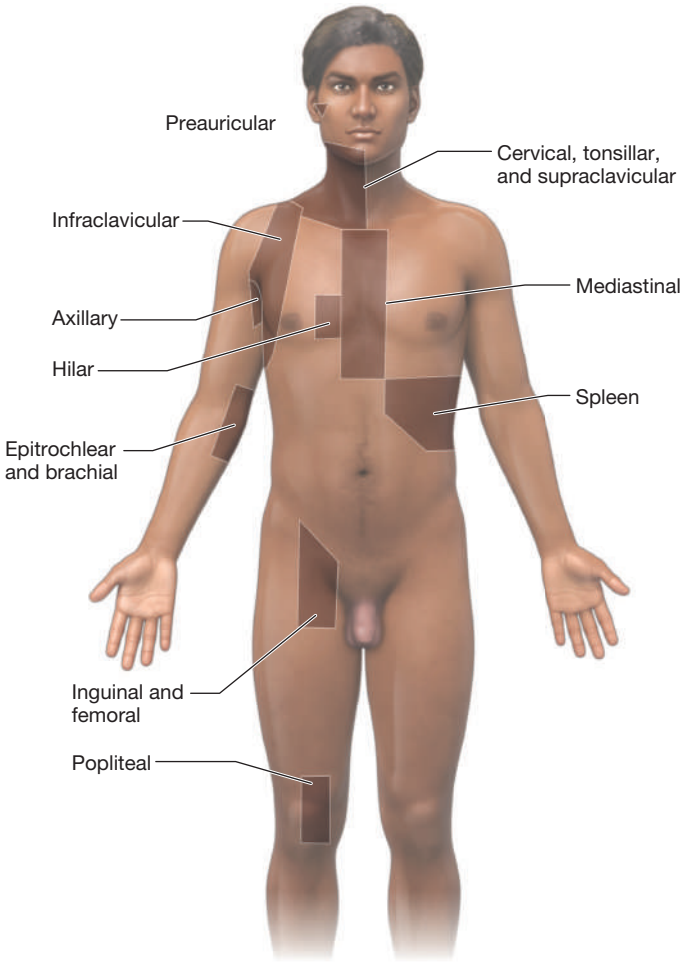

FIGURE 175–2 Characteristic sites of lymphoid tissue engagement in tularemia. *(From https://training.seer.cancer.gov/lymphoma/anatomy/lymph-nodes.html.)*

FIGURE 175–3 Patient presenting with ulceroglandular tularemia 3 weeks after onset of high fever and influenza-like illness. Lymph nodes of the left thigh were red, tender, and swollen. A tularemia ulcer was present on the left ankle (not shown). *(Photo from patient care at Region Västerbotten, Sweden.)*

The primary tularemia ulcer is often a small break in the skin, with limited signs of inflammation, and may require careful clinical examination to be detected. In some cases, it may not be detectable and the disease form will then be classified as glandular. Red, tender, swollen lymph regional nodes are often the most remarkable clinical examination findings in patients with acute ulceroglandular tularemia **(Fig. 175–3)**.

In oropharyngeal and oculoglandular tularemia, there is more often pronounced local inflammation at the primary site of infection with acute pharyngitis or conjunctivitis, respectively. The respiratory or pneumonic form of tularemia acquired by inhalation of *F. tularensis* may, more often than other clinical forms, be bacteremic and progress to severe disease requiring inpatient care, particularly in patients aged 65 and over and those with comorbidities. In the respiratory/pneumonic clinical form of tularemia, onset of dry cough may occur more than 7 days after onset of the influenza-like illness. Bronchoscopy findings may include signs of local tracheitis and pneumonitis, and the lymphoid tissue engaged will be in the mediastinum or lung hila. "Typhoidal tularemia" is an older medical classification term referring to a disease syndrome like typhoid fever with prolonged high fever, fatigue, headache, and nausea. It is recommended to avoid using this term, if possible, as it is believed that historically, most cases of typhoidal tularemia were acquired by inhalation and were, in fact, respiratory/pneumonic tularemia. For type A tularemia, historic disease descriptions suggest that respiratory/pneumonic tularemia or meningitis may also occur as secondary manifestations in severe cases of ulceroglandular disease. Data from the United States in 2006–2021 on 1046 cases with primary disease manifestations available showed 47% ulceroglandular, 18% glandular, 17% pneumonic or respiratory, 14% typhoidal, 2% oculoglandular, and 2% oropharyngeal disease according to CDC statistics.

Routine biochemical testing of blood generally is not helpful in tularemia because findings are unspecific and may or may not reveal elevated liver enzymes or red blood cells in the urine. In a recent more extensive case series from Sweden of type B tularemia of primarily outpatients, white blood cell counts remained within normal limits for 70% of patients, and the median C-reactive protein level was moderately elevated, peaking at day 7–9 after disease onset at a median of 78 mg/L (range, 30–130). A recent analysis of 33 patients hospitalized with severe respiratory type B tularemia showed peak C-reactive protein levels at 100–400 mg/L among patients with *F. tularensis* growth in blood cultures and 50–220 mg/L among nonbacteremic patients.

TABLE 175-1 Clinical Forms of Tularemia

FORM[a]	*F. TULARENSIS* INFECTION ROUTE
Ulceroglandular or glandular	Skin inoculation by blood-feeding arthropods or direct contact (touching infected animal or *F. tularensis* contaminated material)
Oropharyngeal	Ingestion of contaminated water or food
Oculoglandular	Touching the eye with contaminated fingers or exposure to contaminated aerosol
Respiratory/pneumonic	Inhalation of contaminated aerosol
Typhoidal	Unknown (likely by inhalation, rarely by ingestion)

[a]Additional less common but well-described clinical invasive manifestations of tularemia exist, including primary tularemia meningitis, endocarditis, and bone and joint infections. In patients with immunosuppression, tularemia manifestations may be indolent with few focal symptoms and signs.

DIAGNOSIS

Laboratory confirmation is recommended and may be based on recovery of an *F. tularensis* isolate, *F. tularensis*–specific antigens or nucleic acids, or the detection of *F. tularensis*–specific antibodies in

blood by serology testing. Appropriate clinical specimens to collect for direct detection of *F. tularensis* by nucleic acids or culture include ulcer specimens, lower respiratory tract specimens (sputum/tracheal washing/bronchoalveolar lavage), lymph node biopsies or aspirates, and blood cultures. Additional clinical specimens with *F. tularensis* growth reported include pharyngeal and ventricular washings. Importantly, sampling from ulcers should be performed from the edge of the wound, preferably selecting a swab with a slightly stiffer stick and some rubbing of the tissue so that it becomes somewhat blood-tinged. If there is a scab, this should be removed before sampling. If culture specimens are sent to a clinical microbiology laboratory, a suspicion of tularemia must be clearly communicated to the laboratory in advance to minimize the risk of laboratory-acquired infections in lab workers.

Direct detection of *F. tularensis*–specific nucleic acid in clinical specimens by polymerase chain reaction or another detection method is a rapid and reliable diagnostic method. For ulcer specimens, the method is comparable with culture in sensitivity and specificity. There is clinical experience of *F. tularensis* nucleic acid detection from other specimen types, including sputum, bronchoalveolar lavage, and lymph node biopsies/aspirates, but formal scientific evaluation of the diagnostic performance is lacking. With increased availability of molecular methods in some clinical microbiology laboratories, nucleic acid–based subtyping without a prior culture step can be performed directly from clinical specimens and may help clinicians to identify *F. tularensis* varieties rapidly. Identification of the subspecies and genetic variety involved in tularemia infections is currently limited in most laboratories but may be of greatest importance in North America, where type A and type B tularemia exist side by side. Cultivation of *F. tularensis* requires Biosafety Level 3 (BSL-3) laboratories, and because *F. tularensis* is a U.S. Department of Health and Human Services (HHS) Tier 1 Select Agent, an accurate culture diagnosis in the clinic is challenging. However, culture identification provides a definitive diagnosis and allows for subsequent genetic methods to identify different *F. tularensis* varieties with varying risks of mortality. Unexpected findings in blood cultures with matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry identification of *F. tularensis* is a scenario that has become more common in recent years with the improvement of blood culture systems and MALDI-TOF reference libraries. *F. tularensis* is a slow-growing bacterium, and an incubation period of 10 days is recommended for optimal sensitivity in blood-culture diagnostics. Serology remains commonly used to confirm tularemia and is the mainstay diagnostic in many clinical microbiology laboratories. Serology is particularly useful in patients when tularemia is suspected as a differential diagnosis at a later stage—the antibody responses against *F. tularensis* are generally detectable in the blood of patients 10–20 days post-infection using an enzyme-linked immunosorbent assay or a microagglutination test. Some commercial serologic tests may detect *F. tularensis*–specific antibodies as early as 1–2 weeks after disease onset. Importantly, the persistence of *F. tularensis* antibodies is prolonged, meaning that up to at least 1 year after acute infection, single titers of antibodies remain above the cutoff set by laboratories to detect acute infections. Therefore, a reliable serologic diagnosis of tularemia in the acute phase should rely on the demonstration of a significant increase of antibody titers between two samples taken 2–4 weeks apart.

Chest imaging is useful in respiratory tularemia. Single or multifocal consolidation may be present, accompanied by pleural effusion with hilar and mediastinal lymphadenopathy **(Fig. 175–4)**.

Computed tomography (CT) scans in the acute phase may reveal multiple rounded consolidations, often in the subpleural region and sometimes with signs of inclusion necrosis with a diffuse marginal zone. Lymph node enlargements in the mediastinal and hilar regions on a CT scan may also contain necrotic inclusions. A relatively common scenario for sporadic cases of tularemia is pulmonary nodules or dense consolidations, which can mimic lung cancer, resulting in more extensive clinical investigation paths to exclude cancer, including CT and positron emission tomography (PET) scans **(Fig. 175–5)**. Endobronchial ultrasound bronchoscopy procedures with biopsy may be performed in some cases before tularemia is suspected. The resolution of tularemia pathology on chest imaging may be slow and take months.

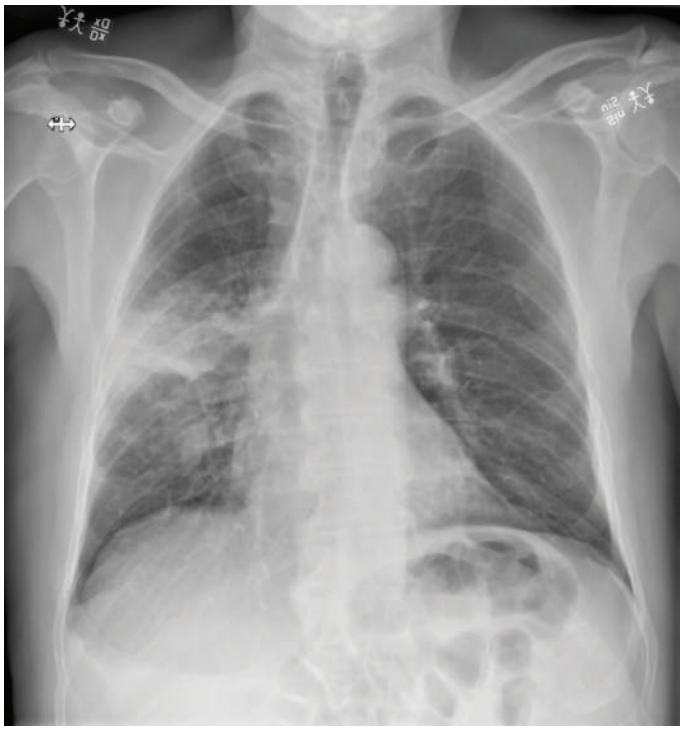

FIGURE 175–4 Frontal projection chest x-ray with acute respiratory/pneumonic tularemia (type B) with consolidation at the right side of the lungs with hilar enlargement. Fever and chills started 10 days before. *(Photo from patient care at Region Västerbotten, Sweden.)*

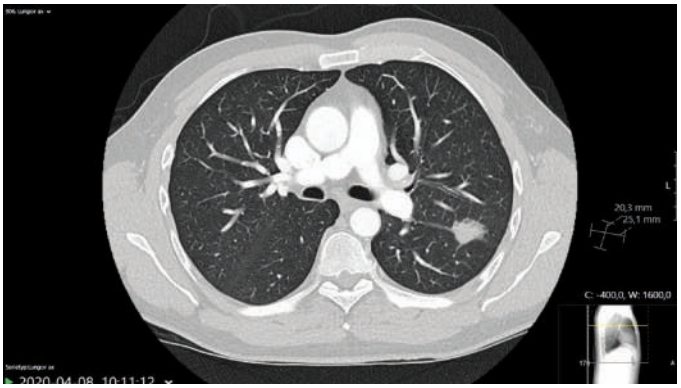
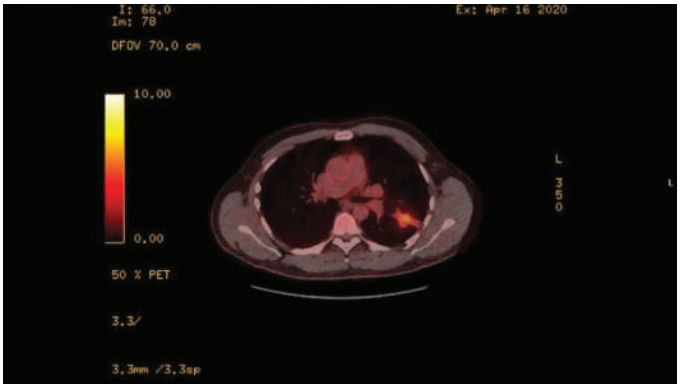


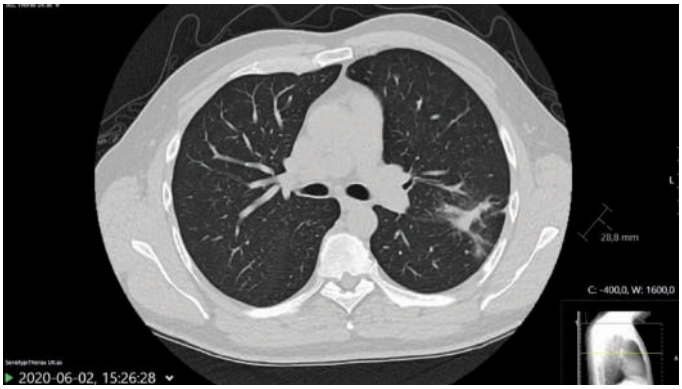
PATHOLOGY

Analyses of tularemia skin lesions of humans infected by skinning of rabbits with tularemia have suggested a scenario with accumulation of lymphocytes, plasma cells, and neutrophils at the infection site during the first week after *F. tularensis* infection of the skin. Microabscesses with neutrophils occur in subcutis along with histiocytes and Langerhans cells in dilated lymph vessels. A skin ulcer and granuloma formation occur only after the first week, along with lymph node engagement. Histopathology findings in other tissues of patients with more advanced tularemia and a more extended disease history include irregular microabscesses and granulomas in samples from liver, spleen, kidney, and lymph nodes. Autopsy samples from the lungs of humans have shown necrotizing pneumonia characterized by abundant fibrin, cellular debris, and neutrophils within alveolar walls and alveolar spaces.



TREATMENT

Specific antimicrobial treatment is highly recommended for tularemia as outlined in **Table 175-2**. The antibiotics of choice are ciprofloxacin, levofloxacin, gentamicin, or doxycycline. Early specific antimicrobial treatment is essential to avoid complications irrespective of targeting type A or type B tularemia. Several commonly used antimicrobials, including all the β-lactam drugs and clindamycin, lack treatment efficacy against *F. tularensis*. Macrolide antibiotics, including erythromycin and azithromycin, show an in vitro effect against *F. tularensis* type A and type B varieties known to be present in the United States, but globally there are very scarce treatment outcome data for these drugs in humans. Generally, macrolide antibiotics are not recommended for tularemia because macrolide-resistant type B strains are common in Europe and Asia, resulting in total lack of treatment effect and overall little experience using these drugs for tularemia treatment. Azithromycin, however, may be an alternative treatment choice for patients with verified type A infection according to recent CDC guidelines.



Streptomycin, classically used to treat tularemia, has been the drug of choice due to its high cure rate in a U.S. case series reported from 1949–1988, but is now considered a less attractive

A

B

C

FIGURE 175–5 Dense consolidation in the left lung of patient with a history of weight loss and cough for 3–4 months. ***A.*** CT scan showed dense consolidation (2.5 × 2.5 × 2.0 cm) in the basal left upper lobe extending to the apical part of the lower lobe and increased hilar lymphoid tissue. ***B.*** Eight days later, PET scan showed increased metabolic activity and progress of the consolidation to 5.0 × 4.5 × 3.5 cm. Tissue biopsy revealed granuloma formation in the adjacent pleura and no malignant cells. ***C.*** A tularemia diagnosis was confirmed by serology, the patient was treated with ciprofloxacin, and a CT scan performed 2 months later showed resolution of the consolidation. *(Photos from patient care at Region Västerbotten, Sweden.)*

alternative to gentamicin due to its drawbacks, including the need for intramuscular administration, limited clinical availability, and a higher risk of vestibular and renal toxicity compared with newer aminoglycoside antibiotics. Chloramphenicol is another drug with a higher risk of adverse effects that, for this reason, is seldom used systemically in modern medicine. Chloramphenicol has an in vitro effect against *F. tularensis* and was reportedly effective in treating tularemia meningitis in the past.

COMPLICATIONS

Inflamed lymph nodes can progress into an abscess with local and/or systemic reaction and may occur in about one-third of patients, especially if there were delays in *F. tularensis*–specific antibiotic treatment. An antibiotic treatment delay of >2–3 weeks after disease onset has been statistically associated with lymph node abscess formation. In some cases, the progression to a lymph node abscess may occur despite ongoing appropriate antibiotic treatment initiated late in the disease course. It is unclear if extending the antibiotic treatment duration is of clinical benefit. Culture specimens from an abscess at this disease stage are typically *F. tularensis* negative, but an additional 10–day course of appropriate antibiotic treatment is often used to avoid further disease progression and may be successful. If the clinician considers that there is a clear and immediate risk of spontaneous rupture of the skin or the mucus membranes in the pharynx with suppuration of pus, open surgical drainage or needle aspiration is recommended for treatment. A more invasive procedure with total surgical excision may be needed in more complicated and long-standing cases. Another complication of uncertain genesis occasionally reported by patients includes postinfectious persisting fatigue and disability. Additional complications or disease manifestations of tularemia have been reported, including adult respiratory distress syndrome, myocarditis, pericarditis, endocarditis, meningitis, osteomyelitis, hepatitis, and renal failure.

TABLE 175-2 Treatment and Postexposure Prophylaxis Recommendations for Adult Patients with Tularemia or with Significant Exposure to an *F. tularensis* Aerosol

ADULTS, INCLUDING PREGNANT WOMEN			
	DRUG	**DOSE[a]**	**DURATION (DAYS)**
Preferred choices	Ciprofloxacin	400 mg every 8 hrs IV or 750 mg every 12 hrs PO	10
	Levofloxacin	750 mg every 24 hrs IV or PO	10
	Gentamicin	5–7 mg/kg IV or IM per day, given every 12 hrs or 24 hrs	10
Alternative choice[b]	Doxycycline[c]	200 mg loading dose, then 100 mg every 12 hrs IV or PO	14–21
Postexposure prophylaxis[d]	Doxycycline	100 mg PO twice daily	14
	Ciprofloxacin	500 mg every 12 hrs PO	10

[a]Patients beginning with IV treatment of ciprofloxacin, levofloxacin, or doxycycline can switch to oral administration when clinically indicated. [b]Other alternative choices having less supporting clinical data are high-dose moxifloxacin, ofloxacin, amikacin, tobramycin, or plazomycin for 10 days. In verified type A-infection, azitromycin may be considered based on in vitro susceptibility analysis. [c]Doxycycline may safely be included as a preferred choice for patients with nonsevere disease but is associated with a higher frequency of fever relapse and needs a more extended treatment duration. Tetracycline 500 mg every 6 hrs IV or PO for 14-21 days is equivalent to doxycycline. [d]For low-risk exposures, preparedness for early treatment may suffice using daily "fever watch": the patient monitors temperature with instructions to seek immediate treatment if developing a fever. Postexposure prophylaxis is recommended for high-risk exposures, including performing aerosol-generating procedures with *F. tularensis* cultures outside a biologic safety cabinet or handling infected animals. There are extensive human data showing that doxycycline is effective.

PROGNOSIS

Prior to the use of antibiotics to treat tularemia, case fatality rates in the United States were typically 5%–15% and could be as high as 60% for patients with respiratory/pneumonic tularemia. Recent surveillance data of tularemia in the United States between 2006 and 2021 show that of 903 patients with illness outcome available, 27 patients (3.0%) died. Culture of *F. tularensis* from a clinical specimen was present in approximately 50% of cases and associated with significantly reduced odds of survival (odds ratio [OR], 0.1; 95% confidence interval [CI], 0.04–0.4). Treatment with at least one high-efficacy antimicrobial drug class (aminoglycoside, fluoroquinolone, or tetracycline) was independently associated with increased odds for survival (adjusted OR, 10.4; 95% CI, 4.4–24.5 after controlling for disease severity). Notably, previous surveillance data from 1964–2004 considering the modern genetic distinction of three epidemiologically important type A genetic varieties in the United States found a 24% fatality outcome for the most lethal

type A variety. For the type B *F. tularensis* variety, the same surveillance data from 1964–2004 showed a 7% fatality outcome. Caution in interpreting these latter data is warranted, as they likely are overestimates of mortality due to selected reporting and disease severity bias from the inclusion of culture-positive cases only. Recent analyses of patients with respiratory/pneumonic type B tularemia in Sweden revealed a 1.5% fatality. Outcome analyses considering all clinical forms of tularemia suggest an overall type B tularemia fatality rate of <1% in Sweden. The frequency of disease complications, including lymphadenopathy, among 327 patients was <10%, much lower than previously reported for tularemia, likely because appropriate antibiotics were often given early, at a median of 7 days after disease onset.

PREVENTION

Standard precautions are recommended for infection control and prevention in the clinic. Face protection using goggles or a face shield and a fluid-resistant medical mask should be used in procedures with a risk of splashes from potentially infected body fluids. Only procedures with a very high risk of aerosol formation that may contain live *F. tularensis*, such as the surgical evacuation of pus from an abscess by applying high pressure or autopsy work with rotating tools, warrant respiratory protection with an N95 mask. Tularemia patients do not need to be isolated, given there is no human-to-human transmission. Because *F. tularensis* is a known risk for laboratory-acquired infection, suspected isolates should, at a minimum, be manipulated at BSL-2 using BSL-3 precautions in a biosafety cabinet. In the United States, specialized reference laboratories should always be consulted and involved in attempts for complete identification and antimicrobial susceptibility testing of *F. tularensis*. Vaccination is a potentially important measure for preventing tularemia. However, no U.S. Food and Drug Administration (FDA)-approved *F. tularensis* vaccines exist. The efficacy of the only available vaccine, LVS, is uncertain given concerns about adverse reactions to the vaccine, potential for reversion, unknown correlates of protection, and variable immunogenicity. Prevention strategies for the public include measures to avoid *F. tularensis* exposure. It is advised to avoid tick-infested areas and mosquito bites in tularemia-endemic areas, wear trousers and long-sleeved shirts, use arthropod repellants, and remove attaching ticks promptly. Exposure to and touching dead or sick wild mammals should be avoided. If touching the mammal is necessary, gloves should be worn and hands should be washed thoroughly after removing the gloves. In addition to avoiding direct contact, exposure to potentially *F. tularensis*–contaminated aerosols should also be avoided, e.g., from handling dry hay or grain where carcasses of rodents are found.

GLOBAL CONSIDERATIONS

Due to its past development as a biologic weapon, there is a risk that *F. tularensis* could be used as a biothreat agent. *F. tularensis* is considered an HHS Tier 1 Select Agent in the United States because it presents the greatest risk of deliberate misuse with the most significant potential for mass casualties or devastating effects to the economy, critical infrastructure, or public confidence. From 1932 to 1945, Japanese research units examined the utility of *F. tularensis* as a biologic weapon. After World War II, there were continuous military studies of tularemia. In the United States, there were federally funded biologic warfare programs from 1943 to 1969, with the development of weapons to disseminate type A *F. tularensis* aerosols. By 1973, the entire *F. tularensis* weapon arsenal of the United States had been destroyed. The former Soviet Union, as part of the civilian component of its offensive Biopreparat program, also incorporated *F. tularensis* into weapons. In 1970, the World Health Organization published a report estimating that an aerosol dispersal of 50 kg of virulent type A *F. tularensis* over a metropolitan area with 5 million inhabitants would result in 250,000 incapacitating causalities, including 19,000 deaths.

Efficacy trials of tularemia vaccines in humans against highly virulent type A tularemia are not feasible, and animal studies are judged to be the best option for screening and evaluating new vaccine candidates. There is ongoing research on the matter, including evaluating vaccines under the FDA "Animal Rule," aimed at bridging the outcomes in animals to use in humans.

New tularemia treatment options with promising results, tested in experimentally infected animals, include the use of passive immunization by *F. tularensis*–specific antibodies and a new triazaacenaphthylene antibiotic, gepotidacin. This new antibiotic class blocks bacterial DNA replication via inhibition of DNA gyrase and topoisomerase IV and is claimed to have no cross-resistance with the fluoroquinolones. Importantly, experience from treatment of humans with tularemia is lacking for both these treatments.

Considerations for tularemia in pregnant women include a recommendation to use antibiotic treatment to avoid a risk of loss of pregnancy. Literature is scarce, but the available data suggest that the risk of adverse outcomes, including lymph node complications in the mother, maternal bleeding, spontaneous abortion, intrauterine fetal death, and preterm birth, is lowered with prompt institution of antibiotic treatment. *F. tularensis* findings in transplacental villi and transplacental transmission to the fetus have been reported without treatment.

176 Plague and Other *Yersinia* Infections

Michael B. Prentice

PLAGUE

Plague is a systemic zoonosis caused by *Yersinia pestis*. It predominantly affects small rodents in rural areas of Africa, Asia, and the Americas and is usually transmitted to humans by an arthropod vector (the flea). Less often, infection follows contact with animal tissues or respiratory droplets. Plague is an acute febrile illness that is treatable with antimicrobial agents, but mortality rates among untreated patients are high.

Ancient DNA studies have confirmed that both the fourteenth-century Black Death and the sixth-century Plague of Justinian in Europe were due to *Y. pestis* infection. Patients can present with the bubonic, septicemic, or pneumonic form of the disease. Although there is concern about epidemic spread of plague by the respiratory route, this is not the most common route of plague transmission, and established infection-control measures for respiratory plague exist. However, the fatalities associated with plague and the capacity for infection via the respiratory tract mean that *Y. pestis* fits the profile of a potential agent of bioterrorism **(Chap. S4)**. Consequently, measures have been taken to restrict access to the organism, including legislation affecting diagnostic and research procedures in some countries (e.g., the United States).

ETIOLOGY

The genus *Yersinia* comprises gram-negative bacteria of the order *Enterobacterales* (class *Gammaproteobacteria*). Overwhelming taxonomic and paleogenomic evidence shows *Y. pestis* recently evolved from *Yersinia pseudotuberculosis*, an enteric pathogen of mammals spread by the fecal–oral route, and thus has a phenotype distinctly different from that of *Y. pestis*. When grown in vivo or at 37°C, *Y. pestis* forms an amorphous capsule made from a plasmid-specified fimbrial protein, Caf or fraction 1 (F1) antigen, which is an immunodiagnostic marker of infection.

EPIDEMIOLOGY

Human plague generally follows an outbreak in a host rodent population (epizootic). Mass deaths among the rodent primary hosts lead to a search by fleas for new hosts, with consequent incidental infection of other mammals. The precipitating cause for an epizootic may ultimately be related to climate or other environmental factors. The reservoir for *Y. pestis* causing enzootic plague in natural endemic foci between epizootics (i.e., when the organism may be difficult to detect in rodents or fleas) is a topic of ongoing research and may not be the same in all regions. The enzootic/epizootic pattern may be the result of complex dynamic interactions of host rodents that have different plague susceptibilities with different flea vectors; alternatively, an environmental reservoir may be important.

GLOBAL FEATURES

In general, the enzootic areas for plague are lightly populated regions of Africa, Asia, and the Americas **(Fig. 176-1)**. Between January 2013 and December 2018, 2886 cases of plague with a global case-fatality rate of 17% were notified to the World Health Organization (WHO) under the International Health Regulations. More than 97% of these cases were in Africa. The majority of cases in each year were from the island of Madagascar, which in 2017 experienced an urban outbreak of over 2400 clinically suspected cases, with an unusually high proportion of pneumonic plague (78%). A decline in reports from the Democratic Republic of the Congo (DRC) may reflect ongoing conflict in that country affecting surveillance rather than a true decrease. In the past decade, outbreaks of pneumonic plague have been recorded in the DRC, Uganda, Algeria, Madagascar, China, and Peru.

Plague was introduced into North America via the port of San Francisco in 1900 as part of the Third Pandemic, which spread around the world from Hong Kong. The disease is presently enzootic on the western side of the continent from southwestern Canada to Mexico. Most human cases in the United States occur in two regions: "Four Corners" (the junction point of New Mexico, Arizona, Colorado, and Utah), especially northern New Mexico, northern Arizona, and southern Colorado; and further west in California, southern Oregon, and western Nevada (*https://www.cdc.gov/plague/maps-statistics/*). From 1970 to 2020, 496 cases of plague were reported in the United States; in recent decades, incidence has fallen to an average of seven cases per year. Most cases occur from May to October—the time of year when people are outdoors and rodents and their fleas are most plentiful. Prior animal contact occurs in at least 50% of cases, and about 60% of these include domestic animals (usually dogs or cats) that brought wild animals or plague-infected fleas home. Infected cats or dogs may transmit plague directly to humans by the respiratory route. A slightly lower percentage of prior animal contacts involve direct handling of living or dead wild small mammals (e.g., rabbits, hares, prairie dogs) or wild carnivores (e.g., wildcats, coyotes, or mountain lions). In 2014, an outbreak of nonfatal pneumonic plague in Colorado affected four people exposed to an infected dog, with possible interhuman transmission in one case. Prior to this report, the most recent case of person-to-person transmission in the United States occurred in the Los Angeles pneumonic plague outbreak of 1924.

Plague most often develops in areas with poor sanitary conditions and infestations of rats—in particular, the widely distributed roof rat *Rattus rattus* and the brown rat *Rattus norvegicus* (which serves as a laboratory model of plague). Rat control in warehouses and shipping facilities has been recognized as important in preventing the spread of plague since the early twentieth century and features in the current WHO International Health Regulations. Urban rodents acquire infection from wild rodents, and the proximity of the former to humans increases the risk of transmission. The oriental rat flea *Xenopsylla cheopis* is the most efficient vector for transmission of plague among rats and onward to humans in Asia, Africa, and South America.

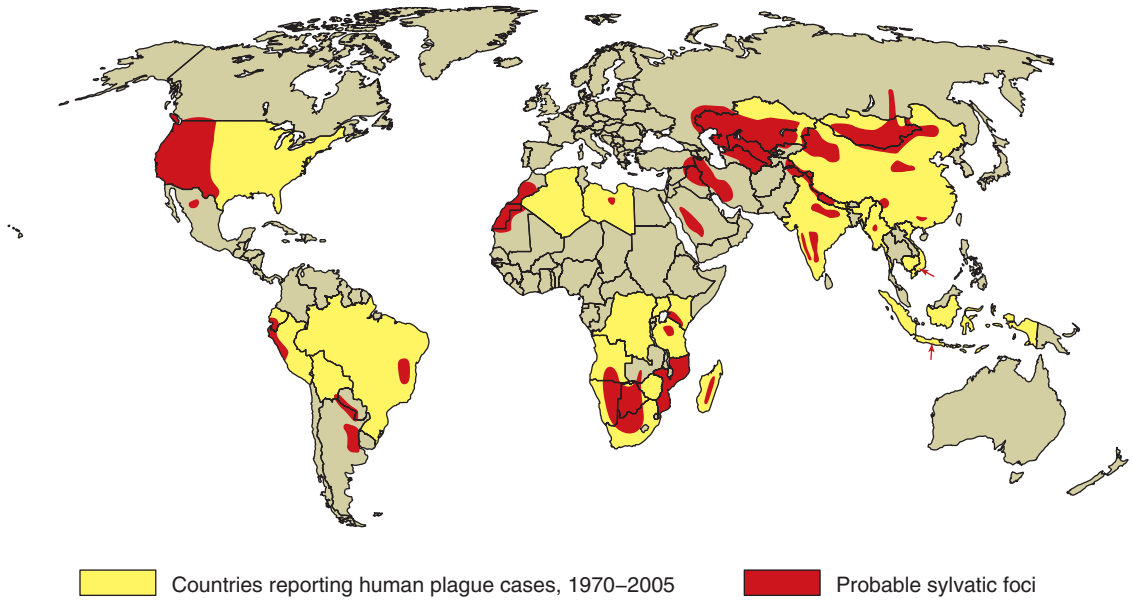

FIGURE 176-1 Approximate global distribution of *Yersinia pestis*. *(Compiled from WHO, CDC, and country sources. Reprinted with permission from DT Dennis, GL Campbell: Plague and other Yersinia infections, in Harrison's Principles of Internal Medicine, 17th ed, AS Fauci et al [eds]. New York, McGraw-Hill, Chap. 152, 2008.)*

Worldwide, bubonic plague is the predominant form reported. A minority of patients (10–20%) present with primary septicemic plague (i.e., systemic *Y. pestis* sepsis with no bubo; see "Clinical Manifestations," below) or pneumonic disease. Primary pneumonic plague is generally the least common and most fatal of the main plague presentations, but, as in the 2017 Madagascar outbreak, it is occasionally predominant. Rare outbreaks of pharyngeal plague following consumption of raw or undercooked camel or goat meat have been reported.

A total of 744 (82%) of the 913 plague cases with clinically documented features (out of 1006 cases reported in total) in the United States from 1900 to 2012 were bubonic disease, 87 (10%) were septicemic disease, and 74 (8%) were pneumonic disease; 6 cases (1%) were pharyngeal. Sixteen percent of cases were fatal in the postantibiotic era from 1942 onward compared with 66% in the period 1900–1941. This century (2000–2018), mortality in the United States has been 8% in patients receiving any antimicrobial and 4% in patients receiving one of the high-efficacy antimicrobials currently recommended as therapy. A systematic review and meta-analysis of the worldwide literature estimated a death rate for treated pneumonic plague of 17%, compared with 98% for untreated pneumonic plague.

PATHOGENESIS

As mentioned earlier, genetic evidence shows *Y. pestis* is a clone derived from the enteric pathogen *Y. pseudotuberculosis* in the recent evolutionary past (7000–50,000 years ago). The change from infection by the fecal–oral route to a two-stage life cycle, with alternate parasitization of arthropod and a wide range of mammalian hosts, occurred as a result of two plasmid gene acquisitions (*pla* on pPCP1/pPst and *ymt* on pFra/pMT1), and the inactivation of a handful of *Y. pseudotuberculosis* genes, in conjunction with preexisting properties of the *Y. pseudotuberculosis* ancestor, including the presence of a virulence plasmid, pYV, and the capacity to cause septicemia. In the arthropod-parasitizing portion of its life cycle, *Y. pestis* multiplies and forms biofilm-embedded aggregates in the flea midgut after ingestion of a blood meal containing bacteria. In some fleas, biofilm-embedded bacteria eventually fill the proventriculus (a valve connecting the esophagus to the midgut) and block normal blood feeding. Both "blocked" fleas and those containing masses of biofilm-embedded *Y. pestis* without complete blockage inoculate *Y. pestis* into each bite site. The ability of *Y. pestis* to colonize and multiply in fleas fed on infected blood from most hosts requires phospholipase D encoded by the *ymt* gene on the pFra (pMT1) plasmid, and biofilm synthesis requires the chromosomal *hms* locus shared with *Y. pseudotuberculosis.* Recently, it has been shown *Y. pestis* does not require an intact *ymt* gene to infect and be transmitted from fleas fed on blood from the brown rat (*Rattus norvegicus*), although this is required for blood from the black rat (*Rattus rattus*). Three *Y. pseudotuberculosis* genes inhibiting biofilm formation or promoting its degradation are inactivated in *Y. pestis*, together with urease (urease activity otherwise causes acute flea gastrointestinal toxicity). Blockage takes days or weeks to come about after initial infection of the flea and is followed by the flea's death. Many flea vectors (including *X. cheopis*) are also able to transmit plague in an early-phase unblocked state for up to a week after feeding, but 10 fleas in this state are required to infect a mammalian host (mass transmission).

Y. pestis disseminates from the site of inoculation in the mammalian host in a process initially dependent on plasminogen activator Pla, which is encoded by the small pPCP1 (pPst) plasmid. This surface protease activates mammalian plasminogen, degrades complement, and adheres to the extracellular matrix component laminin. Pla is essential for the high-level virulence of *Y. pestis* in mice by subcutaneous or intradermal injection (laboratory proxies for fleabites) and for the development of primary pneumonic plague. When actual fleabite inoculation is used in mouse models, the fimbrial capsule-forming protein (Ca1 or fraction 1; F1 antigen) encoded on pFra increases the efficiency of transmission, and plasminogen activator is required for the formation of buboes.

Paleogenomics (sequencing of DNA extracts from teeth of ancient human remains) shows that the 14th-century Black Death and the 6th-century Plague of Justinian were caused by *Y. pestis* and suggests Black Death mortality selected for protective immune response gene variants now associated with autoimmune disease. It has also revealed that *Y. pestis* infection was a common cause of death in Eurasia in the Bronze Age and Neolithic period. Remarkably, the *ymt* gene is absent from the pFra (pMT1) plasmid in *Y. pestis* sequences from some remains >4000 years old, whereas *pla* is present with intact urease and biofilm regulatory genes. This suggests that plague was a common fatal human infection before flea-borne transmission was fully optimized, possibly spread by the pneumonic or gastrointestinal route.

Macrophages, neutrophils, and dendritic cells are all involved in the innate immune response to flea-transmitted *Y. pestis*. The organism is taken up by macrophages but avoids being killed by autophagy and can also survive and replicate in neutrophils. Rapid transport of the bacteria to regional lymph nodes occurs. *Y. pestis* then undergoes extracellular replication with full expression of its antiphagocytic systems: the type III secretion machines and their effectors encoded by pYV as well as the F1 capsule. These factors prevent neutrophil uptake, and the type III secretion effectors also block extrusion of microbicidal DNA by neutrophils and trigger apoptotic cell death. Immune cell targeting follows binding of the N-formylpeptide receptor (FPR1) on phagocytic cells by LcrV, the needle cap protein of the type III secretion system. Overproduction of LcrV also exerts an anti-inflammatory effect, reducing host immune responses. Likewise, *Y. pestis* lipopolysaccharide is modified to minimize stimulation of host Toll-like receptor 4, thereby reducing protective host inflammatory responses during peripheral infection and prolonging host survival with high-grade bacteremia—an effect that probably enhances the pathogen's subsequent transmission by fleabite.

Replication of *Y. pestis* in a regional lymph node results in the local swelling of the lymph node and periglandular region known as a *bubo*. On histology, the node is found to be hemorrhagic or necrotic, with thrombosed blood vessels, and the lymphoid cells and normal architecture are replaced by large numbers of bacteria and fibrin. Periglandular tissues are inflamed and also contain large numbers of bacteria in a serosanguineous, gelatinous exudate.

Continued spread through the lymphatic vessels to contiguous lymph nodes produces second-order primary buboes. Infection is initially contained in the infected regional lymph nodes, although transient bacteremia can be detected. As infection progresses, spread via efferent lymphatics to the thoracic duct produces high-grade bacteremia. Hematogenous spread to the spleen, liver, and secondary buboes follows, with subsequent uncontrolled septicemia leading to death. In some patients, this septicemic phase occurs without obvious prior bubo development or lung disease (septicemic plague). Hematogenous spread to the lungs results in secondary plague pneumonia, with bacteria initially more prominent in the interstitium than in the air spaces (the reverse being the case in primary plague pneumonia). Hematogenous spread to other organs, including the meninges, can occur.

CLINICAL MANIFESTATIONS

Bubonic Plague After an incubation period of 2–6 days, the onset of bubonic plague is sudden and is characterized by fever (>38°C), malaise, myalgia, dizziness, and increasing pain due to progressive lymphadenitis in the regional lymph nodes near the fleabite or other inoculation site. Lymphadenitis manifests as a tense, tender swelling (bubo) that, when palpated, has a boggy consistency with an underlying hard core. Generally, there is one painful and erythematous bubo with surrounding periganglionic edema. The bubo is most commonly inguinal but can also be crural, axillary **(Fig. 176-2)**, cervical, or submaxillary, depending on the site of the bite. Abdominal pain from intraabdominal node involvement can occur without other visible signs. Children are most likely to present with cervical or axillary buboes.

The differential diagnosis includes acute focal lymphadenopathy of other etiologies, such as streptococcal or staphylococcal infection, tularemia, cat-scratch disease, tick typhus, infectious mononucleosis, or lymphatic filariasis. These infections do not progress as rapidly, are not as painful, and are associated with visible cellulitis or ascending lymphangitis—both of which are absent in plague.

FIGURE 176-2 Plague patient in the southwestern United States with a left axillary bubo and an unusual plague ulcer and eschar at the site of the infective flea bite. *(Reprinted with permission from DT Dennis, GL Campbell: Plague and other Yersinia infections, in Harrison's Principles of Internal Medicine, 17th ed, AS Fauci et al [eds]. New York, McGraw-Hill, Chap. 152, 2008.)*

Without treatment, *Y. pestis* dissemination occurs and causes serious illness, including pneumonia (secondary pneumonic plague) and meningitis. Secondary pneumonic plague can be the source of person-to-person transmission of respiratory infection by productive cough (droplet infection), with the consequent development of primary plague pneumonia. Appropriate treatment of bubonic plague results in fever resolution within 2–5 days, but buboes may remain enlarged for >1 week after initial treatment and can become fluctuant.

Primary Septicemic Plague A minority (10–25%) of infections with *Y. pestis* present as gram-negative septicemia (hypotension, shock) without preceding lymphadenopathy. Septicemic plague occurs in all age groups, but persons >40 years of age are at elevated risk. Some chronic conditions may predispose to septicemic plague: in 2009 in the United States, a fatal laboratory-acquired infection with an attenuated *Y. pestis* strain manifested as septicemic plague in a 60-year-old researcher with diabetes mellitus and undiagnosed hemochromatosis. These conditions also carry an increased risk of septicemia with other pathogenic *Yersinia* species. The term *septicemic plague* can be confusing since most patients with buboes have detectable bacteremia at some stage, with or without systemic signs of sepsis. In laboratory experiments, however, septicemic disease without histologic changes in lymph nodes is seen in a minority of mice infected via fleabites.

Pneumonic Plague Primary pneumonic plague results from inhalation of infectious bacteria in droplets expelled from another person or an animal with primary or secondary plague pneumonia. This syndrome has a short incubation period, averaging from a few hours to 2–3 days (range, 1–7 days), and is characterized by a sudden onset of fever, headache, myalgia, weakness, nausea, vomiting, and dizziness. Respiratory signs—cough, dyspnea, chest pain, and sputum production with hemoptysis—typically arise after 24 h. Progression of initial segmental pneumonitis to lobar pneumonia and then to bilateral lung involvement may occur **(Fig. 176-3)**. The possible release of aerosolized *Y. pestis* bacteria in a bioterrorist attack, manifesting as an outbreak of primary pneumonic plague in nonendemic regions or in an urban setting where plague is rarely seen, has been a source of public health concern. Secondary pneumonic plague is a consequence of bacteremia occurring in ~10–15% of patients with bubonic plague. Bilateral alveolar infiltrates are seen on chest x-ray, and diffuse interstitial pneumonitis with scanty sputum production is typical.

Meningitis Meningeal plague is uncommon, occurring in ≤6% of plague cases reported in the United States. Presentation with headache and fever typically occurs >1 week after the onset of bubonic or septicemic plague and may be associated with suboptimal antimicrobial therapy (delayed therapy, penicillin administration, or low-dose tetracycline treatment) and cervical or axillary buboes.

Pharyngitis Symptomatic plague pharyngitis can follow the consumption of contaminated meat from an animal dying of plague or contact with persons or animals with pneumonic plague. This condition can resemble tonsillitis, with peritonsillar abscess and cervical lymphadenopathy. Asymptomatic pharyngeal carriage of *Y. pestis* can also occur in close contacts of patients with pneumonic plague.

LABORATORY DIAGNOSIS

Because of the scarcity of laboratory facilities in regions where human *Y. pestis* infection is most common, and because of the potential significance of *Y. pestis* isolation in a nonendemic area or an area from which human plague has been absent for many years, the WHO recommends an initial presumptive diagnosis followed by reference laboratory confirmation **(Table 176-1)**. In the United States, comprehensive national diagnostic facilities for plague have been in place since 1999 (Laboratory Response Network for Biological Threats [LRN-B]; *https://emergency.cdc.gov/lrn/index.asp*) to detect possible use of biological terrorism agents, including *Y. pestis*. Routine diagnostic clinical

TABLE 176-1 World Health Organization Case Definitions of Plague

Suspected Case
Clinical presentation suggestive of plague
And
Epidemiological context suggesting possible exposure to plague (exposure to infected humans or animals, or residence in or travel to a known endemic focus within 10 days prior to onset of the disease)
Probable Case
Meeting the definition of a suspected case
***plus* 1 of the following**
• F1 antigen detected in bubo aspirate, sputum, blood, or postmortem tissues by rapid antigen test or direct immunofluorescence
• A single anti-F1 serology without evidence of previous *Yersinia pestis* infection or immunization
• Direct microscopy in a clinical sample: gram-negative coccobacilli that display bipolar staining with Wayson or Wright-Giemsa stain
Confirmed Case
Meeting the definition of a suspected case
***Plus* at least 1 of the following**
• Isolation of *Y. pestis* from a clinical sample (based on appropriate colonial morphology and at least 2 of the following tests positive: phage lysis of cultures at 20–25°C and 37°C; biochemical profile; F1 antigen detection)
• Seroconversion or a fourfold difference in anti-F1 antibody titer in paired serum samples drawn at least 2 weeks apart
• *Y. pestis* DNA positive by species-specific PCR on either clinical sample or culture
Not a case (exclusion of diagnosis)
Meeting the definition of a suspected case
***And* either of the following**
• At least two laboratory tests (rapid antigen test or direct immunofluorescence against F1 antigen, direct microscopy, convalescent serology, culture, PCR) are conducted AND they are negative
• When no confirmatory tests can be performed, 2 negative rapid antigen tests for F1 antigen on 2 clinical specimens collected at 24-h intervals

Abbreviation: PCR, polymerase chain reaction.

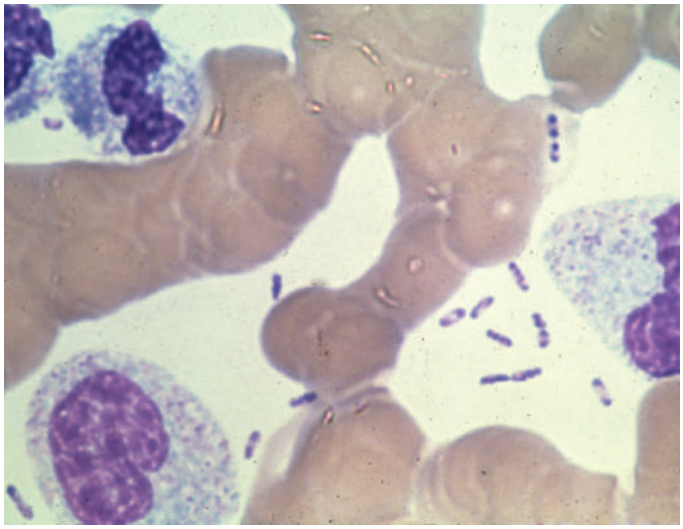

FIGURE 176-4 Peripheral-blood smear from a patient with fatal plague septicemia and shock, showing characteristic bipolar-staining *Yersinia pestis* bacilli (Wright's stain, oil immersion). *(Reprinted with permission from DT Dennis, GL Campbell: Plague and other Yersinia infections, in Harrison's Principles of Internal Medicine, 17th ed, AS Fauci et al [eds]. New York, McGraw-Hill, Chap. 152, 2008.)*

microbiology laboratories that are included in this network as sentinel-level laboratories use joint protocols from the Centers for Disease Control and Prevention (CDC) and the American Society for Microbiology (*https://asm.org/Articles/Policy/Laboratory-Response-Network-LRN-Sentinel-Level-C*) to identify suspected *Y. pestis* isolates and to refer these specimens to LRN-B reference laboratories for confirmatory tests. *Y. pestis* is designated a "Tier 1 select agent" under the Public Health Security and Bioterrorism Preparedness and Response Act of 2002 and subsequent executive orders; the provisions of this act, the Patriot Act of 2001, and related executive orders apply to all U.S. laboratories and individuals working with *Y. pestis*. Details of the applicable regulations are available from the CDC (*www.selectagents.gov*).

Yersinia species are gram-negative coccobacilli (short rods with rounded ends) 1–3 μm in length and 0.5–0.8 μm in diameter. *Y. pestis* in particular appears bipolar (with a "closed safety pin" appearance) and pleomorphic when stained with a polychromatic stain (Wayson or Wright-Giemsa; **Fig. 176-4**). Its lack of motility distinguishes *Y. pestis* from other *Yersinia* species, which are motile at 25°C and nonmotile at 37°C. Transport medium (e.g., Cary-Blair medium) preserves the viability of *Y. pestis* if transport is delayed.

The appropriate specimens for diagnosis of bubonic, pneumonic, and septicemic plague are bubo aspirate, bronchoalveolar lavage fluid or sputum, and blood, respectively. Culture of postmortem organ biopsy samples also can be diagnostic. A bubo aspirate is obtained by injection of 1 mL of sterile normal saline into a bubo under local anesthetic and aspiration of a small amount of (usually blood-stained) fluid. The WHO has provided guidance on how to aspirate buboes and collect sputum from patients with suspected pneumonic plague (*https://www.who.int/emergencies/outbreak-toolkit/disease-outbreak-toolboxes/plague-outbreak-toolbox*; *https://www.who.int/publications/i/item/operational-guidelines-on-plague-surveillance-diagnosis-prevention-and-control*). Gram's staining of these specimens may reveal gram-negative rods, which are shown by Wayson or Wright-Giemsa staining to be bipolar. These bacteria may even be visible in direct blood smears in septicemic plague (Fig. 176-4); this finding indicates very high numbers of circulating bacteria and a poor prognosis.

Y. pestis grows on nutrient agar and other standard laboratory media but forms smaller colonies than do other Enterobacteriaceae. Specimens should be inoculated onto nutrient-rich media such as sheep blood agar (SBA), into nutrient-rich broth such as brain-heart infusion broth, and onto selective agar such as MacConkey or eosin methylene blue (EMB) agar. *Yersinia*-specific CIN (cefsulodin, triclosan [Irgasan], novobiocin) agar can be useful for culture of contaminated specimens, such as sputum. Blood should be cultured in a standard blood culture system. The optimal growth temperature is <37°C (25–29°C), with pinpoint colonies only on SBA at 24 h. Slower growth occurs at 37°C. *Y. pestis* is oxidase-negative, catalase-positive, urease-negative, indole-negative, and lactose-negative. Automated biochemical or mass spectrometry identification systems can misidentify *Y. pestis* as *Y. pseudotuberculosis* or other bacterial species.

Reference laboratory tests for definitive identification of isolates include direct immunofluorescence for F1 antigen; polymerase chain reaction (PCR) for specific *Y. pestis* targets (see below); and specific bacteriophage lysis. PCR can also be applied to diagnostic specimens, as can direct immunofluorescence for F1 antigen (produced in large amounts by *Y. pestis*) by slide microscopy. An immunochromatographic test strip for F1 antigen detection by monoclonal antibodies in clinical specimens (rapid diagnostic test based on the F1 antigen [F1RDT]) has been devised in Madagascar. This method is effective for both laboratory and near-patient use on bubo aspirates and sputum and is now widely used in endemic countries. A similar test strip for Pla antigen has been developed and could be used to detect wild-type or engineered F1-negative virulent strains. Recent clinical experience, including the 2017 Madagascar outbreak, found F1RDT to be at least as sensitive as laboratory culture for diagnosis of bubonic or pneumonic plague. However, there was a low diagnostic yield of culture in this outbreak, possibly due to widespread prehospital use of antimicrobials. The specificity of F1RDT for pneumonic plague diagnosed by culture was 71%; thus, while a positive sputum test is useful in determining whether a symptomatic patient in an endemic area is a probable case requiring treatment, additional laboratory tests are required to confirm

a diagnosis of pneumonic plague. F1RDT had a high negative predictive value in the limited studies available; thus, when other laboratory tests are unavailable, two negative F1RDT tests on clinical specimens 1 day apart can help exclude a diagnosis of plague in a symptomatic patient. This use of F1RDT has been incorporated in the revised WHO international definition of plague introduced following the 2017 Madagascar outbreak.

The WHO requires diagnostic PCR or real-time PCR (RT-PCR) assays to show positivity for at least two different targets specific for *Y. pestis* from a short list comprising the plasmid-based *caf1* (specifying the F1 antigen) and *pla* (specifying plasminogen activator) genes and three other chromosomal genes. *Y. pestis* is included in the U.S. Food and Drug Administration (FDA)-authorized Biofire FilmArray Next Generation Diagnostic System (NGDS) Warrior Panel for use with the FilmArray 2.0 system (Biomérieux) as a medical diagnostic device suitable for whole blood (ethylenediaminetetraacetic acid [EDTA]), blood cultures, and sputum specimens used by U.S. Department of Defense laboratories and laboratories in the CDC-managed LRN-B network. It is also one of 14 viral, bacterial, and protozoan pathogens diagnosable from blood samples with the BioFire Global Fever Special Pathogens Panel recently authorized by the FDA. Detailed phylogeographic DNA sequence data based on culture collections have been accumulated to trace plague evolution, and this approach could be adapted in the future to real-time clinical plague epidemiology.

In the absence of other positive laboratory diagnostic tests, a retrospective serologic diagnosis may be made on the basis of rising titers of hemagglutinating antibody to F1 antigen. Enzyme-linked immunosorbent assays (ELISAs) for IgG and IgM antibodies to F1 antigen are also available.

The white blood cell (WBC) count is generally raised (to 10,000–20,000/μL) in plague, with neutrophilic leukocytosis and a left shift (numerous immature neutrophils); in some cases, however, the WBC count is normal or leukopenia develops. WBC counts are occasionally very high, especially in children (>100,000/μL). Levels of fibrinogen degradation products are elevated in a majority of patients, but platelet counts are usually normal or low-normal. However, disseminated intravascular coagulation, with low platelet counts, prolonged prothrombin times, reduced fibrinogen, and elevated fibrinogen degradation product levels, occurs in a significant minority of patients.

TREATMENT

Plague

Guidelines for the treatment of plague are given in **Table 176-2**. A 10- to 14-day course of antimicrobial therapy (or a course continued until 2 days after fever subsides) is recommended. Streptomycin has historically been the parenteral treatment of choice for plague and is approved for this indication by the FDA. Although not yet approved by the FDA for plague, gentamicin has proved safe and effective in clinical trials in Tanzania and Madagascar and in retrospective reviewed cases in the United States. In view of streptomycin's adverse-reaction profile and limited availability, some experts now recommend gentamicin over streptomycin. The FDA has approved levofloxacin, moxifloxacin, and ciprofloxacin for prophylaxis and treatment of plague (including septicemic and pneumonic plague) under a regulatory approach based on animal studies alone, known as the Animal Rule. Levofloxacin has more efficacy than ciprofloxacin in postexposure prophylaxis of inhalational anthrax in animal models and has also received FDA approval for this indication **(Chap. S4)**; thus, it is a suitable agent for prophylaxis against two diseases in possible bioterrorism exposures. The WHO issued new guidelines in 2021 adding these three fluoroquinolones to the recommended list of first-line medicines for treating bubonic, pneumonic, or septicemic plague. It also recommended moxifloxacin and ofloxacin for plague meningitis, and ciprofloxacin for postexposure prophylaxis.

While systemic chloramphenicol therapy is available in the resource-poor countries primarily affected by plague, it is less likely to be available or used in high-income countries because of its adverse effect profile. Tetracyclines are also effective and can be given by mouth but are not generally recommended for children age <7 years because of tooth discoloration. Doxycycline is the tetracycline of choice; at an oral dosage of 100 mg twice daily, this drug was as effective as intramuscular gentamicin (2.5 mg/kg twice daily) in a trial in Tanzania. There is recent evidence that doxycycline does not cause dental staining in children because it binds calcium less readily than other tetracyclines.

Although *Y. pestis* is sensitive to β-lactam drugs in vitro and these drugs have been efficacious against plague in some animal models, the response to penicillins has been poor in some clinical cases; thus β-lactams and macrolides are not generally recommended as first-line therapy. Chloramphenicol, alone or in combination, is recommended for some focal complications of plague (e.g., meningitis, endophthalmitis, myocarditis) because of its tissue penetration properties. Fluoroquinolones, effective in vitro

TABLE 176-2 Guidelines for the Treatment of Plague

DRUG	DAILY DOSE	DOSING INTERVAL, h	ROUTE
Gentamicin			
Adult	5 mg/kg[a]	24	IM/IV
Child	4.5–7.5 mg/kg[a]	24	IM/IV
Streptomycin			
Adult	2 g	12	IM
Child	30 mg/kg (maximum 1 g per dose)	12	IM
Levofloxacin			
Adult (child >50 kg)	750 (500–750) mg	24	PO/IV
Child <50 kg and ≥6 months of age	16 mg/kg (maximum, 250 mg/dose)	12	PO/IV
Ciprofloxacin			
Adult	1500 mg	12	PO
	1200 mg	8	IV
Child	30–45 mg/kg (maximum, 500 mg/dose)	8–12	PO
	20–30 mg/kg (maximum, 400 mg/dose)	8–12	IV
Moxifloxacin			
Adult	400 mg	24	PO/IV
Doxycycline			
Adult and child ≥45 kg	200 mg (200 mg loading dose)	12	PO/IV
Child <45 kg	4.4 mg/kg (maximum, 100 mg/dose, 4.4 mg/kg loading dose)	12	PO/IV
Tetracycline			
Adult	2 g	6	PO/IV
Child >8 y	40–50 mg/kg	6	PO/IV
Chloramphenicol			
Adult	50–100 mg/kg	6	PO/IV
Child >2 y	50–100 mg/kg (maximum, 4 g)	6	PO/IV

[a]Aminoglycoside dose is adjusted with impaired renal function. No trial data have been published for once-daily gentamicin therapy for plague in adults or children, but this regimen is efficacious in gram-negative sepsis of other etiologies and has been successful in a recent outbreak of pneumonic plague in the Democratic Republic of the Congo. Neonates (up to 1 week of age) and premature infants should receive gentamicin at 4 mg/kg IV once daily.

Source: CA Nelson et al: Antimicrobial treatment and prophylaxis of plague: Recommendations for naturally acquired infections and bioterrorism response. MMWR Recomm Rep 70(No. RR-3):1, 2021. Provides detailed guidelines on recommended regimens for pneumonic versus bubonic plague, plague meningitis, treatment during pregnancy and lactation, and neonatal infection. Recommends dual therapy with two different classes of antimicrobials for initial treatment of patients with severe pneumonic or septicemic plague and patients infected after intentional release of *Yersinia pestis*.

and in animal models, are recommended in guidelines for possible bioterrorism-associated pneumonic plague and are increasingly used in plague therapy.

PREVENTION

In endemic areas, the control of plague in humans is based on reduction of the likelihood of being bitten by infected fleas or exposed to infected droplets from either humans or animals with plague pneumonia. In the United States, residence and outdoor activity or contact with wild or pet animals in rural areas of western states where epizootics occur are the main risk factors for infection. To assess potential risks to humans in specific areas, surveillance for *Y. pestis* infection among animal plague hosts and vectors is carried out regularly as well as in response to observed animal die-offs. Personal protective measures include avoidance of areas where a plague epizootic has been identified and publicized (e.g., by warning signs or closure of campsites). Sick or dead animals should not be handled by the general public. Hunters, zoologists, and pet owners should wear gloves if handling wild-animal carcasses in endemic areas. General measures to avoid rodent fleabite during outdoor activity are appropriate and include the use of insect repellent, insecticide, and protective clothing. General measures to reduce peridomestic and occupational human contact with rodents are advised and include rodent-proofing of buildings and food-waste stores and removal of potential rodent habitats (e.g., woodpiles and junk heaps). Flea control by insecticide treatment of wild rodents is an effective means of minimizing human contact with plague if an epizootic is identified in an area close to human habitation. Any attempt to reduce rodent numbers must be preceded by flea suppression to reduce the migration of infected fleas to human hosts. An oral F1-V subunit vaccine using raccoon poxvirus (RCN) as a vector (sylvatic plague vaccine) is partially protective against plague when administered to wild prairie dogs in field trials and may in the future provide a means of reducing the risk of human exposure to *Y. pestis*.

Patients in whom pneumonic plague is suspected should be managed in isolation (with negative pressure, if available), with droplet precautions observed until pneumonia is excluded or effective antimicrobial therapy has been given for 48 h. Review of the literature published before the advent of antimicrobial agents suggests that the main infective risk is posed by patients in the final stages of disease who are coughing up sputum with plentiful visible blood and/or pus. Cotton and gauze masks were protective in these circumstances. Current surgical masks capable of barrier protection against droplets, including large respiratory particles, are probably protective, but the differential diagnosis of fever and hemoptysis in plague-endemic areas includes small airborne particle-transmitted infections such as tuberculosis. In addition, WHO guidance recommends that personal protective equipment for potential aerosol-generating procedures (e.g., collection of respiratory samples from patients with suspected or confirmed plague) or handling the remains of someone who was infected with plague should include a fit-tested N95 face mask, a gown, gloves, and a face shield or goggles.

Antimicrobial Prophylaxis Postexposure antimicrobial prophylaxis lasting 7 days is recommended following household, hospital, or other close contact with persons with untreated pneumonic plague. (*Close contact* is defined as contact with a patient at <2 m.) In animal aerosol-infection studies, levofloxacin and ciprofloxacin are associated with higher survival rates than doxycycline **(Table 176-3)**.

Immunization Studies with candidate plague vaccines in animal models show that neutralizing antibody provides protection against exposure but that cell-mediated immunity is critical for protection and clearance of *Y. pestis* from the host. A killed whole-cell vaccine used in humans required multiple doses, caused significant local and systemic reactions, and was not protective against pneumonic plague; this vaccine is not currently available. A live attenuated vaccine based on strain EV76 is still used in countries of the former Soviet Union and China but has significant side effects. Different subunit vaccines devised by governmental agencies in the United States, United Kingdom, and China all comprising recombinant F1 (rF1) and various recombinant V (rV) proteins produced in *Escherichia coli*, combined either as a fusion protein or as a mixture, purified, and adsorbed to aluminum hydroxide for injection are close to licensing. This combination protects mice and various nonhuman primates in laboratory models of bubonic and pneumonic plague and has been evaluated in phase 2 clinical trials. Prelicensing field-efficacy studies (phase 3 trials) are difficult to devise because of plague epidemiology. In the United States, the FDA will assess plague vaccines for human use under the Animal Rule, using efficacy data from animal studies and antibodies and other correlates of immunity from human vaccinees (*https://www.fda.gov/emergency-preparedness-and-response/mcm-regulatory-science/animal-rule-information*), and the rF1-V subunit vaccine has orphan drug status. The WHO has produced a Target Product Profile (TPP) for phase 3 trial design and prioritization of the vaccine candidates. Candidate vaccines include protein subunit, live-attenuated, and bacterial, viral, and bacteriophage vectors, DNA, and mRNA vaccines. Antigens other than F1 and V are being investigated because of the recovery of F1-negative *Y. pestis* strains from natural sources and the observation that F1 antigen is not required for virulence in primate models of pneumonic plague.

TABLE 176-3 Guidelines for Plague Prophylaxis

DRUG	DAILY DOSE	DOSING INTERVAL, h	ROUTE
Doxycycline			
Adult	200 mg	12 or 24	PO
Child ≥8 y	≥45 kg: adult dose	12	PO
	≤45 kg: 4.4 mg/kg (maximum, 200 mg)	12	PO
Tetracycline			
Adult	2 g	6 or 12	PO
Child ≥8 y	40 mg/kg (maximum 500 mg dose)	6 or 12	PO
Levofloxacin			
Adult and child >50 kg	500–750 mg	24	PO

YERSINIOSIS

Yersiniosis is a zoonotic infection with an enteropathogenic *Yersinia* species, usually *Y. enterocolitica* or *Y. pseudotuberculosis*. The usual hosts for these organisms are pigs and other wild and domestic animals; humans are usually infected by the oral route, and outbreaks from contaminated food occur. Yersiniosis is most common in childhood and in colder climates. Patients present with abdominal pain and sometimes with diarrhea (which may not occur in up to 50% of cases). *Y. enterocolitica* is more closely associated with terminal ileitis and *Y. pseudotuberculosis* with mesenteric adenitis, but both organisms may cause mesenteric adenitis and symptoms of abdominal pain and tenderness that result in pseudoappendicitis, with the surgical removal of a normal appendix. Diagnosis was historically based on culture of the organism or convalescent serology, but some proprietary multiplex PCR systems for gastrointestinal infection diagnosis now include *Y. enterocolitica* (but not *Y. pseudotuberculosis*). *Y. pseudotuberculosis* and some rarer strains of *Y. enterocolitica* are especially likely to cause systemic infection, which is also more likely in patients with diabetes or iron overload. Systemic sepsis is treatable with antimicrobial agents, but postinfective arthropathy responds poorly to such therapy. Over

twenty other *Yersinia* species lacking the virulence plasmid pYV common to *Y. pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica* are now recognized, primarily from genome sequencing. These are, at most, opportunistic pathogens of humans (including *Y. aldovae*, *Y. aleksiciae*, *Y. bercovieri*, *Y. entomophaga*, *Y. frederiksenii*, *Y. hibernica*, *Y. intermedia*, *Y. kristensenii*, *Y. massiliensis*, *Y. mollaretii*, *Y. nurmii*, *Y. pekkanenii*, *Y. rohdei*, *Y. similis*, *Y. ruckeri*, and *Y. wautersii*). Molecular phylogeny shows that *Y. enterocolitica* is more distantly related to *Y. pseudotuberculosis* than these other *Yersinia* species, and the similar virulence plasmid they share has probably been acquired independently by at least one of the two since the species diverged.

EPIDEMIOLOGY

Y. enterocolitica *Y. enterocolitica* is found worldwide and has been isolated from a wide variety of wild and domestic animals and environmental samples, including samples of food and water. In vitro, *Y. enterocolitica* is resistant to predation by the protozoon *Acanthamoeba castellani* and can survive inside it, suggesting a possible mode of environmental persistence. Strains are classically differentiated by biochemical reactions (biovar or biotype) combined with serogroup and, increasingly, by whole genome sequence data used for core genome multilocus sequence typing (cgMLST) (see "Laboratory Diagnosis," below).

Yersiniosis, >99% due to *Y. enterocolitica*, remains the third most common bacterial food-borne zoonosis reported in Europe, especially prevalent in Germany and Scandinavia. The incidence is highest among children; children <4 years of age are more likely to present with diarrhea than are older children. Abdominal pain with mesenteric adenitis and terminal ileitis is more prominent among older children and adults. Septicemia is more likely in patients with preexisting conditions such as diabetes mellitus, liver disease, any condition involving iron overload (including thalassemia and hemochromatosis), advanced age, malignancy, or HIV/AIDS. As in enteritis of other bacterial etiologies, postinfective complications such as reactive arthritis occur mainly in individuals who are HLA-B27 positive. Erythema nodosum **(Fig. A1-39)** following *Yersinia* infection is not associated with HLA-B27 and is more common among women than among men.

Consumption or preparation of raw pork products (such as chitterlings) and some processed pork products is strongly linked with infection because a high percentage of pigs carry pathogenic *Y. enterocolitica* strains. Outbreaks of *Y. enterocolitica* infection have been associated with consumption of milk (pasteurized, unpasteurized, and chocolate-flavored) and various ready-to-eat vegetables including fresh spinach that were processed or washed with water. Person-to-person transmission is suspected in a few cases (e.g., in nosocomial and familial outbreaks) but is much less likely with *Y. enterocolitica* than with other causes of gastrointestinal infection, such as *Salmonella*. A multivariate analysis indicates that contact with companion animals is a risk factor for *Y. enterocolitica* infection among children in Sweden, and low-level colonization of dogs and cats with *Y. enterocolitica* has been reported. Transfusion-associated septicemia due to *Y. enterocolitica*, while recognized as a very rare but frequently fatal event for >30 years, has been difficult to eradicate.

Y. pseudotuberculosis *Y. pseudotuberculosis* is much less frequently reported as a cause of human disease than *Y. enterocolitica*, and infection with *Y. pseudotuberculosis* is more likely to present as fever and abdominal pain due to mesenteric lymphadenitis and be identified from a blood culture isolate. This organism is associated with wild mammals (rodents, rabbits, and deer), birds, and domestic pigs. Although outbreaks are generally rare, several have recently occurred associated by food culture or dietary history with consumption of lettuce or raw carrots (Finland, New Zealand), tomatoes (France), or unpasteurized milk (Finland). Strains have historically been differentiated by combined biochemical reactions (biovar) and serogroup. cgMLST is now used for investigation of both *Y. enterocolitica* and *Y. pseudotuberculosis* outbreaks in several countries.

PATHOGENESIS

The usual route of infection is oral. Studies with both *Y. enterocolitica* and *Y. pseudotuberculosis* in animal models suggest that initial replication in the small intestine is followed by invasion of Peyer's patches of the distal ileum via M cells, with onward spread to mesenteric lymph nodes. The liver and spleen can also be involved after oral infection. The characteristic histologic appearance of enteropathogenic *Yersinia* after invasion of host tissues is as extracellular microabscesses surrounded by an epithelioid granulomatous lesion.

Experiments involving oral infection of mice with tagged *Y. enterocolitica* show that only a very small proportion of bacteria in the gut invade tissues. Individual bacterial clones from an orally inoculated pool give rise to each microabscess in a Peyer's patch, and the host restricts the invasion of previously infected Peyer's patches. A prior model positing progressive bacterial spread from Peyer's patches and mesenteric lymph nodes to the liver and spleen appears to be inaccurate: spread of *Y. pseudotuberculosis* and *Y. enterocolitica* to the liver and spleen of mice occurs independently of regional lymph node colonization and in mice lacking Peyer's patches.

Invasion requires the expression of several nonfimbrial adhesins, such as invasin (Inv) and—in *Y. pseudotuberculosis*—*Yersinia* adhesin A (YadA). Inv interacts directly with β1 integrins, which are expressed on the apical surfaces of M cells but not enterocytes. YadA of *Y. pseudotuberculosis* interacts with extracellular matrix proteins such as collagen and fibronectin to facilitate host cell integrin association and invasion. YadA of *Y. enterocolitica* lacks a crucial N-terminal region and binds collagen and laminin but not fibronectin and does not cause invasion. Inv is chromosomally encoded, whereas YadA is encoded on the virulence plasmid pYV. YadA also helps to confer serum resistance in *Y. enterocolitica* by binding host complement regulators such as factor H and C4-binding protein. Another chromosomal gene, *ail* (attachment and invasion locus), encodes the extracellular protein Ail, which is the main factor conferring serum resistance in *Y. pseudotuberculosis* by binding these complement regulators.

By binding to host cell surfaces, YadA allows targeting of immune effector cells by the pYV plasmid–encoded type III secretion system (injectisome). As a consequence, the host's innate immune response is altered; toxins (*Yersinia* outer proteins, or Yops) are injected into host macrophages, neutrophils, and dendritic cells, affecting signal transduction pathways, resulting in reduced phagocytosis and inhibited production of reactive oxygen species by neutrophils, and triggering apoptosis of macrophages. Other factors functional in invasive disease include yersiniabactin (Ybt), a siderophore produced by some strains of *Y. pseudotuberculosis* and *Y. enterocolitica* as well as other Enterobacterales. Ybt allows bacteria to access iron from saturated lactoferrin during infection and reduces production of reactive oxygen species by innate immune effector cells, thereby decreasing bacterial killing. *Y. pseudotuberculosis* and *Y. pestis* make other siderophores apart from Ybt.

CLINICAL MANIFESTATIONS

Self-limiting diarrhea is the most common reported presentation in infection with pathogenic *Y. enterocolitica*, especially in children <4 years of age, who form the single largest group in most case series. Blood may be detected in diarrheal stool. Older children and adults are more likely than younger children to present with abdominal pain, which can be localized to the right iliac fossa—a situation that often leads to laparotomy for presumed appendicitis (pseudoappendicitis). Appendectomy is not indicated for *Yersinia* infection causing pseudoappendicitis. Thickening of the terminal ileum and cecum is seen on endoscopy and ultrasound, with elevated round or oval lesions that may overlie Peyer's patches. Mesenteric lymph nodes are enlarged. Ulcerations of the mucosa are noted on endoscopy. Gastrointestinal complications include granulomatous appendicitis, a chronic inflammatory condition affecting the appendix that is responsible for ≤2% of cases of appendicitis; *Yersinia* is involved in a minority of cases. *Y. enterocolitica* infection can present as acute pharyngitis with or without other gastrointestinal symptoms. Fatal *Y. enterocolitica* pharyngitis has been recorded. Mycotic aneurysm can follow *Y. enterocolitica* bacteremia, as can focal infection (abscess) in many other sites and body compartments (liver, spleen, kidney, bone, meninges, endocardium).

Y. pseudotuberculosis infection is more likely to present as abdominal pain and fever than as diarrhea. A superantigenic toxin—

Y. pseudotuberculosis mitogen (YPM)—is produced by strains seen in eastern Russia in association with Far Eastern scarlet-like fever (FESLF), a childhood illness with desquamating rash, arthralgia, and toxic shock. A similar illness is recognized in Japan (Izumi fever) and Korea. Similarities have been noted with Kawasaki disease, the idiopathic acute systematic vasculitis of childhood. There is an epidemiologic link between exposure of populations to superantigen-positive *Y. pseudotuberculosis* and an elevated incidence of Kawasaki disease.

Y. enterocolitica or *Y. pseudotuberculosis* septicemia presents as a severe illness with fever and leukocytosis, often without localizing features, and is significantly associated with predisposing conditions such as diabetes mellitus, liver disease, and iron overload. Hemochromatosis combines several of these risk factors. Administration of iron chelators like desferrioxamine, which provide iron accessible to *Yersinia* (and have an inhibitory effect on neutrophil function), may result in *Yersinia* septicemia in patients with iron overload who presumably have an otherwise mild gastrointestinal infection. HIV/AIDS has been associated with *Y. pseudotuberculosis* septicemia. The unusual phenomenon of transfusion-associated septicemia is linked to the ability of *Y. enterocolitica* to multiply at refrigerator temperature (psychrotrophy). Typically, the transfused unit has been stored for >20 days, and it is believed that small numbers of yersiniae from an apparently healthy donor with subclinical bacteremia are amplified to very high numbers by growth inside the bag at ≤4°C, with consequent septic shock after transfusion. Complete prevention of this very rare event (one case in several million transfused units in countries such as the United States and France) without unacceptable restriction in the blood supply has not yet been devised.

POSTINFECTIVE PHENOMENA

As in other invasive intestinal infections (salmonellosis, shigellosis), reactive arthritis (articular arthritis of multiple joints developing within 2–4 weeks of a preceding infection) occurs as a result of autoimmune activity initiated by the deposition of bacterial components (not viable bacteria) in joints in combination with the immune response to invading bacteria. The majority of individuals affected by reactive arthritis due to *Yersinia* are HLA-B27 positive. Myocarditis with electrocardiographic ST-segment abnormalities may occur with *Yersinia*-associated reactive arthritis. Most *Yersinia*-associated cases follow *Y. enterocolitica* infection (presumably because it is more common than infection with other species), but *Y. pseudotuberculosis*–associated reactive arthritis is also well documented in Finland, where sporadic and outbreak infections with *Y. pseudotuberculosis* are more common than in other countries. Of infected individuals identified in a recent *Y. pseudotuberculosis* serotype O:3 outbreak in Finland, 12% developed reactive arthritis affecting the small joints of the hands and feet, knees, ankles, and shoulders and lasting >6 months in most cases. Erythema nodosum **(Fig. A1-39)** occurs after *Yersinia* infection (more commonly in women) with no evidence of HLA-B27 linkage.

There is a long-standing association between antithyroid and anti-*Yersinia* antibodies. Antibody evidence of prior *Y. enterocolitica* infection in Graves' disease and increased levels of antithyroid antibody in patients with *Y. enterocolitica* antibodies were first noted in the 1970s. *Y. enterocolitica* contains a thyroid-stimulating hormone (TSH)–binding site that is recognized by antibodies to TSH from Graves' disease patients. Raised titers of antibodies to *Y. enterocolitica* whole cells and Yops have been found in some series of Graves' disease patients but not in others. It remains unclear whether this cross-reactivity is significant in the etiology of Graves' disease.

LABORATORY DIAGNOSIS

Standard laboratory culture methods can be used to isolate enteropathogenic *Yersinia* species from sterile samples, including blood and cerebrospinal fluid. Culture on specific selective media (CIN agar), with or without pre-enrichment in broth or phosphate-buffered saline at either 4°C or 16°C, is the basis of most schema for isolation of yersiniae from stool or other nonsterile samples. Outside known high-incidence areas, specific culture may only be carried out by laboratories on request, or if a multiplex PCR screen detects *Y. enterocolitica*–specific DNA in feces. Several CE-marked, FDA-approved kits for enteric pathogens now offer *Y. enterocolitica* detection (the precise assay targets are not disclosed), and their use has increased detection of *Y. enterocolitica*. These kits generally do not detect *Y. pseudotuberculosis*. A standard for PCR detection of pathogenic *Y. enterocolitica* and *Y. pseudotuberculosis* in food samples is available from the International Organization for Standardization.

Matrix-assisted laser desorption ionization time of flight (MALDI-TOF) mass spectrometry systems can speciate isolates of *Y. enterocolitica* and *Y. pseudotuberculosis* (but cannot separate *Y. pestis* from *Y. pseudotuberculosis*). Most clinical infections from typical presentations described above are associated with virulence plasmid-containing low-pathogenic strains, which genome sequencing has assigned to four phylogroups that correspond to the classical groups of Biotype 2/3 serogroup O:9 (BT2/3 O:9), BT4 O:3, BT2/3 O:5,27, and BT5. A highly pathogenic (mouse-lethal) virulence plasmid-containing phylogroup (BT1B O:8) used to be commonly reported from North America, where it is now rare, but occasional cases are now reported from Europe and Japan. A current area under active research is the clinical significance of a further phylogroup comprising Biotype 1A *Y. enterocolitica* strains of various serotypes. These comprise >50% of *Y. enterocolitica* fecal isolates in recent clinical studies from England, France, and China and >20% in New Zealand. They have generally been regarded as nonpathogenic because they lack the virulence plasmid and are not pathogenic in mouse-infection models. However, they do contain other genes associated with *Yersinia* pathogenesis, invade epithelial cells and macrophages in vitro, and are pathogenic in an insect model. They form the majority of *Y. enterocolitica* cultures from food sampled in the United Kingdom and France.

Because of the frequency with which the virulence plasmid is lost on laboratory subculture, combined biochemical identification (with biotyping according to a standard schema) and serologic identification was usually required to interpret the significance of an isolate of *Y. enterocolitica* from a nonsterile site. Whole genome DNA sequencing applying a *Yersinia* genus wide seven-gene multilocus sequence typing (MLST) scheme can now speciate *Y. enterocolitica, Y. pestis,* and *Y. pseudotuberculosis* and differentiate *Y. enterocolitica* biotypes. A cgMLST scheme provides a more detailed population structure and has been used for outbreak tracing and revealing novel, as yet phenotypically undefined *Yersinia* species.

Agglutinating or ELISA antibody titers to specific O-antigen types are used in the retrospective diagnosis of both *Y. enterocolitica* and *Y. pseudotuberculosis* infections. IgA and IgG antibodies persist in patients with reactive arthritis. Serologic cross-reactions between *Y. enterocolitica* serogroup O:9 and *Brucella* are due to the similarity of their lipopolysaccharide structures. Multiple assays are required to cover even the predominant serogroups (*Y. enterocolitica* O:3, O5,27, and O:9; *Y. pseudotuberculosis* O:1a, O:1b, and O:3), and these assays are generally available only in reference laboratories. ELISA and western blot tests for antibodies to Yops, which are expressed by all pathogenic strains of *Y. enterocolitica* and *Y. pseudotuberculosis*, are also available; most of the positivity in these assays probably relates to previous infection with *Y. enterocolitica*.

TREATMENT

Yersiniosis

Most cases of diarrhea caused by enteropathogenic *Yersinia* are self-limiting. Data from clinical trials do not support antimicrobial treatment for adults or children with *Y. enterocolitica* diarrhea. Systemic infections with bacteremia or focal infections outside the gastrointestinal tract generally require antimicrobial therapy. Infants <3 months of age with documented *Y. enterocolitica* infection may require antimicrobial treatment because of the increased likelihood of bacteremia in this age group. *Y. enterocolitica* strains nearly always express β-lactamases. Because of the relative rarity of systemic *Y. enterocolitica* infection, there are no clinical trial data to guide antimicrobial choice or to suggest the optimal dose and

duration of therapy. On the basis of retrospective case series and in vitro sensitivity data, fluoroquinolone therapy is effective for bacteremia in adults; for example, ciprofloxacin is given at a typical dose of 500 mg twice daily by mouth or 400 mg twice daily IV for at least 2 weeks (longer if positive blood cultures persist). A third-generation cephalosporin is an alternative—e.g., cefotaxime (typical dose, 6–8 g/d in 3 or 4 divided doses) or ceftriaxone. In children, third-generation cephalosporins are effective; for example, cefotaxime is given to children ≥1 month of age at a typical dose of 75–100 mg/kg per day in 3 or 4 divided doses, with an increase to 150–200 mg/kg per day in severe cases (maximal daily dose, 8–10 g). Amoxicillin and amoxicillin-clavulanate have shown poor efficacy in case series. Trimethoprim-sulfamethoxazole, gentamicin, and imipenem are all active in vitro. *Y. pseudotuberculosis* strains do not express β-lactamase but are intrinsically resistant to polymyxin. Because human infection with *Y. pseudotuberculosis* is less common than that with *Y. enterocolitica*, less case information is available; however, studies in mice suggest that ampicillin is ineffective. Drugs similar to those used against *Y. enterocolitica* should be used. The best results have been obtained with a quinolone.

Some trials of treatment for reactive arthritis (with a large proportion of cases due to *Yersinia*) found that 3 months of oral ciprofloxacin therapy did not affect outcome. One trial in which the same therapy was given specifically for *Y. enterocolitica*–reactive arthritis found that, while outcome indeed was not affected, there was a trend toward faster remission of symptoms in the treated group. Follow-up 4–7 years after initial antibiotic treatment of reactive arthritis (predominantly following *Salmonella* and *Yersinia* infections) demonstrated apparent efficacy in the prevention of chronic arthritis in HLA-B27-positive individuals. A trial showing that azithromycin therapy did not affect outcome in reactive arthritis included cases thought to have followed yersiniosis, although no breakdown of cases was provided.

PREVENTION AND CONTROL

Current control measures are similar to those used against other enteric pathogens like *Salmonella* and *Campylobacter*, which colonize the intestine of food animals. The focus is on safe handling and processing of food. No vaccine is effective in preventing intestinal colonization of food animals by enteropathogenic *Yersinia*. Consumption of food made from raw pork (which is popular in Germany and Belgium) should be discouraged at present because it is not possible to eliminate contamination with the enteropathogenic *Yersinia* strains found worldwide in pigs. Exposure of infants to raw pig intestine during domestic preparation of chitterlings is inadvisable. Modification of abattoir technique in Scandinavian countries from the 1990s onward included the removal of pig intestines in a closed plastic bag; levels of carcass contamination with *Y. enterocolitica* were reduced, but such contamination was not eliminated. Experimental pig herds free of pathogenic *Y. enterocolitica* O:3 (and also of *Salmonella*, *Campylobacter*, *Toxoplasma*, and *Trichinella*) have been established by selective breeding in Norway but remain rare. In the food industry, vigilance is required because of the potential for large outbreaks if small numbers of enteropathogenic yersiniae contaminate any ready-to-eat food whose safe preservation is based on refrigeration before consumption.

The rare phenomenon of contamination of blood for transfusion has proved impossible to eradicate. However, leukodepletion is now practiced in most blood transfusion centers, primarily to prevent nonhemolytic febrile transfusion reactions and alloimmunization against HLA antigens. This measure reduces but does not eliminate the risk of *Yersinia* blood contamination.

Notification of yersiniosis is now obligatory in some countries.

177 *Bartonella* Infections, Including Cat-Scratch Disease

Michael Giladi, Moshe Ephros

Bartonella species are fastidious, facultative intracellular, slow-growing, gram-negative bacteria that cause a broad spectrum of diseases in humans. This genus includes >40 distinct species or subspecies, of which at least 20 have been recognized as confirmed or potential human pathogens; *Bartonella bacilliformis*, *Bartonella quintana*, and *Bartonella henselae* are most commonly identified **(Table 177-1)**. Most *Bartonella* species have successfully adapted to survival in specific domestic or wild mammals. Prolonged intraerythrocytic and endothelial cell infection in these animals creates a niche where the bacteria are protected from both innate and adaptive immunity and which serves as a reservoir for human infections. Chronic bacteremia, which may persist even following prolonged antimicrobial therapy, is a typical finding in *Bartonella*-hosting mammals. Adhesion and entry to endothelial cells and erythrocytes is facilitated by the *Bartonella* adhesin A or variably expressed outer-membrane proteins. *Bartonella* characteristically evades the host immune system by modification of its virulence factors (e.g., lipopolysaccharides or flagella) and by attenuation of the immune response. Arthropod vectors are often involved. Humans are incidental hosts for most *Bartonella* species with the exception of *B. quintana* and *B. bacilliformis*, which are not considered zoonotic agents. Isolation and characterization of *Bartonella* species are difficult and require special techniques. Clinical presentation generally depends on both the infecting *Bartonella* species and the immune status of the infected individual. *Bartonella* species are susceptible to many antibiotics in vitro; however, clinical responses to therapy and studies in animal

TABLE 177-1 *Bartonella* Species Known or Suspected to Be Human Pathogens

BARTONELLA SPECIES[a]	DISEASE(S)[b]	RESERVOIR HOST(S)[c]	ARTHROPOD VECTOR
B. alsatica	Endocarditis, lymphadenitis, vascular graft infection	Rabbits	Fleas
B. ancashensis	Verruga peruana, bacteremia	Unknown	Unknown
B. bacilliformis	Carrión's disease	Humans	Sandflies (*Lutzomyia verrucarum*)
B. clarridgeiae	Possibly cat-scratch disease	Cats, dogs	Unknown
B. doshiae	Bacteremia, arthralgia, blurred vision	Voles, rats	Unknown
B. elizabethae	Endocarditis	Rats, dogs	Fleas
B. grahamii	Lymphadenopathy, possibly retinitis and retinal vascular occlusion	Mice, voles, rats, deer	Fleas
B. henselae	Cat-scratch disease, bacillary angiomatosis, bacillary peliosis, bacteremia, endocarditis	Cats, other felines	Cat fleas (*Ctenocephalides felis*): associated with cat-to-cat, but not with cat-to-human, transmission
B. koehlerae	Endocarditis	Cats	Unknown
B. kosoyi	Lymphadenopathy	Rats	Fleas
"Candidatus Bartonella *mayotimonensis"*[d]	Endocarditis	Bats	Unknown
"Candidatus Bartonella *melophagi"*[d]	Various clinical manifestations	Sheep	Sheep keds
B. quintana	Trench fever, chronic bacteremia, bacillary angiomatosis, endocarditis	Humans	Human body lice (*Pediculus humanus corporis*)
B. rochalimae	Bacteremia, fever, splenomegaly	Foxes, coyotes, dogs, skunks, rats, other rodents	Fleas
B. schoenbuchensis	Bacteremia, fever, myalgia, deer ked dermatitis?	Cattle, roe deer, moose	Unknown
B. tamiae	Bacteremia, fever, myalgia, rash	Rats	Unknown
B. tribocorum	Bacteremia, myalgia, headache	Rats, mice	Unknown
B. vinsonii subsp. *arupensis*	Endocarditis, febrile illness	Mice, dogs	Ticks
B. vinsonii subsp. *berkhoffii*	Endocarditis	Domestic dogs, coyotes, gray foxes	Ticks
"Candidatus Bartonella *washoensis"*[d]	Endocarditis, myocarditis, meningitis	Squirrels, rabbits, prairie dogs, possibly other rodents	Fleas, ticks

[a]Many other *Bartonella* species exist but are not recognized as human pathogens. [b]Animal-associated *Bartonella* species (*B. henselae, B. doshiae, B. schoenbuchensis,* and *B. tribocorum*) were isolated from blood of patients who reported tick bites and chronic symptoms such as fatigue and myalgia. DNA of *B. henselae, B. vinsonii* subsp. *berkhoffii, B. koehlerae,* or *B. melophagi* or co-infection with more than one *Bartonella* species was detected by polymerase chain reaction in blood samples from patients with extensive arthropod and animal exposure who presented with chronic neurologic or neurocognitive syndromes. The causal relationship between bacteremia with these pathogens, tick bites, and clinical manifestations needs to be established. [c]Animals are implicated when existing evidence supports their infection with *Bartonella* species. Data supporting animal-to-human transmission may be lacking. [d]*Candidatus* is a taxonomic status for bacteria that cannot be described in sufficient detail to warrant establishment of a novel taxon or cannot be cultured or propagated in culture media. The phylogenetic relatedness of these bacteria has been determined by gene amplification and sequence analysis.

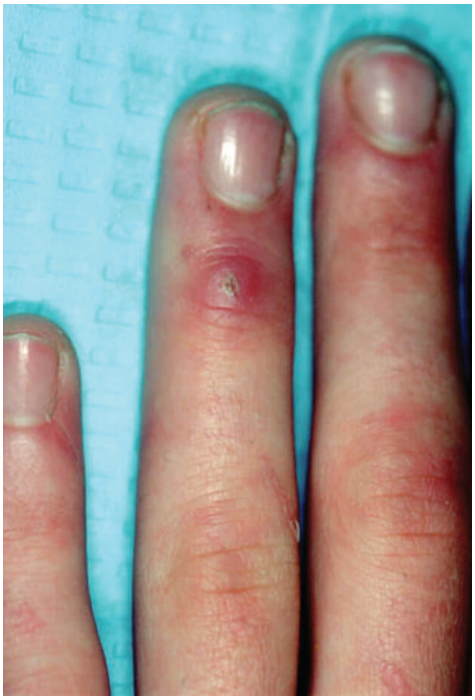
models suggest that the minimal inhibitory concentrations of many antimicrobial agents correlate poorly with the drugs' in vivo efficacies in patients with *Bartonella* infections.

CAT-SCRATCH DISEASE

DEFINITION AND ETIOLOGY

Usually a self-limited illness, cat-scratch disease (CSD) has two general clinical presentations. *Typical* CSD, the more common, is characterized by subacute regional lymphadenopathy; *atypical* or *extranodal* CSD is the collective designation for numerous extranodal manifestations involving various organs. *B. henselae* is the principal etiologic agent of CSD. Rare cases have been associated with *Afipia felis* and other *Bartonella* species.

EPIDEMIOLOGY



CSD occurs worldwide, favoring warm and humid climates. In temperate climates, incidence peaks during fall and winter. Adults are affected nearly as frequently as children. Intrafamilial clustering is rare, and person-to-person transmission does not occur. Apparently healthy bacteremic cats constitute the major reservoir of *B. henselae*, and cat fleas (*Ctenocephalides felis*) may be responsible for cat-to-cat transmission. CSD usually follows contact with cats (especially kittens), but other animals (e.g., dogs) have been implicated as possible reservoirs in rare instances. In the United States, the estimated annual disease incidence is 4–9 outpatient cases per 100,000 population with a higher incidence among those who lived in the southern United States and among children 5–9 years of age. About 5–10% of patients in the United States are hospitalized. A higher proportion of hospitalization has been reported in Israel.

PATHOGENESIS

Although cat fleas are likely responsible for cat-to-cat transmission, the mode of cat-to-human transmission is undetermined. *B. henselae*–infected cats' saliva spreads to claws by self-licking, and *B. henselae*–contaminated flea feces can be inoculated by a scratch or a bite. Infection of mucous membranes or conjunctivae via droplets or licking may occur as well. With lymphatic drainage to one or more regional lymph nodes in immunocompetent hosts, a T_H1 response can result in necrotizing granulomatous lymphadenitis. Dendritic cells, along with their associated chemokines, play a role in the host inflammatory response and granuloma formation.

CLINICAL MANIFESTATIONS AND PROGNOSIS

Of patients with CSD, 85–90% have *typical* disease. The primary lesion, a small (0.3- to 1-cm) painless erythematous papule or pustule, develops at the inoculation site within days to 2 weeks in about one-third to two-thirds of patients **(Fig. 177-1*A*, *B*)**. Lymphadenopathy develops 1–3 weeks or longer after cat contact. The affected lymph node(s) are enlarged and usually painful, sometimes have overlying erythema, and suppurate in ~10% of cases **(Fig. 177-1*C*, *D*, and *E*)**. Axillary/epitrochlear nodes are most commonly involved, followed by head/neck nodes and inguinal/femoral nodes. Approximately 50% of patients have fever, malaise, and anorexia. A smaller proportion experience weight loss and night sweats mimicking the presentation of lymphoma. Fever is usually low-grade but infrequently rises to ≥39°C. Resolution is slow, requiring

weeks (for fever, pain, and accompanying signs and symptoms) to months (for node shrinkage).

Atypical CSD occurs in 10–15% of patients in the absence or presence of lymphadenopathy. Atypical disease includes Parinaud's oculoglandular syndrome (conjunctivitis with ipsilateral preauricular lymphadenitis; Fig. 177-1*E*), hepatosplenic disease, neuroretinitis (often presenting as unilateral deterioration of vision; **Fig. 177-1*F***) and other ophthalmologic manifestations, neurologic manifestations (encephalitis, seizures, myelitis, facial and other cranial nerve palsies, peripheral neuritis), fever of unknown origin (FUO), pneumonitis, debilitating myalgia, arthritis or arthralgia (affecting mostly women >20 years old), osteomyelitis (including multifocal disease), and dermatologic manifestations (including erythema nodosum **[see Fig. A1-39]**, sometimes accompanying arthropathy). CSD-associated FUO is a unique syndrome that may be severe and debilitating, often mimics malignancy, and may present with multiorgan involvement, including hepatosplenic space-occupying lesions, abdominal/mediastinal lymphadenopathy, ocular disease, and multifocal osteomyelitis. Fever may be continuous or relapsing. Other manifestations and syndromes (e.g., idiopathic thrombocytopenic purpura, Henoch-Schönlein purpura, erythema multiforme **[see Fig. A1-24*A*]**, myocarditis) also have been associated with CSD; however, a causal role for *B. henselae* has yet to be established. In elderly patients (>60 years old), lymphadenopathy is more often absent but encephalitis and FUO are more common than in younger patients. In immunocompetent individuals, CSD—whether typical or atypical—usually resolves without treatment and without sequelae, although some of the ophthalmologic manifestations may occasionally result in moderate to severe vision loss. Lifelong immunity is the rule.

DIAGNOSIS

Routine laboratory tests usually yield normal or nonspecific results. Histopathology initially shows lymphoid hyperplasia and later demonstrates stellate granulomata with necrosis, coalescing microabscesses, and occasional multinucleated giant cells—findings that, although nonspecific, may narrow the differential diagnosis. Serologic testing (immunofluorescence or enzyme immunoassay) is the most commonly used laboratory diagnostic approach, with variable sensitivity and specificity. CSD serodiagnosis is often based on the presence of IgG alone (i.e., in the absence of IgM), and seroconversion may take a few weeks; these two factors may pose difficulties in the interpretation of serologic results. Other tests are of low sensitivity (culture, Warthin-Starry silver staining), of low specificity (cytology, histopathology), or of limited availability in routine diagnostic laboratories (polymerase chain reaction [PCR], immunohistochemistry). PCR of pus aspirated from lymph nodes or the primary inoculation lesion is highly sensitive and specific and is particularly useful for definitive and rapid diagnosis in seronegative patients. PCR of a lymph node biopsy specimen may be less sensitive, perhaps because of sampling error.

APPROACH TO THE PATIENT

Cat-Scratch Disease

A history of cat contact, a primary inoculation lesion, and regional lymphadenopathy—especially axillary/epitrochlear lymphadenopathy—are highly suggestive of CSD. A characteristic clinical course and corroborative laboratory tests make the diagnosis very likely. Conversely, when acute- and convalescent-phase sera are negative (as is the case in 10–20% of CSD patients), when spontaneous regression of lymph node size does not occur, and particularly when constitutional symptoms persist, malignancy must be ruled out. Pyogenic lymphadenitis, mycobacterial infection, brucellosis, syphilis, tularemia, plague, toxoplasmosis, sporotrichosis, and histoplasmosis also should be considered. In clinically suspected CSD in a seronegative individual, fine-needle aspiration may be adequate and PCR can confirm the diagnosis. When data are less supportive of CSD, lymph node biopsy rather than fine-needle aspiration is preferred. In seronegative CSD patients with lymphadenopathy and severe complications (e.g., encephalitis or neuroretinitis), early biopsy is important to establish a specific diagnosis.

TREATMENT

Cat-Scratch Disease

(Table 177-2) Treatment regimens are based on only minimal data. Suppurative nodes should be drained by large-bore needle aspiration and not by incision and drainage to avoid chronic draining tracts. Systemic antibiotics are recommended in immunocompromised patients.

TABLE 177-2 Antimicrobial Therapy for Disease Caused by *Bartonella* Species in Adults

DISEASE	ANTIMICROBIAL THERAPY
Typical cat-scratch disease	Not routinely indicated; for patients with extensive lymphadenopathy, consider azithromycin (500 mg PO on day 1, then 250 mg PO once a day for 4 days)
Cat-scratch disease neuroretinitis	Value of systemic antibiotics is controversial, particularly when visual acuity is not significantly compromised. For more severe cases, doxycycline (100 mg PO bid) *plus* rifampin (300 mg PO bid) for 4–6 weeks is given. Consider adding systemic glucocorticoids.
Other atypical cat-scratch disease manifestations[a]	As per neuroretinitis. Treatment duration should be individualized.
Trench fever or chronic bacteremia with *B. quintana*	Gentamicin (3 mg/kg IV once a day for 14 days) *plus* doxycycline (200 mg PO once a day or 100 mg PO bid for 6 weeks)
Suspected *Bartonella* endocarditis	Gentamicin[b] (1 mg/kg IV q8h for ≥14 days) *plus* doxycycline (100 mg PO/IV bid for 6 weeks[c]) *plus* ceftriaxone (2 g IV once a day for 6 weeks)
Confirmed *Bartonella* endocarditis	As for suspected *Bartonella* endocarditis *minus* ceftriaxone
Bacillary angiomatosis	Erythromycin[d] (500 mg PO qid for 3 months) *or* Doxycycline (100 mg PO bid for 3 months)
Bacillary peliosis	Erythromycin[d] (500 mg PO qid for 4 months) *or* Doxycycline (100 mg PO bid for 4 months)
Carrión's disease	
Oroya fever	Chloramphenicol (500 mg PO/IV qid for 14 days) *plus* another antibiotic (β-lactam preferred) *or* Ciprofloxacin (500 mg PO bid for 10 days) ± ceftriaxone (1–2 g IV once a day for 10 days)
Verruga peruana	Azithromycin (500 mg PO once a day for 7 days) *or* Ciprofloxacin (500 mg PO bid for 7–10 days) *or* Rifampin (10 mg/kg PO once a day, to a maximum of 600 mg, for 14 days) *or* Streptomycin (15–20 mg/kg IM once a day for 10 days)

[a]Data on treatment efficacy for encephalitis and hepatosplenic cat-scratch disease are lacking. Therapy similar to that given for neuroretinitis is reasonable. [b]Some experts recommend gentamicin at 3 mg/kg IV once a day. If gentamicin is contraindicated, rifampin (300 mg PO bid) can be added to doxycycline for documented *Bartonella* endocarditis. [c]Some experts recommend extending oral doxycycline therapy for 3–6 months and measuring anti-*Bartonella* IgG titers every 8–10 weeks as a guide to duration of therapy, particularly when the infected valve was not resected. [d]Other macrolides are probably effective and may be substituted for erythromycin or doxycycline.

Source: Recommendations are modified from JM Rolain et al: Antimicrob Agents Chemother 48:1921, 2004.

PREVENTION

Avoiding cats (especially kittens) and instituting flea control are options for immunocompromised patients and for patients with valvular heart disease.

TRENCH FEVER AND CHRONIC BACTEREMIA

DEFINITION AND ETIOLOGY

Trench fever, also known as *5-day fever* or *quintan fever*, is a febrile illness caused by *B. quintana*. It was first described as an epidemic in the trenches of World War I; however, recent paleomicrobiological studies have provided evidence that *B. quintana* has been associated with human infection for 4000 years. This infection recently reemerged as chronic bacteremia seen most often in homeless people, also referred to as *urban* or *contemporary trench fever*.

EPIDEMIOLOGY

In addition to epidemics in World Wars I and II, sporadic outbreaks of trench fever have been reported in many regions of the world. The human body louse has been identified as the vector and humans as the only known reservoir for human infections. Recently, macaque monkeys from China and Japan also were found to be natural hosts of *B. quintana,* without evidence for macaque-to-human transmission. After a hiatus of several decades during which trench fever was almost forgotten, small clusters of cases of *B. quintana* chronic bacteremia were reported sporadically, primarily from the United States and France, in homeless people without HIV infection. Alcoholism and louse infestation were identified as risk factors.

CLINICAL MANIFESTATIONS

The typical incubation period is 15–25 days (range, 3–38 days). "Classic" trench fever, as described in 1919, ranges from a mild febrile illness to a recurrent or protracted and debilitating disease. Fever is often periodic, lasting 4–5 days with 5-day (range, 3- to 8-day) intervals between episodes. Other symptoms and signs include headache, back and limb pain, profuse sweating, shivering, myalgia, arthralgia, splenomegaly, a maculopapular rash in occasional cases, and nuchal rigidity in some cases. Untreated, the disease usually lasts 4–6 weeks. Death is rare. The clinical spectrum of *B. quintana* bacteremia in homeless people ranges from asymptomatic infection to a febrile illness with headache, severe leg pain, and thrombocytopenia. Endocarditis sometimes develops.

DIAGNOSIS

Definitive diagnosis requires isolation of *B. quintana* by blood culture. Some patients have positive blood cultures for several weeks. Patients with acute trench fever typically develop significant titers of antibody to *Bartonella*, whereas those with chronic *B. quintana* bacteremia may be seronegative. Patients with high titers of IgG antibodies should be evaluated for endocarditis. In epidemics, trench fever should be differentiated from epidemic louse-borne typhus and relapsing fever, which occur under similar conditions and share many features.

TREATMENT

B. quintana Bacteremia

(Table 177-2) In a small, randomized, placebo-controlled trial involving homeless people with *B. quintana* bacteremia, therapy with gentamicin and doxycycline was superior to administration of placebo in eradicating bacteremia. Treatment of bacteremia is important, even in clinically mild cases, to prevent endocarditis. Optimal therapy for trench fever without documented bacteremia is uncertain.

BARTONELLA ENDOCARDITIS

DEFINITION AND ETIOLOGY

Coxiella burnetii **(Chap. 192)** and *Bartonella* species are the most common pathogens of culture-negative endocarditis **(Chap. 133)**. In France, for example, *Bartonella* species were identified as the etiologic agents in 28% of 348 cases of culture-negative endocarditis. Prevalence, however, varies by geographic location and epidemiologic setting. *B. quintana* and *B. henselae* are the most common *Bartonella* species implicated in endocarditis, and other *Bartonella* species have reportedly caused rare cases (Table 177-1).

EPIDEMIOLOGY

Bartonella endocarditis has been reported worldwide. Most patients are adults; more are male than female. Risk factors associated with *B. quintana* endocarditis include homelessness, alcoholism, and body louse infestation; however, individuals with no risk factors have had *Bartonella* endocarditis diagnosed as well. *B. henselae* endocarditis is associated with exposure to cats. Most cases involve native rather than prosthetic valves; the aortic valve accounts for ~60% of cases. Patients with *B. henselae* endocarditis usually have preexisting valvulopathy, whereas *B. quintana* often infects normal valves.

CLINICAL MANIFESTATIONS

Clinical manifestations are usually characteristic of subacute endocarditis of any etiology. However, a substantial number of patients have a prolonged, minimally febrile or even afebrile indolent illness, with mild nonspecific symptoms lasting weeks or months before the diagnosis is made. Initial echocardiography may not show vegetations. Acute, aggressive disease is rare.

DIAGNOSIS

Blood cultures, even with use of special techniques (lysis centrifugation or EDTA-containing tubes), are positive in only ~25% of cases—mostly those caused by *B. quintana* and only rarely those caused by *B. henselae*. Prolonged incubation of cultures (up to 6 weeks) is required. Serologic tests—either immunofluorescence or enzyme immunoassay—usually demonstrate high-titer (≥1:800) IgG antibodies to *Bartonella*. Because of cross-antigenicity, routine serology does not distinguish between *B. quintana* and *B. henselae* and may also be cross-reactive with other pathogens, such as *C. burnetii* and *Chlamydia* species. Approximately 40–50% of patients with Q fever endocarditis have antibodies that significantly react with *B. henselae* and/or *B. quintana;* however, in the majority of cases, IgG titers against the true pathogen are several dilutions higher than those for the pathogen causing the false-positive serology, thus allowing the correct diagnosis to be made. Identification of *Bartonella* to the species level is usually accomplished by application of PCR and DNA sequencing methods to valve tissue or, infrequently, blood specimens.

TREATMENT

Bartonella Endocarditis

(Table 177-2) For patients with culture-negative endocarditis suspected to be due to *Bartonella* species, empirical treatment consists of gentamicin, doxycycline, and ceftriaxone; the major role of ceftriaxone in this regimen is to adequately treat other potential causes of culture-negative endocarditis, including members of the HACEK group **(Chap. 163)**. Once a diagnosis of *Bartonella* endocarditis has been established, ceftriaxone is discontinued. Aminoglycosides, the only antibiotics known to be bactericidal against *Bartonella*, should be included in the regimen for ≥2 weeks. Indications for valvular surgery are the same as in subacute endocarditis due to other pathogens; however, the proportion of patients who undergo surgery (~60%) is high, probably as a consequence of delayed diagnosis.

BACILLARY ANGIOMATOSIS AND PELIOSIS

DEFINITION AND ETIOLOGY

Bacillary angiomatosis (sometimes called *bacillary epithelioid angiomatosis* or *epithelioid angiomatosis*) is a disease of severely immunocompromised patients, is caused by *B. henselae* or *B. quintana*, and is characterized by neovascular proliferative lesions involving various organs. Both species cause cutaneous lesions; hepatosplenic lesions

are caused only by *B. henselae*, whereas subcutaneous and lytic bone lesions are more frequently associated with *B. quintana*. *Bartonella* angiogenic factor A, a proangiogenic autotransporter identified in *B. henselae*, activates the host vascular endothelial growth factor pathway to drive angiogenesis. Bacillary peliosis is a closely related angioproliferative disorder caused by *B. henselae* and involving primarily the liver (peliosis hepatis) but also the spleen and lymph nodes. Bacillary peliosis is characterized by blood-filled cystic structures whose size ranges from microscopic to several millimeters.

EPIDEMIOLOGY

Bacillary angiomatosis and bacillary peliosis occur primarily in HIV-infected persons **(Chap. 208)** with CD4+ T-cell counts of <100/μL but also affect other immunosuppressed patients and, in rare instances, immunocompetent patients. The incidence has decreased since the introduction of effective antiretroviral therapy and the routine use of rifabutin and macrolides to prevent *Mycobacterium avium* complex infection in AIDS patients. Contact with cats or cat fleas increases the risk of *B. henselae* infection. Risk factors for *B. quintana* infection are low income, homelessness, and body louse infestation.

CLINICAL MANIFESTATIONS

Bacillary angiomatosis presents most commonly as one or more cutaneous lesions that are not painful and may be tan, red, or purple in color. Subcutaneous, often tender nodules, superficial ulcerated plaques **(Fig. 177-2)**, and verrucous growths are also seen. Nodular forms resemble those seen in fungal or mycobacterial infections. Painful osseous lesions, most often involving long bones, may underlie cutaneous lesions and occasionally develop in their absence. Other organs are rarely involved. Patients usually have constitutional symptoms, including fever, chills, malaise, headache, anorexia, weight loss, and night sweats. In patients with advanced immunodeficiency, *B. henselae* and *B. quintana* are important causes of FUO. In osseous disease, lytic lesions are generally seen on radiography, and technetium scan shows focal uptake. The differential diagnosis of cutaneous bacillary angiomatosis includes Kaposi's sarcoma, pyogenic granuloma, subcutaneous tumors, and verruga peruana. In bacillary peliosis, hypodense hepatic areas are usually evident on imaging.

PATHOLOGY

Bacillary angiomatosis consists of lobular proliferations of small blood vessels lined by enlarged endothelial cells interspersed with mixed infiltrates of neutrophils and lymphocytes, with predominance of the former. Histologic examination of organs with bacillary peliosis reveals small blood-filled cystic lesions partially lined by endothelial cells that can be several millimeters in size. Peliotic lesions are surrounded by fibromyxoid stroma containing inflammatory cells, dilated capillaries, and clumps of granular material. Warthin-Starry silver staining of bacillary angiomatosis and peliosis lesions reveals clusters of bacilli. Cultures are usually negative.

DIAGNOSIS

Bacillary angiomatosis and bacillary peliosis are diagnosed by histologic examination. Blood cultures may be positive.

TREATMENT

Bacillary Angiomatosis and Peliosis

(Table 177-2) Prolonged therapy with a macrolide or doxycycline is recommended for both bacillary angiomatosis and bacillary peliosis.

PREVENTION

Reasonable strategies for HIV-infected persons consist of control of cat-flea infestation and avoidance of cat scratches (for prevention of

FIGURE 177-2 Lesions of cutaneous bacillary angiomatosis (BA) in three severely immunocompromised AIDS patients. Left panel shows a 1.5-cm ulcerated, bleeding BA lesion with an erythematous base; middle panel shows numerous small, 2-mm, scattered angiomatous BA lesions; right panel shows a 2.0-cm friable BA lesion on the thigh. *(Photos courtesy of Timothy Berger, MD; Jordan Tappero, MD, MPH; and Jane Koehler, MA, MD.)*

B. henselae) and avoidance and treatment of body louse infestation (for prevention of *B. quintana*). Primary prophylaxis is not recommended, but suppressive therapy with a macrolide or doxycycline is indicated in HIV-infected patients with bacillary angiomatosis or bacillary peliosis until CD4+ T-cell counts are >200/μL. Relapse may necessitate lifelong suppressive therapy in individual cases.

CARRIÓN'S DISEASE (OROYA FEVER AND VERRUGA PERUANA)

DEFINITION AND ETIOLOGY

Carrión's disease is a biphasic disease caused by *B. bacilliformis*. Oroya fever is the initial, bacteremic, systemic form, and verruga peruana—or "Peruvian warts"—is its late-onset, eruptive manifestation.

EPIDEMIOLOGY AND PREVENTION

Infection is endemic to the geographically restricted Andes valleys of Peru, Ecuador, and Colombia (~500–3200 m above sea level). Sporadic epidemics occur. The disease is transmitted by the phlebotomine sandfly *Lutzomyia verrucarum*. Maternal-fetal transmission as well as transmission by blood transfusion have been reported. Humans are the only known reservoir of *B. bacilliformis*. Sandfly control measures (e.g., insecticides) and personal protection measures (e.g., repellents, screening, bed nets) may decrease the risk of infection.

PATHOGENESIS

After inoculation by the sandfly, bacteria invade the blood vessel endothelium and proliferate; the reticuloendothelial system and various organs also may be involved. Upon reentry into blood vessels, *B. bacilliformis* invades, replicates, and ultimately destroys erythrocytes, with consequent massive hemolysis and sudden, severe anemia. Microvascular thrombosis results in end-organ ischemia. Survivors sometimes develop cutaneous hemangiomatous lesions characterized by various inflammatory cells, endothelial proliferation, and the presence of *B. bacilliformis* (verruga peruana).

CLINICAL MANIFESTATIONS

The incubation period is 3 weeks (range, 2–14 weeks). Oroya fever may present as a nonspecific bacteremic febrile illness without anemia or as an acute, severe hemolytic anemia with hepatomegaly and jaundice of rapid onset leading to vascular collapse and clouded sensorium. Myalgia, arthralgia, lymphadenopathy, and abdominal pain may develop. Temperature is elevated but not extremely so; high fever may suggest intercurrent infection. Subclinical asymptomatic infection also occurs. Secondary infection with *Salmonella* (*typhi* and non-*typhi*) is common, though other secondary infections have been reported and should be suspected when fever persists or recurs after defervescence. In verruga peruana, red, hemangioma-like, cutaneous vascular lesions of various sizes appear either weeks to months after systemic illness or with no previous suggestive history. These lesions persist for months up to 1 year. Mucosal and internal lesions also may develop.

DIAGNOSIS AND APPROACH TO THE PATIENT

Systemic illness (with or without anemia) or the development of cutaneous lesions in a person who has been to an endemic area raises the possibility of *B. bacilliformis* infection. Severe anemia with exuberant reticulocytosis—and sometimes thrombocytopenia—can occur. In systemic illness, Giemsa-stained blood films may show typical intraerythrocytic bacilli. Blood and bone marrow cultures may be positive, but growth is slow (1–6 weeks) and requires lower incubation temperature. Serologic assays may be helpful. Diagnosis of verruga peruana is largely clinical, although biopsy may be required to confirm the diagnosis. Several PCR assays have been described; however, their role in diagnosis remains to be clinically validated. Differential diagnosis includes coendemic systemic febrile illnesses (e.g., typhoid fever, malaria, brucellosis) and diseases producing cutaneous vascular lesions (e.g., hemangiomata, bacillary angiomatosis, Kaposi's sarcoma).

TREATMENT

Carrión's Disease

(Table 177-2) Antibiotic therapy for systemic *B. bacilliformis* infection usually results in rapid defervescence. Additional antibiotic treatment of intercurrent infection is often required. Blood transfusion may be necessary. Treatment of verruga peruana is not always required. Patients with numerous lesions, especially lesions that have been present for only a short period, may respond well to antibiotic therapy.

COMPLICATIONS AND PROGNOSIS

Mortality rates associated with Oroya fever have been reported to be as high as 40% without treatment but are considerably lower (~10%) with treatment. Complications such as bacterial superinfection and neurologic and cardiac manifestations occur frequently. Generalized massive edema (anasarca) and petechiae are associated with poor outcome. Permanent immunity usually develops.

178 Donovanosis

Nigel O'Farrell

Donovanosis is a chronic, progressive bacterial infection that usually involves the genital region. The condition is generally regarded as a sexually transmitted infection of low infectivity. This infection has been known by many other names, the most common being *granuloma inguinale*.

ETIOLOGY

The causative organism has been reclassified as *Klebsiella granulomatis comb nov* on the basis of phylogenetic analysis, although there is ongoing debate about this decision. Some authorities consider the original nomenclature (*Calymmatobacterium granulomatis*) to be more appropriate in light of analysis of 16S rRNA gene sequences.

Donovanosis was first described in Calcutta in 1882, and the causative organism was recognized by Charles Donovan in Madras in 1905. He identified the characteristic Donovan bodies, measuring 1.5 × 0.7 μm, in macrophages and the stratum malpighii. The organism was not reproducibly cultured until the mid-1990s, when its isolation in peripheral-blood monocytes and human epithelial cell lines was reported.

EPIDEMIOLOGY

Donovanosis has an unusual geographic distribution that has included Papua New Guinea, parts of southern Africa, India, the Caribbean, French Guyana, Brazil, and Aboriginal communities in Australia. In Australia, donovanosis has been almost entirely eliminated through a sustained program backed by strong political commitment and resources at the primary health care level. In South Africa, donovanosis is also very close to elimination. Although few cases are now reported in the United States, donovanosis was once prevalent in this country, with 5000–10,000 cases recorded in 1947. The largest epidemic recorded was in Dutch South Guinea, where 10,000 cases were identified in a population of 15,000 (the Marind-anim) between 1922 and 1952.

Donovanosis is associated with poor hygiene and is more common in lower socioeconomic groups than in those who are better off and in men than in women. Infection in sexual partners of index cases occurs to a limited extent. Donovanosis is a risk factor for HIV infection **(Chap. 208)**.

Globally, the incidence of donovanosis has decreased significantly in recent times. This decline probably reflects a greater focus on effective management of genital ulcers because of their role in facilitating HIV transmission.

CLINICAL FEATURES

A lesion starts as a papule or subcutaneous nodule that later ulcerates after trauma. The incubation period is uncertain, but experimental infections in humans indicate a duration of ~50 days. Four types of lesions have been described: (1) the classic ulcerogranulomatous lesion **(Fig. 178-1)**, a beefy red ulcer that bleeds readily when touched; (2) a hypertrophic or verrucous ulcer with a raised irregular edge; (3) a necrotic, offensive-smelling ulcer causing tissue destruction; and (4) a sclerotic or cicatricial lesion with fibrous and scar tissue.

The genitals are affected in 90% of patients and the inguinal region in 10%. The most common sites of infection are the prepuce, coronal sulcus, frenum, and glans in men and the labia minora and fourchette in women. Cervical lesions may mimic cervical carcinoma. In men, lesions are associated with lack of circumcision. Lymphadenitis is uncommon. Extragenital lesions occur in 6% of cases and may involve the lip, gums, cheek, palate, pharynx, larynx, and chest. Hematogenous spread with involvement of liver and bone has been reported. During pregnancy, lesions tend to develop more quickly and respond more slowly to treatment. Polyarthritis and osteomyelitis are rare complications. In newborn infants, donovanosis may present with ear infection. Cases in children have been attributed to sitting on the laps of infected adults. As the incidence of donovanosis has decreased, the number of unusual case reports has appeared to be increasing.

Complications include neoplastic changes, pseudoelephantiasis, and stenosis of the urethra, vagina, or anus.

FIGURE 178-1 Ulcerogranulomatous penile lesion of donovanosis, with some hypertrophic features.

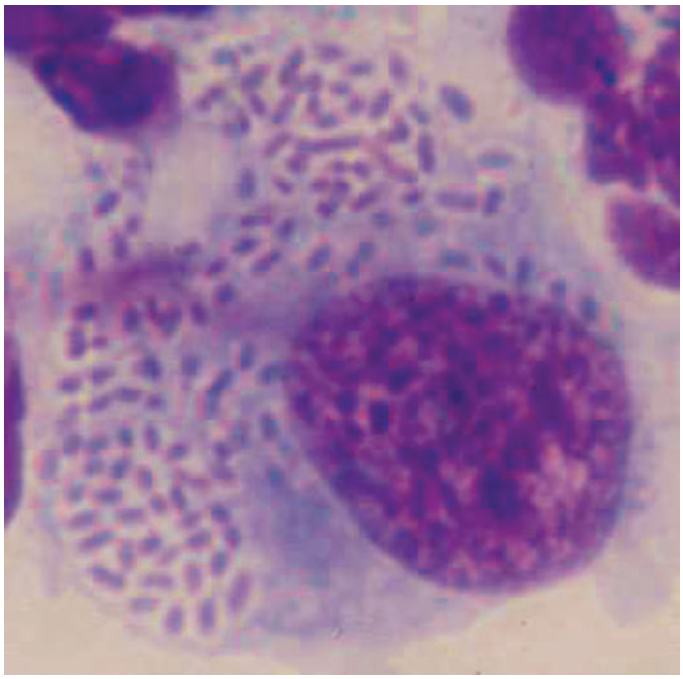

FIGURE 178-2 Pund cell stained by rapid Giemsa (RapiDiff) technique. Numerous Donovan bodies are visible.

DIAGNOSIS

A clinical diagnosis of donovanosis made by an experienced practitioner on the basis of the lesion's appearance usually has a high positive predictive value. The diagnosis is confirmed by microscopic identification of Donovan bodies **(Fig. 178-2)** in tissue smears. Preparation of a good-quality smear is important. If donovanosis is suspected on clinical grounds, the smear for Donovan bodies should be taken before swab samples are collected to be tested for other causes of genital ulceration so that enough material can be collected from the ulcer. A swab should be rolled firmly over an ulcer previously cleaned with a dry swab to remove debris. Smears can be examined in a clinical setting by direct microscopy with a rapid Giemsa or Wright's stain. Alternatively, a piece of granulation tissue crushed and spread between two slides can be used. Donovan bodies can be seen in large, mononuclear (Pund) cells as gram-negative intracytoplasmic cysts filled with deeply staining bodies that may have a safety-pin appearance. These cysts eventually rupture and release the infective organisms. Histologic changes include chronic inflammation with infiltration of plasma cells and neutrophils. Epithelial changes include ulceration, microabscesses, and elongation of rete ridges.

A diagnostic polymerase chain reaction (PCR) test was based on the observation that two unique base changes in the *phoE* gene eliminate Hae111 restriction sites, enabling differentiation of *K. granulomatis comb nov* from related *Klebsiella* species. PCR analysis with a colorimetric detection system can now be used in routine diagnostic laboratories. A genital ulcer multiplex PCR that includes *K. granulomatis* has been developed. Serologic tests are only poorly specific and are not currently used.

The differential diagnosis of donovanosis includes primary syphilitic chancres, secondary syphilis (condylomata lata), chancroid, lymphogranuloma venereum, genital herpes, neoplasm, and amebiasis. Mixed infections are common. Histologic appearances should be distinguished from those of rhinoscleroma, leishmaniasis, and histoplasmosis.

TREATMENT

Donovanosis

Many patients with donovanosis present quite late with extensive ulceration. They may be embarrassed and have low self-esteem related to their disease. Reassurance that they have a treatable

TABLE 178-1 Effective Antibiotics for the Treatment of Donovanosis

ANTIBIOTIC	ORAL DOSE
Azithromycin	1 g on day 1, then 500 mg daily for 7 days or 1 g weekly for 4 weeks
Trimethoprim-sulfamethoxazole	960 mg bid for 14 days
Doxycycline	100 mg bid for 14 days
Erythromycin	500 mg qid for 14 days (in pregnant women)
Tetracycline	500 mg qid for 14 days

condition is important, as are the administration of antibiotics and the monitoring of patients for an adequate interval (see below). Epidemiologic treatment of sexual partners and advice about how to improve genital hygiene are recommended.

The recommended drug regimens for donovanosis are shown in Table 178-1. Gentamicin can be added if the response is slow. Ceftriaxone, chloramphenicol, and norfloxacin also are effective. Patients treated for 14 days should be monitored until lesions have healed completely. Those treated with azithromycin probably do not need such rigorous follow-up.

Surgery may be indicated for very advanced lesions.

CONTROL AND PREVENTION

Donovanosis is probably the cause of genital ulceration that is most readily recognizable clinically. Donovanosis is now limited to a few specific locations, and its global eradication is a distinct possibility.

Section 7 Miscellaneous Bacterial Infections

179 Nocardiosis

Michael S. Abers, Gregory A. Filice

INTRODUCTION

Bacteria of the genus *Nocardia* are saprophytic filamentous aerobes ubiquitous in soil and water worldwide. In the past, the majority of isolates associated with pneumonia and systemic disease were identified biochemically as *Nocardia asteroides*, but the development of genome sequencing has demonstrated that at least 53 of the more than 100 species of *Nocardia* are associated with human disease. Most cases of systemic nocardiosis are caused by *N. farcinica*, *N. cyriacigeorgica*, *N. nova*, *N. abscessus*, *N. otitidiscaviarum*, *N. transvalensis*, *N. brasiliensis*, *N. pseudobrasiliensis*, *N. paucivorans*, or *N. brevicatena* (Fig. 179-1). *N. brasiliensis* is usually associated with disease limited to the skin. Nocardiosis is usually an opportunistic infection, occurring primarily in individuals with impairments in host defenses. Infections following local inoculation and pulmonary or systemic disease have distinct pathogenesis, microbiology, and management.

MICROBIOLOGY

Nocardiae are Gram-positive, weakly acid-fast, and catalase positive. Like other members of the Mycobacteriales order, the cell walls of nocardiae contain mycolic acids (45–65 carbon atoms) and trehalose. *Nocardia* tend to clump together when grown in liquid media. On solid agar, *Nocardia* species typically form chalky, wrinkled colonies with a whitish-yellow or orange-brown hue. Growth is optimal at 37°C but can occur at temperatures up to 45°C.

EPIDEMIOLOGY AND RISK FACTORS

Nocardiae are ubiquitous environmental saprophytes found in soil, water, and decaying organic matter worldwide. Humans are frequently exposed via inhalation or direct inoculation of the skin or an eye. Most immunocompetent individuals readily clear nocardiae without developing clinical disease. Certain impairments in host defenses predispose to invasive infection after inhalation. Primary cutaneous infection usually remains local. Nearly all cases are sporadic, but outbreaks have been reported in nosocomial settings among immunocompromised patients and in immunocompetent individuals related to surgical procedures or intravenous drug use. Person-to-person spread is not well documented. There is no known seasonality.

The incidence of nocardiosis in the general population, estimated on three continents (North America, Europe, and Australia), is approximately ~0.375 cases per 100,000 persons per year. *Nocardia* infections are more common among adults than among children and more common among males than females. In contrast to the other forms of nocardiosis that occur worldwide, cases of actinomycetoma have been reported mostly in tropical and subtropical regions, especially in Mexico, Sudan, and India. The most important risk factors are lower socioeconomic status and frequent contact with soil or vegetable matter. Many cases are in laborers.

Most cases of systemic nocardiosis occur in patients with host defense defects, including cell-mediated immunity and specific phagocyte defects. Those with nocardiosis typically possess one or more of the following risk factors: solid organ transplantation, hematopoietic stem cell transplantation, systemic corticosteroid use or Cushing syndrome, immunosuppressive therapy, or HIV infection. Among transplant recipients, risk factors for nocardiosis include corticosteroid dose, recent augmentation of immunosuppression for rejection or graft-versus-host disease, elevated calcineurin inhibitor levels, and patient age. Rare but well-described syndromes associated with nocardiosis include pulmonary alveolar proteinosis (PAP), neutralizing autoantibodies to granulocyte-macrophage colony-stimulating factor (GM-CSF), chronic granulomatous disease (CGD), and interleukin 12 (IL-12) or IL-12R deficiency. In the absence of any major risk factor for *Nocardia* infection, children and adults with nocardiosis should be tested for CGD.

PATHOGENESIS

Pulmonary and systemic nocardiosis both occur following inhalation of fragmented bacterial mycelia. In healthy individuals, a variety of host defense mechanisms, including both innate and adaptive immune responses, help control and eliminate nocardiae from the respiratory tract without causing clinical disease. The importance of neutrophils and macrophages in antinocardial host defense is suggested by the frequency of nocardiosis in patients with CGD. Nocardiae have evolved a number of properties that enable survival within phagocytes, including neutralization of oxidants, prevention of phagosome–lysosome fusion, and prevention of phagosome acidification. Neutrophils phagocytose nocardiae and limit their growth but do not kill them efficiently. Neutralizing autoantibodies against GM-CSF have been found in the majority of patients with autoimmune PAP and appear to be central to the pathogenesis of this disease. Nocardiae stimulate the production of GM-CSF in phagocytes in vitro, and extrapulmonary nocardiosis has been observed in several patients with autoantibodies to GM-CSF, most of whom had not had pulmonary alveolar proteinosis. The relationships between pulmonary alveolar proteinosis, nocardiosis, and antibodies to GM-CSF remain incompletely defined.

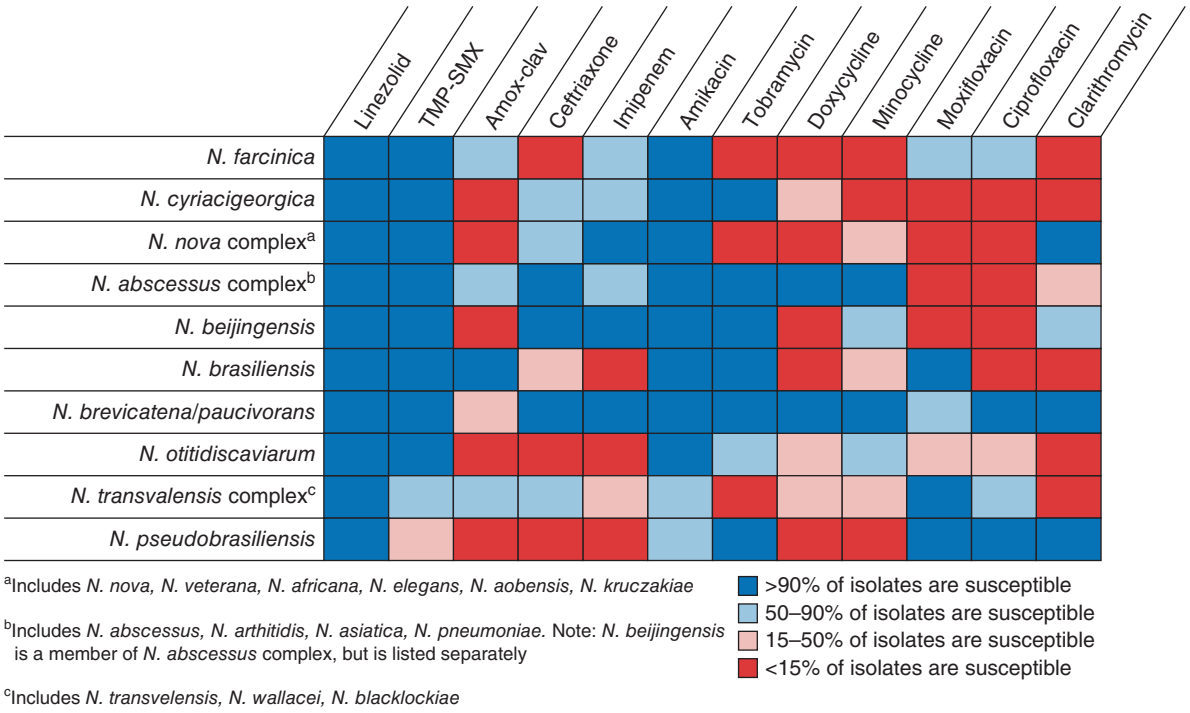

FIGURE 179-1. *Nocardia* species most commonly associated with human disease and their in vitro susceptibility patterns. TMP-SMX: trimethoprim-sulfamethoxazole. *(Adapted from multiple sources.)*

Primary cutaneous nocardiosis typically follows penetrating injury of the skin by an object contaminated with soil or vegetable matter. Thorn-associated injuries, such as those associated with gardening, are a particularly common source of infection. Nocardiae may spread to draining lymph nodes, but dissemination to anatomically distant sites is uncommon. The ocular epithelium serves as a barrier that excludes nocardiae from the deeper tissues. Traumatic injury of the corneal epithelium provides a portal of entry for nocardiae to enter the ocular tissues, resulting in keratitis. The infectious process is limited to the superficial tissues.

PATHOLOGY

The characteristic histologic feature of nocardiosis is an abscess with extensive infiltration of neutrophils and prominent necrosis. Granulation tissue may surround the lesion, but extensive fibrosis and encapsulation are uncommon. Pyogranulomatous inflammation occurs in a minority of cases. In contrast, actinomycetoma is characterized by granulomatous inflammation and the formation of sinus tracts.

CLINICAL MANIFESTATIONS

Pleuropulmonary Disease The onset of pulmonary nocardiosis is typically subacute, with symptoms evolving over days to weeks prior to presentation. Among severely immunocompromised patients, the onset may be more acute. Cough is prominent and produces small amounts of thick, purulent sputum that is not malodorous. Fever, anorexia, and malaise are common; weight loss, dyspnea, pleuritic chest pain, and hemoptysis are uncommon. Without definitive treatment, patients frequently experience remissions and exacerbations over a period of weeks to months.

Typical radiographic patterns include infiltrates, nodules, and masses in one or more lobes **(Figs. 179-2 and 179-3)**. Nodules frequently cavitate (Fig. 179-3). Pleural effusion or empyema occurs in about one-third of cases. In some cases, empyema may occur in the absence of lung involvement.

Extrapulmonary Disease Dissemination to anatomically distant sites occurs in up to one-third of patients with pneumonia. While blood cultures are frequently negative, nocardiae likely reach metastatic sites of infection via hematogenous spread. Virtually any organ can be involved, but the central nervous system (CNS) and skin and subcutaneous tissues are the most common sites.

The CNS is involved in up to two-thirds of cases of disseminated nocardiosis. The vast majority of patients present with one or more brain abscesses. One-third of patients have no symptoms of CNS involvement, and one-fourth of patients do not have apparent pulmonary disease at presentation. Brain imaging demonstrates one or more ring-enhancing lesions that characteristically have a multilobulated appearance **(Fig. 179-4)**. Multiple abscesses are seen in two-thirds of patients. Many abscesses can be detected with contrast-enhanced computed tomography (CT), but magnetic resonance imaging (MRI) with intravenous gadolinium is more sensitive. *N. farcinica* appears to have a special predilection for CNS involvement. Meningitis is uncommon and is usually due to spread from a nearby brain abscess.

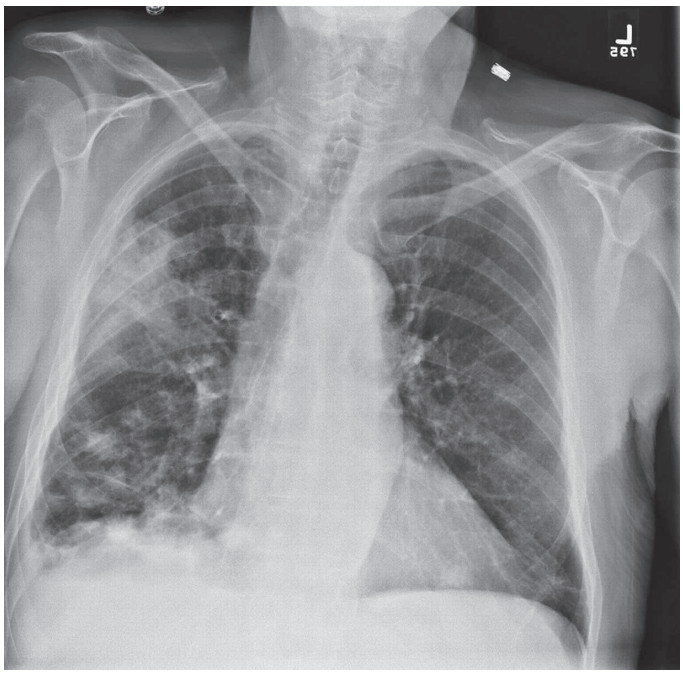

FIGURE 179-2. *Nocardia* pneumonia. A dense infiltrate with a possible cavity and several nodules are apparent in the right lung.

FIGURE 179-3. Pulmonary nocardiosis. A computed tomography scan shows solid nodules *(yellow arrows)* and a cavitated nodule *(yellow arrowhead)* in the right lung as well as a right-sided pleural effusion and an abscess of the right chest wall *(red asterisk)*. Bronchiectasis, which was unrelated to nocardiosis, is present in the left lung.

A neutrophilic pleocytosis is typically seen in the cerebrospinal fluid, but cultures are rarely positive.

Involvement of the skin and subcutaneous tissues occurs in one-fifth of patients with disseminated disease. Typical manifestations include subcutaneous abscesses, papules, nodules, and ulcers. Skin abscesses involve adjacent muscle in a minority of cases. Abscesses involving virtually every organ have been described with the most common sites being kidney, adrenal gland, muscle, bone, joint, eye, lymph node, and thyroid gland. Endocarditis has been reported and can affect native or prosthetic valves. Central venous catheter infections have been reported. Peritonitis has been reported in patients undergoing peritoneal dialysis.

Primary Cutaneous Nocardiosis Primary cutaneous nocardiosis follows transcutaneous nocardial inoculation and takes one of three forms: cellulitis, lymphocutaneous syndrome, or actinomycetoma.

Cellulitis begins 1–3 weeks after a recognized breach of the skin, often with soil contamination. Pain, swelling, erythema, and warmth develop over days to weeks. The lesions are usually firm and not fluctuant. Depending on the nature of the inoculation injury, disease may spread to nearby muscles, tendons, bones, and joints. Dissemination is rare.

Lymphocutaneous disease usually begins as a pyodermatous nodule at the site of inoculation, followed by central ulceration and purulent or honey-colored drainage. Subcutaneous nodules often appear along lymphatics that drain the primary lesion. Most cases follow inoculation of a limb, but cases involving the face have been reported, especially in children. Most cases of nocardial lymphocutaneous syndrome are associated with *N. brasiliensis*. Similar disease occurs with other pathogens, most notably *Sporothrix schenckii* **(Chap. 225)** and *Mycobacterium marinum* **(Chap. 185)**.

Mycetoma is an indolent, slowly progressive infection of the skin and subcutaneous tissues with nodular swellings and draining sinuses. Actinomycetoma refers to cases of mycetoma caused by filamentous bacteria. Nearly all cases of *Nocardia*-associated actinomycetoma are caused by *N. brasiliensis.* Clinical manifestations usually begin with a nodular swelling, sometimes at a site of local trauma. Lesions **(Fig. 179-5)** typically develop on the feet or lower legs but may involve the hands, the posterior part of the neck, the upper back, the head, and other sites. The nodule eventually breaks down, and a fistula appears, typically followed by others. The fistulae tend to come and go, with new ones forming as old ones disappear. The discharge is serous or purulent, may be bloody, and often contains 0.1 to 2-mm white granules consisting of masses of mycelia (Fig. 179-5). The lesions spread slowly along fascial planes to involve adjacent areas of skin, subcutaneous tissue, and bone. Over months or years, there may be extensive deformation of the affected part. Lesions involving soft tissues are only mildly painful; those affecting bones or joints are more so (Fig. 179-5). Systemic symptoms are absent or minimal, but mycetoma cases are often associated with prolonged, severe disability. Infection rarely disseminates from actinomycetoma, but lesions on the head, neck, and trunk can invade locally to involve deep organs. The World Health Organization has designated mycetoma a neglected tropical disease.

Primary Ocular Disease Primary ocular nocardiosis includes keratitis, scleritis, and exogenous endophthalmitis. These infections typically occur in otherwise healthy individuals. Patients may report recent exposure to soil. Ocular trauma, surgery, and the use of contact lenses are common risk factors. The onset of disease is typically subacute. Signs and symptoms alone cannot distinguish nocardiosis from other ocular diseases. Spread beyond the eye does not occur.

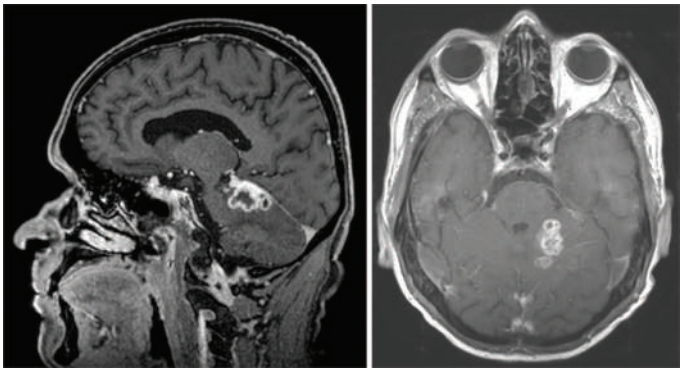

FIGURE 179-4. Multiloculated *Nocardia* brain abscess in the left cerebellum.

DIAGNOSIS

The first step in diagnosis is examination of sputum or pus for branching, beaded, Gram-positive filaments 1 μm wide and up to 50 μm long **(Fig. 179-6)**. These filaments tend to fragment; this may produce apparent cocci and coccobacilli forms. Most nocardiae are acid-fast in direct smears if a weak acid is used for decolorization (e.g., in the modified Kinyoun, Ziehl-Neelsen, and Fite-Faraco methods). The organisms often take up silver stains. Recovery from specimens containing mixed flora can be improved with selective media (colistin–nalidixic acid agar, modified Thayer-Martin agar, or buffered charcoal–yeast extract agar). Nocardiae grow well on most fungal and mycobacterial media, but procedures used for decontamination of specimens for mycobacterial culture can kill nocardiae and should not be used when nocardiosis is on the differential diagnosis.

Nocardiae grow relatively slowly; colonies may take up to 2 weeks to appear and may not develop their characteristic appearance—white, yellow, or orange, with aerial hyphae—for up to 4 weeks. When the diagnosis of nocardiosis is being considered, clinicians should inform the microbiology laboratory so that cultures can be incubated for prolonged periods of time.

Sputum smears are frequently negative in patients with pulmonary nocardiosis. In such cases, bronchoalveolar lavage fluid or a lung biopsy specimen should be obtained. Isolation of *Nocardia* from a respiratory specimen does not always indicate pulmonary infection. *Nocardia* may colonize the respiratory tract of patients with underlying bronchiectasis or other structural lung diseases. In such cases, isolation of *Nocardia* from a respiratory sample must be considered in the greater clinical context. When nocardiae are present in respiratory specimens from patients with intact host defenses, pulmonary nocardiosis should be diagnosed only when clinical and radiographic features are supportive. Nocardiosis is less likely if Gram-stained specimens are negative and cultures are not consistently positive. In contrast, a positive culture in an immunosuppressed patient usually reflects clinical disease, and empirical antimicrobial therapy should be started.

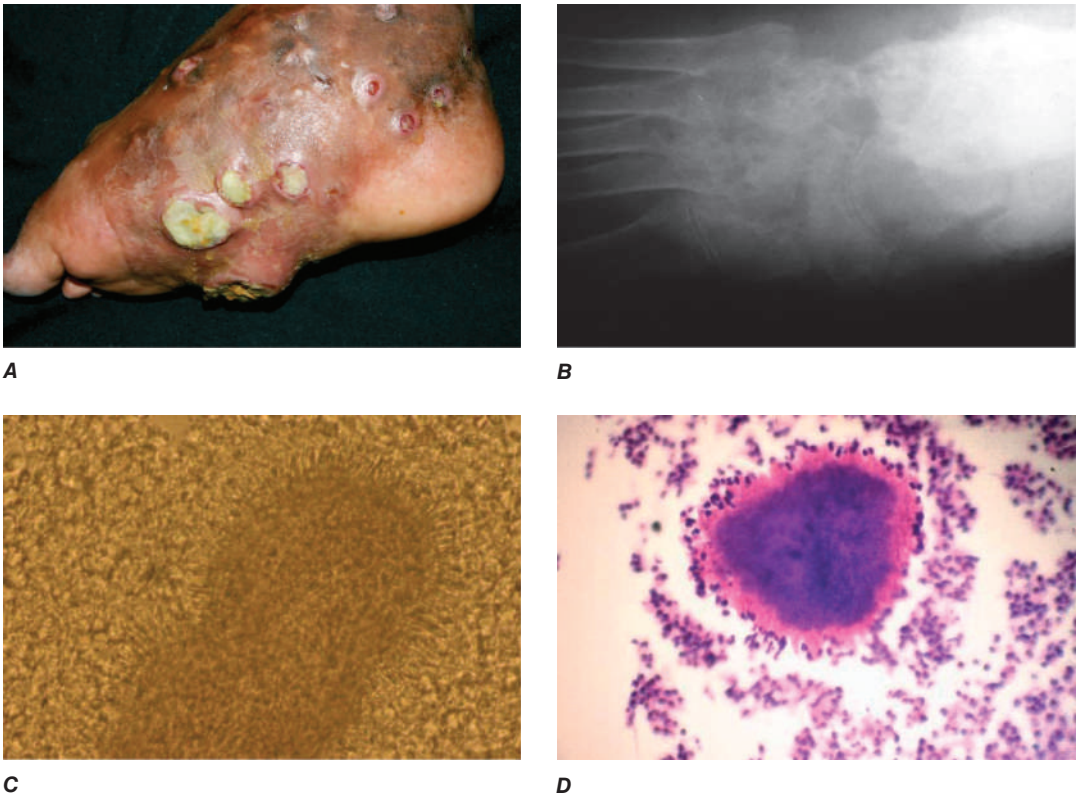

FIGURE 179-5. ***Nocardia brasiliensis*** **mycetoma.** ***A.*** Draining sinuses and giant white grains with a seropurulent discharge. ***B.*** Radiography of the foot showing marked soft tissue enlargement and bony lytic lesions. ***C.*** Direct microscopy of grains stained with Lugol's iodine (×40). ***D.*** Periodic acid–Schiff stain of skin biopsy (×40). *(Images provided by Roberto Arenas and Mahreen Ameen, St. John's Institute of Dermatology, Guy's & St Thomas' NHS Trust, London, UK. Reprinted from R Arenas, M Ameen: Lancet Infect Dis 10:66, 2010, with permission from Elsevier.)*

Occasionally, *Nocardia* isolated from blood cultures may represent contamination in individuals without risk factors for nocardiosis, particularly those who lack clinical manifestations suggestive of nocardial disease.

Actinomycetoma, eumycetoma (cases involving fungi; **Chap. 225**), and botryomycosis (cases involving cocci or bacilli, often *Staphylococcus aureus*) are difficult to distinguish clinically but are readily distinguished with microbiologic testing or biopsy. Granules should be sought in any discharge. Suspect particles should be washed in saline, examined microscopically, and cultured. Granules in actinomycetoma are usually white, pale yellow, pink, or red. They consist of tight masses of fine filaments (0.5–1 μm wide) radiating outward from a central core (Fig. 179-5). Granules in eumycetoma cases are white, yellow, brown, black, or green; under the microscope, they appear as masses of broader filaments (2–5 μm wide) encased in a matrix. Granules of botryomycosis consist of loose masses of cocci or bacilli. Organisms can also be seen in wound discharge or histologic specimens. Culture is the most reliable method for determining the causative organism in cases of mycetoma.

When possible, isolates should be speciated at least to a complex level, by either matrix-assisted laser desorption/ionization–time of flight mass spectrometry (commonly referred to as MALDI-TOF) or genomic sequencing (typically 16S rRNA, *secA1*, *hsp65*, *or gyrB*). When possible, antimicrobial susceptibility testing should be performed, ideally with a Clinical Laboratory Standards Institute–approved broth dilution test. E-tests are less definitive. Nocardiae grow more slowly than most clinically important bacteria, and they tend to clump in suspension so that susceptibility test endpoints are difficult to interpret. Thus, experience is required for interpretation of susceptibility testing results.

EVALUATION OF PATIENTS WITH ESTABLISHED NOCARDIOSIS

Timely identification of metastatic sites of infection is a critical component of managing patients with nocardiosis. Disseminated nocardiosis is exceedingly uncommon in patients with primary cutaneous or ocular disease that develops following traumatic injury. Patients with other forms of nocardiosis, regardless of symptoms, should undergo contrast-enhanced imaging of the CNS to identify undiagnosed brain abscesses. MRI is the preferred imaging modality, with CT reserved for scenarios when MRI cannot be performed.

The presence of a previously undiagnosed immunologic defect should be considered in patients with disseminated nocardiosis who lack typical risk factors for infection. Such patients should undergo testing for HIV infection. Further testing for underlying immunologic disorders should be guided by a careful history and physical examination.

TABLE 179-1 Treatment Duration for Nocardiosis

DISEASE	DURATION
Pulmonary or systemic	
Intact host defenses	6–12 months
Deficient host defenses	12 months[a]
CNS disease	12 months[b]
Primary cutaneous disease (cellulitis, lymphocutaneous disease)	2 months
Osteomyelitis, arthritis, laryngitis, sinusitis	4 months
Actinomycetoma	6–12 months after clinical cure
Keratitis	Topical: until clinical cure Systemic: until 2–4 months after clinical cure

[a]In some patients with AIDS and CD4$^+$ T lymphocyte counts of <200/μL or with chronic granulomatous disease, therapy for pulmonary or systemic disease may be continued indefinitely.

[b]If all apparent central nervous system (CNS) disease has been excised, the duration of therapy may be reduced to 6 months.

TREATMENT

Nocardiosis

Trimethoprim-sulfamethoxazole (TMP-SMX) is the drug of choice for most cases of nocardiosis (Fig. 179-1 and **Table 179-1**). At the outset, 10–20 mg/kg of TMP and 50–100 mg/kg of SMX are given each day in two divided doses. Later, daily doses can be reduced to as little as 5 mg/kg and 25 mg/kg, respectively. In persons with sulfonamide allergies, desensitization usually allows continuation of therapy with these effective and inexpensive drugs.

Linezolid is highly bioavailable and uniformly active against all *Nocardia* species. Treatment-limiting toxicity frequently develops after 2–3 weeks of standard-dose therapy. Tedizolid is associated with less toxicity, but clinical experience is limited.

Amikacin is active against nearly all *Nocardia* species with the notable exceptions of *N. transvalensis* and some *N. pseudobrasiliensis* isolates. Doses of 5–7.5 mg/kg every 12 h or 15 mg/kg every 24 h are typically used. Serum drug levels should be monitored during prolonged therapy, especially in patients with diminished renal function and in the elderly.

Among the β-lactams, ceftriaxone and imipenem have activity against many *Nocardia* species and are frequently used when combination therapy is indicated. Ceftriaxone is not active against *N. farcinica*, which is among the most common species isolated in nocardiosis. In patients with CNS involvement, meropenem is preferred to imipenem as the latter is associated with a higher risk of seizures. Amoxicillin (875 mg) combined with clavulanate (125 mg), given twice a day, has been effective in treating *N. brasiliensis* and some cases of *N. farcinica*.

Among the quinolones, moxifloxacin appears to be most active. Minocycline (100–200 mg twice daily) is often effective; other tetracyclines are usually less effective. Tigecycline appears to be active in vitro against some species, but clinical experience is limited.

Empirical treatment of patients with severe disease should consist of combination therapy with two or three of the following agents: TMP-SMX, linezolid, amikacin, and imipenem (or meropenem if the CNS is involved). Clinical improvement is usually noticeable after 1–2 weeks of therapy but may take longer. After definite clinical improvement, therapy can be continued with a single oral drug, usually TMP-SMX. Some experts use two or more drugs for the entire course of therapy, but whether multiple drugs are better than a single agent is not known, and additional drugs increase the risk of toxicity.

Surgical management of nocardial disease is similar to that of other bacterial diseases. Brain abscesses should be aspirated, drained, or excised if the diagnosis is unclear, if an abscess is large, or if an abscess fails to respond to antimicrobial therapy. Surgical options include needle aspiration and open drainage/excision. Needle aspiration is less invasive, but patients frequently require multiple aspirations. Small or inaccessible brain abscesses can be treated medically. Brain imaging should be repeated to document the resolution of lesions, although radiographic improvement typically lags behind clinical improvement.

With appropriate treatment, the mortality rate for localized pulmonary nocardiosis is <10%. Disseminated nocardiosis carries a higher mortality rate, especially among patients with CNS involvement.

Primary cutaneous and ocular nocardiosis often respond to antimicrobial therapy. Occasionally, surgical management is required for patients with actinomycetoma or scleritis that fails to response to antimicrobial therapy. The mortality rate for actinomycetoma is exceedingly low, but patients suffer often from substantial morbidity, disfigurement, disability, and/or stigmatization. Patients with nocardial keratitis should not receive adjunctive topical corticosteroids.

PREVENTION

Use of TMP-SMX in high-risk populations to prevent *Pneumocystis* disease may reduce but does not eliminate the risk of nocardiosis. The incidence of nocardiosis is low enough that prophylaxis solely to prevent a first episode of *Nocardia* infection (i.e., primary prophylaxis) is not recommended. The role of secondary prophylaxis to prevent recurrent nocardiosis has not been adequately studied. Some experts recommend secondary prophylaxis for patients who remain at high risk for *Nocardia* infection after the completion of antimicrobial therapy.

180 Actinomycosis

Thomas A. Russo, John C. Hu

Actinomycosis is uncommon, and most physicians' personal experience with its clinical presentations is limited. Laboratory identification of the etiologic agents from the order Actinomycetales is not routine. Thus, actinomycosis remains a diagnostic challenge, even for a skilled clinician. However, this infection is usually curable with medical therapy alone. Therefore, an awareness of the full spectrum of clinical syndromes can expedite diagnosis and treatment and minimize unnecessary surgical interventions, morbidity, and mortality.

Classical actinomycosis is an indolent, slowly progressive infection caused by anaerobic or microaerophilic bacteria, primarily of the genus *Actinomyces*, that colonize the mouth, colon, and vagina. Mucosal disruption may lead to infection at virtually any site in the body. In vivo growth of actinomycetes usually results in the formation of characteristic clumps called *grains* or *sulfur granules*. The clinical presentations of actinomycosis are myriad. Common in the preantibiotic era, actinomycosis has diminished in incidence, as has its timely recognition. Actinomycosis has been called the most misdiagnosed disease, and it has been said that no disease is so often missed by experienced diagnosticians.

Three "classic" clinical presentations that should prompt consideration of this unique infection are (1) the combination of chronicity, progression across tissue boundaries, and mass-like features (mimicking malignancy, with which it is often confused); (2) the development of a sinus tract, which may spontaneously resolve and recur; and (3) a refractory or relapsing infection after a short course of therapy, since cure of established actinomycosis requires prolonged treatment.

ETIOLOGIC AGENTS

Actinomycosis is most commonly caused by *A. israelii, A. naeslundii, Schaalia (Actinomyces) odontolyticus, A. viscosus, Schaalia (Actinomyces) meyeri, A. graevenitzii*, and *A. gerencseriae*. Infections due to *Winkia* (*Actinomyces) neuii* have been increasingly recognized. Most if not all actinomycotic infections are polymicrobial. *Aggregatibacter (Actinobacillus) actinomycetemcomitans, Eikenella corrodens*, Enterobacteriaceae, and species of *Fusobacterium, Bacteroides, Capnocytophaga, Staphylococcus*, and *Streptococcus* are commonly isolated with actinomycetes in various combinations, depending on the site of infection. Their contribution to the pathogenesis of actinomycosis is uncertain.

Genome-based analysis and comparative 16S rRNA gene sequencing have led to the identification of an ever-expanding list of *Actinomyces* species and a reclassification of some species to other genera. In recent years, many prior *Actinomyces* species have been placed into new genera including *Schaalia, Winkia, Gleimia,* and *Pauljensenia,* though most publications have yet to adapt these new taxonomic changes. At present, 33 species remain in the *Actinomyces* genus with at least 26 species implicated as causes of human disease. *Gleimia (Actinomyces) europaeus, A. radingae, Schaalia (Actinomyces) turicensis, Schaalia (Actinomyces) cardiffensis, A. urogenitalis, Pauljensenia (Actinomyces) hongkongensis, Schaalia (Actinomyces) georgiae, Schaalia (Actinomyces) massiliensis, A. timonensis, Schaalia* (*Actinomyces) funkei*, *Trueperella* (*Arcanobacterium*) *pyogenes*, *Trueperella* (*Arcanobacterium*) *bernardiae*, and *Propionibacterium propionicum* are additional causes of human actinomycosis, albeit not always with a "classic" presentation.

EPIDEMIOLOGY

Actinomycosis has no geographic boundaries and occurs throughout life, with a peak incidence in the middle decades. Males have a threefold higher incidence than females, possibly because of poorer dental hygiene and/or more frequent trauma. Improved dental hygiene and the initiation of antimicrobial treatment before actinomycosis fully develops have probably contributed to a decrease in incidence since the advent of antibiotics. Individuals who do not seek or have access to health care, those who have an intrauterine contraceptive device (IUD) in place for a prolonged period (see "Pelvic Disease," below), and those who receive bisphosphonate treatment (see "Oral–Cervicofacial Disease," below) are probably at higher risk.

PATHOGENESIS AND PATHOLOGY

The etiologic agents of actinomycosis are members of the normal oral flora and are often cultured from the bronchi, the gastrointestinal tract, and the female genital tract. The critical step in the development of actinomycosis is disruption of the mucosal barrier. Local infection may ensue. Once established, actinomycosis spreads contiguously in a slow, progressive manner, ignoring tissue planes. Although acute inflammation may initially develop at the infection site, the hallmark of actinomycosis is the characteristic chronic, indolent phase manifested by lesions that usually appear as single or multiple indurations. Central necrosis consisting of neutrophils and sulfur granules develops and is virtually diagnostic. The fibrotic walls of the mass are typically described as "wooden." The responsible bacterial and/or host factors have not been identified. Over time, sinus tracts to the skin, adjacent organs, or bone may develop. In rare instances, distant hematogenous seeding may occur; lymphatic spread and associated lymphadenopathy are uncommon. As mentioned above, these unique features of actinomycosis mimic malignancy, with which it is often confused.

Foreign bodies appear to facilitate infection. This association most frequently involves IUDs. Reports have described an association of actinomycosis with HIV infection; transplantation; common variable immunodeficiency; chronic granulomatous disease; treatment with anti–tumor necrosis factor α agents, glucocorticoids, or bisphosphonates; and radio- or chemotherapy. Actinomycosis after SARS-CoV-2 infection is reported but the association is not well-established. Ulcerative mucosal infections (e.g., by herpes simplex virus or cytomegalovirus) may facilitate disease development.

CLINICAL MANIFESTATIONS

Oral–Cervicofacial Disease Actinomycosis occurs most frequently at an oral, cervical, or facial site, usually as a soft tissue swelling, abscess, mass, or ulcerative lesion that is often mistaken for a neoplasm. Dental diseases or procedures are common precipitating factors. The angle of the jaw is generally involved, but a diagnosis of actinomycosis should be considered with any mass lesion or relapsing infection in the head and neck. Radiation therapy and medication-related osteonecrosis of the jaw (MRONJ) due to antiresorptive therapy with bisphosphonates and anti–receptor activator of nuclear factor-κβ ligand (RANKL) such as denosumab, angiogenesis inhibitors, and tyrosine kinase inhibitors have all been recognized as contributing to an increasing incidence of actinomycotic infection of the mandible and maxilla **(Fig. 180-1)**. Canaliculitis (commonly due to *P. propionicum*),

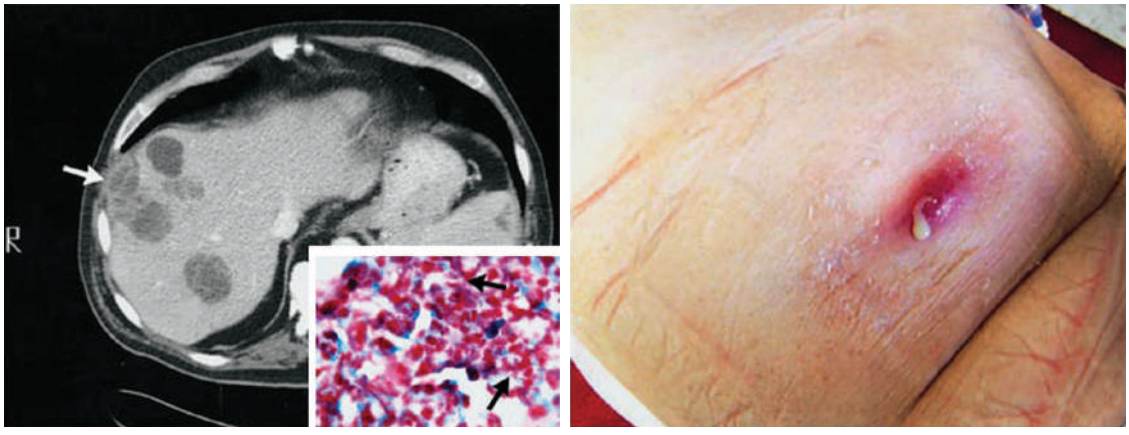
FIGURE 180-2 Thoracic actinomycosis. ***A.*** A chest wall mass from extension of pulmonary infection. ***B.*** Pulmonary infection is complicated by empyema (*open arrow*) and extension to the chest wall (*closed arrow*). *(Courtesy of Dr. C. B. Hsiao, Division of Infectious Diseases, Department of Medicine, State University of New York at Buffalo.)*

otitis, sinusitis, and laryngeal disease also can develop. Pain, fever, and leukocytosis are variably reported. Contiguous extension to the cranium, cervical spine, or thorax is a potential sequela.

Thoracic Disease Thoracic actinomycosis, which may be facilitated by aspirated foreign material such as animal bones or teeth, usually follows an indolent progressive course, with involvement of the pulmonary parenchyma and/or the pleural space. Chest pain, fever, and weight loss are common. A cough, when present, is variably productive. The usual radiographic finding is either a mass lesion or pneumonia. On computed tomography (CT), central areas of low attenuation and ring-like rim enhancement may be seen; cavitary disease may develop. More than 50% of cases include pleural thickening, effusion, or empyema **(Fig. 180-2)**. Rarely, pulmonary nodules or endobronchial lesions occur. Lesions suggestive of actinomycosis include those that cross fissures or pleura; extend into the mediastinum, contiguous bone, or chest wall (*empyema necessitatis or empyema necessitans*); or are associated with a sinus tract. In the absence of these findings, thoracic actinomycosis is usually mistaken for a neoplasm or pneumonia due to more usual causes.



Mediastinal infection is uncommon, usually arising from thoracic extension but rarely from perforation of the esophagus, trauma, or extension of head and neck or abdominal disease. The structures within the mediastinum and the heart can be involved in various combinations; consequently, the possible presentations are diverse. Primary endocarditis (in which *W. neuii* has been increasingly described), esophageal infection, and isolated disease of the breast occur.

Abdominal Disease Abdominal actinomycosis poses a great diagnostic challenge. Months or years usually pass from the inciting event (e.g., appendicitis, diverticulitis, peptic ulcer disease, spillage of gallstones or bile during cholecystectomy, foreign-body perforation, bowel surgery, or ascension from IUD-associated pelvic disease) to clinical recognition. Because of the flow of peritoneal fluid and/or the direct extension of primary disease, virtually any abdominal organ, region, or space can be involved. The disease usually presents as an abscess, a mass, or a mixed lesion that is often fixed to underlying tissue and mistaken for a tumor. On CT, enhancement is most often heterogeneous and adjacent bowel is thickened. Sinus tracts to the abdominal wall, to the perianal region, or between the bowel and other organs may develop and mimic inflammatory bowel disease **(Chap. 337)**. Recurrent disease or a wound or fistula that fails to heal suggests actinomycosis.

Hepatic infection usually presents as one or more abscesses or masses **(Fig. 180-3)**. Isolated disease presumably develops via hematogenous seeding from cryptic foci. Imaging and percutaneous techniques have resulted in improved diagnosis and treatment.

All levels of the urogenital tract can be infected. Renal disease usually presents as pyelonephritis and/or renal and perinephric abscess. Bladder involvement, usually due to extension of pelvic disease, may result in ureteral obstruction or fistulas to bowel, skin, or uterus. *Actinomyces* can be detected in urine with appropriate stains and cultures.

Pelvic Disease Actinomycotic involvement of the pelvis occurs most commonly in association with an IUD but can also be associated with other foreign bodies, such as surgical mesh. When an IUD is in place or

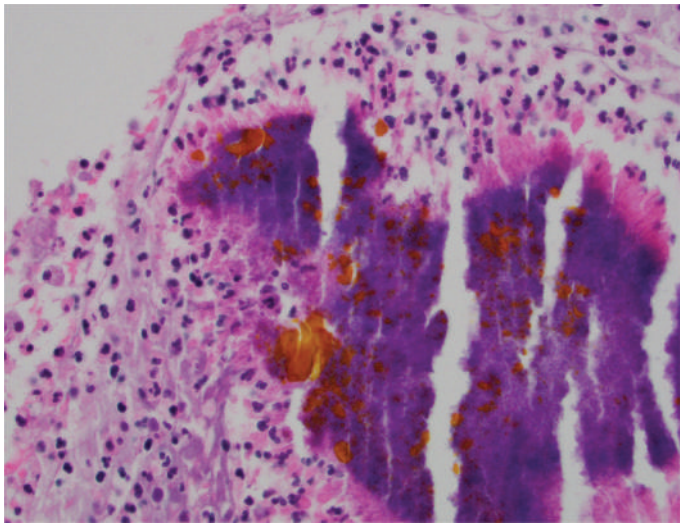
has been used but removed, pelvic symptoms should prompt consideration of actinomycosis. The risk, although not quantified, appears small. The disease rarely develops when the IUD has been in place for <1 year, but the risk increases with time. Symptoms are typically indolent; fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge are the most common. The earliest stage of disease—often endometritis—commonly progresses to pelvic masses or a tuboovarian abscess **(Fig. 180-4)**. Unfortunately, because the diagnosis is often delayed, a "frozen pelvis" mimicking malignancy or endometriosis can develop by the time of recognition, which may lead to unnecessary surgery. Cancer antigen 125 levels may be elevated, further contributing to misdiagnosis. In contrast to malignancy and tuberculosis, pelvic actinomycosis only uncommonly includes ascites and lymphadenopathy. An endometrial biopsy may enable diagnosis in a minimally invasive fashion.

Actinomyces-like organisms (ALOs), which are identified in Papanicolaou-stained specimens in (on average) 7% of women using an IUD, have a low positive predictive value for diagnosis. The detection of ALOs in an asymptomatic patient warrants education and close follow-up but not removal of the IUD unless a suitable contraceptive alternative is agreed on. In the presence of symptoms that cannot be accounted for, it seems prudent to remove the IUD and—if advanced disease is excluded—to initiate a 14-day course of empirical treatment for possible early endometritis.

Central Nervous System Disease Actinomycosis of the central nervous system (CNS) is rare. Single or multiple brain abscesses are most common. Individuals with hereditary hemorrhagic telangiectasia are at increased risk for brain abscess with *Actinomyces* as the potential etiologic agent. An abscess usually appears on CT as a ring-enhancing lesion with a thick wall that may be irregular or nodular. Magnetic resonance perfusion and spectroscopy findings have also been described, as have primary meningitis, epidural or subdural space infection, and cavernous sinus syndrome.

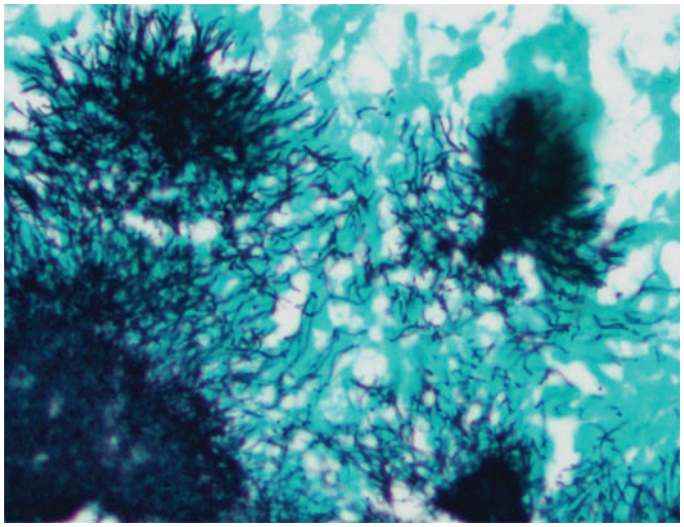
Musculoskeletal and Soft Tissue Infection Actinomycotic infection of bones and joints is usually due to adjacent soft tissue infection but may be associated with trauma, injections, surgery (e.g., prostheses), osteoradionecrosis and bisphosphonate osteonecrosis (limited to mandibular and maxillary bones), or hematogenous spread. Because of slow disease progression, new bone formation and bone destruction can be seen concomitantly. Infection of soft tissue is uncommon and is usually a result of trauma. Actinomycetoma is a slowly progressive infection of the skin and subcutaneous tissue that is usually seen in warm climates. Despite the name being suggestive of *Actinomyces* as a causative agent, it is most commonly caused by *Nocardia* or *Actinomadura* species **(Chap. 179)**.

Disseminated Disease Hematogenous dissemination of disease from any location rarely results in multiple-organ involvement. *S. meyeri* is most commonly involved. The lungs and liver are most often affected, with the presentation of multiple nodules mimicking disseminated malignancy. The clinical presentation may be surprisingly indolent given the extent of disease.



DIAGNOSIS

The diagnosis of actinomycosis is rarely considered. All too often, actinomycosis is first mentioned by the pathologist after extensive surgery. Since medical therapy alone is frequently sufficient for cure, the challenge for the clinician is to consider the possibility of actinomycosis, to diagnose it in the least invasive fashion, and to avoid unnecessary surgery. The clinical and radiographic presentations that suggest actinomycosis are discussed above. Of note, hypermetabolism has been demonstrated by ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) in actinomycotic disease. Aspirations and biopsies (with or without CT or ultrasound guidance) are being used successfully to obtain clinical material for diagnosis, although surgery may be required. The microscopic identification of sulfur granules (an in vivo matrix of bacteria, calcium phosphate, and host material) in pus or tissues, which increases with the examination of additional histopathologic sections and the use of positively charged slides to optimize adhesion, is the most common means of diagnosis. Occasionally, these granules are identified grossly from draining sinus tracts or pus. Periodic acid–Schiff (PAS), Grocott methenamine silver (GMS), and Gram stains may be helpful to identify actinomycotic aggregates in surgical specimens. On hematoxylin-eosin stain, the granules may be eosinophilic or variably surrounded by a radiating fringe of eosinophilic clubs called the Splendore-Hoeppli phenomenon **(Fig. 180-5)**. Although sulfur granules are a defining characteristic of actinomycosis, granules also are found in mycetoma **(Chaps. 179 and 225)** and botryomycosis (a chronic suppurative bacterial infection of soft tissue or, in rare cases, visceral tissue that produces clumps of bacteria resembling granules). These entities can easily be differentiated from actinomycosis with appropriate histopathologic and microbiologic studies. Microbiologic identification of actinomycetes is often precluded by prior antimicrobial therapy or failure to perform appropriate microbiologic cultures. For optimal yield, the avoidance of even a single dose of antibiotics is mandatory. Although some species can grow aerobically, isolation is maximized under anaerobic conditions, usually requiring 5–7 days but potentially up to 2–4 weeks. The use of 16S rRNA gene amplification and sequencing by clinical microbiology laboratories is increasing and is enhancing diagnostic sensitivity and specificity. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) holds similar promise, but databases are still being optimized. Because actinomycetes are components of the normal oral and genital-tract flora, their identification in the absence of sulfur granules in sputum, bronchial washings, and cervicovaginal secretions may reflect colonization rather than infection.



TREATMENT

Actinomycosis

Decisions about treatment are based on the collective clinical experience of the past 75 years. Actinomycosis requires prolonged treatment with high doses of antimicrobial agents; suitable antimicrobial agents and those deemed unreliable are listed in **Table 180-1**. The need for intensive treatment is presumably due to the drugs' poor penetration of the thick-walled masses common in this infection and/or the sulfur granules themselves, which may represent a biofilm. Although therapy must be individualized, the IV administration of 18–24 million units of penicillin daily for 2–6 weeks, followed by oral therapy with penicillin or amoxicillin (total duration, 6–12 months), is a reasonable guideline for serious infections and bulky disease. For penicillin-allergic patients, tetracyclines, ceftriaxone, or carbapenems are reasonable alternatives. Less extensive disease, particularly that involving the oral–cervicofacial region or

TABLE 180-1 Appropriate and Inappropriate Antibiotic Therapy for Actinomycosis[a]

CATEGORY	AGENT
Extensive successful clinical experience[b]	Penicillin: 3–4 million units IV q4h[c,d] Amoxicillin: 500 mg PO q6h Erythromycin: 500–1000 mg IV q6h or 500 mg PO q6h[c] Tetracycline: 500 mg PO q6h Doxycycline: 100 mg IV or PO q12h Minocycline: 100 mg IV or PO q12h Clindamycin: 900 mg IV q8h or 300–450 mg PO q6h[c]
Anecdotal successful clinical experience	Ceftriaxone[d] Imipenem-cilastatin Piperacillin-tazobactam
Agents predicted to be efficacious on the basis of in vitro activity	Vancomycin Dalbavancin Linezolid Rifampin Ertapenem[d] Meropenem Tigecycline[d] Eravacycline Azithromycin[d]
Agents that should be avoided	Metronidazole Aminoglycosides Oxacillin, dicloxacillin Cephalexin Ceftazidime Daptomycin Fluoroquinolones

[a]Additional coverage for concomitant "companion" bacteria may be required. [b]Controlled evaluations have not been performed. Dose and duration require individualization depending on the host, site, and extent of infection. As a general rule, a maximal parenteral antimicrobial dose for 2–6 weeks followed by oral therapy, for a total duration of 6–12 months, is required for serious infections and bulky disease, whereas a shorter course may suffice for less extensive disease, particularly in the oral–cervicofacial region. Monitoring the impact of therapy with computed tomography or magnetic resonance imaging is advisable when appropriate. [c]Recent in vitro data have demonstrated resistance in up to 33% of isolates. [d]This agent can be considered for at-home parenteral therapy; penicillin requires a continuous infusion pump.

the isolation of *Actinomyces* in the absence of tissue changes associated with actinomycosis, may be cured with a shorter course. For home IV therapy, the ease of once-a-day dosing makes ceftriaxone appealing in certain circumstances; however, a greater body of literature supporting its efficacy would be desirable. The availability of portable infusion pumps for home therapy allows for both the appropriate dosing and practical administration of IV penicillin. For infections in critical sites (e.g., CNS), this approach remains the safest until more information is available on other agents. The pharmacokinetic properties, availability of oral and parenteral formulations, and potential efficacy of azithromycin also make this agent appealing. Unfortunately, few in vitro and no clinical data exist on its use to treat actinomycosis. If therapy is extended beyond the resolution of measurable disease, the risk of relapse—a clinical hallmark of this infection—will be minimized; CT and magnetic resonance imaging (MRI) are generally the most sensitive and objective techniques by which to accomplish this goal. A similar approach is reasonable for immunocompromised patients, although refractory disease has been described in HIV-infected individuals. While the role played by "companion" microbes in actinomycosis is unclear, many isolates are pathogens in their own right, and a regimen covering these organisms during the initial treatment course is reasonable. Isolation of *Actinomyces* from blood cultures in the absence of defined infection may represent contamination or transient bacteremia from a mucosal site of colonization, in which case treatment may not be necessary.

Combined medical–surgical therapy is still advocated in some reports. However, an increasing body of literature now supports an initial attempt at cure with medical therapy alone, even in extensive disease. CT and MRI should be used to monitor the response to therapy. In most cases, either surgery can be avoided or a less extensive procedure can be used. This approach is particularly valuable in sparing critical organs, such as the bladder or the reproductive organs in women of childbearing age. For a well-defined abscess, percutaneous drainage in combination with medical therapy is a reasonable approach. When a critical location is involved (e.g., the epidural space, the CNS), when there is significant hemoptysis, or when suitable medical therapy fails, surgical intervention may be appropriate. In the absence of optimal data, the combination of a prolonged course of antimicrobial therapy and resection—at least of necrotic bone for radiation- and medication-related osteonecrosis of the jaw—is a reasonable approach.

181 Whipple Disease

Thomas A. Russo, Seth R. Glassman

Whipple disease (WD), described by George Whipple in 1907, is a chronic infection caused by *Tropheryma whipplei*. Most commonly, years pass from the onset of symptoms to the recognition of the disease because of its rarity, its various manifestations mimicking other conditions, and the need to perform nonroutine diagnostic tests. The long-held belief that WD is an infection was supported by observations on its responsiveness to antimicrobial therapy in the 1950s and the identification of bacilli via electron microscopy in small-bowel biopsy specimens in the 1960s. This hypothesis was finally confirmed by amplification and sequencing of a partial 16S rRNA polymerase chain reaction (PCR)–generated amplicon from duodenal tissue in 1991. The subsequent successful cultivation of *T. whipplei* enabled whole genome sequencing and the development of additional diagnostic tests. The development of PCR-based diagnostics has broadened our understanding of both the epidemiology of and the clinical syndromes attributable to *T. whipplei*. Exposure to *T. whipplei*, which appears to be much more common than has been appreciated, can be followed by asymptomatic carriage, acute disease, or chronic infection. Chronic infection—WD—is a rare development after exposure. "Classic" WD is manifested by some combination of arthralgias/arthritis, weight loss, chronic diarrhea, abdominal pain, and fever. Variable involvement at other sites also occurs; neurologic and cardiac disease are most common. Acute infection and chronic organ disease in the absence of intestinal involvement (see "Isolated Infection," below) are described with increasing frequency. Since untreated WD is often fatal and delayed diagnosis may lead to irreparable organ damage (e.g., in the central nervous system [CNS]), knowledge of the clinical scenarios in which WD should be considered and of an appropriate diagnostic strategy is mandatory.

ETIOLOGIC AGENT

T. whipplei is a weakly staining gram-positive bacillus. Genomic sequence data have revealed that the organism has a small (<1-megabase) chromosome, with many biosynthetic pathways absent or incomplete. This finding is consistent with a host-dependent intracellular pathogen or a pathogen that requires a nutritionally rich extracellular environment. It is one of the slowest growing human pathogens, with a doubling time of 18 days. A genotyping scheme based on a variable region has disclosed >100 genotypes to date. All genotypes appear to be capable of causing similar clinical syndromes.

EPIDEMIOLOGY

WD is rare but has been increasingly recognized since the advent of PCR-based diagnostic tools. Prevalence had been previously estimated at 1–3 cases per 1 million population, although a recent U.S. epidemiologic survey places the number closer to 10 cases per million. Seroprevalence studies indicate that ~50% of Western Europeans and ~75% of Africans from rural Senegal have been exposed to *T. whipplei*. Higher prevalence may be attributable to differences in sanitation. Humans are the only known host. In most studies, males more commonly develop WD; WD is more common in Caucasians and increases with age. To date, no clear animal or environmental reservoir has been demonstrated. However, the organism has been identified by PCR in sewage water and human feces. Workers with direct exposure to sewage are more likely to be asymptomatically colonized than controls, a pattern suggesting fecal–oral spread. Fecal PCR detection rates of 38% among family members of carriers or patients with infection support oral–oral or fecal–oral spread, although a common environmental exposure cannot be excluded. Further, the development of acute *T. whipplei* pneumonia in children raises the possibility of droplet or airborne transmission.

PATHOGENESIS AND PATHOLOGY

Rates of asymptomatic carriage of *T. whipplei* are far higher than rates of chronic infection (<0.01% of those exposed). Both decreased host pathogen-specific inflammatory response and pathogen-driven modulation of host inflammatory response likely play a role in establishing chronic infection. The human leukocyte antigen (HLA) alleles DRB1(*)13 and DQB1(*)06, which stimulate humoral rather than cell-mediated immune responses, are associated with an increased risk of infection. However, only a minority of infected patients possess these haplotypes, suggesting a role for other host factors. IRF4, a transcription factor involved with the immune response, could be such a factor as evidenced by four related family members with WD who possessed IFR4 haploinsufficiency due to a loss-of-function mutation; the distribution of WD in this extended family was consistent with an autosomal dominant trait with incomplete penetrance.

Flow cytometry performed in WD patients demonstrates B-cell subset abnormalities when compared to matched controls. Chronic infection is associated with an impaired T_H1 response, enhanced production of anti-inflammatory cytokines, increased activity of regulatory T cells, M2 polarization of macrophages with diminished antimicrobial activity and impaired phagosome–lysosome fusion and ensuing apoptosis, and blunted development of *T. whipplei*–specific T cells. Therapies that blunt cell-mediated host immune responses (e.g. systemic glucocorticoids or anti–tumor necrosis factor α [TNF-α] agents) may accelerate progression of chronic disease. Impaired cell-mediated immunity may play a role in establishing chronic carriage of *T. whipplei*, as is evidenced by higher rates of detection in the secretions of HIV-infected persons.

T. whipplei has a tropism for myeloid cells, which it invades and in which it can avoid being killed. Infiltration of infected tissue by

large numbers of foamy macrophages containing periodic acid–Schiff (PAS)–staining inclusions (representing ingested bacteria) is a characteristic and most common finding. With gastrointestinal disease progression, villus atrophy, lymphangiectasia, crypt hyperplasia, and apoptosis of surface epithelial cells are observed in the small intestine, with resultant diarrhea due to decreased absorption and increased leak of water and solutes. Occasionally, involvement of lymphatic or hepatic tissue may manifest as noncaseating granulomas that can mimic sarcoid or granulomatous vasculitis.

CLINICAL MANIFESTATIONS

Asymptomatic Colonization/Carriage Studies using primarily PCR have detected *T. whipplei* sequence in stool, saliva, duodenal tissue, and (rarely) blood in the absence of symptoms. Although prevalence rates are still being defined, in Western European countries, detection in saliva (0.2%) is less common than that in stool (1–11%) and appears to occur only with concomitant fecal carriage. The prevalence of fecal carriage is elevated among individuals with exposure to waste water or sewage (12–26%) and among children living in tropical Africa and Asia (20–48%). A duration of carriage of 7 years for the same strain has been described in a sewer worker. Evolution of the carrier state into chronic disease is uncommon. Bacterial loads are lighter in asymptomatic carriage than in active disease.

Acute Infection *T. whipplei* has been implicated as a cause of acute gastroenteritis in children. It was also detected via PCR in the blood of 4.6% of febrile patients (75% of whom were <15 years of age) from two rural villages in Senegal as opposed to 0.25% of healthy controls. Further, *T. whipplei* has been implicated as a cause of acute pneumonia. These data suggest that primary acquisition may result in symptomatic pulmonary or intestinal infection or a febrile syndrome, which perhaps are more common than is generally appreciated.

Chronic Infection • **"CLASSIC" WD** So-called classic WD was the initial clinical syndrome recognized, with consequent identification of *T. whipplei*. This chronic infection is defined by involvement of the duodenum and/or jejunum that develops over years. In most individuals, the initial phase of disease manifests primarily as intermittent, often symmetrical, occasionally chronic, and rarely destructive migratory oligo- or polyarthralgias/seronegative arthritis involving the knees, wrists, ankles, and metacarpal-interphalangeal joints most commonly. Less frequently, spondylitis, sacroiliitis, discitis, tenosynovitis, bursitis, and prosthetic hip infection also have been described. Intermittent fever, myalgias, and skin nodules may accompany joint symptoms. Tests for rheumatoid factor and antinuclear antibody are usually negative. This initial stage is often confused with a variety of rheumatologic disorders and, on average, lasts 6–8 years before gastrointestinal symptoms commence. Treatment of presumed inflammatory arthritis with immunosuppressive agents (e.g., glucocorticoids, anti-TNF-α, anakinra) can accelerate progression of the disease process; thus, screening for WD prior to initiation of immunosuppressant therapy may be appropriate, depending on the clinical scenario. Alternatively, antimicrobial therapy for another indication may reduce symptoms, and this situation should also prompt consideration of WD. The intestinal symptoms that develop in the majority of cases are characterized by diarrhea with accompanying weight loss and may be associated with fever and abdominal pain. Occult gastrointestinal blood loss, vitamin deficiencies, hepatosplenomegaly (10–15%), and ascites (10%) are less common. Anemia and hypereosinophilia may be detected. The most common finding on abdominal computed tomography is mesenteric and/or retroperitoneal lymphadenopathy (usually raising concern about lymphoma). The endoscopic or video-capsule observation of pale, yellow, or shaggy mucosa with erythema or ulceration past the first portion of the duodenum suggests WD (Fig. 181-1). When endoscopy with duodenal biopsy is nondiagnostic, a video-capsule study may assist in identifying more distal lesions for subsequent biopsy. ^{18}F-Fluorodeoxyglucose positron emission tomography (FDG-PET) studies in patients with WD suggest the entire small bowel can be involved. Diagnostic misdirection can be caused by co-infection with *Giardia lamblia*, which is occasionally identified. The intestinal phase can also be confused with Crohn or celiac disease. In addition to rheumatologic and intestinal disease, neurologic (6–63%), cardiac (17–55%), pulmonary (10–50%), lymphatic (10–55%), ocular (5–10%), dermal (5–30%), and less commonly other sites are variably involved in classic WD.

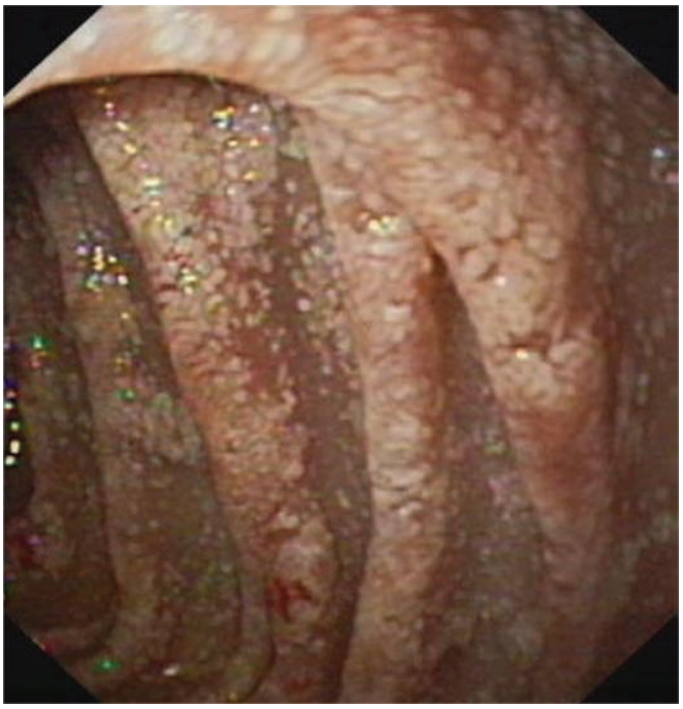

FIGURE 181-1 Endoscopic view of the jejunal mucosa demonstrating a thickened, granular mucosa and "white spots" due to dilated lacteals. *(Reprinted with permission from J Bureš et al: Whipple's disease: Our own experience and review of the literature. Gastroenterol Res Pract, 2013.)*

Neurologic Disease CNS disease, defined by PCR-based detection of *T. whipplei* in cerebrospinal fluid (CSF), develops in ~50% of patients, many of whom are asymptomatic. A variety of neurologic manifestations have been reported and portend a poor prognosis. The most common are cognitive changes including memory impairment progressing to dementia, personality and mood alterations, hypothalamic involvement (e.g., polyuria/polydipsia, sleep-cycle disorders), and supranuclear ophthalmoplegia. In addition, neuro-ophthalmologic manifestations of WD include supranuclear gaze palsy (usually vertical), oculomasticatory and oculofacial myorhythmia (highly suggestive of WD), nystagmus, and retrobulbar neuritis. Focal neurologic presentations (dependent on lesion location), seizures, ataxia, meningitis, encephalitis, rhombo- or limbic encephalitis, hydrocephalus, myelopathy, myoclonus, choreiform movements, and distal polyneuropathy also have been described. Neurologic sequelae occur with CNS disease, and the mortality risk is significant.

Magnetic resonance imaging (MRI) results may be normal. Identified lesions (solitary or multifocal) are usually T2 and fluid-attenuated inversion recovery (FLAIR) hyperintense and may enhance with gadolinium. All sites can be involved, and the nature of lesions is variable (e.g., nodular, infiltrative, tumor-like). Although imaging findings are myriad and are not diagnostic, the median temporal lobe, midbrain, hypothalamus, and thalamus are commonly affected. FDG-PET may reveal increased uptake. CSF analysis may be normal; when abnormal, leukocytosis (generally lymphocyte-predominant) and an elevated protein concentration are common. A low CSF glucose level has been reported.

Cardiac Disease Endocarditis is increasingly recognized in WD (85% of cases in males), causes 2.6–6.3% of culture-negative endocarditis cases, and may be complicated by congestive heart failure (40% of cases), embolic events, arrhythmias, mycotic aneurysm, or rarely hypotension. Fever is often absent, and the Duke clinical criteria are rarely met.

Vegetations are identified by echocardiography in 50–75% of cases. All valves, alone or in combination, can be affected; most commonly involved are the aortic and mitral valves. Preexisting valvular disease is found in only a minority of cases, although infection of bioprosthetic valves has been described. Mural, myocardial, aortic (aortitis), or pericardial disease also occurs alone or in combination with valvular involvement. Constrictive pericarditis develops infrequently. The diagnosis of cardiac disease is rarely made prior to surgical intervention.

Pulmonary Disease Some combination of interstitial disease, nodules, parenchymal infiltrate, and pleural effusion is observed. An association with pulmonary hypertension has also been reported. The clinical significance of *T. whipplei* sequence identified in bronchoalveolar lavage fluid (BALF) from asymptomatic HIV-infected individuals or in a case of interstitial lung disease is unresolved but suggests caution in diagnosing "isolated" pneumonia based on sequence alone. Notably, while the bacterium seems to exist in the airways of HIV-infected persons at higher rates, its presence is not clearly associated with increased inflammation or a discernible decrease in lung function.

Lymphatic Disease Mesenteric and retroperitoneal lymphadenopathy are common with intestinal disease, and mediastinal adenopathy may be associated with pulmonary infection. Peripheral adenopathy is less common.

Ocular Disease (Non–Neuro-Ophthalmologic) Uveitis is the most common form of ocular disease, usually presenting as a change in vision or "floaters." Anterior (anterior chamber), intermediate (vitreous), and posterior (retina/choroid) uveitis can occur alone or in combination. Treatment with glucocorticoids alone can worsen uveitis and unmask extraocular disease. Likewise, use of local or systemic glucocorticoids after ocular surgery can precipitate ocular infection, likely as a result of asymptomatic or subclinical disease. Keratitis, crystalline keratopathy, and optic neuritis also have been reported. Patients may be misdiagnosed with sarcoid or Behçet's disease prior to the recognition of WD.

Dermatologic Disease Skin hyperpigmentation (melanoderma), particularly in light-exposed areas in the absence of adrenal dysfunction, is suggestive of WD. A variety of other cutaneous manifestations have been described, including erythematous macular lesions, nonthrombocytopenic purpura, subcutaneous nodules, and hyperkeratosis.

Miscellaneous Sites Thyroid, renal, testicular, epididymal, gallbladder, skeletal muscle, and bone marrow involvement and membranous nephropathy have all been described. In fact, almost any organ can be involved in classic WD, with varying frequency, variable combinations, and myriad signs and symptoms. As a result, WD should be considered in the setting of a chronic multisystemic process. Despite its rarity, the combination of rheumatologic and intestinal disease with weight loss, with or without neurologic and cardiac involvement, warrants heightened suspicion.

ISOLATED INFECTION This entity has been defined as infection in the absence of intestinal symptoms, although an occasional small-bowel biopsy may be PAS-positive or more commonly PCR-positive in this setting. "Isolated infection" is something of a misnomer since multiple nonintestinal sites of *T. whipplei* infection are not uncommon. Infection at the same nonintestinal sites (single or multiple) that are variably involved in classic WD may also present as "isolated infection." Further, intestinal disease can subsequently develop. Endocarditis, neurologic disease, uveitis, rheumatologic manifestations, and pulmonary involvement are most commonly described. Signs and symptoms are similar to those described for *T. whipplei* infection of these sites in classic WD. With enhanced PCR-based diagnostic capabilities, *T. whipplei* infection without concomitant intestinal involvement (of which endocarditis is the best example) will probably be diagnosed increasingly often.

REINFECTION/RELAPSING DISEASE/IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME (IRIS) It has been suggested that, if an underlying host immune defect places an individual at risk for chronic infection, then that person may be at risk for reinfection due to occupational exposure or contact with family members who are asymptomatically colonized. One case of apparent reinfection that was due to a different genotype supports this contention.

Optimal treatment regimens and durations are still being defined. However, it is clear, especially in the setting of occult or overt CNS disease, that treatment with oral tetracycline or trimethoprim-sulfamethoxazole (TMP-SMX) alone may result in disease relapse. Relapses or perhaps reinfections occurring years to decades after initial therapy have been described.

As in patients treated for HIV or mycobacterial disease, IRIS has been described in up to 17% of patients treated for *T. whipplei* infection. Prior immunosuppressive therapy increases the likelihood of IRIS, in which inflammation recurs after an initial clinical response to treatment and loss of PCR detection of *T. whipplei*. In patients with chronic WD, IRIS may be related to sustained disruption of the epithelial barrier, leading to increased translocation of gut-derived microbial products and dysbalanced T-cell restoration. Manifestations include the development of fever, arthritis, skin lesions, subcutaneous nodules, pleuritis, uveitis, and orbital and periorbital inflammation; some cases have been fatal.

DIAGNOSIS

Considering *T. whipplei* infection and ensuring that the appropriate tests are performed are the critical steps in making the diagnosis, which otherwise will likely be missed. Serology is of little value since patients with active infection usually mount a poor IgM/IgG response to *T. whipplei* and a positive result most likely reflects prior exposure and clearance. The clinical presentation will in part dictate which clinical specimens are most likely to enable the diagnosis. In the presence (and perhaps the absence) of gastrointestinal symptoms, postbulbar duodenal biopsies should be performed, although a normal macroscopic appearance is common. As a general rule, the diagnostic yield is greater for tissue specimens than for body fluids. Biopsy of normal-appearing skin may detect *T. whipplei* in the setting of classic WD and serve as a minimally invasive means to establish the diagnosis. It is prudent to collect CSF even in the absence of CNS symptoms; asymptomatic disease is common, the CNS is the most common site for relapse, and thus the information gained by CSF examination could influence the design and duration of the treatment regimen.

The diagnosis of classic WD was originally based on histologic findings in intestinal biopsy specimens. Although this diagnostic procedure remains important, it is not optimally sensitive. Infiltration of the lamina propria with macrophages containing PAS-positive inclusions that are resistant to diastase is observed. However, PAS is nonspecific, also yielding positive results with mycobacteria as well as other microorganisms. Staining of other tissues or fluids (e.g., ocular aspirations) for PAS-positive inclusions in macrophages can be performed to support the diagnosis. The sensitivity of identification of PAS-positive inclusions in WD may be decreased by anti-TNF-α therapy. Electron microscopy can be used to identify the trilaminar cell wall of *T. whipplei*. When available, immunohistochemistry has greater specificity and sensitivity than PAS staining and can be performed on archived fixed tissue. Alternatively, the use of fluorescence in situ hybridization (FISH) has been reported as a complementary diagnostic tool with various tissue samples.

The development and implementation of specific PCR-based diagnostics have significantly increased the sensitivity and specificity of *T. whipplei* identification. PCR can be applied to affected tissues (with greater sensitivity for non-formalin-fixed than for formalin-fixed tissue) in support of histologic findings and to various body fluids. It is important to note that the interpretation of a PCR-based diagnostic approach must take into account limitations such as false-positive results due to sample contamination, false-negative results due to low organism load, poor sample quality, inadequate DNA extraction, and variability in performance of various PCR assays. Quantitative comparisons from different sites can add specificity to PCR-based diagnostics of WD and distinguish between WD patients and asymptomatic carriers. In patients suspected of having WD, PCR testing of duodenal biopsy specimens with a cycle threshold value of ≤30 can help confirm the diagnosis, even in cases with negative PAS staining. As with all diagnostic tests, consideration of pretest probability is critical

for interpretation, and a negative result does not exclude WD. Urine PCR for *T. whipplei* infection may hold promise for the noninvasive diagnosis of classic and isolated WD. In one study of 12 cases, urine PCR was positive in nine cases (75%) prior to treatment compared to zero (0%) of 110 controls, including 11 controls that were presumed carriers in whom feces PCR was positive, although there was no evidence of disease. In addition, urine PCR is a potential tool to evaluate the success of WD therapy. Saliva and fecal PCR are inappropriate as the sole diagnostic tools for WD due to low positive predictive values, which more commonly identify colonization, not disease; a positive result requires confirmation from an appropriate end-organ tissue or body fluid.

Next-generation sequencing techniques to evaluate for cell-free DNA (cfDNA) in plasma may lead to increased recognition of *T. whipplei* as a cause of endocarditis.

T. whipplei has been successfully cultured from blood, CSF, synovial fluid, BALF, valve tissue, duodenal tissue, skeletal muscle, and lymph nodes, but culture is not practical since it takes months to obtain a positive result.

Affected anatomic sites in WD patients may demonstrate uptake on FDG-PET, which in turn could guide tissue sampling for use in specific tests.

TREATMENT

Whipple Disease

Data on treatment are emerging, but the optimal regimen and duration for chronic infection, which may depend on the sites involved (e.g., CNS and heart valve), are unclear. Appropriate treatment usually results in a rapid—and at times remarkable—clinical response (e.g., in CNS disease), but eradication requires prolonged treatment. Maintenance of a durable response has been more challenging because of both relapse and host predisposition to reinfection.

Rates of relapse, particularly of CNS disease, were unacceptable with oral tetracycline or TMP-SMX monotherapy. Sequence data now indicate that TMP is not active against *T. whipplei* (given the absence of dihydrofolate reductase in *T. whipplei*) and that resistance to SMX and sulfadiazine can occur. However, a randomized controlled trial in 40 patients, who received either ceftriaxone (2 g IV q24h) or meropenem (1 g IV q8h) for 2 weeks followed by oral TMP-SMX (160/800 mg) twice a day for 1 year, demonstrated outstanding efficacy. The only case in which therapy failed—an asymptomatic CNS infection that was not eradicated by either regimen—was subsequently cured with oral minocycline and chloroquine (250 mg/d after a loading dose). A follow-up trial reported similar efficacy with a regimen of ceftriaxone (2 g IV q24h) for 2 weeks followed by oral TMP-SMX for 3 months. One issue in these trials was that the doses—and perhaps the duration of ceftriaxone and meropenem treatment as well—were not optimal for CNS infection. By contrast, in a small retrospective series, outcome was better in patients treated with oral doxycycline (100 mg twice a day) plus hydroxychloroquine (200 mg three times a day to raise phagosome pH and increase drug activity in vitro) than in patients initially treated with TMP-SMX.

Until more data become available, it seems prudent—at least in asymptomatic/symptomatic CNS disease (which is present in many cases of WD)—first to administer CNS-optimized doses of IV ceftriaxone (2 g q12h) or meropenem (2 g q8h) for 2–4 weeks and then to treat with oral doxycycline, or minocycline plus hydroxychloroquine for at least 1 year, if tolerated. Although TMP-SMX has been frequently used as the oral alternative with reported success, a number of relapses or reinfections with TMP-SMX treatment have been reported, thereby suggesting caution for its use in patients with infection in critical locations such as the CNS and the heart. Although data on the use of PCR to guide therapy do not exist, it seems reasonable that continued *T. whipplei* detection by PCR, especially in the CSF and perhaps urine, should dictate at least continuation of therapy or perhaps consideration of an alternative regimen when in conjunction with a poor clinical response.

Timely recognition may result in cure with medical management alone. Surgery may be needed in the setting of endocarditis with significant valve dysfunction or myocardial abscess. Current European guidelines for the treatment of endocarditis caused by *T. whipplei* recommend oral doxycycline plus hydroxychloroquine for ≥18 months or, alternatively, ceftriaxone (2 g q24h IV) or penicillin (2 million units q4h IV) plus streptomycin (1 g q24h IV) for 2–4 weeks followed by oral TMP-SMX (800 mg q12h); a small study from Spain reported that treatment durations of 12–13 months with these regimens or variations were efficacious.

Data on isolated infection and certain site-specific treatment issues are even more limited. Anecdotal reports describe successful treatment of uveitis with oral TMP-SMX with or without rifampin, whereas treatment with tetracycline alone has resulted in relapse. Although a role for adjunctive intraocular therapy has been reported, the data are unclear on this point. There is a single case report of clearance of infection in a chronically relapsing patient by the addition of interferon gamma to antimicrobials; supplementation to antimicrobials may be a consideration to address refractory disease or potential issues with antibiotic resistance.

Although data on the treatment of foreign body–associated infection are virtually nonexistent, medical treatment for a prosthetic hip infection was apparently successful; however, follow-up was limited.

The occurrence of a Jarisch-Herxheimer reaction within 24 h of treatment initiation has been described, with rapid resolution. The addition of glucocorticoids may be beneficial in the management of IRIS, and thalidomide has been used in steroid-refractory cases.

Importantly, although data are lacking, due to the inherent risk of relapse or reinfection, lifelong suppressive therapy with doxycycline after completion of the initial treatment regimen has been advocated. Regardless of the therapeutic approach chosen, an effort to ensure compliance and close follow-up for potential relapse or reinfection, which can occur many years after an apparent cure, will maximize the chances for a good outcome.

PREVENTION

Attempts are underway to develop a peptide-based vaccine against *T. whipplei*. However, the role for this may be limited given the relative rarity of infection.

182 Infections Due to Mixed Anaerobic Organisms

Neeraj K. Surana, Dennis L. Kasper

Anaerobes constitute the predominant class of bacteria of the normal human microbiota that reside on mucous membranes and predominate in many infectious processes, particularly those arising from mucosal surfaces. These organisms generally cause disease subsequent to the breakdown of mucosal barriers and the leakage of the microbiota into normally sterile sites. Infections resulting from contamination by the microbiota are usually polymicrobial and involve both aerobic and anaerobic bacteria. However, the difficulties encountered in handling specimens in which anaerobes may be important and the technical challenges entailed in cultivating and identifying these organisms in clinical microbiology laboratories continue to leave the anaerobic etiology of an infectious process unproven in many cases. Therefore, an understanding of the types of infections in which anaerobes can play a role is crucial in selecting appropriate microbiologic tools to identify the organisms in clinical specimens and in choosing the most appropriate treatment, including antibiotics and surgical drainage or debridement of the infected site. This chapter focuses on infections caused by anaerobic bacteria other than *Clostridium* species, which are covered elsewhere **(Chaps. 139 and 159)**.

HISTORIC PERSPECTIVE

Anaerobic organisms were first identified by Antonie van Leeuwenhoek in 1680—nearly a century before oxygen itself was discovered. Leeuwenhoek set up culture medium (crushed pepper powder and clean rainwater) in two glass tubes—one open to ambient air and the other sealed closed—that he incubated for several days. Although he did not expect to observe anything in the sealed tube, he was surprised to find "animalcules" in both tubes. He noted that these bacteria in the sealed tube were "bigger than the biggest sort" in the tube left open to air. It was not until the mid- to late nineteenth century that Leeuwenhoek's findings were confirmed by Pasteur and others. However, these principles described by Leeuwenhoek underlie the basic pathogenesis of anaerobic infections: development of an anaerobic environment in a closed space is due to consumption of oxygen by aerobic organisms and results in the outgrowth of anaerobic organisms.

DIFFERENCES BETWEEN ANAEROBIC AND AEROBIC ORGANISMS

Anaerobic bacteria can be categorized as *obligate anaerobes* (killed in the presence of ≥0.5% oxygen), *aerotolerant organisms* (can tolerate the presence of oxygen but cannot use it for growth), and *facultative anaerobes* (can grow in the presence or absence of oxygen). Most clinically relevant anaerobes, such as *Bacteroides fragilis*, *Prevotella melaninogenica*, and *Fusobacterium nucleatum*, are relatively aerotolerant. These organisms contrast with *obligate aerobes*, which require high concentrations of oxygen for growth, and *microaerophilic organisms*, which are damaged by atmospheric concentrations of oxygen (~21%) but require low concentrations of oxygen (typically 2–10%) for growth. Given that molecular oxygen can reduce to superoxide (O_2^-) and hydrogen peroxide (H_2O_2), which are damaging to cells, the ability to tolerate the presence of oxygen is due, in part, to the expression of superoxide dismutase and catalase. The variation in anaerobic organisms tolerating anywhere from <0.5 to 8% O_2 may reflect the amount of these enzymes that is produced.

Furthermore, aerobic and anaerobic organisms differ in their energy metabolism. Cellular respiration requires establishment of an electrochemical gradient across the membrane, resulting in an electric potential (often related to a proton gradient) across the membrane. In aerobic respiration, electrons are shuttled through an electron transport chain, with oxygen as the final electron acceptor. Anaerobic organisms can metabolize energy by either anaerobic respiration or fermentation. Given that the final electron acceptor in anaerobic respiration (e.g., sulfate, nitrate, carbon dioxide, or fumarate) is not as highly oxidizing as oxygen, this pathway is less efficient than aerobic respiration and produces less ATP per glucose molecule. In contrast, fermentation does not use an electrochemical gradient. Rather, it releases energy from an organic molecule (e.g., pyruvate and its derivatives) via substrate-level phosphorylation and is therefore a less efficient process than either aerobic or anaerobic respiration; for comparison, fermentation results in ~5% of the energy released by aerobic respiration. For these reasons, facultative anaerobes will preferentially utilize oxygen if it is available; in oxygen-limiting situations, organisms will use anaerobic respiration rather than fermentative processes, if possible.

ANAEROBES OF THE HUMAN MICROBIOTA

Most human mucocutaneous surfaces harbor a rich indigenous normal microbiota composed of aerobic and anaerobic bacteria. These surfaces are dominated by anaerobic bacteria, which often account for 99.0–99.9% of the cultivable microbiota and range in concentration from 10^3/mL in the nose to 10^{12}/mL in gingival scrapings and the colon **(Table 182-1)**. It is interesting that anaerobes inhabit many areas of the body that are exposed to air: skin, nose, mouth, and throat. Anaerobes are thought to reside in the portions of these sites that either are relatively well protected from oxygen (e.g., gingival crevices) or have a local anaerobic environment conferred by neighboring aerobic organisms (e.g., tooth surfaces). The ability to cultivate these organisms is improving, and—with strict attention to anaerobic conditions—more than 80% of the microscopic counts in fecal samples can be cultured. However, culture-independent approaches (e.g., sequencing of the 16S rDNA gene) show that the overwhelmingly diverse low-abundance bacterial species present in the microbiota remain uncultivated. Several projects, including the Human Microbiome Project (funded by the U.S. National Institutes of Health) and MetaHIT (financed by the European Commission), have characterized the normal microbiota of healthy individuals and have demonstrated the presence of >10,000 different bacterial species in the collective human microbiota. The human gut

TABLE 182-1 The Anaerobic Human Microbiota: An Overview

ANATOMIC SITE	TOTAL BACTERIA[a]	ANAEROBIC/ AEROBIC RATIO	POTENTIAL PATHOGEN(S)
Nose	10^3–10^4	2:1	*Peptostreptococcus* spp., *Prevotella* spp.
Oral cavity			
Saliva	10^8–10^9	10:1	*Fusobacterium nucleatum*, *Prevotella melaninogenica*, *Prevotella oralis* group, *Bacteroides ureolyticus* group, *Peptostreptococcus* spp.
Tooth surface	10^{10}–10^{11}	1:1	
Gingival crevices	10^{11}–10^{12}	10^3:1	
Gastrointestinal tract			
Stomach	10^0–10^3	1:10	*Lactobacillus* spp.
Duodenum	10^1–10^5	1:1	*Lactobacillus* spp., *Streptococcus* spp.
Jejunum	10^3–10^6	1:1	*Streptococcus* spp., *Lactobacillus* spp., *Peptostreptococcus* spp.
Ileum	10^4–10^9	10:1	*Bacteroides* spp., *Streptococcus* spp., *Enterococcus* spp.
Cecum and colon	10^{11}–10^{12}	10^3:1	*Bacteroides* spp. (principally members of the *B. fragilis* group), *Prevotella* spp., *Clostridium* spp.
Female genital tract	10^7–10^9	10:1	*Peptostreptococcus* spp., *Bacteroides* spp., *Prevotella bivia*
Skin	10^4–10^6	100:1	*Cutibacterium acnes*

[a]Per gram or milliliter.

alone harbors >1000 bacterial species, with 100–200 species present in any given individual.

The major reservoir of anaerobic bacteria is the lower gastrointestinal tract, but these organisms are also present in considerable numbers in the oral cavity, skin, and female genital tract (Table 182-1). In the oral cavity, the ratio of anaerobic to aerobic bacteria ranges from 1:1 on the surface of a tooth to 1000:1 in the gingival crevices. *Prevotella* and *Porphyromonas* species make up much of the indigenous oral anaerobic microbiota. *Fusobacterium* and *Bacteroides* (non–*B. fragilis* group) species are present in lower numbers. Anaerobic bacteria are not found in appreciable numbers in the normal stomach and proximal small intestine. In the distal ileum, the microbiota begins to resemble that of the colon, where the ratio of anaerobes to aerobic species is high (~1000:1). The predominant anaerobes in the human intestine belong to the phyla Bacteroidetes and Firmicutes and include a number of *Prevotella* and *Bacteroides* species (e.g., members of the *B. fragilis* group, such as *B. fragilis*, *B. thetaiotaomicron*, *B. ovatus*, *B. vulgatus*, *B. uniformis*, and *Parabacteroides distasonis*) as well as various *Clostridium*, *Peptostreptococcus*, *Blautia*, and *Fusobacterium* species. In the female genital tract, there are ~10^9 organisms/mL of secretions, with an anaerobe-to-aerobe ratio of ~10:1. The predominant anaerobes in the female genital tract are *Prevotella*, *Bacteroides*, *Fusobacterium*, *Clostridium*, and the anaerobic *Lactobacillus* species. The skin microbiota contains anaerobes as well; *Cutibacterium acnes* (which was previously *Propionibacterium acnes* and will be considered as one of the *Propionibacterium* species for the remainder of this chapter) is the predominant species, and other species of propionibacteria and peptostreptococci are present in lower numbers.

ANAEROBES AND HUMAN HEALTH

Commensal anaerobes have been implicated as crucial mediators of physiologic, metabolic, and immunologic functions in the mammalian host. The intestinal microbiota is essential for fermenting dietary carbohydrates into forms that are more usable by the host, among which polysaccharides are the most abundant biologic source of energy. Of the organisms found within the intestines, *Bacteroides* species express the widest array of polysaccharide-degrading enzymes, providing important nutrients for both the host and other commensal organisms. For example, *B. thetaiotaomicron* expresses 172 glycosyl hydrolases. The anaerobic intestinal microbiota is also responsible for the production of secreted products that promote human health (e.g., vitamin K and bile acids useful in fat absorption and cholesterol regulation).

One of the most important roles that anaerobes serve as components of the normal colonic microbiota is the promotion of resistance to colonization. The presence of commensal bacteria effectively interferes with colonization by potentially pathogenic bacterial species through the depletion of oxygen and nutrients, the production of enzymes and toxic end products, and the modulation of the host's intestinal innate immune response. For example, the normal intestinal microbiota plays an important role in protection against enteric infections, including those due to *Salmonella enterica* serotype Typhimurium and *Clostridium difficile*.

The anaerobic intestinal microbiota also has immunomodulatory properties that help regulate the immune system. The first example of this role was demonstrated with *B. fragilis*, which can balance the effector functions of T cells in the peripheral immune system and induce colonic regulatory T cells via expression of polysaccharide A (PSA). Moreover, *B. fragilis* expresses a glycosphingolipid that regulates the number of colonic invariant natural killer T cells. There are now numerous examples of commensal anaerobes that can modulate different aspects of the intestinal and extraintestinal immune system—everything from specific effector T cells to dendritic cells to antimicrobial peptides.

Clearly, the gut microbiota confers many benefits, and its dysregulation may play a role in the pathogenesis of diseases characterized by inflammation and aberrant immune responses, such as inflammatory bowel disease, rheumatoid arthritis, multiple sclerosis, asthma, and type 1 diabetes. Furthermore, the gut microbiota has been associated with obesity and metabolic syndrome. A more complete discussion of the intersection between the microbiota and human health is covered elsewhere **(Chap. 484)**.

ETIOLOGY

There are >10,000 species of bacteria—the overwhelming majority of which are anaerobes—in the human microbiota, with each individual colonized by hundreds of species. Anaerobic infections occur when the harmonious relationship between the host and the host's microbiota is disrupted. Any site in the body is susceptible to infection with these indigenous organisms if they are introduced into otherwise sterile tissue, either through disruption of mucosal surfaces (e.g., intestinal perforation, ischemia, surgery) or via direct inoculation of organisms into tissue (e.g., bite wounds, trauma). Because the sites that are colonized by anaerobes contain many species of bacteria, the resulting infections are often polymicrobial, involving multiple species of anaerobes in combination with synergistically acting facultative and/or microaerophilic organisms.

Despite the complex array of bacteria in the normal microbiota, relatively few genera are isolated commonly from human infections **(Fig. 182-1)**. While the specific organisms identified vary with the site and source of infection, the etiologic agents typically reflect the neighboring microbiota. For example, organisms normally found in the oro- and nasopharyngeal microbiota (e.g., *P. melaninogenica*, *Fusobacterium necrophorum*, *F. nucleatum*, *Peptostreptococcus* species, *Porphyromonas gingivalis*, *Porphyromonas asaccharolytica*, and *Actinomyces* species) can cause disease in contiguous areas, including odontogenic infections, peripharyngeal space infections, chronic sinusitis, and pleuropulmonary infections. In female genital tract infections, organisms normally colonizing the vagina (e.g., *Prevotella bivia* and *Prevotella disiens*) are the most common isolates. *Escherichia coli* and *B. fragilis*, both of which are components of the intestinal microbiota, are the most commonly identified isolates from intraabdominal abscesses. Indeed, the *B. fragilis* group, which encompasses 25 species and includes *B. thetaiotaomicron*, *B. vulgatus*, *B. uniformis*, and *B. ovatus*, contains the anaerobic organisms among the most frequently isolated from clinical infections.

It is useful to think about anaerobic infectious etiologies with regard not only to their anatomic location but also to their microbiologic features. While many anaerobic gram-negative bacilli cause disease (e.g., *Prevotella*, *Bacteroides*, *Fusobacterium*, and *Porphyromonas* species), *Veillonella* species, which are part of the oral and intestinal microbiota, are among the few anaerobic gram-negative cocci that have been implicated in human disease. Similarly, the peptostreptococci (e.g., *P. micros*, *P. asaccharolyticus*, and *P. anaerobius*) and *Finegoldia magnus* (which was previously *Peptostreptococcus magnus* and will be considered as part of the peptostreptococci for the remainder of this chapter) are the chief anaerobic gram-positive cocci that have pathogenic potential. *Clostridium* species are the primary anaerobic spore-forming gram-positive rods that produce human disease **(Chap. 159)**. Uncommonly, anaerobic gram-positive non-spore-forming bacilli cause infection;

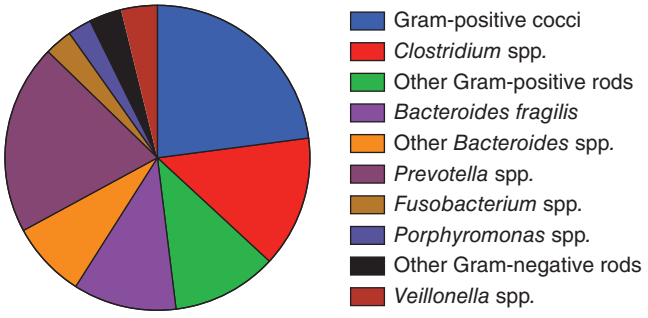

FIGURE 182-1 Distribution of anaerobic organisms isolated from clinical materials. *(Data combined from Y Park et al: Clinical features and prognostic factors of anaerobic infections: A 7-year retrospective study. Korean J Intern Med 24:13, 2009; and Japanese Association for Anaerobic Infections Research: Anaerobic infections (general): Epidemiology of anaerobic infections. J Infect Chemother 17:4, 2011.)*

C. acnes, a component of the skin microbiota and a cause of foreign-body infections, and *Actinomyces* species are relevant examples.

PATHOGENESIS

First and foremost, anaerobic infections require an anaerobic environment with a lowered oxidation-reduction potential. In some circumstances, this environment can occur directly—e.g., in tissue ischemia, trauma, surgery, or a perforated viscus. In many other situations, the infection is polymicrobial, and the facultative organisms maintain a lowered oxidation-reduction potential in the local microenvironment that allows for the propagation of obligate anaerobes. Once the proper anaerobic environment is established, the organisms must still contend with the host's immune defenses. Similar to aerobic organisms, anaerobes express an array of virulence factors that help evade host defenses, they can form abscesses as a protective measure, and they can act synergistically with other bacteria to better persist in the host.

Virulence factors associated with anaerobes typically confer the ability to evade host defenses, adhere to cell surfaces, produce toxins and/or enzymes, or display surface structures such as capsular polysaccharides and lipopolysaccharides that contribute to pathogenic potential. The ability of an organism to adhere to host tissues is often critical to the establishment of infection. Some oral species adhere to the epithelium in the oral cavity. *P. gingivalis*, a common isolate in periodontal disease, has fimbriae that facilitate attachment. In supragingival plaque, many oral anaerobes are able to attach directly to aerobic bacteria (e.g., *Streptococcus* species) that are adherent to the tooth's surface. *F. nucleatum* is a notable example of these secondary colonizers: it expresses receptors to which almost all oral bacteria can bind and serves as an important bridge between the primary colonizers and subsequent layers of bacteria. *B. fragilis* synthesizes pili, fimbriae, and hemagglutinins that aid in attachment to host cell surfaces in the intestine.

Anaerobic bacteria produce several exoproteins that can enhance the organisms' virulence. *P. gingivalis* produces a collagenase that enhances tissue destruction. Exotoxins produced by clostridial species, including botulinum toxins, tetanus toxin, *C. difficile* toxins A and B, and five toxins produced by *Clostridium perfringens*, are among the most virulent bacterial toxins in mouse lethality assays. Anaerobic gram-negative bacteria, such as *B. fragilis*, *P. gingivalis*, and *Prevotella intermedia*, possess lipid A molecules (endotoxins) that are 100–1000 times less biologically potent than endotoxins associated with aerobic gram-negative bacteria; these differences relate to variations in acylation status, length of fatty acids, and number of phosphate groups. This relative biologic inactivity may account for the lower frequency of disseminated intravascular coagulation and purpura in anaerobic gram-negative bacteremia than in facultative and aerobic gram-negative bacillary bacteremia. An exception is the lipopolysaccharide from *Fusobacterium*, which may account for the severity of Lemierre's syndrome (see "Complications of Anaerobic Head and Neck Infections," below).

The most extensively studied virulence factor of the nonsporulating anaerobes is the capsular polysaccharide complex of *B. fragilis*. This organism is unique among anaerobes in its potential for virulence during growth at normally sterile sites. Although it constitutes only 0.5–1% of the normal colonic microbiota, *B. fragilis* is the anaerobe most commonly isolated from intraabdominal infections and bacteremia. In an animal model of intraabdominal sepsis, the capsular polysaccharide was identified as the major virulence factor of *B. fragilis*; this polymer plays a specific, central role in the induction of abscesses. A series of detailed biologic and molecular studies of this virulence factor showed that *B. fragilis* produces at least eight distinct capsular polysaccharides, far more than the number reported for any other encapsulated bacterium. *B. fragilis* can exhibit distinct surface polysaccharides either alone or in combination by regulating the expression of these different capsules in an on–off manner through a reversible inversion of DNA segments within the promoters for operons containing the genes required for polysaccharide synthesis. Structural analysis of two of these polysaccharides, PSA and polysaccharide B (PSB), revealed that each polymer consists of repeating units with positively charged free amino groups and negatively charged groups. This structural feature is rare among bacterial polysaccharides, and the ability of PSA—and, to a lesser extent, PSB—to induce abscesses in animals depends on this zwitterionic charge motif. Intraabdominal abscess induction is related to the capacity of PSA to stimulate macrophages to release cytokines and chemokines—in particular, interleukin (IL) 8, IL-17, and tumor necrosis factor α (TNF-α)—from resident peritoneal cells through a Toll-like receptor 2–dependent mechanism. The release of cytokines and chemokines results in the chemotaxis of polymorphonuclear neutrophils (PMNs) into the peritoneum, where they adhere to mesothelial cells induced by TNF-α to upregulate their expression of intercellular adhesion molecule 1 (ICAM-1). PMNs adherent to ICAM-1-expressing cells probably represent the nidus for an abscess. PSA also activates T cells to produce certain cytokines, including IL-17 and interferon γ, that are necessary for abscess formation.

These virulence factors not only promote persistence of the anaerobe that produces them but also aid in the survival of bystander organisms and result in bacterial synergies. Clinically, these synergies are evidenced by the fact that anaerobic infections typically involve three to six different organisms. Examples of this synergistic pathogenesis include creation of a favorable environment for growth (e.g., establishment and maintenance of an anaerobic environment by facultative organisms), inhibition of host defenses (e.g., production of short-chain fatty acids and succinic acid that inhibit the ability of phagocytes to clear facultative organisms), provision of necessary growth factors for other organisms (e.g., oral diphtheroids that produce vitamin K, which is needed by *P. melaninogenica*), and creation of tissue damage that promotes spread of the infection. In these ways, facultative and obligate anaerobes synergistically potentiate abscess formation.

APPROACH TO THE PATIENT

Infections Due to Anaerobic Bacteria

The physician must consider several points when approaching the patient with a possible infection due to anaerobic bacteria.

1. The organisms colonizing mucosal sites are commensals, very few of which typically cause disease. When these organisms do cause disease, it often occurs in proximity to the mucosal site they colonize.
2. For anaerobes to cause tissue infection, they must spread beyond the normal mucosal barriers.
3. Conditions favoring the propagation of anaerobic bacteria, particularly a lowered oxidation-reduction potential, are necessary. These conditions exist at sites of trauma, tissue destruction, compromised vascular supply, and necrosis.
4. Frequently, a complex array of infecting microbes can be found, occasionally with >10 different species isolated from a suppurative site.
5. Anaerobic organisms tend to be found in abscess cavities or in necrotic tissue. The failure of an abscess to yield organisms on routine culture is a clue that the abscess is likely to contain anaerobic bacteria. Often smears of this "sterile pus" are found to be teeming with bacteria when Gram's stain is applied. Although some facultative organisms (e.g., *Staphylococcus aureus*) are also capable of causing abscesses, abscesses in organs or deeper body tissues should call anaerobic infection to mind.
6. Gas is found in many anaerobic infections of deep tissues but is not diagnostic because it can be produced by aerobic bacteria as well.
7. Although a putrid-smelling infection site or discharge is considered diagnostic for anaerobic infection, this manifestation usually develops late in the course and is present in only 30–50% of cases.
8. Some species (the best example being the *B. fragilis* group) require specific therapy. However, many synergistic infections can be cured with antibiotics directed at some but not all of the organisms involved. Antibiotic therapy, combined with debridement and drainage, disrupts the interdependent relationship

among the bacteria, and some species that are resistant to the antibiotic do not survive without the co-infecting organisms.
9. Manifestations of severe sepsis and disseminated intravascular coagulation are unusual in patients with purely anaerobic infection.

EPIDEMIOLOGY

Difficulties in the performance of appropriate cultures, contamination of cultures by components of the normal microbiota, and the lack of readily available, reliable culture techniques have made it challenging to obtain accurate data on the incidence or prevalence of anaerobic infections. However, anaerobic infections are encountered frequently, with anaerobes constituting 7–8% and 13–15% of bacteria isolated from inpatients and outpatients, respectively. Bacteremia and soft tissue infections are the most common types of anaerobic infection **(Fig. 182-2)**. Typically, anaerobic bacteria account for <1% of all cases of bacteremia.

CLINICAL MANIFESTATIONS

Although anaerobes can cause infection anywhere in the body, certain clinical findings and characteristics are commonly found. These include abscess formation, putrid purulence (due to volatile fatty acid by-products), septic thrombophlebitis, tissue necrosis, and failure to respond clinically to broad-spectrum antibiotics that lack activity against anaerobes.

Anaerobic Infections of the Mouth, Head, and Neck Anaerobic bacteria are commonly involved in infections of the mouth, head, and neck **(Chap. 37)**. The predominant isolates are components of the normal microbiota of the upper airways—mainly *Prevotella* species, *P. asaccharolytica*, *Fusobacterium* species, peptostreptococci, and microaerophilic streptococci.

OROFACIAL INFECTIONS The most common oral infections are odontogenic and include dental caries and periodontal disease (gingivitis and periodontitis). While dental caries usually manifest with pain, sensitivity, and discoloration of the tooth, periodontal disease involves inflammation of the gums and underlying tissue. In its more severe forms, periodontitis can result in difficulty chewing, loose teeth, and occasionally tooth loss. Severe orofacial infections typically develop as a consequence of dental infection, and the infection can spread from the tooth to different anatomic areas that provide the least resistance, resulting in periapical, periodontal, or pericoronal infections. If the dental surface is completely breached, an endodontic infection (pulpitis) can occur. In late stages of pulpitis, the tooth is generally very sensitive to heat, but cold stimuli may provide relief. Left untreated, pulpitis can progress to invade the alveolar bone and develop into a periapical abscess. The abscesses, particularly those involving the second and third molars, can occasionally extend into the submandibular, sublingual, and submental spaces (*Ludwig's angina*). This infection results in marked local swelling of tissues, with pain, trismus, and superior and posterior displacement of the tongue. Submandibular swelling of the neck and obstruction by the tongue can impair swallowing and cause respiratory obstruction. In some cases, tracheotomy is lifesaving.

Microbiologically, dental caries begin with the binding of *Streptococcus mutans* and *Streptococcus sanguis* to the tooth surface, with subsequent further colonization by anaerobes. In contrast, periodontitis is typically associated with *P. gingivalis*, *Tannerella forsythia*, *Aggregatibacter actinomycetemcomitans*, and *Treponema denticola*. *Fusobacterium*, *Actinomyces*, *Peptostreptococcus*, and *Bacteroides* species (other than *B. fragilis*) are the organisms most commonly isolated from periapical abscesses.

ACUTE NECROTIZING ULCERATIVE GINGIVITIS Gingivitis may become a necrotizing infection (*trench mouth*, *Vincent's stomatitis*). The onset of disease is usually sudden and is associated with painful bleeding gums, foul breath, and a bad taste. The gingival mucosa, especially the papillae between the teeth, becomes ulcerated and may be covered by a yellowish-white or gray "pseudomembrane," which is removable with gentle pressure. Patients may become systemically ill, developing fever, malaise, cervical lymphadenopathy, and leukocytosis. The infection can sometimes extend into the pharynx, resulting in an extremely sore throat, foul breath, and tonsillar pillars that are swollen, red, ulcerated, and covered by a pseudomembrane. *Prevotella*, *Treponema*, and *Fusobacterium* species have been implicated.

In some cases, acute necrotizing gingivitis can rapidly progress to noma (*cancrum oris*), a gangrenous infection that destroys the soft and hard tissues related to the oral cavity. Noma occurs most frequently in young children (1–4 years of age) who have immune dysfunction related to malnutrition and endemic infections (particularly measles). This infection occurs worldwide but is most common in sub-Saharan Africa, where the incidence is 1–7 cases per 1000 children. Although the pathogenesis is not fully understood, infections with *F. necrophorum* and *P. intermedia* are thought to be key drivers of this disease. Without treatment, the mortality rate is 70–90%.

PERIPHARYNGEAL SPACE INFECTIONS These infections arise from the spread of organisms from the upper airways to potential spaces formed by the fascial planes of the head and neck. The etiology is typically polymicrobial and represents the normal microbiota of the mucosa of the originating site.

Peritonsillar abscess (*quinsy*) is the most common peripharyngeal infection and occurs as a complication of acute tonsillitis. Consistent with its association with tonsillitis, adolescents are most commonly affected. Patients present with a sore throat, dysphagia, peritonsillar swelling, muffled voice, and uvular deviation to the contralateral side. The abscess material typically grows group A *Streptococcus* in conjunction with obligate anaerobes (e.g., *Bacteroides*, *Prevotella*, and *Peptostreptococcus* species) **(Chap. 37)**. Retropharyngeal abscesses typically occur in children 2–4 years of age, although they can occur at any age. Although a suppurative infection of the retropharyngeal lymph nodes is the usual precursor to these abscesses in children, foreign-body ingestion and/or local trauma is more commonly the inciting factor in adults. The clinical presentation shares many features with peritonsillar abscesses, but difficulty extending the neck and torticollis are more common with retropharyngeal abscesses. The etiologic agents are the same as in peritonsillar abscesses, with additional aerobic organisms (e.g., *S. aureus*, viridans streptococci) also playing a role.

SINUSITIS AND OTITIS Anaerobic bacteria have been implicated in chronic sinusitis but play little role in acute sinusitis. Numerous studies related to the microbiology of chronic sinusitis have been conducted; on average, anaerobic bacteria have been found in two-thirds of patients, with many studies demonstrating their presence in >90% of patients. Anaerobic bacteria represent ~40% of all bacteria cultured, with *Peptostreptococcus*, *Prevotella*, and *Porphyromonas* species the most commonly isolated anaerobes. *S. aureus* and Enterobacteriaceae are the aerobes most commonly recovered in chronic sinusitis. Anaerobic bacteria have been isolated in ~60% of cases of chronic suppurative otitis media in children, but they are not involved in acute otitis media.

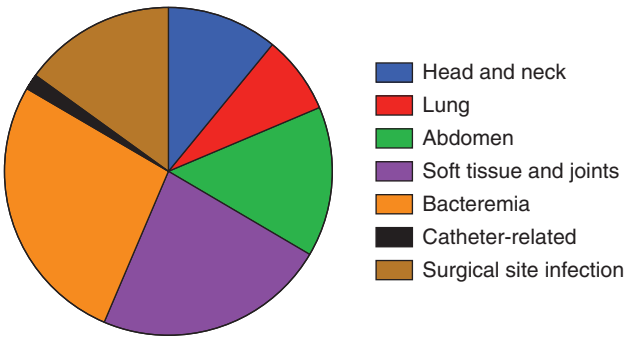

FIGURE 182-2 Distribution of types of infection from which anaerobic organisms were cultured at a single hospital over a 7-year period. Head and neck infections included sinusitis, otitis media, and retropharyngeal abscess; abdominal infections included liver abscess, biliary tract infection, bowel obstruction, and intraabdominal abscess; catheter-related infections included those related to peritoneal dialysis catheters and ventriculoperitoneal shunts. *(Data from Y Park et al: Clinical features and prognostic factors of anaerobic infections: A 7-year retrospective study. Korean J Intern Med 24:13, 2009.)*

COMPLICATIONS OF ANAEROBIC HEAD AND NECK INFECTIONS Direct extension of these infections into contiguous areas can result in additional disease manifestations. Cranial spread of these infections can result in osteomyelitis of the skull or mandible or in intracranial infections, such as brain abscess and subdural empyema. Caudal spread can produce mediastinitis or pleuropulmonary infection. Hematogenous complications can also result from anaerobic infections of the head and neck. Bacteremia, which occasionally is polymicrobial, can lead to endocarditis or other distant infections. Lemierre's syndrome **(Chap. 37)**, which is usually due to *F. necrophorum*, is an acute oropharyngeal infection with secondary septic thrombophlebitis of the internal jugular vein and frequent septic emboli, most commonly to the lung. This infection typically begins with pharyngitis, which is followed by local invasion in the lateral pharyngeal space, with resultant internal jugular vein thrombophlebitis.

Central Nervous System (CNS) Infections CNS infections associated with anaerobic bacteria are brain abscess, epidural abscess, and subdural empyema, in which anaerobes are recovered in up to 30, 20, and 10% of cases, respectively. The frequency with which anaerobes are recovered depends in large part on the underlying reason for the infection. For example, brain abscesses are typically due to hematogenous seeding, contiguous spread, penetrating head trauma, or recent surgical intervention. Anaerobic bacteria are most commonly associated with brain abscesses resulting from contiguous spread (related to otogenic, odontogenic, and sinus infections), and the pathogens recovered are the same as in these antecedent infections. Facultative or microaerophilic streptococci and coliforms are often part of a mixed infecting flora in brain abscesses. The location of the abscess may also provide insight into the pathogens. Abscesses in the frontal lobe (often associated with sinusitis) are due to anaerobes, streptococci, and staphylococci; temporal lobe and cerebellar abscesses are often related to the oral microbiota and middle-ear pathogens.

Obligate anaerobes rarely cause meningitis. Only one obligate anaerobe was identified in a seminal study of 188 bacterial meningitis isolates, and a U.S. national surveillance study of 18,642 such isolates collected between 1977 and 1981 found only five obligate anaerobes. This low incidence may be due, in part, to the fact that many clinical microbiology laboratories do not routinely culture cerebrospinal fluid (CSF) for anaerobes.

Pleuropulmonary Infections The lungs are constantly seeded with organisms from the oral microbiota via subclinical microaspiration that normally occurs in all people. Even though the lung is the site of oxygen exchange and is therefore an overwhelmingly aerobic environment, the organisms most abundant in the lower respiratory tract (as assessed by culture-independent methods) include anaerobes such as *Prevotella* and *Veillonella* species, with oral microaerophilic streptococcal species (e.g., the *Streptococcus milleri* group) also present in significant abundances. In patients who have impaired bacterial clearance (due to decreased cough, dysfunctional mucociliary transport, or alcohol intoxication) and/or increased rates of aspiration (due to neurologic disorders, impaired consciousness, or swallowing dysfunction), these anaerobic bacteria can establish an infection and result in aspiration pneumonia, lung abscess, or empyema. These anaerobic infections have an indolent course that may serve as a clinical clue differentiating them from conditions with other etiologies (e.g., chemical pneumonitis, pneumococcal pneumonia) that often present more acutely.

ASPIRATION PNEUMONIA Bacterial aspiration pneumonia must be distinguished from two other clinical syndromes associated with aspiration that are not of bacterial etiology. One syndrome results from aspiration of food or, rarely, other foreign bodies. Obstruction of major airways typically results in difficulty breathing, atelectasis, and moderate nonspecific inflammation. Therapy consists of removal of the foreign body. The second aspiration syndrome relates to chemical pneumonitis caused by inhalation or aspiration of alveolar irritants. Perhaps the most common cause of chemical pneumonitis is *Mendelson syndrome*, which results from regurgitation and aspiration of acidic gastric juices. Pulmonary inflammation—including the destruction of the alveolar lining, with transudation of fluid into the alveolar space—occurs with remarkable rapidity. This syndrome typically develops within 4–6 h, often following anesthesia when the gag reflex is depressed. The patient becomes tachypneic, tachycardic, and hypoxic, often in the absence of fever. The leukocyte count may rise, and the chest x-ray may evolve from normal to a complete bilateral "whiteout" within 8–24 h. Sputum production is minimal. The pulmonary signs and symptoms often resolve quickly with symptom-based therapy, but this condition can culminate in respiratory failure due, in part, to pulmonary edema. Antibiotic therapy is not indicated unless bacterial superinfection occurs.

In contrast to these syndromes, bacterial aspiration pneumonia develops over a period of several days or weeks rather than hours. The pathogenesis includes some combination of an increased bacterial burden, increased virulence of the organisms aspirated, and potential airway damage related to aspiration of gastric fluid. Patients generally report fever, malaise, and sputum production. In some patients, weight loss and anemia reflect a more chronic process. Usually the history reveals factors predisposing to aspiration, such as significant alcohol consumption or neurologic impairment due to a previous stroke. Severe dental disease is often associated with aspiration pneumonia, but it is not clear whether this association relates to an increased number of oral microbes and/or the presence of organisms with increased virulence. Sputum characteristically is not malodorous unless the process has been ongoing for at least a week. Chest x-rays show consolidation in dependent pulmonary segments: in the basilar segments of the lower lobes if the patient has aspirated while upright and in either the posterior segment of the upper lobe (usually on the right side, given that the right mainstem bronchus has a more vertical orientation) or the superior segment of the lower lobe if the patient has aspirated while supine.

A mixed bacterial population with many PMNs is evident on Gram's staining of sputum. Expectorated sputum is unreliable for anaerobic cultures because of inevitable contamination by the normal oral microbiota. Reliable specimens for culture can be obtained by transtracheal or transthoracic aspiration—techniques that are rarely used at present. Although the culture of protected-brush specimens or bronchoalveolar lavage fluid obtained by bronchoscopy is controversial, more recent data suggest that these approaches can be used without oropharyngeal contamination and can recover anaerobic organisms from the lower respiratory tract in a site-directed manner. Further research is needed to determine how these approaches compare with the previous gold standards.

ANAEROBIC LUNG ABSCESSES **(See also Chap. 132)** These abscesses result from subacute anaerobic pulmonary infection. The clinical presentation typically involves a history of constitutional signs and symptoms (including malaise, weight loss, fever, night sweats, and foul-smelling sputum) that have typically persisted for 1–3 weeks prior to hospitalization. Patients who develop lung abscesses often, but not always, have an antecedent dental infection. Abscess cavities may be single or multiple and generally occur in dependent pulmonary segments **(Fig. 182-3)**. The differential diagnosis for lung abscesses includes pneumonia (including necrotizing pneumonia), a purulent pleural effusion with a bronchopleural fistula, and a pneumatocele. Of note, infection with some aerobic organisms, particularly *S. aureus*, can develop into a lung abscess without an anaerobic component. Approximately 90% of cases have an anaerobe identified—usually three to six isolates per sample—if careful attention is paid to handling and processing of the abscess sample. The most common isolates include peptostreptococci, *Prevotella* and *Porphyromonas* species, and *F. nucleatum*. An important finding is that ~90% of cultures also demonstrate the presence of aerobic organisms, such as *S. aureus*, *Streptococcus pneumoniae*, and *Klebsiella pneumoniae*. Consistent with the notion that anaerobes are contributing to disease, patients often do not improve clinically until they receive an antibiotic regimen that includes anaerobic coverage.

EMPYEMA Empyema is a manifestation of long-standing anaerobic pulmonary infection and manifests with thick, purulent material in

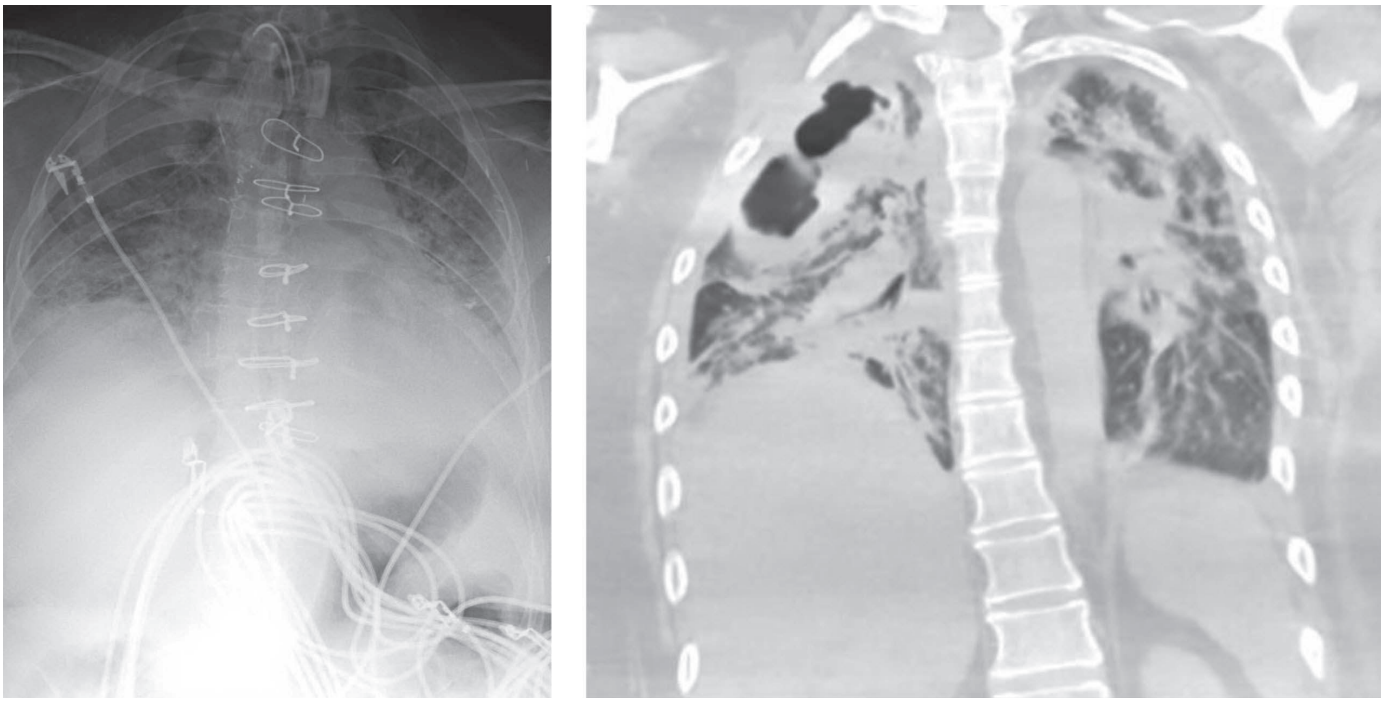

FIGURE 182-3 Chest radiograph (*left*) and CT image (*right*) of a lung abscess. The patient aspirated while supine and developed an abscess in the posterior segment of the right upper lobe. Cultures were pretreated and grew only *Klebsiella pneumoniae*. *(Images provided by Gita N. Mody, MD, MPH, Division of Cardiothoracic Surgery, Department of Surgery, The University of North Carolina at Chapel Hill.)*

the pleural space, often in association with a bronchopleural fistula. Alternatively, a subdiaphragmatic infection may extend into the pleural space and similarly result in an empyema. The clinical presentation resembles that of other anaerobic pulmonary infections and may include foul-smelling sputum, pleuritic chest pain, and marked chest-wall tenderness. This disease process must be differentiated from a parapneumonic effusion resulting from more routine causes of pneumonia (e.g., *S. pneumoniae*). In the latter instance, the fluid is a thin exudate that has a mean white blood cell (WBC) count of ~5000 cells/mL, a lactate dehydrogenase level of >200 IU/L, and a pH of ~7.4. In contrast, empyema is characterized by foul-smelling thick pus with a mean WBC count of ~55,000 cells/mL, a lactate dehydrogenase level of >1000 IU/L, and a pH of <7.2 as well as loculations and a thick pleural peel on imaging. Drainage and occasionally decortication of the visceral and parietal pleura are required. Defervescence, a return to a feeling of well-being, and resolution of the process may require several months, particularly in the absence of surgical intervention.

Intraabdominal Infections Breach of the gut mucosal surface (e.g., due to trauma, intestinal perforation, or malignancy) allows members of the microbiota to enter the normally sterile peritoneum. Accordingly, the offending organisms reflect the microbiota in the affected intestinal region. For example, recovery of *Candida* species from intraabdominal infections should prompt evaluation of the stomach and proximal small bowel for potential perforation. Furthermore, a study of patients with perforated and gangrenous appendicitis demonstrated that virtually all samples yielded *E. coli* and members of the *B. fragilis* group; peptostreptococci and *Bilophila wadsworthia*—additional components of the appendiceal and colonic microbiota—also were recovered from >50% of samples. Notably, some studies have identified an average of 10 different bacterial species, with an anaerobe-to-aerobe ratio of ~3:1. Given that >1000 bacterial species are present in the colonic microbiota, the dominance of such a limited repertoire of bacterial genera and species recovered in intraabdominal infections reflects a combination of two factors: the increased propensity of these organisms to result in intraabdominal abscesses and the difficulty faced by clinical microbiology laboratories in culturing the diverse organisms present in these samples. **See Chap. 137 for a complete discussion of intraabdominal infections.**

Neutropenic enterocolitis (typhlitis) involves marked thickening of the bowel wall (typically >4 mm) in the setting of neutropenia, abdominal pain, and fever. This condition most commonly affects the cecum and may extend to the neighboring terminal ileum and/or proximal colon, but any intestinal region may be involved. Typhlitis generally occurs after 1–2 weeks of chemotherapy-induced neutropenia associated with treatment of hematologic or, less commonly, solid tumor malignancies, but it can occur regardless of the cause of neutropenia. At least 5% of adults hospitalized for malignancy are thought to develop typhlitis, but this is likely an underestimate. Although the right lower quadrant is the most common location of abdominal pain and tenderness, these symptoms are absent in nearly half of cases; moreover, some patients, particularly those taking glucocorticoids, may not experience abdominal pain at all. Given the weakened integrity of the bowel wall and the associated neutropenia, patients often develop bacteremia due to one or more organisms related to the microbiota of the affected intestinal segment. Patients who develop bacteremia due to *Clostridium septicum* often have relatively severe disease, and identification of this organism is highly associated with the presence of malignancy—notably, colon cancer. Medical management including bowel rest, intestinal decompression, and broad-spectrum antibiotic administration is generally successful, although surgical intervention may be required in cases of persistent intestinal bleeding, necrotic bowel, or clinical deterioration suggestive of an ongoing intestinal process.

Pelvic Infections Anaerobes are frequently encountered in pelvic inflammatory disease, pelvic abscess, endometritis, tubo-ovarian abscess, septic abortion, and postoperative or postpartum infections. These infections are often of mixed etiology, involving both anaerobes and coliforms; pure anaerobic infections without coliform or other facultative bacterial species occur more often in pelvic than in intraabdominal sites. The major anaerobic pathogens in pelvic abscesses are *P. bivia*, *P. disiens*, and the *B. fragilis* group, but many other anaerobes also have been implicated. **See Chap. 141 for a complete discussion of pelvic inflammatory disease.**

Anaerobic bacteria have been thought to be contributing factors in bacterial vaginosis. This syndrome of unknown etiology is characterized by a profuse malodorous discharge and a change in bacterial ecology that results in replacement of the *Lactobacillus*-dominated normal microbiota with an overgrowth of anaerobic bacterial species.

Culture-based and culture-independent approaches have identified numerous organisms, including *Gardnerella vaginalis*, peptostreptococci, genital mycoplasmas, and species within the genera *Prevotella*, *Mobiluncus*, *Atopobium*, *Leptotrichia*, *Megasphaera*, and *Eggerthella*. This wide array of implicated bacteria may reflect differences in the overall disease spectrum of bacterial vaginosis and/or a shared physiologic response to these different organisms.

Skin and Soft Tissue Infections Similar to other anatomic sites, skin or soft tissue injured by trauma, ischemia, or surgery creates a suitable environment for anaerobic infections. The infecting bacteria either are introduced directly (e.g., wounds associated with intestinal surgery, decubitus ulcers, or human bites) or originate in contiguous areas (e.g., cutaneous abscesses, rectal abscesses, and axillary sweat gland infections [*hidradenitis suppurativa*]). Anaerobes also are often cultured from foot ulcers of diabetic patients. The most common locations for anaerobic cellulitis include the neck, trunk, groin (including the genitalia), and legs. The deep soft tissue infections associated with anaerobic bacteria are gas gangrene, synergistic cellulitis (both progressive and necrotizing), necrotizing fasciitis, and myositis **(Chaps. 134 and 159)**.

Gas gangrene (crepitus cellulitis) is most often due to *C. perfringens*, although other clostridial species have been implicated as well. This infection involves extensive gas formation in the tissue leading to crepitus and a thin, dark, occasionally malodorous discharge. True gas gangrene typically presents with fever and tenderness around the lesion and can rapidly spread; in contrast, there are somewhat more indolent forms of anaerobic cellulitis that may involve some gas formation but often present without fever or extensive local pain and can spread over the course of days rather than minutes.

Progressive bacterial synergistic gangrene (*Meleney gangrene*) is characterized by an area of exquisite pain, redness, and swelling followed by ulceration. As the ulcer enlarges, it is surrounded by a violaceous ring that fades into a pink edematous border. If it is not promptly treated, the ulcer continues to enlarge, and new, distant ulcers may emerge. Symptoms are limited to pain; fever is not typical. Peptostreptococci and microaerophilic streptococci are commonly found in the leading edge of the lesions, and *S. aureus* and *Proteus* species can be isolated from the ulcerated lesion. Treatment includes surgical removal of necrotic tissue and antimicrobial administration. In contrast, synergistic necrotizing cellulitis involves the deep fascia and occurs near the point of bacterial entry. Pain, fever, and systemic symptoms are common. If this form of cellulitis involves the scrotum, perineum, and anterior abdominal wall, it is referred to as *Fournier gangrene*. *S. aureus*, the *B. fragilis* group, *Peptostreptococcus* species, *Clostridium* species, *Fusobacterium* species, and members of the family Enterobacteriaceae are the predominant organisms identified.

Necrotizing fasciitis, a rapidly spreading destructive disease of the fascia, is usually attributed to group A streptococci **(Chap. 153)** but can also be a mixed infection involving anaerobes and aerobes. Polymicrobial necrotizing fasciitis differs from stereotypical group A streptococcal necrotizing fasciitis in that the initial erythematous, swollen, tender lesions progress over 3–5 days (as opposed to 1–3 days), with consequent skin breakdown and cutaneous gangrene. Fever, subcutaneous gas, development of anesthesia (often before skin necrosis), and a foul-smelling discharge are common. The particular clinical findings sometimes suggest the causative agent: regional lymphadenopathy suggests the *B. fragilis* group; necrosis and gangrene suggest *Clostridium* species, peptostreptococci, the *B. fragilis* group, and Enterobacteriaceae; bullous lesions suggest Enterobacteriaceae; a foul-smelling odor suggests *Bacteroides* and *Clostridium* species; and subcutaneous gas suggests peptostreptococci, *Clostridium* species, and the *B. fragilis* group. Moreover, diabetic infections are often associated with *Bacteroides* species, Enterobacteriaceae, and *S. aureus*, and infections related to trauma are associated with *Clostridium* species.

Although *S. aureus* is the typical cause of myositis, anaerobes—particularly *C. perfringens*—are often recovered from patients with pyogenic myositis. In anaerobic streptococcal myonecrosis, peptostreptococci are often identified along with group A streptococci or *S. aureus*. Patients typically present with fever, muscle pain, fatigue, and an elevated creatinine kinase level suggestive of muscle inflammation.

Bone and Joint Infections A comprehensive review of the world literature on anaerobic bone infections through 1975 included >650 cases. Of these, ~400 cases were caused by *Actinomyces* species; anaerobic cocci and *Bacteroides*, *Fusobacterium*, and *Clostridium* species were most commonly identified in the remaining cases. Actinomycotic involvement of the jaw was the most common bone infection, with the mandible involved four times as frequently as the maxilla. Patients with cervicofacial actinomycosis **(Chap. 180)** are often described as having a "lumpy jaw" because of the prominent soft tissue swelling that is sometimes mistaken for malignancy or granulomatous disease. These infections can be chronic in nature, can include the development of sinus tracts, can progress across normal tissue boundaries, and can require prolonged antibiotic treatment to prevent relapse. The vertebrae are the second most common location for *Actinomyces* infection; involvement of the thorax, abdomen, or pelvis is much less frequent.

Osteomyelitis involving anaerobes other than *Actinomyces* species most commonly develops by extension of an adjacent infection (e.g., soft tissue, paranasal sinus, or middle-ear infection). For example, diabetic foot ulcers and decubitus ulcers may be complicated by mixed aerobic–anaerobic osteomyelitis **(Chap. 136)**. Hematogenous seeding of bone by anaerobes is uncommon and is thought to occur in fewer than 10% of cases. The most common sites of anaerobic osteomyelitis are the head (skull and jaw) and the extremities. Fusobacteria have been isolated in pure culture from infections of the mastoid, mandible, and maxilla. *Clostridium* species have been reported as anaerobic pathogens in cases of osteomyelitis of the long bones following trauma. Anaerobic and microaerophilic cocci are most frequently isolated from infections involving the skull or mastoid; usually, these organisms are present in mixed cultures.

In contrast to anaerobic osteomyelitis, anaerobic arthritis **(Chap. 135)** is uncommon, typically involving a single isolate, and most cases are secondary to hematogenous spread. Although *Fusobacterium* species accounted for nearly one-third of cases in the preantibiotic era, *C. acnes*, peptostreptococci, and *B. fragilis* are now among the more frequent causes of anaerobic septic arthritis. Peptostreptococci and *C. acnes* are often found in association with prosthetic joints, *Fusobacterium* species have a predilection for the sternoclavicular and sacroiliac joints, and clostridial arthritis is especially common after trauma. As a frequent cause of bacteremia, *B. fragilis* is a common cause of anaerobic septic arthritis; however, arthritis occurs in fewer than 5% of patients with *B. fragilis* bacteremia.

Bacteremia *B. fragilis* is the anaerobe most commonly isolated from blood cultures. Although the frequency of positive cultures appeared to be decreasing in the 1980s, more recent evidence suggests that the rate is now increasing and that the increase may be related to changing demographics, with more patients who are elderly, immunocompromised, and/or receiving medications that may disrupt the mucosal barrier (e.g., chemotherapy). The source of bacteremia is most often an abscess in the abdomen, female genital tract, or soft tissue. At a large tertiary-care U.S. hospital, 0.8% of all positive blood cultures yielded an anaerobic gram-negative bacillus, with 0.5% yielding *B. fragilis*. A similar study in France revealed that 0.6% of all positive blood cultures yielded an anaerobic organism; 60% of these isolates were *Bacteroides* species, and 22% were *Clostridium* species. *Peptostreptococcus* and *Fusobacterium* species are also recovered with significant frequency.

Once the organism in the blood has been identified, both the portal of bloodstream entry and the underlying problem that probably led to seeding of the bloodstream can often be deduced from an understanding of the organism's normal site of residence. For example, mixed anaerobic bacteremia including *B. fragilis* usually implies a colonic pathology, with mucosal disruption from neoplasia, diverticulitis, or some other inflammatory lesion. The initial manifestations are determined by the portal of entry and reflect the localized condition. Although the clinical manifestations of *B. fragilis* bacteremia (e.g., rigors, hectic fevers) are similar to those of aerobic gram-negative

bacillary bacteremia, the incidence of septic shock is lower with *B. fragilis*. This difference may be due to differences in the immunostimulatory effects of the different endotoxin structures.

In virtually all cases, isolation of a member of the *B. fragilis* group from blood indicates underlying infection that is associated with a mortality rate of 60% if untreated. It has been suggested that the mortality rate depends in part on the species recovered (*B. thetaiotaomicron* > *P. distasonis* > *B. fragilis*), but it is unclear whether differences in mortality rates relate to intrinsic differences in the virulence of these organisms, in their antimicrobial susceptibility profiles, and/or in the host's immune response. Case–fatality rates appear to increase with the increasing age of the patient (with reported rates of >66% among patients >60 years old), with the isolation of multiple species from the bloodstream, and with the failure to surgically remove a focus of infection.

Endocarditis (See also Chap. 133) Although gram-negative anaerobic bacteria only rarely cause endocarditis, their involvement is associated with significant mortality rates (21–43%). Members of the *B. fragilis* group are the most commonly identified gram-negative anaerobes in endocarditis. Anaerobic streptococci, which are often classified incorrectly, are likely responsible for this disease more frequently than is generally appreciated. Compared with aerobic bacterial endocarditis, endocarditis due to *Bacteroides* species is less likely to be associated with a history of cardiovascular disease and more likely to involve thromboembolic complications.

DIAGNOSIS

There are three critical steps in the diagnosis of anaerobic infection: (1) proper collection of specimens; (2) rapid transport of the specimens to the microbiology laboratory, preferably in anaerobic transport media; and (3) proper handling of the specimens by the laboratory. Specimens must be collected by meticulous sampling of infected sites, with avoidance of contamination by the normal microbiota. Samples from sites known to harbor numerous anaerobes (e.g., the mouth, nose, vagina, feces) are not acceptable for anaerobic culture as the presence of the normal microbiota will complicate interpretation of the results in a clinically meaningful manner. In contrast, samples from normally sterile locations (e.g., blood, pleural fluid, peritoneal fluid, CSF, and aspirates or biopsy samples from normally sterile sites) are appropriate for anaerobic culture in clinical microbiology laboratories. As a general rule, liquid or tissue specimens are preferred; if swab specimens must be used, special anaerobic swab systems should be used to help maintain persistence of anaerobes. Liquid samples should be collected in an air-free syringe that is then capped, injected into anaerobic transport bottles, or quickly transported to the clinical microbiology laboratory for immediate culture.

Because of the time and difficulty involved in the isolation of anaerobic bacteria, the diagnosis of anaerobic infections must frequently be based on presumptive evidence. As mentioned previously, anaerobic infections are sometimes suggested by specific clinical factors, such as origins from a site with an anaerobic-rich microbiota (e.g., the intestinal tract, oropharynx), the presence of an abscess, involvement of sites with lowered oxidation-reduction potential (e.g., avascular necrotic tissues), a foul odor, and the presence of gas in tissues. None of these features is necessarily pathognomonic or required for the diagnosis of an anaerobic infection, but these are helpful clues to keep in mind when constructing a differential diagnosis.

When cultures of obviously infected sites or purulent material yield no growth, streptococci only, or a single aerobic species (such as *E. coli*) and Gram's staining reveals a mixed bacterial population, the involvement of anaerobes should be suspected; the implication is that the anaerobic microorganisms have failed to grow because of inadequate transport and/or culture techniques. It is also important to remember that prior antibiotic therapy reduces the cultivability of these bacteria. Failure of an infection to respond to antibiotics that are not active against anaerobes (e.g., aminoglycosides and—in some circumstances—penicillin, cephalosporins, or tetracyclines) suggests an anaerobic etiology.

TREATMENT

Anaerobic Infections

Similar to successful therapy for other types of infection, treatment for anaerobic infections requires the administration of appropriate antibiotics, surgical debridement of devitalized tissues, and drainage of any large abscess. Any mucosal breach must be closed promptly to prevent ongoing infection.

ANTIBIOTIC THERAPY AND RESISTANCE

The antibiotics used to treat anaerobic infections should be active against both aerobic and anaerobic organisms because many of these infections are of mixed etiology. Antibiotic regimens can usually be selected empirically on the basis of the location of infection (which provides insight into the likely species involved), the severity of infection, and knowledge of local antimicrobial resistance patterns. Other factors influencing the selection of antibiotics include need for penetration into certain organs (such as the brain) and associated toxicity (Chap. 149). As with all infections, the general maxim is to use the the narrowest-spectrum agent(s) possible so as to minimize the impact on the normal microbiota and the development of resistance.

Because of the slow growth rate of many anaerobes, the lack of standardized testing methods and of clinically relevant standards for resistance, and the generally good results obtained with empirical therapy, the role of antibiotic susceptibility testing of these organisms has been limited in most clinical microbiology laboratories. Instead, isolates are sent to reference laboratories for susceptibility testing when an infection is serious (e.g., brain abscess, meningitis, joint infection), is refractory, or requires prolonged therapy (e.g., osteomyelitis, prosthetic joint infection, endocarditis). Such testing should also be considered when a patient is not responding to antimicrobial therapy as expected; multidrug-resistant anaerobes have been reported. Antimicrobial susceptibility testing is also helpful in monitoring the activity of new drugs and recording current resistance patterns among anaerobic pathogens.

The need for susceptibility testing of anaerobic organisms is highlighted by increasing rates of antimicrobial resistance, geographic and institutional differences in susceptibility profiles, species-specific antibiograms, and the potential for worse clinical outcomes when ineffective antibiotics are used. These differences preclude making any sweeping generalizations regarding antibiotic therapy for anaerobic infections. For example, rates of resistance to piperacillin-tazobactam have remained low (≤1%) for all *Bacteroides* species in the United States, but *B. thetaiotaomicron* isolates in Korea have a notably higher resistance rate (17%). Clindamycin was historically effective against members of the *B. fragilis* group, but rates of resistance have increased to 30–43% in the United States and are >80% in some parts of the world. Furthermore, metronidazole is effective against many different anaerobic organisms and is considered a first-line agent for many anaerobic infections worldwide, but, in a population of Colombian patients with refractory periodontitis, 45% of *Fusobacterium* isolates and 25% of *Prevotella* and *Porphyromonas* strains were resistant to metronidazole; this finding underscores the importance of understanding the local antibiogram and of assessing susceptibility profiles in refractory disease.

Empirical Therapy Not every anaerobe isolated must be specifically targeted by the antibiotic regimen. Given that infections involving anaerobes are typically polymicrobial, that the cultivation and identification of anaerobes are challenging (i.e., not all organisms may be recovered), and that organisms often depend on one another for persistence, clinical resolution of the infection is often achieved with empirical antibiotics targeting the bulk of the organisms recovered. Antibiotics that demonstrate no useful activity against anaerobes include aminoglycosides, monobactams, and trimethoprim-sulfamethoxazole. With the caveat that susceptibility profiles may change with time and geography, the antibiotics that are commonly used

TABLE 182-2 Antimicrobial Therapy That Is Typically Active against Commonly Encountered Anaerobes

ANTIBIOTIC(S)	CAVEATS
Metronidazole	This drug is clinically unreliable against gram-positive non-spore-forming anaerobes (e.g., *Actinomyces* spp., *Propionibacterium* spp., *Peptostreptococcus* spp.).
β-Lactam/β-lactamase inhibitor combinations (ampicillin-sulbactam, ticarcillin–clavulanic acid, piperacillin-tazobactam)	Rates of resistance are increasing in some gram-negative anaerobes. The newer cephalosporin/β-lactamase combinations have limited anaerobic activity.
Clindamycin	Rates of resistance are increasing in *Bacteroides* spp.
Carbapenems (meropenem, imipenem, ertapenem, doripenem)	Rates of resistance are currently very low (<5%), although some carbapenemase-producing strains have been identified.
Chloramphenicol	Some clinical failures have been noted, even when the isolate is found to be susceptible by in vitro testing.

as empirical therapy against anaerobic bacteria include metronidazole, β-lactam/β-lactamase inhibitor combinations, clindamycin, carbapenems, and chloramphenicol **(Table 182-2)**.

Metronidazole is active against gram-negative anaerobes, including nearly all isolates of *Bacteroides* species, and gram-positive spore-forming organisms, such as *C. difficile* **(Chap. 139)** and other *Clostridium* species. Given intrinsically reduced susceptibility, metronidazole is clinically unreliable against gram-positive non-spore-forming organisms, such as *Actinomyces*, *Propionibacterium*, *Lactobacillus*, *Bifidobacterium*, *Eubacterium*, and *Peptostreptococcus*. Of note, a few metronidazole-resistant *Bacteroides* isolates have been identified in the United States, and rates of such resistance have been increasing in Europe. Moreover, the rate of resistance to metronidazole has probably been greatly underestimated in some countries (e.g., the United Kingdom) that use metronidazole susceptibility to discriminate between obligate and facultative anaerobes (with obligate anaerobes defined by their susceptibility). Although the majority of metronidazole-resistant isolates have been identified in patients who have been exposed to the drug, resistant organisms have also been found in metronidazole-naïve patients.

More than 90% of clinical isolates from the *B. fragilis* group produce β-lactamases that are predominantly active against cephalosporins and that are highly active, cell associated, and produced constitutively. Thus, members of the *B. fragilis* group are presumed to be resistant to penicillin and ampicillin but may remain susceptible to extended-spectrum penicillins, particularly in combination with a β-lactamase inhibitor (e.g., ampicillin-sulbactam, piperacillin-tazobactam). Rates of resistance to ampicillin-sulbactam are increasing, particularly in *P. distasonis*, which has a reported resistance rate of 21% in the United States. Because β-lactamase production is not common in *Clostridium* species, these combination agents are usually effective. Of note, the newer cephalosporin/β-lactamase inhibitors (e.g., ceftolozane-tazobactam, ceftazidime-avibactam) have limited anaerobic activity.

Clindamycin is active against many anaerobes. However, rates of resistance to clindamycin among *Bacteroides* species increased in the United States from 7% in 1981 to 33% in 2010–2012. Resistance to clindamycin among non-*Bacteroides* gram-negative anaerobes is much less common (<10%). Some *Clostridium* species are resistant to clindamycin, although *C. perfringens* typically is not.

Carbapenems (ertapenem, doripenem, meropenem, and imipenem) are active against anaerobes, with fewer than 3% of *Bacteroides* isolates resistant. There is little difference among resistance rates for specific species, and, of the carbapenems, imipenem typically has the lowest resistance rate. Although the β-lactamase produced by most *Bacteroides* species is unable to inactivate carbapenems, rare *B. fragilis* strains have been reported to produce a carbapenemase.

Resistance to chloramphenicol is rare in *Bacteroides* species. Nationwide surveys in the United States have identified no resistant organisms, but some isolates with elevated minimal inhibitory concentrations (MICs)—i.e., 16 μg/mL—have been noted. Although chloramphenicol has excellent in vitro activity against all clinically relevant anaerobes, some clinical failures have been documented. Therefore, this drug may be less preferable if other active agents are available.

Other antibiotics with more variable activity against anaerobes include the fluoroquinolones and tigecycline. Although many fluoroquinolones (e.g., ciprofloxacin, levofloxacin, ofloxacin) display reasonable activity against anaerobic organisms other than *Bacteroides* species, these agents exhibit poor activity against the *B. fragilis* group. Rates of resistance to moxifloxacin are relatively high (39–83%) among *Bacteroides* isolates obtained in the United States but are much lower among *B. fragilis* and *B. thetaiotaomicron* isolates collected in Korea (8 and 2%, respectively) or Taiwan (8 and 15%, respectively). Tigecycline is active against most anaerobic bacteria, although MICs are somewhat higher for *Clostridium* species. Tigecycline's efficacy for treatment of complicated intraabdominal infections is comparable to that of imipenem, and it is therefore recommended as single-agent therapy for these infections.

Infections at Specific Sites In clinical situations, specific antibiotic regimens and durations must be tailored to the initial site of infection; the reader is referred to specific chapters on infections at specific sites for recommendations. In general, anaerobic infections are often broadly categorized as originating above or below the diaphragm. This distinction is clinically useful in that the predominant pathogens—and therefore the empirical antibiotic regimens—differ between these two categories of infection.

Infections above the diaphragm usually reflect the orodental microbiota, which includes *Prevotella*, *Porphyromonas*, *Fusobacterium*, and *Bacteroides* species other than the *B. fragilis* group along with streptococci (both aerobic and microaerophilic). Accordingly, antibiotic regimens should cover both aerobic and anaerobic bacteria. Given that >70% of these infections include a β-lactamase-producing organism, β-lactam drugs (penicillins and cephalosporins) are poor options as monotherapy. The recommended regimens include clindamycin, a β-lactam/β-lactamase inhibitor combination, or metronidazole in combination with a drug active against microaerophilic and aerobic streptococci (e.g., penicillin).

Anaerobic infections arising below the diaphragm (e.g., colonic and intraabdominal infections) must be treated specifically with agents active against *Bacteroides* species, including *B. fragilis*. Single agents suitable for this purpose include cefoxitin, moxifloxacin, a β-lactam/β-lactamase inhibitor combination, or a carbapenem. A two-drug regimen is an alternative, with one drug active against anaerobes and the other against coliforms (e.g., metronidazole with either a cephalosporin or a fluoroquinolone). In addition, if the clinician suspects that gram-positive facultative organisms such as enterococci are involved, therapeutic regimens should include ampicillin or vancomycin. Although clindamycin and cefotetan were previously considered acceptable options for intraabdominal infections involving anaerobes, these drugs are no longer recommended because of escalating rates of resistance in the *B. fragilis* group. Ampicillin-sulbactam is not recommended because of high rates of resistance among community-acquired strains of *E. coli* rather than because of resistance in anaerobic bacteria.

CNS infections involving anaerobic organisms may be treated with metronidazole, a carbapenem, chloramphenicol, or—if only gram-positive anaerobes are involved—penicillin. Clindamycin and cefoxitin have poor penetration into the CSF and should not be used. Cases of osteomyelitis in which a polymicrobial infection is identified from a bone biopsy specimen should be treated with a regimen that covers both aerobes and anaerobes, as some organisms that are often regarded as a contaminant (e.g., *C. acnes*) may have a pathogenic role. When an anaerobic organism is recognized as a

major or sole pathogen infecting a joint, the duration of treatment should be similar to that used for arthritis caused by aerobic bacteria (Chap. 135).

Although not every anaerobe needs to be covered with pathogen-directed therapy in most polymicrobial infections, several studies of *Bacteroides* bacteremia have clearly demonstrated that patients receiving effective therapy have lower mortality rates and more rapid sterilization of blood cultures than patients receiving ineffective therapy.

FAILURE OF THERAPY

Anaerobic infections that fail to respond to treatment or that relapse should be reassessed. Potential causes include an uncontrolled source of infection (e.g., ongoing intestinal leak into the peritoneum), superinfection with a new organism, and/or antibiotic failure. Additional imaging may be useful to discern whether surgical drainage or debridement is warranted. Obtaining additional culture specimens will help identify whether an organism resistant to the antibiotics being used is present. Strong consideration should be given to obtaining susceptibility profiles for the isolates.

Section 8 Mycobacterial Diseases

183 Tuberculosis

Mario C. B. Raviglione, Andrea Gori

Tuberculosis (TB), which is caused by bacteria of the *Mycobacterium tuberculosis* complex, is one of the oldest diseases known to affect humans. In 2023, after being replaced by COVID-19 during the three previous years, TB probably returned to be the top cause of infectious death from a single infectious agent. Population genomic studies suggest that *M. tuberculosis* may have emerged ~70,000 years ago in Africa and subsequently disseminated along with anatomically modern humans, expanding globally during the Neolithic Age as human density started to increase. This disease most often affects the lungs, although other organs are involved in up to one-third of cases. If properly treated, TB caused by drug-susceptible strains is curable in the vast majority of cases. If untreated, the disease may be fatal in more than 70% of people. Transmission usually takes place through the airborne spread of droplet nuclei produced by patients with infectious pulmonary TB. Through pharmacologic prophylaxis, the development of the disease can be prevented in those who have contracted TB infection.

ETIOLOGIC AGENT

Mycobacteria belong to the family Mycobacteriaceae and the order Actinomycetales. Of the pathogenic species belonging to the *M. tuberculosis* complex, which comprises eight distinct subgroups, the most common and important agent of human disease by far is *M. tuberculosis* (*sensu stricto*). A closely related organism isolated from cases in West, Central, and East Africa is *M. africanum*. The complex includes some zoonotic members, such as *M. bovis* (the bovine tubercle bacillus—characteristically resistant to pyrazinamide, once an important cause of TB transmitted by unpasteurized milk, and currently responsible for 140,000 human cases worldwide in 2020, half of them in Africa) and *M. caprae* (related to *M. bovis*). In addition, other organisms that have been reported rarely as causing TB include *M. pinnipedii* (a bacillus infecting seals and sea lions in the southern hemisphere and recently isolated from humans), *M. mungi* (isolated from banded mongooses in southern Africa), *M. orygis* (described in oryxes and other Bovidae in Africa and Asia and a potential cause of infection in humans), and *M. microti* (the "vole" bacillus, a less virulent organism). Finally, *M. canetti* is a rare isolate from East African cases that produces unusual smooth colonies on solid media and is considered closely related to a supposed progenitor type. There is no known environmental reservoir for any of these organisms.

M. tuberculosis is a rod-shaped, non-spore-forming, thin aerobic bacterium measuring 0.5 μm by 3 μm. Mycobacteria, including *M. tuberculosis*, are often neutral on Gram staining. However, once stained, the bacilli cannot be decolorized by acid alcohol; this characteristic justifies their classification as acid-fast bacilli (AFB; Fig. 183-1). Acid fastness is due mainly to the organisms' high content of mycolic acids, long-chain cross-linked fatty acids, and other cell-wall lipids. Microorganisms other than mycobacteria that display some acid fastness include species of *Nocardia* and *Rhodococcus*, *Legionella micdadei*, and the protozoa *Isospora* and *Cryptosporidium*. In the mycobacterial cell wall, lipids (e.g., mycolic acids) are linked to underlying arabinogalactan and peptidoglycan. This structure results in very low

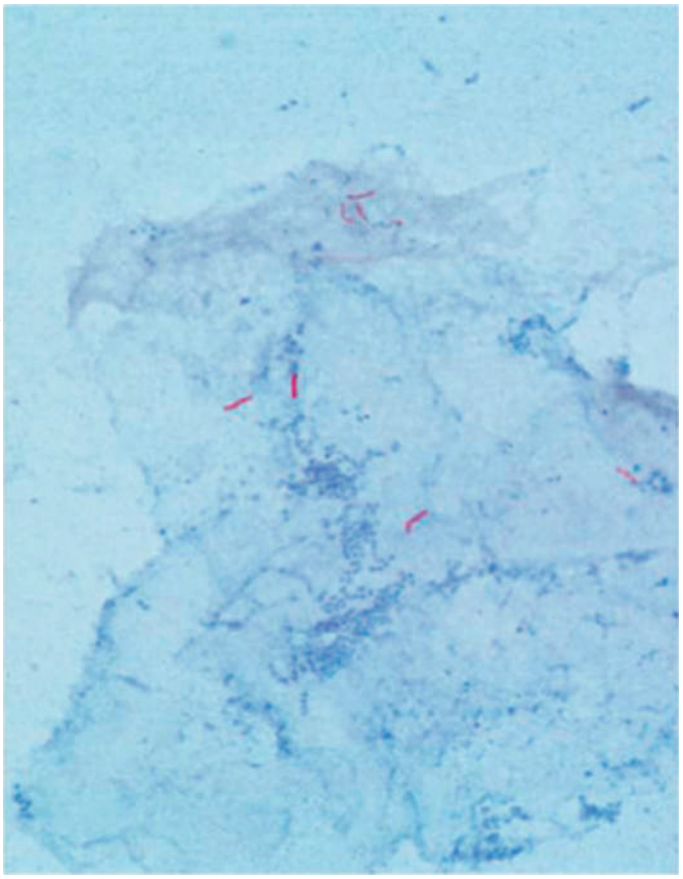

FIGURE 183-1 Acid-fast bacillus smear showing *M. tuberculosis* bacilli. *(Courtesy of the Centers for Disease Control and Prevention, Atlanta.)*

permeability of the cell wall, thus reducing the effectiveness of most antibiotics.

The complete genome sequence of *M. tuberculosis* comprises 4.4 million base pairs, 4043 genes encoding 3993 proteins, and 50 genes encoding stable RNAs; its high guanine-plus-cytosine content (65.6%) is indicative of an aerobic "lifestyle." A large proportion of genes are devoted to the production of enzymes involved in cell wall metabolism. Substantial genetic variability exists among the innumerable *M. tuberculosis* strains from different parts of the world. Based on such genetic variability it is possible to distinguish and compare different strains. Their distinction is important to study transmission dynamics and identify outbreaks. Starting in the 1990s, reproducible genotyping methods were developed to type the bacterium. Initially, they included insertion sequence 6110 (IS6110), restriction fragment length polymorphism (RFLP) typing, and spoligotyping. Lately, most studies utilize mycobacterial interspersed repetitive unit variable number tandem repeats (MIRU-VNTRs) and whole genome sequencing analysis.

EPIDEMIOLOGY

In 2023, 8.2 million new cases of TB (all forms, both pulmonary and extrapulmonary) were reported to the World Health Organization (WHO), around 97% of which were reported from low- and middle-income countries. However, because of insufficient case detection and incomplete notification, reported cases represent only about two-thirds of the total estimated cases. The WHO estimated that 10.8 million (range, 10.1–11.7 million, rate 134 per 100,000 persons) new (incident) cases of TB occurred worldwide in 2023. Eight countries accounted for two thirds of all cases: India (26%), Indonesia (10%), China (6.8%), the Philippines (6.8%), Pakistan (6.3%), Nigeria (4.6%), Bangladesh (3.5%) and the Democratic Republic of the Congo (3.1%). Of all cases, 55% occurred in male patients, 33% in female patients, and 12% in children. It is further estimated that 1.25 million (range 1.13–1.37 million) deaths from TB, including 160,000 among persons with HIV co-infection, occurred in 2023; 98% of these deaths were in low- and middle-income countries. Estimates of TB incidence and mortality rates (per 100,000 population) in 2022 are depicted in **Figs. 183-2 and 183-3**, respectively).

During the past few years, numbers of reported cases have stabilized or are slowly declining in most high-income countries. In the United States, TB cases and incidence rates steadily decreased from 1992 to 2021. In 2022, 8300 cases of TB (2.5 cases per 100,000 population) were reported to the U.S. Centers for Disease Control and Prevention (CDC), a slight increase from the 7882 cases reported in 2021. In the United States, TB is uncommon among young white adults of European descent, who have only rarely been exposed to *M. tuberculosis* infection during recent decades. In contrast, because of a high risk of transmission in the past, the prevalence of *M. tuberculosis* infection is relatively high among elderly whites; overall, 13 million persons are estimated to be "latently" infected. In general, adults ≥65 years of age have the highest incidence rate per capita and children <14 years of age the lowest. Of the total 7882 cases in 2021, 28% were among U.S.-born persons and 71% among non-U.S.-born persons. Non-Hispanic Black or African American persons accounted for the highest proportion of cases (34%), followed by non-Hispanic White persons (29%), and Hispanic/Latinos (24%). Among non-U.S.-born persons in the United States in 2021, 48% occurred in persons born in Asia, 33% among Hispanic/Latino persons, and 12% among African American persons. Overall, the highest rates per capita were among non-U.S.-born persons of more than one ethnicity (30 cases per 100,000 population). In 2020 in the United States 600 deaths were caused by TB, the highest number since 2006. In 2021 in Canada, TB cases and rates per 100,000 population were 1829 and 4.8, respectively. Of these cases, 76% occurred in foreign-born persons. However, the highest rates per 100,000 population were among Inuit (135) and First Nation persons (16). Similarly, in Europe, TB has reemerged as an important public health problem, mainly as a result of cases among immigrants from high-incidence countries and among marginalized populations, often in large urban settings. In most Western European countries, there are more cases annually among foreign-born than native populations.

In 2023 TB incidence was decreasing in Africa, resuming a slow decline in the European, Eastern Mediterranean, and Southeast Asia

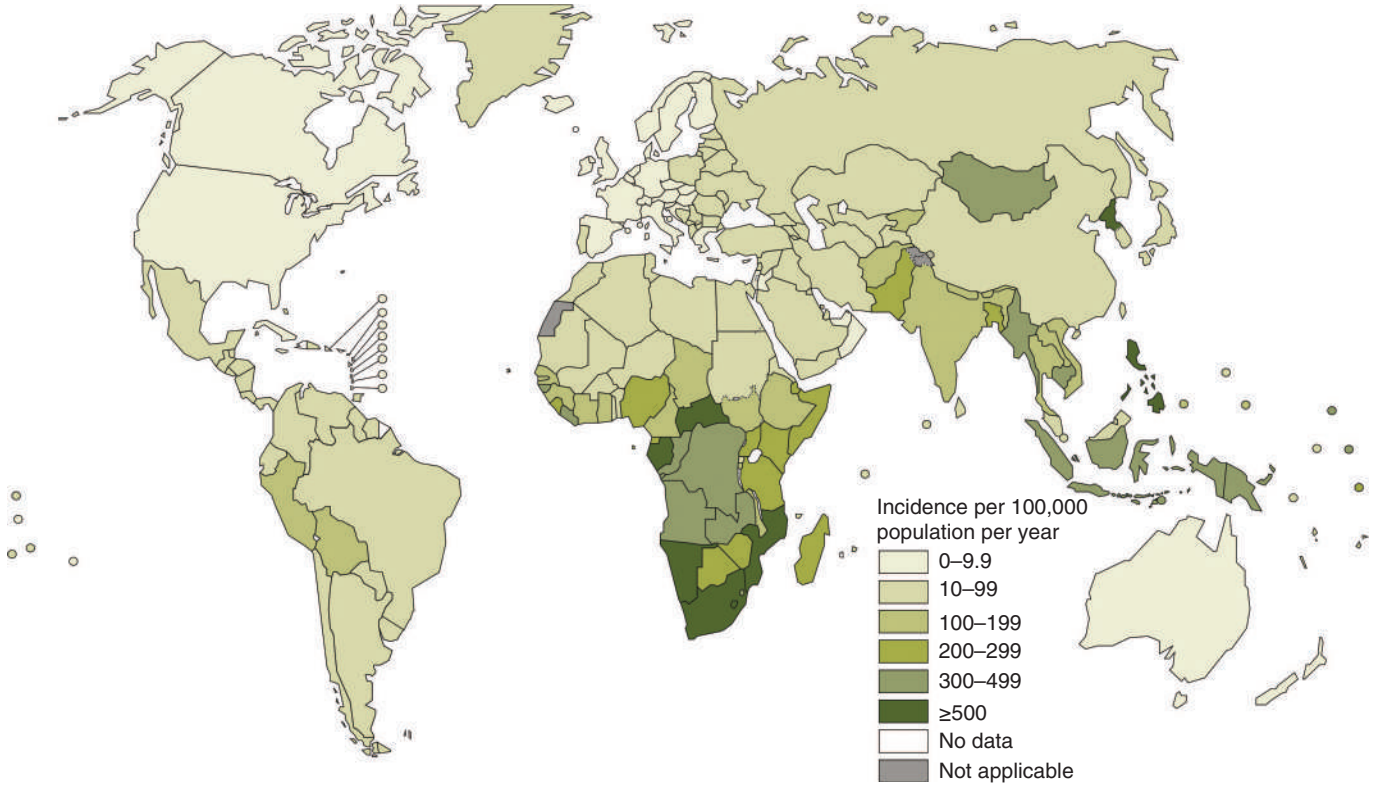

FIGURE 183-2 Estimated tuberculosis (TB) incidence rates (per 100,000 population) in 2022. FIGURE 183-3 Estimated tuberculosis (TB) mortality rates in HIV-negative persons in 2022. *(See disclaimer in Fig. 183-2. Reproduced with permission from Global Tuberculosis Report 2023. Geneva, World Health Organization; 2023.)*

regions following the COVID-19 pandemic, and still increasing in the Americas and the Western Pacific. Globally, TB incidence has increased by nearly 5% since 2020 as a result of essential service disruptions during the worst period of the pandemic.

Of the estimated 10.8 million new cases of TB in 2023, 6.1% were in people living with HIV, with the majority of them occurring in Africa. Furthermore, an estimated 400,000 (range, 360,000-440,000) cases of rifampin-resistant (also called rifampicin-resistant) TB (RR-TB) and multidrug-resistant TB (MDR-TB)—a form of the disease caused by bacilli resistant at least to isoniazid and rifampin—occurred in 2023, representing 3.2% and 16%, respectively, of all new and previously treated cases. Only 189,000 MDR/RR-TB cases were enrolled on treatment in 2023 because of a lack of culture and drug susceptibility testing (DST) capacity in many settings worldwide. The countries of the former Soviet Union remain those with the highest proportions of MDR/RR disease among new TB cases, reaching up to one-third of the total. Overall, more than 50% of all MDR/RR-TB cases occur in India (27%), the Russian Federation (7.4%), Indonesia (7.4%), China (7.3%) and the Philippines (7.2%). Cases of extensively drug-resistant TB (XDR-TB), in which MDR-TB is compounded by additional resistance to any fluoroquinolones and at least one additional group A drug (e.g., bedaquiline and linezolid), and cases of pre-XDR-TB, a form in which MDR/RR-TB strains are also resistant to any fluoroquinolone, occur worldwide. However, the vast majority of XDR-TB cases remain undiagnosed because reliable methods for DST are still lacking and laboratory capacity in low-income countries is limited.

FROM EXPOSURE TO INFECTION

M. tuberculosis is most commonly transmitted from a person with infectious pulmonary TB by droplet nuclei containing *M. tuberculosis* bacteria, which are aerosolized by coughing, sneezing, or speaking. The tiny droplets dry rapidly; the smallest (<5–10 μm in diameter) may remain suspended in the air for several hours and may reach the terminal air passages when inhaled. Other routes of transmission of tubercle bacilli (e.g., through the skin or the placenta) are uncommon and of no epidemiologic significance. The risk of transmission and of subsequent acquisition of *M. tuberculosis* infection is determined mainly by exogenous factors, although endogenous factors also may play a role. The probability of contact with a person who has an infectious form of TB, the intimacy and duration of that contact, the degree of infectiousness of the case, and the shared environment in which the contact takes place are all important determinants of the likelihood of transmission. The most infectious patients whose sputum contains AFB visible by microscopy have cavitary pulmonary disease or, much less commonly, laryngeal TB and produce sputum containing as many as 10^5–10^7 AFB/mL. Patients with sputum smear–negative/culture-positive TB are less infectious, although they have been responsible for up to 20% of transmission in some studies in the United States. Those with culture-negative pulmonary TB and extrapulmonary TB are essentially noninfectious. Because persons with both HIV infection and TB are less likely to have cavitations, they may be less infectious than those without HIV co-infection. Crowding in poorly ventilated rooms is one of the most important factors in the transmission of tubercle bacilli because it increases the intensity of contact with a case. The virulence of the transmitted organism is also an important factor in establishing infection. Endogenous factors such as the degree of immune competence also are important. In particular, HIV-infected patients, persons undergoing cancer treatment, or those administered immunosuppressive drugs may be at higher risk of TB infection acquisition. Attempts to estimate the basic reproductive number R_0 for TB have resulted in a wide range of values depending on environmental conditions and social behaviors of populations: from 0.24 in the Netherlands during the period 1933–2007 to 4.3 in China in 2012, reflecting the status of disease control.

FROM INFECTION TO DISEASE

Unlike the risk of acquiring infection with *M. tuberculosis*, the risk of developing disease after being infected depends largely on endogenous factors, such as the individual's innate immunologic and nonimmunologic defenses and the level at which the individual's cell-mediated immunity is functioning. Clinical illness directly following infection is classified as *primary TB* and is common among children in the first few years of life and among immunocompromised persons. Although primary TB may be severe and disseminated, it generally is not associated with high-level transmissibility. When infection is acquired later in life, the chance is greater that the mature immune system will

TABLE 183-1 Risk Factors for Active Tuberculosis in Persons Who Have Been Infected with Tubercle Bacilli

FACTOR	RELATIVE RISK/ODDS[a]
Recent infection (<1 year)	12.9
Fibrotic lesions (spontaneously healed)	2–20
Comorbidities and iatrogenic causes	
HIV infection	21–>30
Silicosis	30
Chronic renal failure/hemodialysis	10–25
Diabetes	2–4
IV drug use	10–30
Excessive alcohol use	3
Immunosuppressive treatment	10
Tumor necrosis factor α inhibitors	4–5
Gastrectomy	2–5
Jejunoileal bypass	30–60
Posttransplantation period (renal, cardiac)	20–70
Tobacco smoking	2–3
Malnutrition and severe underweight	2

[a]Old infection = 1.

contain it at least temporarily. Bacilli, however, may persist for years before reactivating to produce *secondary* (or *postprimary*) *TB*, which, because of frequent cavitation, is more often infectious than is primary disease. Overall, it is estimated that up to 10% of infected persons will eventually develop active TB in their lifetime—half of them during the first 18 months after infection. The risk is much higher among immunocompromised individuals and, particularly, HIV-infected persons. Reinfection of a previously infected individual, which is common in areas with high rates of TB transmission, may also favor the development of disease. At the height of the TB resurgence in the United States in the early 1990s, molecular typing and comparison of strains of *M. tuberculosis* suggested that up to one-third of cases of active TB in some inner-city communities were due to recent transmission rather than to reactivation of old infection. Age is an important determinant of the risk of disease after infection. Among infected persons, the incidence of TB is highest during late adolescence and early adulthood; the reasons are unclear. The incidence among women peaks at 25–34 years of age. In this age group, rates among women may be higher than those among men, whereas at older ages the opposite is true. The risk increases in the elderly, possibly because of waning immunity and comorbidity.

A variety of diseases and conditions favor the development of active TB **(Table 183-1)**. In absolute terms, the most potent risk factor for TB among infected individuals is HIV co-infection, which suppresses cellular immunity. The risk that infection will proceed to active disease is directly related to the patient's degree of immunosuppression. In a study of people living with HIV (PLWH), those who were tuberculin skin test (TST)–positive had risks varying from 2.6 to 13.3 cases per 100 person-years, which increased as the CD4+ T cell count decreased.

NATURAL HISTORY OF DISEASE

Studies conducted in various countries before the advent of antimicrobial TB therapy showed that untreated TB is often fatal. About one-third of patients died within 1 year after diagnosis. Historic data also show that 55% of sputum smear-positive cases were dead within 5 years and up to 86% (weighted mean, 70%) within 10 years. A lower case fatality rate, around 20%, was estimated for untreated paucibacillary smear-negative cases at 5 years. Of the survivors at 5 years, ~60% had undergone spontaneous remission, while the remainder were still excreting tubercle bacilli. With effective, timely, and proper antimicrobial TB treatment, patients have a very high chance of being cured. However, improper use of anti-TB drugs, while reducing mortality rates, may also result in large numbers of chronic infectious cases, often with drug-resistant bacilli.

PATHOGENESIS AND IMMUNITY

INFECTION AND MACROPHAGE INVASION

The interaction of *M. tuberculosis* with the human host begins when droplet nuclei containing viable microorganisms, propelled into the air by infectious patients, are inhaled by a close bystander. Although the majority of inhaled bacilli are trapped in the upper airways and expelled by ciliated mucosal cells, a fraction (usually <10%) reach the alveoli, a unique immunoregulatory environment. There, in the very early phases of infection, the predominant cells infected by *M. tuberculosis* are myeloid dendritic cells. Subsequently, alveolar macrophages that have not yet been activated (prototypic alternatively activated macrophages) phagocytose the bacilli. Adhesion of mycobacteria to macrophages results largely from binding of the bacterial cell wall to a variety of macrophage cell-surface receptor molecules, including complement receptors, the mannose receptor, the immunoglobulin G Fcγ receptor, and type A scavenger receptors. Surfactants may also play a role in the early phase of interaction between the host and the pathogen, and surfactant protein D can prevent phagocytosis. Phagocytosis is enhanced by complement activation, leading to opsonization of bacilli with C3 activation products such as C3b and C3bi. Concomitantly, binding of certain receptors, such as the mannose receptor, regulates postphagocytic events like phagosome–lysosome fusion and inflammatory cytokine production. After a phagosome forms, the survival of *M. tuberculosis* in the cell seems to depend in part on reduced acidification due to lack of assembly of a complete vesicular proton-adenosine triphosphatase. A complex series of events is generated by the bacterial cell-wall lipoglycan lipoarabinomannan, which inhibits the intracellular increase of Ca^{2+}. Thus, the Ca^{2+}/calmodulin pathway (leading to phagosome–lysosome fusion) is impaired, and the bacilli survive within the phagosomes by blocking fusion. The *M. tuberculosis* phagosome inhibits the production of phosphatidylinositol 3-phosphate, which normally earmarks phagosomes for membrane sorting and maturation (including phagolysosome formation), which would destroy the bacteria. Bacterial factors block the host defense of autophagy, in which the cell sequesters the phagosome in a double-membrane vesicle (*autophagosome*) that is destined to fuse with lysosomes. If the bacilli are successful in arresting phagosome maturation, then bacterial replication begins and the macrophage eventually ruptures and releases its bacillary contents. This process is mediated by the ESX-1 secretion system that is encoded by genes contained in the region of difference 1 (RD1). Other uninfected phagocytic cells are then recruited to continue the infection cycle by ingesting dying macrophages and their bacillary content, thus, in turn, becoming infected themselves and expanding the infection.

VIRULENCE OF TUBERCLE BACILLI

M. tuberculosis must be viewed as a complex formed by a multitude of strains that differ in virulence and are capable of producing a variety of manifestations of disease. Since the elucidation of the *M. tuberculosis* genome in 1998, large mutant collections have been generated, and many bacterial genes that contribute to *M. tuberculosis* virulence have been found. Moreover, different patterns of virulence defects have been defined in various animal models—predominantly mice but also guinea pigs, rabbits, and nonhuman primates. The *katG* gene encodes for a catalase/peroxidase enzyme that protects against oxidative stress and is required for isoniazid activation and subsequent bactericidal activity. RD1 is a 9.5-kb locus that encodes two key small protein antigens—the 6-kDa early secretory antigen (ESAT-6) and culture filtrate protein 10 (CFP-10)—as well as a putative secretion apparatus that may facilitate their egress; the absence of this locus in the vaccine strain *M. bovis* bacille Calmette-Guérin (BCG) is a key attenuating mutation. Mutants lacking key enzymes of bacterial biosynthesis become auxotrophic for the missing substrate and often are totally unable to proliferate in animals; these include the *leuCD* and *panCD* mutants, which require leucine and pantothenic acid, respectively. The isocitrate lyase gene (*icl1*) encodes a key step in the glyoxylate shunt that facilitates bacterial growth on fatty acid substrates; this gene is required for long-term persistence of *M. tuberculosis* infection

in mice with chronic TB. *M. tuberculosis* mutants in regulatory genes such as sigma factor C and sigma factor H (*sigC* and *sigH*) are associated with normal bacterial growth in mice, but they fail to elicit full tissue pathology. Finally, the mycobacterial protein CarD (expressed by the *carD* gene) seems essential for the control of rRNA transcription that is required for mycobacterial replication and persistence in the host cell. Its loss exposes mycobacteria to oxidative stress, starvation, DNA damage, and ultimately sensitivity to killing by a variety of host mutagens and defense mechanisms.

INNATE RESISTANCE TO INFECTION

Several observations suggest that genetic factors play a key role in innate resistance to infection with *M. tuberculosis* and the development of disease. The existence of this resistance, which is polygenic in nature, is suggested by the differing degrees of susceptibility to TB in different populations. This mechanism of elimination of the pathogen may be accompanied by negative results in the TST and interferon γ (IFN-γ) release assays (IGRAs). In mice, a gene called *Nramp1* (natural resistance–associated macrophage protein 1) plays a regulatory role in resistance/susceptibility to mycobacteria. The human homologue *NRAMP1*, which maps to chromosome 2q, may play a role in determining susceptibility to TB, as is suggested by a study among West Africans. Studies of mice identified a novel host resistance gene, *ipr1*, that is encoded within the *sst1* locus; *ipr1* encodes an IFN-inducible nuclear protein that interacts with other nuclear proteins in macrophages primed with IFNs or infected by *M. tuberculosis*. In addition, polymorphisms in multiple genes, such as those encoding for various major histocompatibility complex alleles, IFN-γ, T cell growth factor β, interleukin (IL) 10, mannose-binding protein, IFN-γ receptor, Toll-like receptor 2, vitamin D receptor, and IL-1, have been associated with susceptibility to TB.

THE HOST RESPONSE, GRANULOMA FORMATION, AND "LATENCY"

In the initial stage of host–bacterium interaction, prior to the onset of an acquired cell-mediated immune (CMI) response, *M. tuberculosis* disseminates widely through the lymph vessels, spreading to other sites in the lungs and other organs, and undergoes a period of extensive growth within naïve inactivated macrophages; additional naïve macrophages are recruited to the early granuloma. How the bacillus accesses the parenchymal tissue still needs to be elucidated: it may directly infect epithelial cells or transmigrate through infected macrophages across the epithelium. Infected dendritic cells or monocytes then begin to transport bacilli to the lymphatic system. Studies suggest that *M. tuberculosis* uses specific virulence mechanisms to subvert host cellular signaling and to elicit an early regulated proinflammatory response that promotes granuloma expansion and bacterial growth during this key early phase. A study of *M. marinum* infection in zebrafish has delineated one molecular mechanism by which mycobacteria induce granuloma formation. The mycobacterial protein ESAT-6 induces secretion of matrix metalloproteinase 9 (MMP9) by nearby epithelial cells that are in contact with infected macrophages. MMP9 in turn stimulates recruitment of naïve macrophages, thus inducing granuloma maturation and bacterial growth. Disruption of MMP9 function results in reduced bacterial growth. Another study has shown that *M. tuberculosis*–derived cyclic AMP is secreted from the phagosome into host macrophages, subverting the cell's signal transduction pathways and stimulating an elevation in the secretion of tumor necrosis factor α (TNF-α) as well as further proinflammatory cell recruitment. Ultimately, the chemoattractants and bacterial products released during the repeated rounds of cell lysis and infection of newly arriving macrophages enable dendritic cells to access bacilli; these cells migrate to the draining lymph nodes and present mycobacterial antigens to T lymphocytes. At this point, the development of cell-mediated and humoral immunity begins. These initial stages of infection are usually asymptomatic.

About 2–4 weeks after infection, two host responses to *M. tuberculosis* develop: a macrophage-activating CMI response and a tissue-damaging response. The *macrophage-activating response* is a T cell–mediated phenomenon resulting in the activation of macrophages that are capable of killing and digesting tubercle bacilli. The *tissue-damaging response* is the result of a delayed-type hypersensitivity reaction to various bacillary antigens; it destroys inactivated macrophages that contain multiplying bacilli but also causes caseous necrosis of the involved tissues (see below). Although both of these responses can inhibit mycobacterial growth, it is the balance between the two that determines the forms of TB that will develop subsequently. With the development of specific immunity and the accumulation of large numbers of activated macrophages at the site of the primary lesion, granulomatous lesions (*tubercles*) are formed. These lesions consist of accumulations of lymphocytes and activated macrophages that evolve toward epithelioid and giant cell morphologies. Initially, the tissue-damaging response can limit mycobacterial growth within macrophages. As stated above, this response, mediated by various bacterial products, not only destroys macrophages but also produces early solid necrosis in the center of the tubercle. Although *M. tuberculosis* can survive, its growth is inhibited within this necrotic environment by low oxygen tension and low pH. At this point, some lesions may heal by fibrosis, with subsequent calcification, whereas inflammation and necrosis occur in other lesions. Some observations have challenged the traditional view that any encounter between mycobacteria and macrophages results in chronic infection. It is possible that an immune response capable of eradicating early infection may sometimes develop as a consequence, for instance, of disabling mutations in mycobacterial genomes rendering their replication ineffective. Individual granulomas that are formed during this phase of infection can vary in size and cell composition; some can contain the spread of mycobacteria, while others cannot. TB infection ensues as a result of this dynamic balance between the microorganism and the host. For many years, TB infection has been called "latent TB infection (LTBI)." This terminology was used to define a state of persistent immune response to stimulation by *M. tuberculosis* antigens with no evidence of clinically manifest, active TB. The qualification "latent" may offer some convenience of distinguishing infection from disease, albeit an inaccurate description of a process that encompasses bacterial generations that are not dormant. *Latency* may be an inaccurate term because bacilli may remain active during this "latent" stage, forming biofilms in necrotic areas within which they temporarily hide. Therefore, some have proposed the term *persister* as a more accurate descriptor of the behavior of the bacilli in this phase. It is important to recognize that infection and disease do not represent a binary state but rather a continuum along which infection will eventually move in the direction of full containment or disease. The ability to predict, through systemic biomarkers, which infected individuals will progress toward disease would be of immense value in devising prophylactic interventions at scale.

MACROPHAGE-ACTIVATING RESPONSE

Cell-mediated immunity is critical at this early stage. In the majority of infected individuals, local macrophages are activated when bacillary antigens processed by macrophages stimulate T lymphocytes to release a variety of lymphokines. These activated macrophages aggregate around the lesion's center and effectively neutralize tubercle bacilli without causing further tissue destruction. In the central part of the lesion, the necrotic material resembles soft cheese (*caseous necrosis*)—a phenomenon that may also be observed in other conditions, such as neoplasms. Even when healing takes place, viable bacilli may remain within macrophages or in the necrotic material for many years. These "healed" lesions in the lung parenchyma and hilar lymph nodes may later undergo calcification.

DELAYED-TYPE HYPERSENSITIVITY

In a minority of cases, the macrophage-activating response is weak, and mycobacterial growth can be inhibited only by intensified delayed hypersensitivity reactions, which lead to lung tissue destruction. The lesion tends to enlarge further, and the surrounding tissue is progressively damaged. At the center of the lesion, the caseous material liquefies. Bronchial walls and blood vessels are invaded and destroyed, and cavities are formed. The liquefied caseous material, containing large

amounts of bacilli, is drained through bronchi. Within the cavity, tubercle bacilli multiply, spill into the airways, and are discharged into the environment through expiratory maneuvers such as coughing and talking. In the early stages of infection, bacilli are usually transported by macrophages to regional lymph nodes, from which they gain access to the central venous return; from there they reseed the lungs and may also disseminate beyond the pulmonary vasculature throughout the body via the systemic circulation. In young children with poor natural immunity, hematogenous dissemination may result in fatal miliary TB or tuberculous meningitis.

ROLE OF MACROPHAGES AND MONOCYTES

While cell-mediated immunity confers partial protection against *M. tuberculosis*, humoral immunity plays a less well-defined role in protection (although evidence is accumulating on the existence of antibodies to lipoarabinomannan, which may prevent dissemination of infection in children). In cell-mediated immunity, two types of cells are essential: macrophages, which directly phagocytose tubercle bacilli, and T cells (mainly CD4+ T lymphocytes, although the role of CD8+ T cells has recently been the subject of much research), which induce protection through the production of cytokines, especially IFN-γ. After infection with *M. tuberculosis*, alveolar macrophages secrete various cytokines responsible for several events (e.g., the formation of granulomas) as well as systemic effects (e.g., fever and weight loss). However, alternatively activated alveolar macrophages may be particularly susceptible to *M. tuberculosis* growth early on, given their more limited proinflammatory and bactericidal activity, which is related in part to being bathed in surfactant. New monocytes and macrophages attracted to the site are key components of the immune response. Their primary mechanism is probably related to production of oxidants (such as reactive oxygen intermediates or nitric oxide) that have antimycobacterial activity and increase the synthesis of cytokines such as TNF-α and IL-1, which in turn regulate the release of reactive oxygen intermediates and reactive nitrogen intermediates. In addition, macrophages can undergo apoptosis—a defensive mechanism to prevent the release of cytokines and bacilli via their sequestration in the apoptotic cell. Recent work also describes the involvement of neutrophils in the host response, although the timing of their appearance and their effectiveness remain uncertain.

ROLE OF T LYMPHOCYTES

Alveolar macrophages, monocytes, and dendritic cells are also critical in processing and presenting antigens to T lymphocytes, primarily CD4+ and CD8+ T cells; the result is the activation and proliferation of CD4+ T lymphocytes, which are crucial to the host's defense against *M. tuberculosis*. Qualitative and quantitative defects of CD4+ T cells explain the inability of HIV-infected individuals to contain mycobacterial proliferation. Activated CD4+ T lymphocytes can differentiate into cytokine-producing T_H1 or T_H2 cells. T_H1 cells produce IFN-γ—an activator of macrophages and monocytes—and IL-2. T_H2 cells produce IL-4, IL-5, IL-10, and IL-13 and may also promote humoral immunity. The interplay of these various cytokines and their cross-regulation determine the host's response. The role of cytokines in promoting intracellular killing of mycobacteria, however, has not been entirely elucidated. IFN-γ may induce the generation of reactive oxygen and nitrogen intermediates and regulate genes involved in bactericidal effects. TNF-α also is important. Although its precise mechanisms are complex and not yet fully clarified, there is a suggested model that foresees an ideal setting for TNF-α between excessive activation—with consequent worsening of immunopathologic reactions—and insufficient activation—with resulting lack of containment—in the control of TB infection. Observations made originally in transgenic knockout mice and more recently in humans suggest that other T cell subsets, especially CD8+ T cells, may play an important role. CD8+ T cells have been associated with protective activities via cytotoxic responses and lysis of infected cells as well as with production of IFN-γ and TNF-α. Finally, natural killer cells act as co-regulators of CD8+ T-cell lytic activities, and γδ T cells are increasingly thought to be involved in protective responses in humans.

MYCOBACTERIAL LIPIDS AND PROTEINS

Lipids are involved in mycobacterial recognition by the innate immune system, and lipoproteins (such as 19-kDa lipoprotein) trigger potent signals through Toll-like receptors present in blood dendritic cells. *M. tuberculosis* possesses various protein antigens. Some are present in the cytoplasm and cell wall; others are secreted. That the latter are more important in eliciting a T lymphocyte response is suggested by experiments documenting the appearance of protective immunity in animals after immunization with live, protein-secreting mycobacteria. Among the antigens that may play a protective role are some proteins of the antigen 85 complex are the 30-kDa major secretory protein (85B) and ESAT-6 antigens. Protective immunity is probably the result of reactivity to many different mycobacterial antigens. These antigens are being incorporated into newly designed vaccines on various platforms.

SKIN-TEST REACTIVITY

Coincident with the appearance of immunity, delayed-type hypersensitivity to *M. tuberculosis* develops. This reactivity is the basis of the TST, which is used primarily for the diagnosis of *M. tuberculosis* infection in persons without symptoms. The cellular mechanisms responsible for TST reactivity are related mainly to previously sensitized CD4+ T lymphocytes, which are attracted to the skin-test site. There, they proliferate and produce cytokines. Although delayed hypersensitivity is associated with protective immunity (TST-positive persons are less susceptible to a new *M. tuberculosis* infection than are TST-negative persons), it by no means guarantees protection against reactivation. In fact, cases of active TB are often accompanied by strongly positive skin-test reactions. There is also evidence of reinfection with new strains of *M. tuberculosis* in patients previously treated for active disease. This evidence underscores the fact that previous infection or active TB does not necessarily confer fully protective immunity.

CLINICAL MANIFESTATIONS

TB is classified as pulmonary, extrapulmonary, or both. Depending on several factors linked to host immunologic status and bacterial strains, extrapulmonary TB may occur in 10–40% of patients. Furthermore, up to two-thirds of HIV-infected patients with TB may have both pulmonary and extrapulmonary TB or extrapulmonary TB alone.

PULMONARY TB

Pulmonary TB is traditionally categorized as primary or postprimary (adult-type, secondary). This distinction has been challenged by molecular evidence from TB-endemic areas indicating that a large percentage of cases of adult pulmonary TB result from recent infection (either primary infection or reinfection) and not from reactivation.

Primary Disease Primary pulmonary TB occurs soon after the initial infection. It may be asymptomatic or may present with fever and occasionally pleuritic chest pain. In areas of high TB transmission, this form of disease is often seen in children. Because most inspired air is distributed to the middle and lower lung zones, these areas are most commonly involved in primary TB. The lesion forming after initial infection (*Ghon focus*) is usually peripheral and accompanied by transient hilar or paratracheal lymphadenopathy, which may or may not be visible on standard chest radiography (CXR) **(Fig. 183-4)**. Some patients develop erythema nodosum on the legs **(see Fig. A1-39)** or phlyctenular conjunctivitis. In the majority of cases, the lesion heals spontaneously and becomes evident only as a small calcified nodule. Pleural reaction overlying a subpleural focus also is common. The Ghon focus, with or without overlying pleural reaction, thickening, and regional lymphadenopathy, is referred to as the *Ghon complex*.

In young children with immature cell-mediated immunity and in persons with impaired immunity (e.g., those with malnutrition or HIV infection), primary pulmonary TB may progress rapidly to clinical illness. The initial lesion increases in size and can evolve in different ways. Pleural effusion, which is found in up to two-thirds of cases, results from the penetration of bacilli into the pleural space from an adjacent subpleural focus. In severe cases, the primary site rapidly enlarges, its central portion undergoes necrosis, and cavitation develops (*progressive primary TB*). TB in young children is almost

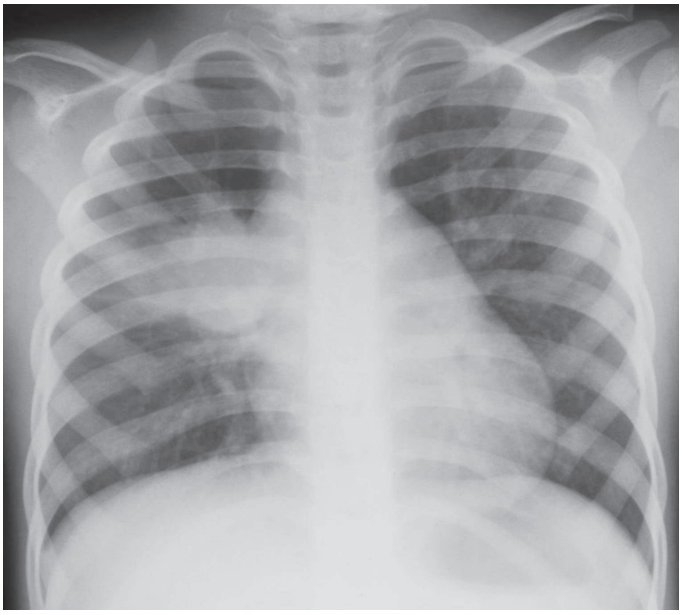

FIGURE 183-4 Chest radiograph showing right hilar lymph node enlargement with infiltration into the surrounding lung tissue in a child with primary tuberculosis. *(Courtesy of Prof. Robert Gie, Department of Paediatrics and Child Health, Stellenbosch University, South Africa; with permission.)*

invariably accompanied by hilar or paratracheal lymphadenopathy due to the spread of bacilli from the lung parenchyma through lymphatic vessels. Enlarged lymph nodes may compress bronchi, causing total obstruction with distal collapse, partial obstruction with large-airway wheezing, or a ball-valve effect with segmental/lobar hyperinflation. Lymph nodes may also rupture into the airway with development of pneumonia, often including areas of necrosis and cavitation, distal to the obstruction. Bronchiectasis **(Chap. 301)** may develop in any segment/lobe damaged by progressive caseating pneumonia. Occult hematogenous dissemination commonly follows primary infection. However, in the absence of a sufficient acquired immune response, which usually contains the infection, disseminated or miliary disease may result **(Fig. 183-5)**. Small granulomatous lesions develop in multiple organs and may cause locally progressive disease or result in tuberculous meningitis; this is a particular concern in very young children and immunocompromised persons (e.g., PLWH).

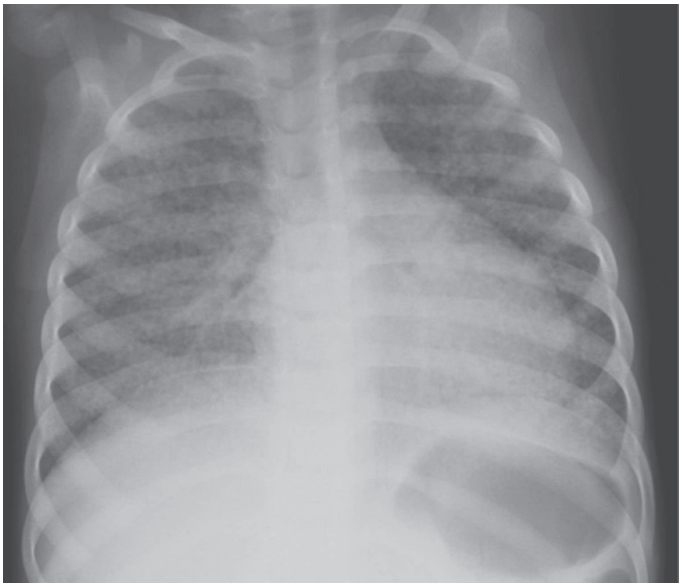

FIGURE 183-5 Chest radiograph showing bilateral miliary (millet-sized) infiltrates in a child. *(Courtesy of Prof. Robert Gie, Department of Paediatrics and Child Health, Stellenbosch University, South Africa; with permission.)*

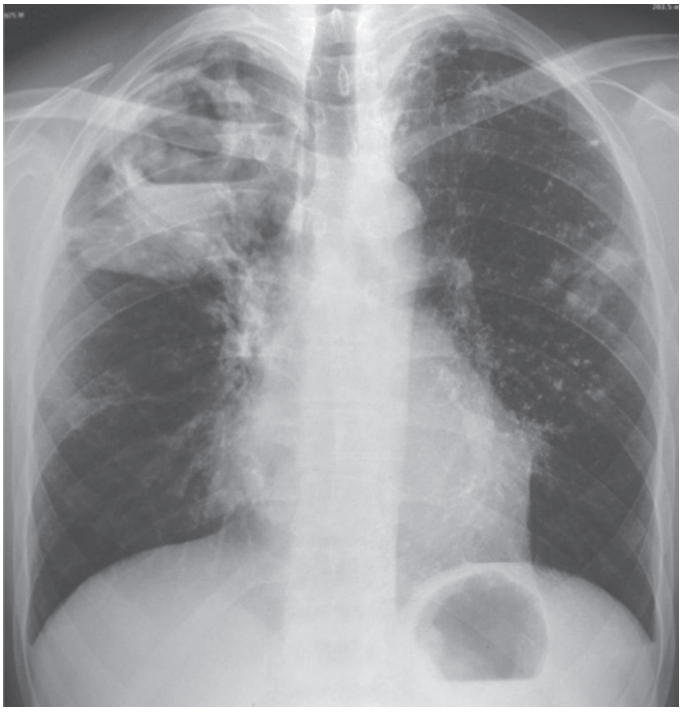

FIGURE 183-6 Chest radiograph showing a right-upper-lobe infiltrate and a cavity with an air-fluid level in a patient with active tuberculosis. *(Courtesy of Dr. Andrea Gori, Infectious Diseases Unit, Fondazione IRCCS Ca' Granda Ospediale Maggiore Policlinico, University of Milan, Milan, Italy; with permission.)*

Postprimary (Adult-Type) Disease Also referred to as *reactivation* or *secondary TB*, postprimary TB is probably most accurately termed *adult-type TB* because it may result from endogenous reactivation of distant or recent infection (primary infection or reinfection). It is usually localized to the apical and posterior segments of the upper lobes, where the substantially higher mean oxygen tension (compared with that in the lower zones) favors mycobacterial growth. The superior segments of the lower lobes also are frequently involved. The extent of lung parenchymal involvement varies greatly, from small infiltrates to extensive cavitary disease. With cavity formation, liquefied necrotic contents are ultimately discharged into the airways and may undergo bronchogenic spread, resulting in satellite lesions within the lungs that may in turn undergo cavitation **(Figs. 183-6 and 183-7)**. Massive involvement of pulmonary segments or lobes, with coalescence of lesions, produces caseating pneumonia. While up to one-third of untreated patients reportedly succumb to severe pulmonary TB

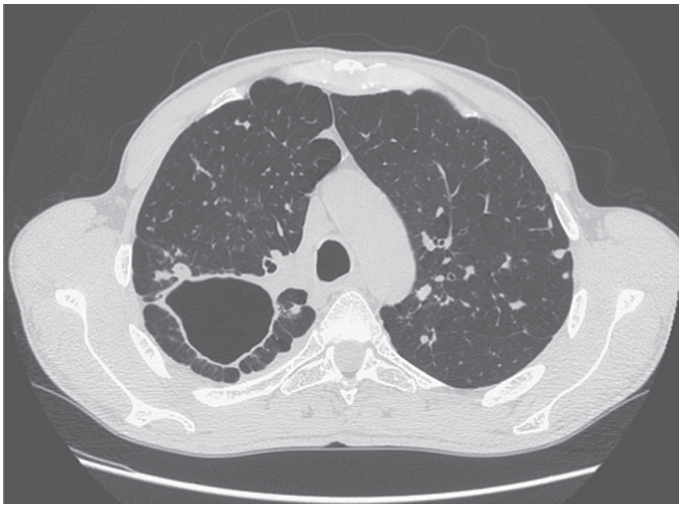

FIGURE 183-7 CT scan showing a large cavity in the right lung of a patient with active tuberculosis. *(Courtesy of Dr. Elisa Busi Rizzi, National Institute for Infectious Diseases, Spallanzani Hospital, Rome, Italy; with permission.)*

within a few months after onset (the classic "galloping consumption" of the past), others may undergo a process of spontaneous remission or proceed along a chronic, progressively debilitating course ("consumption" or *phthisis*). Under these circumstances, some pulmonary lesions become fibrotic and may later calcify, but cavities persist in other parts of the lungs. Individuals with such chronic disease continue to discharge tubercle bacilli into the environment. Most patients respond to treatment, with defervescence, decreasing cough, weight gain, and a general improvement in well-being within several weeks.

Early in the course of disease, symptoms and signs are often nonspecific and insidious, consisting mainly of fever, often diurnal, and night sweats due to defervescence, weight loss, anorexia, general malaise, and weakness. However, in up to 90% of cases, cough eventually develops—often initially nonproductive and limited to the morning and subsequently accompanied by the production of purulent sputum, sometimes with blood streaking. Hemoptysis develops in 20–30% of cases, and massive hemoptysis may ensue as a consequence of the erosion of a blood vessel in the wall of a cavity. Hemoptysis, however, may also result from rupture of a dilated vessel in a cavity (*Rasmussen's aneurysm*) or from aspergilloma formation in an old cavity. Pleuritic chest pain sometimes develops in patients with subpleural parenchymal lesions or pleural disease. Extensive disease may produce dyspnea and, in rare instances, adult respiratory distress syndrome. Physical findings are of limited use in pulmonary TB. Many patients have no abnormalities detectable by chest examination, whereas others have detectable rales in the involved areas during inspiration, especially after coughing. Occasionally, rhonchi due to partial bronchial obstruction and classic amphoric breath sounds in areas with large cavities may be heard. Systemic features include fever (often low-grade and intermittent) in up to 80% of cases and wasting. Absence of fever, however, does not exclude TB. In some recurrent cases and among patients with low Karnofsky score, finger clubbing has been reported. The most common hematologic findings are mild anemia, leukocytosis, and thrombocytosis with a slightly elevated erythrocyte sedimentation rate and/or C-reactive protein level. None of these findings is consistent or sufficiently accurate for diagnostic purposes. Hyponatremia due to the syndrome of inappropriate secretion of antidiuretic hormone also has been reported.

EXTRAPULMONARY TB

In descending order of frequency, the extrapulmonary sites most involved in TB are the lymph nodes, pleura, genitourinary tract, bones and joints, meninges, peritoneum, and pericardium. However, virtually any organ system may be affected. As a result of hematogenous dissemination in PLWH, extrapulmonary TB is seen more commonly today than in the past in settings of high HIV prevalence.

Lymph Node TB (Tuberculous Lymphadenitis) The most common presentation of extrapulmonary TB in both HIV-seronegative individuals and PLWH (35% of cases worldwide and >40% of cases in the United States in recent series), lymph node disease is particularly frequent among PLWH and among children **(Fig. 183-8)**. In the United States, besides children, women (particularly non-Caucasians) seem to be especially susceptible. Once caused mainly by *M. bovis*, tuberculous lymphadenitis today is due largely to *M. tuberculosis*. Lymph node TB presents as painless swelling of the lymph nodes, most commonly at posterior cervical and supraclavicular sites (a condition historically referred to as *scrofula*). Lymph nodes are usually discrete in early disease but develop into a matted nontender mass over time; a fistulous tract draining caseous material may result. Associated pulmonary disease is present in fewer than 50% of cases, and systemic symptoms are uncommon except in HIV-infected patients. The diagnosis is established by fine-needle aspiration biopsy (with a yield of up to 80%) or surgical excision biopsy. Bacteriologic confirmation is achieved in most cases, granulomatous lesions with or without visible AFBs are typically seen, and cultures are positive in 70–80% of cases. Among PLWH, granulomas are less well organized and are frequently absent entirely, but bacterial loads are heavier than in HIV-seronegative patients, with higher yields from microscopy and culture. Differential diagnosis includes a variety of infectious conditions, neoplastic diseases such as lymphomas or metastatic carcinomas, and rare disorders like Kikuchi disease (necrotizing histiocytic lymphadenitis), Kimura disease, and Castleman disease.

FIGURE 183-8 Tuberculous lymphadenitis affecting the cervical lymph nodes in a 2-year-old child from Malawi. *(Courtesy of Prof. S. Graham, Centre for International Child Health, University of Melbourne, Australia; with permission.)*

Pleural TB Involvement of the pleura accounts for ~20% of extrapulmonary cases in the United States and elsewhere. Isolated pleural effusion usually reflects recent primary infection, and the collection of fluid in the pleural space represents a hypersensitivity response to mycobacterial antigens. Pleural disease may also result from contiguous parenchymal spread, as in many cases pleurisy accompanies postprimary disease. Depending on the extent of reactivity, the effusion may be small, remain unnoticed, and resolve spontaneously or may be sufficiently large to cause symptoms such as fever, pleuritic chest pain, and dyspnea. Physical findings are those of pleural effusion: dullness to percussion and absence of breath sounds. CXR reveals the effusion and, in up to one-third of cases, also shows a parenchymal lesion. Thoracentesis is required to ascertain the nature of the effusion and to differentiate it from manifestations of other etiologies. The fluid is straw-colored and at times hemorrhagic; it is an exudate with a protein concentration >50% of that in serum (usually ~4–6 g/dL), a normal to low glucose concentration, a pH of ~7.3 (occasionally <7.2), and detectable white blood cells (usually 500–6000/μL). Neutrophils may predominate in the early stage, but lymphocyte predominance is typical later. Mesothelial cells are generally rare or absent. AFBs are rarely seen on direct smear, and cultures often may be falsely negative for *M. tuberculosis*; positive cultures are more common among postprimary cases. An elevated pleural concentration of adenosine deaminase is consistent with TB, while TB may be excluded if the value is very low. Lysozyme also is present in the pleural effusion. Measurement of IFN-γ, either directly or through stimulation of sensitized T cells with mycobacterial antigens, can be diagnostically helpful. Needle biopsy of the pleura is often required for diagnosis and is recommended over pleural fluid analysis; it reveals granulomas and/or yields a positive culture in up to 80% of cases. Pleural biopsy can yield a positive result in ~75% of cases when real-time automated nucleic acid amplification is used (the Xpert MTB/RIF assay [Cepheid; Sunnyvale, CA]; see "Nucleic Acid Amplification Technology," below); testing of pleural fluid with this assay is not recommended because of low sensitivity. This form of pleural TB responds rapidly to chemotherapy and may resolve spontaneously. Concurrent glucocorticoid administration may reduce the duration of fever and/or chest pain but is not of proven benefit.

Tuberculous empyema is a less common complication of pulmonary TB. It is usually the result of the rupture of a cavity, with spillage of a large number of organisms into the pleural space. This process may create a bronchopleural fistula with evident air in the pleural space.

CXR shows hydropneumothorax with an air-fluid level. The pleural fluid is purulent and thick and contains large numbers of lymphocytes. Acid-fast smears and mycobacterial cultures are often positive. Surgical drainage is usually required as an adjunct to chemotherapy. Tuberculous empyema may result in severe pleural fibrosis and restrictive lung disease. Removal of the thickened visceral pleura (*decortication*) is occasionally necessary to improve lung function.

TB of the Upper Airways Nearly always a complication of advanced cavitary pulmonary TB, TB of the upper airways may involve the larynx, pharynx, and epiglottis. Symptoms include hoarseness, dysphonia, and dysphagia in addition to chronic productive cough. Findings depend on the site of involvement, and ulcerations may be seen on laryngoscopy. Acid-fast smear of the sputum is often positive, but biopsy may be necessary in some cases to establish the diagnosis. Carcinoma of the larynx may have similar features but is usually painless.

Genitourinary TB Genitourinary TB, which accounts for ~10–15% of all extrapulmonary cases in the United States and elsewhere, may involve any portion of the genitourinary tract. Clinical manifestations are cryptic and protean. Patients may be asymptomatic and their disease discovered only after destructive lesions of the kidneys have developed. Symptoms are often nonspecific and include those of urinary tract infection with frequency, dysuria, nocturia and hematuria, and abdominal or flank pain. Without a high index of suspicion, this form of TB may result in delayed diagnosis with irreversible organ damage. Up to 75% of patients have abnormalities on CXR suggesting previous or concomitant pulmonary disease. Urinalysis gives abnormal results in 90% of cases, revealing pyuria and hematuria. The documentation of culture-negative pyuria in acidic urine should raise the suspicion of TB. IV pyelography, abdominal CT, or MRI **(Fig. 183-9)** may show deformities and obstructions; calcifications and ureteral strictures are suggestive findings. Culture of three morning urine specimens yields a definitive diagnosis in nearly 90% of cases. Severe ureteral strictures may lead to hydronephrosis, serious renal damage, and, ultimately, renal failure. Genital TB is diagnosed more commonly in female than in male patients. In female patients, it affects the fallopian tubes and the endometrium and may cause infertility, pelvic pain, and menstrual abnormalities. Diagnosis requires biopsy or culture of specimens obtained by dilation and curettage. In male patients, genital TB preferentially affects the epididymis, producing a slightly tender mass that may drain externally through a fistulous tract; orchitis and prostatitis also may develop. In almost half of cases of genitourinary TB, urinary tract disease is also present. Genitourinary TB responds well to chemotherapy.

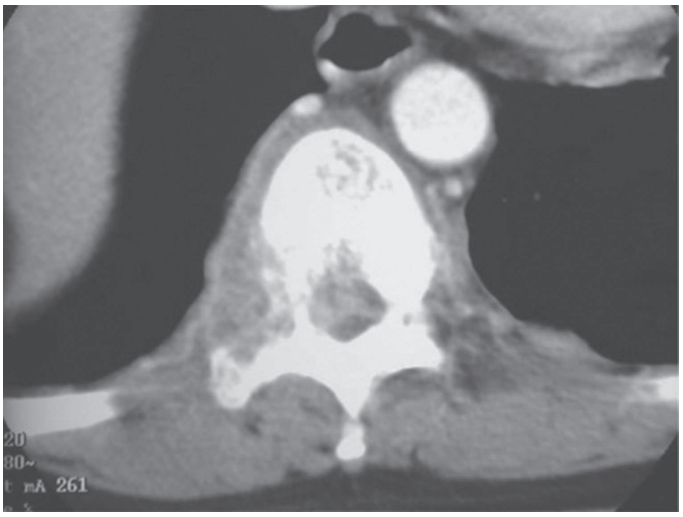

FIGURE 183-10 CT scan demonstrating destruction of the right pedicle of T10 due to Pott's disease. The patient, a 70-year-old Asian woman, presented with back pain and weight loss and had biopsy-proven tuberculosis. *(Courtesy of Charles L. Daley, MD, University of California, San Francisco; with permission.)*

Skeletal TB In the United States, TB of the bones and joints is responsible for ~10% of extrapulmonary cases. In bone and joint disease, pathogenesis is related to reactivation of hematogenous foci or to spread from adjacent paravertebral lymph nodes. Weight-bearing joints (the spine in 40% of cases, the hips in 13%, and the knees in 10%) are most commonly affected. Spinal TB (Pott's disease or tuberculous spondylitis; **Fig. 183-10**) often involves two or more adjacent vertebral bodies. Whereas the upper thoracic spine is the most common site of spinal TB in children, the lower thoracic and upper lumbar vertebrae are usually affected in adults. From the anterior superior or inferior angle of the vertebral body, the lesion slowly reaches the adjacent body, later affecting the intervertebral disk. With advanced disease, collapse of vertebral bodies results in kyphosis (*gibbus*). A paravertebral "cold" abscess also may form. In the upper spine, this abscess may track to and penetrate the chest wall, presenting as a soft tissue mass; in the lower spine, it may reach the inguinal ligaments or present as a psoas abscess. CT or MRI reveals the characteristic lesion and suggests its etiology. The differential diagnosis includes tumors and other infections. Pyogenic bacterial osteomyelitis involves the disk very early and produces rapid sclerosis. Aspiration of the abscess or bone biopsy confirms the tuberculous etiology, as cultures are usually positive and histologic findings highly typical. A catastrophic complication of Pott's disease is paraplegia, which is usually due to an abscess or a lesion compressing the spinal cord. Paraparesis due to a large abscess is a medical emergency and requires rapid drainage. TB of the hip joints, usually involving the head of the femur, causes pain; TB of the knee produces pain and swelling. If the disease goes unrecognized, the joints may be destroyed. Diagnosis requires examination of the synovial fluid, which is thick in appearance, with a high protein concentration and a variable cell count. Although synovial fluid culture is positive in a high percentage of cases, synovial biopsy and tissue culture may be necessary to establish the diagnosis. Skeletal TB responds to chemotherapy, but severe cases may require surgery.

Tuberculous Meningitis and Tuberculoma TB of the central nervous system (CNS) accounts for ~5% of extrapulmonary cases in the United States. It is seen most often in young children but also develops in adults, especially those infected with HIV. Tuberculous meningitis results from the hematogenous spread of primary or postprimary pulmonary TB or from the rupture of a subependymal tubercle into the subarachnoid space. In more than half of cases, evidence of old pulmonary lesions or a miliary pattern is found on CXR. The disease

often presents subtly as headache and slight mental changes after a prodrome of weeks of low-grade fever, malaise, anorexia, and irritability. If not recognized, tuberculous meningitis may evolve acutely with severe headache, confusion, lethargy, altered sensorium, and neck rigidity. Typically, the disease evolves over 1–2 weeks, a course longer than that of typical bacterial meningitis. Because meningeal involvement is pronounced at the base of the brain, paresis of cranial nerves (ocular nerves in particular) is a frequent finding, and the involvement of cerebral arteries may produce focal ischemia. The ultimate evolution is toward coma, with hydrocephalus and intracranial hypertension.

Lumbar puncture is the cornerstone of diagnosis. In general, examination of cerebrospinal fluid (CSF) reveals a high leukocyte count (up to 1000/μL), usually with a predominance of lymphocytes but sometimes with a predominance of neutrophils in the early stage; a protein content of 1–8 g/L (100–800 mg/dL); and a low glucose concentration. However, any of these three parameters can be within the normal range. AFBs are infrequently seen on direct smear of CSF sediment, but repeated lumbar punctures increase the yield. Culture of CSF is diagnostic in up to 80% of cases and remains the gold standard. Real-time automated nucleic acid amplification (the Xpert MTB/RIF assay) has a sensitivity of up to 80% and is the preferred initial diagnostic option. Treatment should be initiated immediately upon a positive Xpert MTB/RIF result. A negative result does not exclude a diagnosis of TB and requires further diagnostic workup. Imaging studies (CT and MRI) may show hydrocephalus and abnormal enhancement of basal cisterns or ependyma. If unrecognized, tuberculous meningitis is uniformly fatal. This disease responds to chemotherapy; however, neurologic sequelae are documented in 25% of treated cases, in most of which the diagnosis has been delayed. Clinical trials have demonstrated that patients given adjunctive glucocorticoids may experience faster resolution of CSF abnormalities and elevated CSF pressure, resulting in lower rates of death or severe disability and relapse. In one study, adjunctive dexamethasone significantly enhanced the chances of survival among persons >14 years but did not reduce the frequency of neurologic sequelae. The dexamethasone schedule was (1) 0.4 mg/kg per day given intravenously with tapering by 0.1 mg/kg per week until the fourth week, when 0.1 mg/kg per day was administered, followed by (2) 4 mg/d given by mouth with tapering by 1 mg per week until the fourth week, when 1 mg/d was administered. The WHO now recommends that adjuvant glucocorticoid therapy with either dexamethasone or prednisolone, tapered over 6–8 weeks, should be used in CNS TB. However, among PLWH, a recent placebo-controlled study demonstrated no benefit with respect to survival or secondary endpoints from a 6- to 8-week tapering course of adjunctive dexamethasone.

Tuberculoma, an uncommon manifestation of TB of the CNS, presents as one or more space-occupying lesions and usually causes seizures and focal signs. CT or MRI reveals contrast-enhanced ring lesions, but biopsy is necessary to establish the diagnosis.

Gastrointestinal TB Gastrointestinal TB is uncommon, making up only 3.5% of extrapulmonary cases in the United States. Various pathogenetic mechanisms are involved: swallowing of sputum with direct seeding, hematogenous spread, or (largely in developing areas) ingestion of milk from cows affected by bovine TB. Although any portion of the gastrointestinal tract may be affected, the terminal ileum and the cecum are the sites most commonly involved. Abdominal pain (at times similar to that associated with appendicitis) and swelling, obstruction, hematochezia, and a palpable mass in the abdomen are common findings at presentation. Fever, weight loss, anorexia, and night sweats also are common. With intestinal wall involvement, ulcerations and fistulae may simulate Crohn disease; the differential diagnosis of this entity is always difficult. Anal fistulae should prompt an evaluation for rectal TB. Because surgery is required in most cases, the diagnosis can be established by histologic examination and culture of specimens obtained intraoperatively.

Tuberculous peritonitis follows either the direct spread of tubercle bacilli from ruptured lymph nodes and intraabdominal organs (e.g., genital TB in women) or hematogenous seeding. Nonspecific abdominal pain, fever, and ascites should raise the suspicion of tuberculous peritonitis. The coexistence of cirrhosis **(Chap. 355)** in patients with tuberculous peritonitis complicates the diagnosis. In tuberculous peritonitis, paracentesis reveals an exudative fluid with a high protein content and leukocytosis that is usually lymphocytic (although neutrophils occasionally predominate). The yield of direct smear and culture is relatively low; culture of a large volume of ascitic fluid can increase the yield, but peritoneal biopsy (with a specimen best obtained by laparoscopy) is often needed to establish the diagnosis.

Pericardial TB (Tuberculous Pericarditis) Due either to direct extension from adjacent mediastinal or hilar lymph nodes or to hematogenous spread, pericardial TB has often been a disease of the elderly in countries with low TB prevalence. However, it also develops frequently in PLWH. Case fatality rates are as high as 40% in some series. The onset may be subacute, although an acute presentation, with dyspnea, fever, dull retrosternal pain, and a pericardial friction rub, is possible. An effusion eventually develops in many cases; cardiovascular symptoms and signs of cardiac tamponade may ultimately appear **(Chap. 281)**. In the presence of effusion, TB must be suspected if the patient belongs to a high-risk population (HIV-infected, originating in a high-prevalence country); if there is evidence of previous TB in other organs; or if echocardiography, CT, or MRI shows effusion and thickness across the pericardial space. A definitive diagnosis can be obtained by pericardiocentesis under echocardiographic guidance. The pericardial fluid must be submitted for biochemical, cytologic, and microbiologic evaluation. The effusion is exudative in nature, with a high count of lymphocytes and monocytes. Hemorrhagic effusion is common. Direct smear examination is very rarely positive. Culture of pericardial fluid reveals *M. tuberculosis* in up to two-thirds of cases, whereas pericardial biopsy has a higher yield. High levels of adenosine deaminase, lysozyme, and IFN-γ may suggest a tuberculous etiology.

Without treatment, pericardial TB is usually fatal. Even with treatment, complications may develop, including chronic constrictive pericarditis with thickening of the pericardium, fibrosis, and sometimes calcification, which may be visible on a chest radiograph. Systematic reviews and meta-analyses show a trend toward benefit from glucocorticoid treatment with regard to death and constrictive pericarditis. However, the largest and most recent study—the IMPI study—failed to show such a benefit. Of the patients enrolled in this trial, 67% were PLWH, and only a fraction was receiving antiretroviral treatment (ART). A supplemental analysis among HIV-negative patients showed a small mortality benefit, as did another small study among PLWH. The WHO currently recommends that, in patients with tuberculous pericarditis, initial adjuvant glucocorticoid therapy may be used. The 2016 guidelines of the American Thoracic Society (ATS), the CDC, and the Infectious Diseases Society of America (IDSA), on the other hand, suggest that glucocorticoid therapy should not be routinely administered.

Caused by direct extension from the pericardium or by retrograde lymphatic extension from affected mediastinal lymph nodes, tuberculous myocarditis is extremely rare. Usually, it is fatal and is diagnosed postmortem.

Miliary or Disseminated TB Miliary TB is due to hematogenous spread of tubercle bacilli. Although in children it is often the consequence of primary infection, in adults it may be due to either recent infection or reactivation of old disseminated foci. The lesions are usually yellowish granulomas 1–2 mm in diameter that resemble millet seeds (thus the term *miliary*, coined by nineteenth-century pathologists). Clinical manifestations are nonspecific and protean, depending on the predominant site of involvement. Fever, night sweats, anorexia, weakness, and weight loss are presenting symptoms in the majority of cases. At times, patients have a cough and other respiratory symptoms due to pulmonary involvement as well as abdominal symptoms. Physical findings include hepatomegaly, splenomegaly, and lymphadenopathy. Eye examination may reveal choroidal tubercles, which are pathognomonic of miliary TB, in up to 30% of cases. Meningismus occurs in fewer than 10% of cases.

A high index of suspicion is required for the diagnosis of miliary TB. Frequently, CXR (Fig. 183-5) reveals a miliary reticulonodular pattern

(more easily seen on underpenetrated film), although no radiographic abnormality may be evident early in the course and among PLWH. Other radiologic findings include large infiltrates, interstitial infiltrates (especially in PLWH), and pleural effusion. Sputum-smear microscopy is negative in most cases. Various hematologic abnormalities may be seen, including anemia with leukopenia, lymphopenia, neutrophilic leukocytosis and leukemoid reactions, and polycythemia. Disseminated intravascular coagulation has been reported. Elevation of alkaline phosphatase levels and other abnormal liver function tests are detected in patients with severe hepatic involvement. TST results may be negative in up to half of cases, but reactivity may be restored during chemotherapy. Bronchoalveolar lavage and transbronchial biopsy are more likely to provide bacteriologic confirmation, and granulomas are evident in liver or bone-marrow biopsy specimens from many patients. If it goes unrecognized, miliary TB is lethal; with proper early treatment, however, it is amenable to cure. Glucocorticoid therapy has not proved beneficial.

A rare presentation seen in the elderly, *cryptic miliary TB* has a chronic course characterized by mild intermittent fever, anemia, and—ultimately—meningeal involvement preceding death. An acute septicemic form, *nonreactive miliary TB*, occurs very rarely and is due to massive hematogenous dissemination of tubercle bacilli. Pancytopenia is common in this form of disease, which is rapidly fatal. At postmortem examination, multiple necrotic but nongranulomatous ("nonreactive") lesions are detected.

Less Common Extrapulmonary Forms TB may cause chorioretinitis, uveitis, panophthalmitis, and painful hypersensitivity-related phlyctenular conjunctivitis. Tuberculous otitis is rare and presents as hearing loss, otorrhea, and tympanic membrane perforation. In the nasopharynx, TB may simulate granulomatosis with polyangiitis. Cutaneous manifestations of TB include primary infection due to direct inoculation, abscesses and chronic ulcers, scrofuloderma, lupus vulgaris (a smoldering disease with cutaneous nodules, plaques, and fissures), miliary lesions, and erythema nodosum. Tuberculous mastitis results from retrograde lymphatic spread, often from the axillary lymph nodes. Adrenal TB is a manifestation of disseminated disease presenting rarely as adrenal insufficiency. Finally, congenital TB results from transplacental spread of tubercle bacilli to the fetus or from ingestion of contaminated amniotic fluid. This rare disease affects the liver, spleen, lymph nodes, and various other organs.

Post-TB Lung Disease and Complications A substantial proportion of TB survivors considered cured experience chronic impairment of lung function, dyspnea, residual cough, bronchiectasis, and pulmonary hypertension. In addition, aspergillomas and chronic pulmonary aspergillosis **(Chap. 223)** have been seen post-TB. Chronic pulmonary aspergillosis may manifest as simple aspergilloma (fungal ball) or chronic cavitary aspergillosis. In the presence of large residual cavities, *Aspergillus fumigatus* may colonize the lesion and produce symptoms such as respiratory impairment, hemoptysis, persistent fatigue, and weight loss, often resulting in the erroneous diagnosis of TB recurrence. The detection of *Aspergillus* precipitins (IgG) in the blood suggests chronic pulmonary aspergillosis, as do radiographic abnormalities such as thickening of the pleura and cavitary walls or the presence of a fungal ball inside the cavity. Treatment is difficult. Recent preliminary studies on the use of triazoles for ≥6 months indicate improvement or stabilization of 60–75% of the radiologic and clinical manifestations. Surgical removal of lesions is risky except in simple aspergilloma.

HIV-Associated TB (See also Chap. 208) TB is one of the most common diseases among PLWH worldwide. Responsible for up to a quarter of all HIV-related mortality (167,000 deaths per year), TB is still one of the main causes of death in this population, especially in Africa **(Fig. 183-11)**.

Classic studies showed that a person with a positive TST who acquires HIV infection has a 3–13% annual risk of developing active TB, with the exact risk depending on the degree of immunosuppression when observation begins. Furthermore, a new TB infection acquired by a PLWH may evolve into active disease in a matter of weeks rather than months or years. TB can appear at any stage of HIV infection, and its presentation varies with the stage. When cell-mediated immunity is only partially compromised, pulmonary TB presents in a typical manner (Figs. 183-6 and 183-7), with upper-lobe infiltrates and cavitation and without significant lymphadenopathy or pleural effusion. In later stages of HIV infection, when the CD4+ T-cell count is <200/μL, a primary TB–like pattern, with diffuse interstitial and subtle infiltrates,

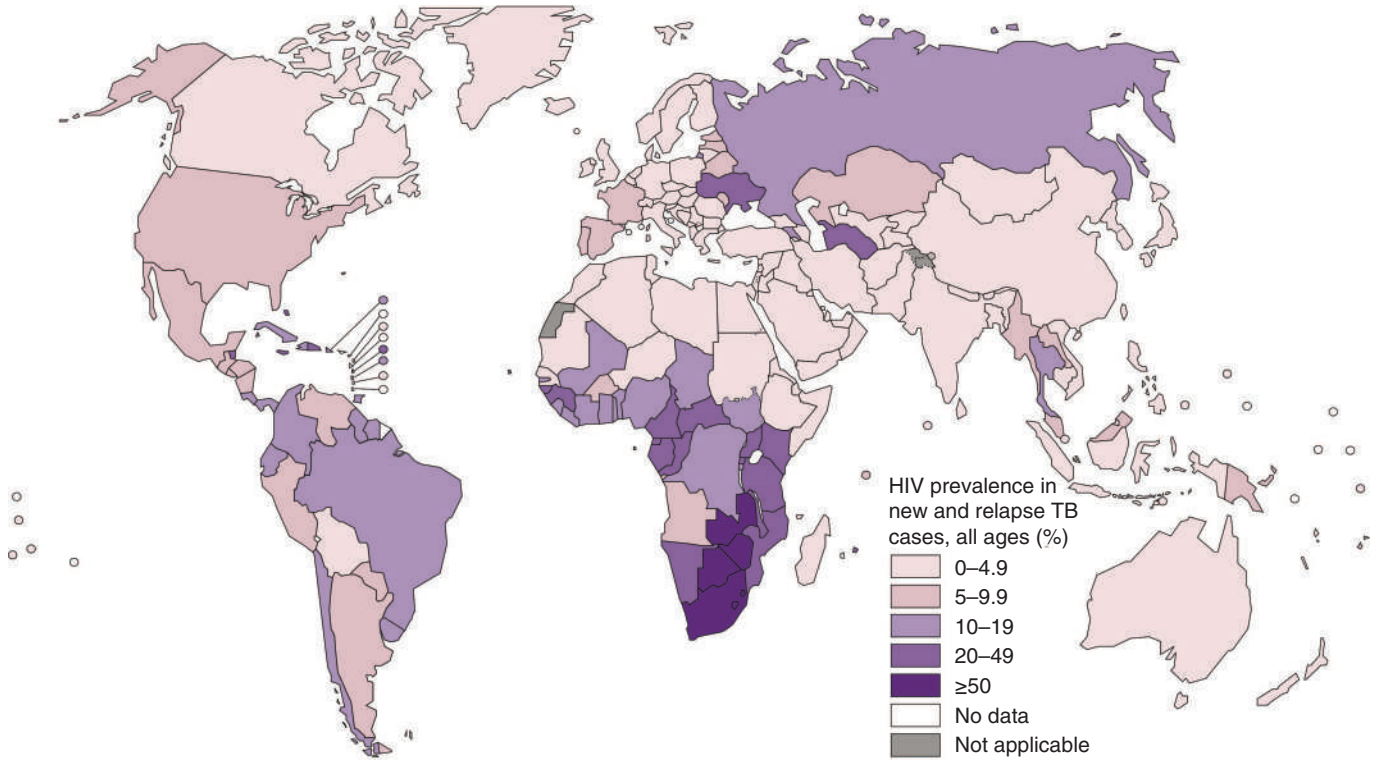

FIGURE 183-11 Estimated HIV prevalence in new and relapse tuberculosis (TB) cases in 2022. *(See disclaimer in Fig. 183-2. Reproduced with permission from Global Tuberculosis Report 2022. Geneva, World Health Organization; 2023.)*

little or no cavitation, pleural effusion, and intrathoracic lymphadenopathy, is more common. However, these forms are becoming less common because of the expanded use of ART. Extrapulmonary TB is common among PLWH. In various series, extrapulmonary TB—alone or in association with pulmonary disease—has been documented in 40–60% of all cases in PLWH. The most common forms are lymphatic, disseminated, pleural, and pericardial. Mycobacteremia and meningitis also are common, particularly in advanced HIV disease. The diagnosis of TB in PLWH can be complicated. The Xpert MTB/RIF assay is the preferred initial diagnostic option for pulmonary TB, ensuring a sensitivity of more than 80% and a specificity of 98%; therapy should be started on the basis of a positive result because treatment delays may be fatal. A negative Xpert MTB/RIF result, however, does not exclude a diagnosis of TB. Culture remains the gold standard. Detection of mycobacterial lipoarabinomannan antigen in urine has shown favorable results in assisting with the diagnosis of TB in PLWH (see "Additional Diagnostic Procedures," below).

The *immune reconstitution inflammatory syndrome* (*IRIS*) or *TB immune reconstitution disease* consists of exacerbations in systemic manifestations (lymphadenopathy, fever) or respiratory signs (worsening of pulmonary infiltrations, pleural effusion) as well as laboratory or radiographic manifestations of TB. This syndrome is rarely seen among non-HIV-infected persons, is associated with the administration of ART, and occurs in ~10% of HIV-infected TB patients. Usually developing 1–3 months after initiation of ART, IRIS is more common among patients with advanced immunosuppression and extrapulmonary TB. "Unmasking IRIS" may develop after the initiation of ART in patients with undiagnosed subclinical TB. The earlier ART is started after TB treatment is initiated and the lower the baseline CD4+ T-cell count, the greater the risk of IRIS. Death due to IRIS is relatively infrequent and occurs mainly among patients who have a high preexisting mortality risk. The presumed pathogenesis of IRIS consists of an immune response that is rapidly improved by HIV suppression and is stimulated by antigens released as bacilli are killed during effective chemotherapy. There is no diagnostic test for IRIS, and its confirmation relies heavily upon case definitions incorporating clinical and laboratory data; a variety of case definitions have been suggested. The first priority in the management of a possible case of IRIS is to ensure that the clinical syndrome does not represent a failure of TB treatment or the development of another infection. Mild paradoxical reactions can be managed with symptom-based treatment and do not worsen outcomes of treatment for TB. However, IRIS can result in serious neurologic complications or death in patients with CNS TB. Therefore, ART should not be initiated during the first 8 weeks of TB treatment in patients with TB meningitis. Glucocorticoids have been used for severe paradoxical reactions; prednisolone given for 4 weeks at a low dosage (1.5 mg/kg per day for 2 weeks and half that dose for the remaining 2 weeks) has reduced the need for hospitalization and therapeutic procedures and has hastened alleviation of symptoms, as reflected by Karnofsky performance scores, quality-of-life assessments, radiographic response, and C-reactive protein levels. The effectiveness of glucocorticoids in alleviating the symptoms of IRIS is probably linked to suppression of proinflammatory cytokine concentrations, as these medications reduce serum concentrations of IL-6, IL-10, IL-12p40, TNF-α, IFN-γ, and IFN-γ-inducible protein 10. Recommendations for the prevention and treatment of TB in PLWH are provided below.

DIAGNOSIS

The key to the early diagnosis of TB is a high index of suspicion. Diagnosis is not difficult in persons belonging to high-risk populations who present with typical symptoms and a classic chest radiograph showing upper-lobe infiltrates with cavities (Fig. 183-6). On the other hand, the diagnosis can easily be missed in an elderly nursing-home resident or a teenager with a focal infiltrate. Often, the diagnosis is first entertained when the chest radiograph of a patient being evaluated for respiratory symptoms is abnormal. If the patient has no complicating medical conditions that cause immunosuppression, the chest radiograph may show typical upper-lobe infiltrates with cavitation (Fig. 183-6). The longer the delay between the onset of symptoms and the diagnosis, the more likely is the finding of cavitary disease. In contrast, immunosuppressed patients, including PLWH, may have "atypical" findings on CXR—e.g., lower-zone infiltrates without cavity formation—or interstitial disease only.

The several approaches to the diagnosis of TB require, above all, a well-organized microbiology laboratory network with an appropriate distribution of tasks at different levels of the health care system. Besides clinical assessment and radiography, screening and referral are the principal tasks at the peripheral and community levels. Diagnosis at a secondary level (e.g., a traditional district hospital in a high-incidence setting) can be accomplished nowadays through real-time automated nucleic acid amplification technology (e.g., the Xpert MTB/RIF assay, which also allows detection of drug resistance) or through traditional AFB microscopy where new tools have not yet been introduced. At a tertiary level, molecular tests, rapid culture, and DST should be applied.

NUCLEIC ACID AMPLIFICATION TECHNOLOGY

Several test systems based on amplification of mycobacterial nucleic acid have become available in the past few years and are now the preferred first-line diagnostic tests. These tests are progressively replacing smear microscopy, as they ensure rapid confirmation of all types of TB. One system that permits rapid diagnosis of TB with high specificity and sensitivity (approaching that of liquid culture) is the fully automated, real-time nucleic acid amplification technology known as the Xpert MTB/RIF assay. Xpert MTB/RIF can simultaneously detect TB and rifampin resistance in <2 h and has minimal biosafety and training requirements. Therefore, it can be housed in nonconventional laboratory settings as long as a stable and uninterrupted power supply can be assured. The WHO recommends its use worldwide as the first-line diagnostic test in all adults and children with signs or symptoms of active TB. Given the test's high sensitivity, the WHO also recommends its use as the initial diagnostic test for PLWH in whom TB is suspected. In the diagnosis of pulmonary TB, this test has an overall sensitivity of 85% reaching 98% among AFB-positive cases and ~70% among AFB-negative specimens; its specificity is 98%. When compared with phenotypic drug susceptibility testing for simultaneous detection of rifampin resistance, Xpert MTB/RIF has an overall sensitivity of 96% and a specificity of 98%. The newer Xpert MTB/RIF Ultra assay (Ultra), which uses the same GeneXpert diagnostic platform, has an overall sensitivity of 90% including "trace calls" (i.e., the "noise" produced by detection of DNA from nonviable bacilli) as positive with the greatest increases among smear-negative, culture-positive cases (+17%) and among PLWH (+12%). If "trace calls" are excluded, sensitivity decreases to 86%. Because of this greater sensitivity and the capacity to also detect nonviable bacilli, the new Ultra cartridge has 2% lower specificity than the original test. However, excluding "trace calls," specificity increases to 98%. Among PLWH Ultra sensitivity is 88% and specificity 95%. Sensitivity and specificity for detection of rifampin resistance by Ultra are 94% and 99%, respectively, similar to those by the Xpert MTB/RIF assay.

In the diagnosis of extrapulmonary TB, Xpert MTB/RIF or Ultra should be the initial tests applied to CSF from patients in whom TB meningitis is suspected as well as a replacement test (preferable to conventional microscopy, culture, and histopathology) for selected nonrespiratory specimens—those obtained by gastric lavage, fine-needle aspiration, or pleural or other biopsies. Sensitivity varies according to specimen type with the lowest in pleural fluid (50% with Xpert MTB/RIF and 71% with Ultra) and the highest in synovial fluid (97%) and lymph node biopsy (100% with Ultra). "Trace calls" in specimens from persons with extrapulmonary TB, as well as for PLWH and children, should be considered true positives, given the high risk of severe morbidity and premature death, while among other cases they warrant additional tests to confirm the diagnosis of TB and prevent overtreatment. Among patients with a recent history of TB, "trace calls" may represent DNA from dead bacilli under degradation.

Truenat MTB and MTB Plus are two other newly introduced rapid adopted rapid molecular tests with sensitivities of 73% and 80%, respectively, if compared with bacteriological culture, and specificities of 98% and 96%, respectively. Truenat MTB-Rif Dx detects

rifampin resistance with a sensitivity of 84% and a specificity of 97%. These rapid tests, being portable and battery-operated, can be used in peripheral care settings rather than smear microscopy, culture, and phenotypic DST. New high-throughput automated platforms for TB diagnosis and drug-resistant variants are now available (Abbott RealTime MTB and RIF/INH, FluoroType MTBDR and MTB, BD Max MDR-TB, cobas MTB and MTB-RIF/INH). These platforms are suitable for centralized laboratories and have the advantage of processing a large number of samples in a reasonable time. Sensitivity is higher than 91% and specificity ranges from 97 to 100%. Head-to-head studies with Xpert MTB/RIF have shown comparable performance. Another available molecular test for detection of *M. tuberculosis* is based on loop-mediated isothermal amplification (LAMP), a temperature-independent technology that amplifies DNA, is relatively simple to use, and is interpreted through a visual display. It may be used as a replacement for sputum-smear microscopy for the diagnosis of adult pulmonary TB and as a follow-up test to smear microscopy for the further investigation of smear-negative specimens from adults with suspected pulmonary TB. The TB-LAMP assay should not replace rapid molecular tests that detect both TB and rifampin resistance, and its usefulness in PLWH in whom TB is suspected remains unclear.

AFB MICROSCOPY

In some low- and middle-income settings, a presumptive diagnosis is still often based on the finding of AFB on microscopic examination, such as a smear of expectorated sputum or of tissue (e.g., a lymph node biopsy). Although inexpensive, AFB microscopy has relatively low sensitivity (40–60%) in culture-confirmed cases of pulmonary TB and does not distinguish TB from nontuberculous mycobacteria. The traditional method—light microscopy of specimens stained with Ziehl-Neelsen basic fuchsin dyes—is satisfactory, although time consuming and operator dependent. Most modern laboratories processing large numbers of diagnostic specimens use auramine–rhodamine staining and fluorescence microscopy; this approach is more sensitive than the Ziehl-Neelsen method. However, it is expensive because it requires high-cost mercury vapor light sources and a darkroom. Less expensive light-emitting diode (LED) fluorescence microscopes are now recommended by the WHO as the microscopy tool of choice. They are as sensitive as—or more sensitive than—traditional fluorescence microscopes. As a result, conventional light and fluorescence microscopes are being replaced with this more recent technology, especially in developing countries. For patients with signs or symptoms of pulmonary TB, it has been recommended that one or two sputum specimens, preferably collected early in the morning, should be submitted to the laboratory for AFB smear and mycobacterial culture. If tissue is obtained, it is critical that the portion of the specimen intended for culture not be put in preservation fluid such as formaldehyde. The use of AFB microscopy in examining urine or gastric lavage fluid is limited by the low numbers of organisms, which can cause false-negative results, or the presence of commensal mycobacteria, which can cause false-positive results.

MYCOBACTERIAL CULTURE
