In acute lymphoblastic leukemia (ALL), the malignant clone arises from hematopoietic progenitors in the bone marrow or lymphatic system resulting in an increase of immature nonfunctioning leukemic cells. Infiltration of bone marrow leads to anemia, granulocytopenia, and thrombocytopenia with the clinical manifestations of fatigue, weakness, infection, and hemorrhage. These symptoms are more often the reason a patient first seeks medical advice rather than consequences of tumor bulk, such as lymph node enlargement, hepatosplenomegaly caused by leukemic infiltration, or symptoms of the central nervous system (meningeosis leukemica).

INCIDENCE AND AGE

ALL is the most frequent neoplastic disease in children with an early peak at the age of 3–4 years. The incidence in adults ranges from 0.7 to 1.8/100,000 per year, being somewhat higher in adolescents and young adults (AYAs), decreasing in adults but increasing again in elderly people. Thus, Philadelphia chromosome–positive ALL (Ph+ ALL; *BCR/ABL* translocation) is observed in half of the elderly B-lineage patients. The frequency of immunologic, cytogenetic, and genetic subtypes changes substantially with age.

ETIOLOGY

The etiology of acute leukemias is unknown. Internal and external factors influence the incidence of leukemia. Exposure to ionizing radiation or to chemicals, including prior chemotherapy, is associated with an increased risk of developing leukemia, more often observed in acute myeloid leukemia (AML). However, increasingly, secondary ALLs have been observed, particularly after cytostatic treatment with alkylating agents and topoisomerase inhibitors as treatment for primary tumors, most often for AML, myelodysplastic syndromes, or breast cancer.

CONGENITAL DISORDERS

Patients with some rare congenital chromosomal abnormalities have a higher risk of developing acute leukemia (e.g., Klinefelter's syndrome, Fanconi's anemia, Bloom's syndrome, ataxia-telangiectasia, and neurofibromatosis). Those with Down's syndrome have a 20-fold increased incidence of leukemia; ALL is increased in childhood and AML at an older age.

INFECTIOUS AGENTS

No direct evidence implicates viruses as a major cause of human acute leukemia. However, viruses are involved in the pathogenesis of two lymphoid neoplasias. In the endemic African type of Burkitt's lymphoma, the Epstein-Barr virus, a DNA virus of the herpes family, has been implicated as a potential causative agent **(see Chap. 199)**. Endemic infection with human T-cell leukemia virus I in Japan and the Caribbean has been shown to be an etiologic agent for rare cases of adult T-cell leukemia/lymphoma **(see Chap. 207)**.

DIAGNOSIS AND CLASSIFICATION

The diagnosis of acute leukemia is first made by examination of the peripheral blood and bone marrow. For further classification of the leukemic blast cells, cytochemical stains, immunologic markers, and cytogenetic and molecular analysis are required. The immunologic markers are still the major criteria to subdivide into B-cell lineage or T-cell lineage ALL leukemias.

PERIPHERAL BLOOD

Peripheral blood counts and a differential count from a Wright-Giemsa–stained blood smear are essential at the time of presentation.

TABLE 111-1 Laboratory Values at Diagnosis of Acute Lymphoblastic Leukemia (ALL)

		ALL
NO.		1273
Initial white blood cell count (× 10^9/L)	<10	41%
	10–50	31%
	>50–100	28%
	>100	16%
Neutrophils (× 10^9/L)	<50–100	12%
	<100,000	16%
Platelets (× 10^9/L)	<20	22%
	21–40	22%
	41–100	29%
	>100	27%
Hemoglobin (g/dL)	<7	20%
	7–9	33%
	>9	47%
Leukemic blasts in peripheral blood	0%	8%
	25–75%	34%
	>75%	36%
Leukemic blasts in bone marrow	<50%	4%
	51–90%	25%
	>90%	71%

Source: Data from three consecutive German Multicenter Trials for Adult ALL (GMALL).

The white blood cell (WBC) count in ~40% of ALL patients is reduced or normal **(Table 111-1)**. Only 16% of patients have a WBC above 100 × 10^5/L. It is noteworthy that in 8% of ALL patients, no circulating leukemic blast cells were observed. Thus, in the frequently used automatic blood cell counting, the diagnosis may not be detected.

Peripheral blood characteristically shows anemia, thrombocytopenia, and neutropenia. Nearly one-third of patients have hemoglobin levels <7–8 g/dL. A platelet count below the critical number of 20 × 10^9/L, associated with the risk of bleeding, and neutropenia (neutrophils <0.5 × 10^9/L), associated with a higher risk of infection, are each noted in one-fifth of adults with ALL.

BONE MARROW EXAMINATION

Bone marrow aspirates/biopsies are important to assess immunologic, cytogenetic, and genetic markers. A biopsy of the bone marrow is essential to confirm the diagnosis of acute leukemia and to distinguish between AML and ALL. The bone marrow is usually heavily packed with leukemic blast cells with >90% in ~70% of patients, and thus, the normal hemopoietic elements are greatly reduced or absent.

LUMBAR PUNCTURE

The examination of the cerebrospinal fluid is an essential routine diagnostic measure for ALL. Central nervous system (CNS) leukemia is diagnosed if ≥5 cells/μL or leukemic blast cells were observed by morphology in cerebrospinal fluid. Opinions differ as to when the first lumbar puncture should be done—i.e., either delay lumbar puncture until remission is achieved to avoid seeding of the CNS with leukemic blast cells from the peripheral blood during the spinal tap or perform the lumbar puncture before treatment starts, since early recognition of CNS disease will lead to immediate CNS-specific therapy. Lumbar puncture is restricted to patients with an adequate platelet count (>20 × 10^9/L) and without manifest clinical hemorrhages. To eliminate potentially transferred blast cells, patients should receive intrathecal methotrexate at the first lumbar puncture.

MORPHOLOGIC SUBTYPES IN ALL

The French-American-British (FAB) classification distinguished three subgroups. L1 and L2 morphology has no clinical consequences. Only the L3 morphology, observed in up to 5% of adult patients, is indicative for mature B-cell lineage ALL (B-ALL) **(see Chap. 65)**.

IMMUNOLOGIC SUBTYPES

A series of monoclonal antibodies is employed to identify antigens expressed on the surface of leukemic cells, corresponding to the pathways of normal B-cell differentiation (see Fig. 113-2). The immunologic classification aims to subdivide ALLs according to the presence or absence of B-cell or T-cell markers. A marker is considered positive if >20% of the cells are stained with the monoclonal antibody.

There are different immunologic classifications, such as that of the European Group for the Immunological Characterization of Leukemias (EGIL), with clear therapeutic implications. Table 111-2 gives a simplified correlation of immunologic subtypes, cytogenetics and molecular aberrations, and clinical characteristics.

B-Cell Lineage ALL (B-ALL) More than 70% of adult ALLs are of B-cell origin, and the most frequent immunologic subtype, common ALL, is characterized by the presence of the ALL antigen CD10 without markers of relatively mature B cells such as cytoplasmic or surface membrane immunoglobulins. Pre-B-ALL (early B-ALL) is characterized by the expression of cytoplasmic immunoglobulin, which is negative in common ALL, but otherwise is identical with respect to all other cell markers. Pro-B-ALL corresponds to early B-cell differentiation and was formerly termed non-T-, non-B-ALL or null ALL because neither T-cell nor B-cell features could be demonstrated. This subtype is HLA-DR, terminal deoxynucleotidyl transferase, and CD19 positive and composes ~12% of adults ALL.

Mature B-ALL is seen in 3–4% of adults and is also known as Burkitt's leukemia. In mature B-ALL, blast cells express surface antigens of mature B cells, including the sIgM.

T-Cell Lineage ALL (T-ALL) Approximately 25% of adult ALLs are of T-cell lineage. All cases express the T-cell antigen CD7 and cytoplasmatic CD3 (CyCD3) or surface CD3. According to their stage of T-cell differentiation, they may express other T-cell antigens (e.g., the E-rosette receptor CD2 and/or the cortical thymocyte antigen CD1a). Early pro/pre-T-ALL (also termed early T precursor ALL [ETP-ALL]), cortical or thymic T-ALL, and mature T-ALL can be distinguished with these markers. ETP-ALL is characterized by lack of CD1a and CD8, weak CD5 expression, and at least one myeloid/stem cell marker.

Biphenotypic or Mixed Leukemias Biphenotypic leukemias are defined as those expressing markers of both lymphoid and myeloid lineages on the same leukemic cells. Bilineage leukemias are those with two populations of blast cells with either lymphoid or myeloid antigens. It is not clear whether these patients should receive an ALL or AML treatment protocol. In pediatric studies, starting with a pediatric ALL protocol seemed preferable, which was then followed by AML consolidation elements.

CYTOGENETIC AND MOLECULAR ANALYSIS

Cytogenetic and molecular analyses should be performed in all cases. They are important to define ALL subtypes, can identify independent prognostic markers of disease-free survival, and may determine specific targeted therapies.

The diagnostic techniques for ALL are standard cytogenetics, fluorescence in situ hybridization, and reverse transcriptase polymerase chain reaction. These methods allow the detection of Ph+ ALL, with the chromosomal translocation t(9;22)(q34;q11) and the detection of the corresponding *BCR-ABL1* gene rearrangement. Further ALL entities that have been identified are t(4;11)(q21;q23)/*MLL-AFA4*, abn11q23/*MLL*, and t(1;19)(q23;p13)/*PBX-E2A*.

Gene expression profiling, single nucleotide polymorphism array analysis, array-comparative genomic hybridization, and next-generation sequencing recognize the newly defined ALL entities: ETP-ALL and Ph-like ALL.

TABLE 111-2 Immunologic, Cytogenetic, Molecular, and Clinical Characteristics of Adult Acute Lymphoblastic Leukemia (ALL)

SUBTYPES	MARKER	INCIDENCE	FREQUENT CYTOGENETIC ABERRATIONS	GENETIC ABERRATIONS AND FUSION TRANSCRIPTS	CLINICAL CHARACTERISTICS	RELAPSE KINETICS AND LOCALIZATION
B-lineage ALL (B-ALL)	**HLA-DR+, TdT+, CD19+, and/or CD79a+, and/or cyCD22+**	**76%**				
Pro B-ALL	No additional differentiation markers Frequent myeloid coexpression (>50%) CD10–	112%	t(4;11) (q21;q23)	70% *ALL1-AF4* (20% Flt3 in MLL+)	High WBC (>100,000/μL) (26%)	Mainly BM (>90%)

TABLE 111-3 Response Parameters According to Minimal Residual Disease (MRD)

TERMINOLOGY	DEFINITION
Complete hematologic remission (CHR)	Leukemic cells not detectable by light microscopy (<5% blast cells in bone marrow [BM])
Complete molecular remission/MRD negativity	Patient in complete remission, MRD not detectable, ≤0.01% = ≤1 leukemia cell in 10,000 BM cells
Molecular failure/MRD positivity	Patient in complete hematologic remission, but not in molecular complete remission >0.01%
Molecular relapse/MRD positivity	Patient still in complete remission, had prior molecular complete remission, leukemic blast cells in BM not detectable (<5%)
Hematologic relapse	>5% blast cells in BM/blood

Ph-like ALL, also known as *BCR-ABL1*-like ALL, is characterized by genetic lesions similar to Ph+ ALL, associated with *IKZF1* (Ikaros) gene deletion, *CLRF2* (gene for cytokine-like receptor-2) overexpression, and tyrosine kinase activating rearrangements involving *ABL1*, *JAK2*, *PDGFRB*, and several other genes; however, it is *BCR-ABL1* negative. The frequency is 10% in children and 25–30% in young adults but does not increase further with age like Ph+ ALL. Treatment based on the underlying genetic lesion with BCR-ABL inhibitors (e.g., dasatinib) or JAK2 inhibitors (e.g., ruxolitinib) has so far had limited success in adults.

MINIMAL RESIDUAL DISEASE

Minimal residual disease (MRD) is the detection of residual leukemic cells that are not recognizable by light microscopy. Methods for determining MRD are based on the detection of leukemia-specific aberrant immunophenotypes by flow cytometry, the evaluation of leukemia-specific rearranged immunoglobulin or T-cell receptor sequences by real-time quantitative polymerase chain reaction, or the detection of fusion genes associated with chromosomal abnormalities (e.g., *BCR-ABL*, *MLL-AF4*). The detection limit with these methods is 10^{-3}–10^{-5} (0.1–0.001%). With new techniques such as next-generation sequencing (NGS) or digital droplet polymerase chain reaction (ddPCR), the sensitivity may increase to 10^{-5}–10^{-6}. The phenotypic aberrations are unique to each patient with ALL and can be detected in up to 95% of individuals. Collection of bone marrow at diagnosis for identification of patients' individual markers is essential for follow-up of MRD.

MOLECULAR RESPONSE AFTER INDUCTION THERAPY AND IMPACT ON OUTCOME

Achievement of molecular complete response/molecular remission is the most relevant independent prognostic factor for disease-free and overall survival in pediatric and adult ALL (Table 111-3). Patients with molecular complete remission after induction therapy have significantly superior outcomes in several studies, with a disease-free survival rate of ~70% compared to <40% for MRD-positive patients. Patients with molecular failure after induction should proceed to a targeted therapy to reduce the tumor load, followed by allogeneic stem cell transplantation (SCT), if possible.

PROGNOSTIC FACTORS, RISK STRATIFICATION, AND MRD

The aim of identification of prognostic parameters at diagnosis, which include age, WBC count, immunophenotype, and cytogenetic and genetic aberrations, is to stratify patients into risk groups: standard-risk patients are patients without any risk factors, and high-risk patients are those with one or more risk factors. High-risk patients are most often candidates for SCT in first complete remission (CR). MRD is thus the most important prognostic factor during therapy (Fig. 111-1); 20–30% of adult ALL patients who are MRD negative after induction will relapse. Potential reasons include loss of sensitivity, evolution of leukemic subclones, and extramedullary origin of disease. If the MRD status of a patient is not available, risk stratification should rely on clinical and laboratory risk factors evaluated at diagnosis.

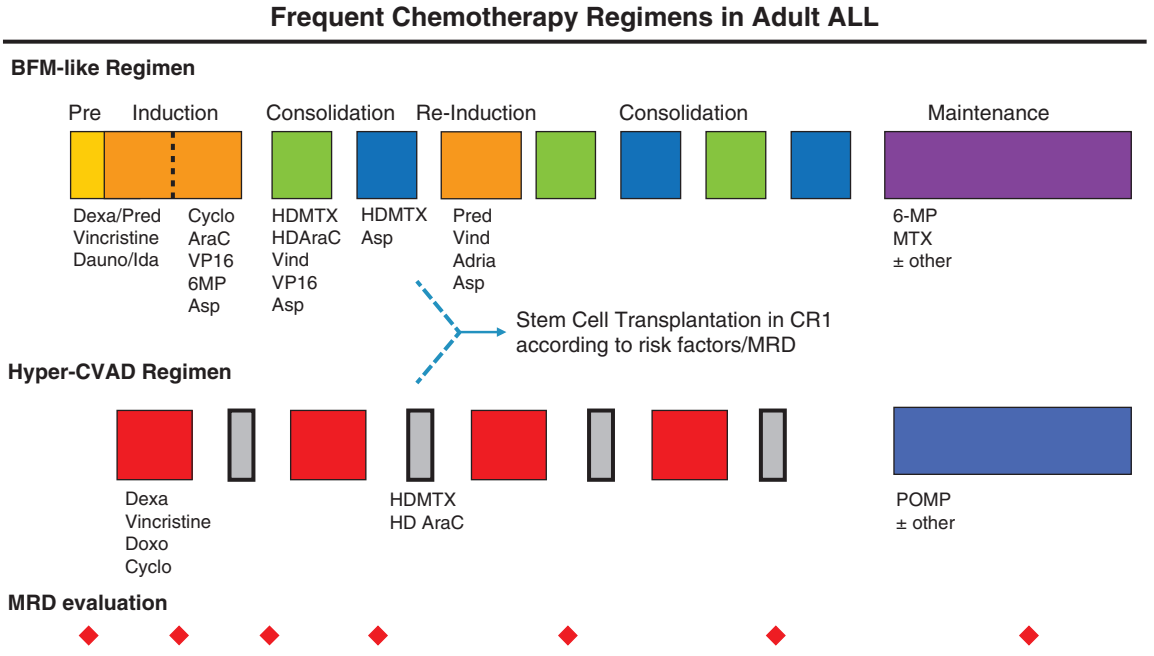

FIGURE 111-1 A schematic treatment algorithm in acute lymphoblastic leukemia (ALL). 6-MP, 6-mercaptopurine; Adria, Adriamycin (doxorubicin); AraC, cytarabine; Asp, asparaginase; BFM, Berlin-Frankfurt-Münster; CNS, central nervous system; CR1, first complete remission; Cyclo, cyclophosphamide; Dauno, daunorubicin; Dexa, dexamethasone; Doxo, doxorubicin; HD, high-dose; Hyper-CVAD, hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone; Ida, idarubicin; MRD, minimal residual disease; MTX, methotrexate; POMP, mercaptopurine, vincristine, methotrexate, and prednisolone; Pred, prednisolone; Vind, vindesine; VP16, etoposide.

TREATMENT PRINCIPLES

Treatment of ALL consists usually of pre-phase therapy, induction therapy, consolidation cycles, and maintenance treatment. Treatment should start immediately when the diagnosis of ALL is established and can later be specified or adapted when ALL subtype is known (e.g., Ph+).

Pre-Phase Therapy Pre-phase therapy consisting of glucocorticoids (prednisone 20–60 mg/d or dexamethasone 6–16 mg/d, both IV or PO) alone or in combination with another drug (e.g., vincristine, cyclophosphamide) is usually given for ~5–7 days. It allows safe tumor reduction to avoid tumor lysis syndrome, to initiate supportive therapy, such as substitution of platelets/erythrocytes, or to treat infections. The time required for pre-phase therapy will also allow time to obtain results of the diagnostic workup (e.g., cytogenetics, molecular genetics).

Induction Therapy The goal of induction therapy is the achievement of a CR or, even better, a molecular CR. With current regimens, the CR rate has increased to 80–90% and is higher for standard-risk patients (>90%) and lower for high-risk patients (~60%).

Induction regimens are centered around vincristine, glucocorticoids, and anthracyclines with or without cyclophosphamide or cytarabine. L-Asparaginase is the only ALL-specific drug and is now more intensively used in adults. Pegylated asparaginase has the advantage of a significantly longer period of asparagine depletion. Dexamethasone is often preferred to prednisone because it penetrates the blood-brain barrier and also acts on resting leukemic blast cells.

Two chemotherapy regimens are widespread (Fig. 111-1). One is patterned after the pediatric BFM (Berlin-Frankfurt-Münster) protocol, which is mostly used in European adult ALL trials. Another approach is to repeat two different alternating intensive chemotherapy cycles, identical for induction and consolidation, for eight cycles, such as Hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone) protocol, which is preferentially used in the United States but also in many other parts of the world.

Postremission Consolidation Usual protocols use six to eight courses and often contain systemic high-dose (HD) therapy to reach sufficient drug levels in sanctuary sites such as the CNS. Most often HD methotrexate (1–1.5 g/m^2 and up to 3–5 g/m^2) and/or HD cytarabine (4–12 doses at 1–3 g/m^2) are administered.

Maintenance Therapy Maintenance therapy, a strategy transferred from childhood ALL, is mandatory. It consists of 6-mercaptopurine and methotrexate plus intrathecal therapy. The potential effect of further intensification cycles during maintenance remains unclear. The duration of maintenance therapy for T-ALL and B-ALL is 2–2.5 years, except for Burkitt's leukemia, for which a half year to 1 year is sufficient. In Ph+ ALL, patients also require maintenance therapy that should include a tyrosine kinase inhibitor (TKI), most likely the TKI that has been used during induction and consolidation therapy. It is also standard to give a TKI after allogeneic SCT. The duration of maintenance therapy with a TKI is also 2–2.5 years and should be guided by MRD evaluation. TKI use is often interrupted or switched to another TKI if toxicity occurs.

TREATMENT OF ALL PATIENTS ACCORDING TO AGE

The outcome of ALL is strictly related to the age of a patient, with cure rates of ~90% in children, decreasing to <10% in elderly or frail patients. Thus, age-adapted protocols have emerged, where the age limits are directed by the hematologic and nonhematologic toxicities. Table 111-4 provides a summary of the best results obtained in adult ALL according to ALL subtype, age, and treatment. The major risk of relapse is in the first 2 years and is less likely after 5 years.

TABLE 111-4 Best Results in Recent Studies for Adult Acute Lymphoblastic Leukemia (ALL)

SUBTYPE	TREATMENT	OVERALL SURVIVAL
Burkitt's leukemia	Short intensive chemotherapy + rituximab; no SCT; no maintenance	80–90%
B-lineage ALL, Ph–		
AYA 15–35/45 years	Pediatric inspired, few/no SCT	≥70–80%
Adults 45–55 years	Intensive chemotherapy +/– SCT	50–60%
Elderly 55–70 years	Less intensive chemotherapy + immunotherapy	~30%
Frail >70/75 years	Various	≤10%
B-lineage ALL, Ph+		
Ph BCR-ABL	Intensive chemotherapy + TKI +/– SCT	60–70%
Ph-like ALL	Chemotherapy + dasatinib/JAK inhibitors	≤50%
T-lineage ALL		
Early (ETP)	Intensive chemotherapy + nelarabine + SCT	40–50%
Cortical/thymic	Intensive chemotherapy + nelarabine, no SCT	70–84%
Mature	Intensive chemotherapy + nelarabine + SCT	30–50%

Abbreviations: AYA, adolescent and young adult; ETP, early T precursor; Ph, Philadelphia chromosome; SCT, stem cell transplantation; TKI, tyrosine kinase inhibitor.

PROPHYLAXIS AND TREATMENT OF CENTRAL NERVOUS SYSTEM LEUKEMIA

Prophylactic CNS therapy in ALL is essential in order to prevent CNS leukemia and to avoid spread of leukemic cells from the CNS back to the periphery. Treatment options include intrathecal therapy, systemic HD chemotherapy, and cranial radiation therapy (CRT). Wide variations exist in CNS prophylaxis regimens. Intrathecal therapy mostly consists of methotrexate as a single drug or in combination with cytosine arabinoside (AC) with or without glucocorticoids. The route of intrathecal therapy application is generally lumbar puncture. Systemic HD chemotherapy may comprise HDAC or HD methotrexate since both drugs reach cytotoxic drug levels in the cerebrospinal fluid and show effectiveness in overt CNS leukemia. CRT (18–24 Gy in 12 fractions over 16 days) is also effective as preventive treatment of CNS leukemia. Using combined modalities for CNS prophylaxis, the CNS relapse rate has decreased to 2–5%.

Particular attention to CNS prophylaxis is required for targeted therapies. In Ph+ ALL, not all TKIs cross the blood-brain barrier equally such as imatinib and nilotinib but dasatinib and probably ponatinib do. In immunotherapies, intrathecal therapy is required because most antibodies do not enter the CNS.

CNS involvement at diagnosis is observed in 5–10% of adult patients and is higher in mature B-ALL (up to 10–15%) and T-ALL (up to 10%). Treatment consists of the standard chemotherapy with additional intrathecal applications 3–5 times per week until blast cells are cleared in the spinal fluid. Patients with initial CNS involvement have a similar overall survival as CNS-negative patients.

Relapse in CNS is usually accompanied by bone marrow involvement, and if blast cells are not seen morphologically, MRD as a sign of discrete infiltration is positive in nearly all cases. CNS relapse requires local as well as systemic therapy. The outcome after CNS relapse is dismal, and salvage chemotherapy followed by allogeneic SCT is the most effective option. Chimeric antigen receptor (CAR) T cells (most often targeting CD19) can cross the blood-brain barrier and achieve CRs in patients with CNS relapse.

Extramedullary manifestation and relapses in ALL are often observed. Patients should have the general treatment and, if required, local intervention (e.g., local radiation if residual mediastinal mass).

STEM CELL TRANSPLANTATION

SCT is an essential part of the treatment strategy for adult ALL. Peripheral blood cells are more often being used as a stem cell source, instead of bone marrow. If no matched sibling stem cell donors are available,

increasingly matched unrelated donors or haploidentical donors are used. Indications for SCT in first CR are controversial. However, in most studies, SCT is recommended for high-risk patients defined either by conventional prognostic factors or by MRD positivity. High-risk patients transplanted in first CR have a survival rate of 50% or greater. Decreasing transplant-related mortality from 20–30% to 10–15% has contributed substantially to better outcomes. For standard-risk patients with sustained molecular remission, allogeneic SCT in first CR is not recommended. Autologous SCT should be restricted to MRD-negative patients, *BCR-ABL*–negative patients and older patients because it is less toxic but associated with a substantially higher relapse rate. For all relapsed adult ALL patients, an allogeneic SCT is thus far the only curative option.

PEDIATRIC-INSPIRED THERAPIES FOR ADOLESCENTS AND YOUNG ADULTS

The principle of pediatric-inspired therapies is to have higher doses and more applications of ALL-specific drugs such as glucocorticoids, vincristine, and L-asparaginase and fewer myeloablative anthracyclines or alkylating agents, with strict adherence to time-dose intensity, thereby reducing the role of SCT. The overall survival rates for AYAs are 70–80%.

ADULT ALL

The treatment results for adult ALL patients have greatly improved with more intensive chemotherapy, optimized SCT, and better supportive care. In several recent multicenter prospective trials, the overall survival rate for standard-risk patients was >70% with chemotherapy alone, and for high-risk patients, the overall survival rate has increased from 20–30% to >50%.

ALL IN THE ELDERLY

Palliative treatment regimens for elderly patients have failed, with CR rates of ~40%, a high early death rate of 24%, and a poor overall survival of only a few months. Intensive chemotherapy has also failed, with a higher CR rate of 56%, but still an early death rate of 23%, and only moderate improvement of overall survival to 14 months. Specific elderly ALL protocols with less intensive therapy based on glucocorticoids, vincristine, and asparaginase, largely avoiding anthracyclines and alkylating agents, have improved outcomes. The early treatment-related death rate decreased to <10%, CR rates improved to ~90%, and overall survival of ~30 months was noted.

Frail patients above the age of 70–75 years have very poor survival of <10%. Hopefully, this will improve with ongoing targeted therapies with either TKIs in Ph+ ALL or immunotherapies.

TARGETED THERAPIES

Substantial progress in adult ALL has been made in the past decade by the introduction of new targeted therapies, including TKIs and immunotherapeutic approaches (Table 111-5).

TYROSINE KINASE INHIBITORS IN PHILADELPHIA-POSITIVE ALL

Patients with Ph+ ALL constitute ~25% of adult B-ALL patients, with the frequency increasing to ~50% among elderly patients. In the pre-imatinib era, CR rates were 60–70%; survival with chemotherapy was ~10%, and after allogeneic SCT, it was ~30%. With the first-generation TKI imatinib, CR rates increased to 80–90%, the rate of *BCR-ABL* negativity increased from 5 to 50%, and the 5- to 10-year overall survival improved to 50–70%.

Faster and deeper molecular responses are achieved with second-generation TKIs (dasatinib, nilotinib), and these responses apparently translate into a survival benefit. The third-generation TKI ponatinib is also effective in tumors bearing mutations (particularly T315I) that convey resistance to earlier-generation TKIs.

Treating adult Ph+ ALL with an allogeneic SCT in first CR is still a good treatment option for adult patients, with a 5-year overall survival of 60–70%. In elderly patients, when low-intensity chemotherapy was combined with dasatinib, the CR rate was >90%. In a next step, by combining mini-chemotherapy with a TKI and adding immunotherapy with inotuzumab (an anti-CD22 antibody), the CR rate was >90% and the overall survival improved further. A pilot experience with a chemotherapy-free regimen composed of dexamethasone, the TKI dasatinib, and the bispecific antibody blinatumomab (anti-CD19 and anti-CD3) demonstrated a CR rate of 98% and 2-year overall and disease-free survival rates of 95% and 88%, respectively. Blinatumomab eliminates Ph+ leukemic cells with resistant mutations.

TABLE 111-5 Targeted Therapies in Adult Acute Lymphoblastic Leukemia (ALL)

Tyrosine Kinase Inhibitors (TKIs)
Ph/BCR-ABL+ ALL
TKIs
Imatinib, dasatinib, nilotinib, bosutinib, ponatinib, asciminib
Ph/BCR-ABL-like ALL
ABL1, ABL2: dasatinib, ponatinib; JAK2: ruxolitinib
Immunologic Approaches
Antibodies directed against leukemia surface antigens
Monovalent antibodies
Bivalent antibodies against the tumor and CD3 (e.g., blinatumomab)
Adoptive cellular therapy
T cells engineered to kill leukemic cells
Checkpoint Inhibitors
PD-1 inhibitors: pembrolizumab, nivolumab
CTLA-4 inhibitors: ipilimumab
Targeted Agents
Proteasome inhibitors: bortezomib, ixazomib
BCL-2 inhibitors: venetoclax, navitoclax

IMMUNOTHERAPEUTIC APPROACHES

Treatments involving monoclonal antibodies or activated T cells are currently changing the treatment paradigm of ALL. The prerequisite is that B-lineage blast cells express a variety of specific antigens, such as CD19, CD20, and CD22 (Table 111-6) that are targetable with a wide variety of monoclonal antibodies. A new treatment principle is the activation of the patient's T cells to destroy their CD19+ leukemic blasts.

Anti-CD20 The anti-CD20 monoclonal antibody rituximab has improved the outcome of patients with de novo Burkitt's leukemia/lymphoma. With repeated short cycles of intensive chemotherapy combined with rituximab, the overall survival increased to >80%. Rituximab is now included in most B-ALL regimens and is given at the usual dose of 375 mg/m^2 on day –1 before chemotherapy for at

TABLE 111-6 Expression of Antigens in B-Cell Lineage Acute Lymphoblastic Leukemia (ALL) for Potential Antibody Therapy

SURFACE ANTIGEN	ALL SUBTYPES	EXPRESSION ON LBC[a]	MONOCLONAL ANTIBODY

least eight or more cycles. This leads to a significant increase in MRD negativity and improved survival.

Anti-CD22 Monoclonal antibodies directed against CD22 are linked to cytotoxic agents, such as calicheamicin (inotuzumab ozogamicin), or to plant or bacterial toxins (epratuzumab). In a randomized trial of relapsed or refractory ALL patients, the CR rate was 66% and significantly superior to the CR rate with standard chemotherapy. Inotuzumab is now included in first-line therapy for Ph+ and Ph– patients.

Anti-CD19 Targeting CD19 is of great interest because this antigen is highly expressed in all B-lineage cells, most likely including early lymphoid precursor cells. A new promising approach is the bispecific antibody blinatumomab, which combines single-chain antibodies to CD19 and CD3, such that T cells lyse the CD19-bearing B cells.

Blinatumomab is particularly effective in MRD-positive patients, with a 70–80% conversion to MRD negativity, translating into improved overall survival; ~25% of MRD-negative patients survived without any further treatment. Blinatumomab has also moved to frontline therapy.

CAR-T Cells The adoptive transfer of CAR-modified T cells directed against CD19 is a promising approach for the treatment of CD19+ childhood or adult ALL. In the first three larger studies in adults with relapsed or refractory ALL, the CR rate ranged from 67 to 91% with MRD negativity in 60–81% of the patients who achieved CR. Overall survival is 50% or more at ≥2 years, which is remarkable for these heavily pretreated patients. CAR-T cells are also effective in CNS leukemia and in other extramedullary sites. CAR-T cell therapy in relapsed or refractory ALL was first considered as a bridge to allogeneic SCT, applied in 10–50% of patients, but the necessity for an allogeneic SCT after CAR-T cells is unclear. CAR-T cell therapies are also moving to the frontline. CD19-negative relapses after CAR-T cell therapy or blinatumomab due to downregulation of CD19 expression are a relevant obstacle.

Toxicities of Immunotherapies The anti-CD22 agent inotuzumab ozogamicin is associated with hepatotoxicity, including veno-occlusive disease, particularly after allogeneic SCT, but can be managed by reduced dosing and limitation of cycles. For anti-CD19 therapies, cytokine release syndrome and severe neurotoxicity are the most prominent toxicities and often require intensive care unit care (more so after CAR-T cells than blinatumomab). Management of these complications has improved with early recognition. Because toxic death after immunotherapies is very low compared to intensive chemotherapy or allogeneic SCT, immunotherapies are now increasingly included in frontline therapy.

TREATMENT OF T-ALL

Immunotherapy for T-ALL is still not available, and intensive chemotherapy is still the mainstay in combination with the T cell–specific drug nelarabine. Currently, γ-secretase targeting *NOTCH1*, checkpoint inhibitors such as bortezomib and venetoclax, and HDAC inhibitors are being explored.

CONCLUSION AND FUTURE DIRECTIONS

Cytogenetic and molecular analysis at diagnosis allows identification of ALL subentities requiring different treatment options. Evaluation of MRD is the most important parameter for treatment decisions. The greatest progress has been achieved by targeted therapies, such as TKIs for Ph+ ALL and new immunotherapeutic approaches. This will lead to further improved outcome of adult ALL patients, 50% of whom are already surviving 5–10 years and are most likely cured. New options and advances, such as low-intensity chemotherapy, reduction of SCT, incorporation of targeted therapies, and reduction of toxicities, will improve the quality of life of patients and lead to individualized approaches for each patient.

112 Chronic Lymphocytic Leukemia

Jennifer A. Woyach, John C. Byrd

Chronic lymphocytic leukemia (CLL) is a monoclonal proliferation of mature B lymphocytes defined by an absolute number of malignant cells in the blood (5×10^9/L). The presence of malignant B cells under this count in the blood without nodal, spleen, or liver involvement and absent cytopenias is a precursor of this disease called *monoclonal B-cell lymphocytosis* (MBL) with ~1–2% chance per year of progressing to overt CLL. CLL is a heterogeneous disease in terms of natural history, with some patients presenting asymptomatically and never requiring therapy, whereas most will need therapy and a small subset will present with symptomatic disease, require multiple lines of therapy, and eventually die of their disease. Over the past two decades, the understanding of CLL origin and biology has grown exponentially, leading first to more refined disease definition, prognostic markers, and, subsequently, introduction of novel therapies that have significantly changed the natural history of this disease to where only a small minority will die from CLL. In this way, CLL has served as a prototype of a cancer where understanding the biologic underpinnings in absence of unified mutation drivers has informed therapy development. In this chapter, we review the epidemiology, biology, and management of CLL, with a focus on new knowledge that has changed and continues to change standards of care.

EPIDEMIOLOGY

CLL is primarily a disease of older adults, with a median age at diagnosis of 71 and an age-adjusted incidence of 4.6/100,000 people in the United States; 18,740 peoples were diagnosed and 4490 people died of CLL in the United States in 2023. The prevalence of CLL has increased over the past decades due to improvements in therapy for this disease and also survival of older patients from other medical ailments. In 1980, the 5-year overall survival of patients was 70%, and this increased to 92% in 2015 and is likely even higher today. The male-to-female ratio is 2:1; however, as patients age, the ratio becomes more even, and over the age of 80, the incidence is equal between men and women. The disease is most common in Caucasians, less common in Hispanic and African Americans, and is rare in the Asian population.

Unlike many other malignancies, there have been no definitive links between CLL and exposures. Indeed, CLL is one of the only types of

leukemia not linked to radiation exposure. Agent Orange exposure has been implicated, and CLL is thus a service-connected condition for those who were exposed to Agent Orange in the Vietnam conflict, burn pit exposure from the Middle East conflicts, and Camp Lejune water.

CLL is one of the most familial-associated malignancies, and the first-degree relative of a CLL patient has an 8.5-fold elevated risk of developing CLL than the general population. MBL is also more common in families with two first-degree relatives having CLL, further supporting a genetic predisposition of this disease. Despite this, specific genes conferring risk in the familial setting outside of specific families have been difficult to identify. In genome-wide association studies (GWAS), ~30 single nucleotide polymorphisms (SNPs) have been identified, which is estimated to account for 19% of the familial risk of CLL. Genes involved in apoptosis, telomere function, B-cell receptor (BCR) activation, and B-cell differentiation have all been implicated in GWAS. Variants in shelterin complex proteins involved in telomere maintenance such as POT1 have been identified in a small number of families.

BIOLOGY AND PATHOPHYSIOLOGY

CELL OF ORIGIN

The cell of origin in CLL has not definitively been established. The morphology, immunophenotype, and gene expression pattern of CLL cells are that of a mature B cell **(Fig. 112-1)**, and so it has long been presumed that the initiating cell is a mature lymphocyte, perhaps memory B cells. However, many facets of CLL biology do not support this idea, including antigen-binding characteristics of CLL cells and the presence of stereotyped BCRs. Other possibilities include a stepwise process including a series of transforming events at various stages of B-cell development, potentially including de-differentiation of more mature cells. The self-renewing, multipotent hematopoietic stem cell (HSC) might also be the originating cell of CLL, postulated based on transplant studies in mice showing clonal leukemic cell development with different characteristics from donor leukemia after transplantation of HSC from CLL patients. More work will be required to elucidate the origins of CLL.

B-CELL RECEPTOR SIGNALING IN CLL

Perhaps the most important advancement in CLL biology is the understanding of the role of BCR signaling in the disease. CLL has distinct BCR signaling as compared to normal B cells, which is characterized by low-level IgM expression, variable response to antigen stimulation, and tonic activation of antiapoptotic signaling pathways that promote tumor survival. CLL cells by gene expression profiling share many features with antigen-activated mature B cells, suggesting a role for activation of BCR signaling in the disease pathogenesis. Tissue-based microarrays have revealed upregulation of BCR pathway genes in the lymph nodes and bone marrow compared to the peripheral blood, suggesting a particular importance of this pathway in microenvironmental homing.

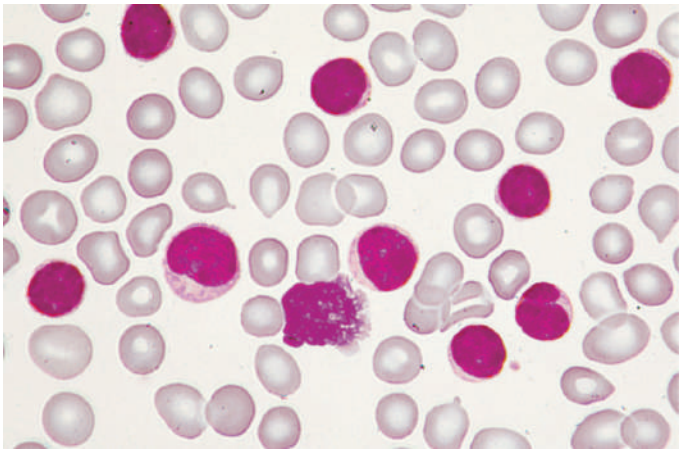

FIGURE 112-1 Chronic lymphoid leukemia in the peripheral blood. *(From Williams Hematology, 7th ed, in M Lichtman et al [eds]: New York, McGraw-Hill, 2005.)*

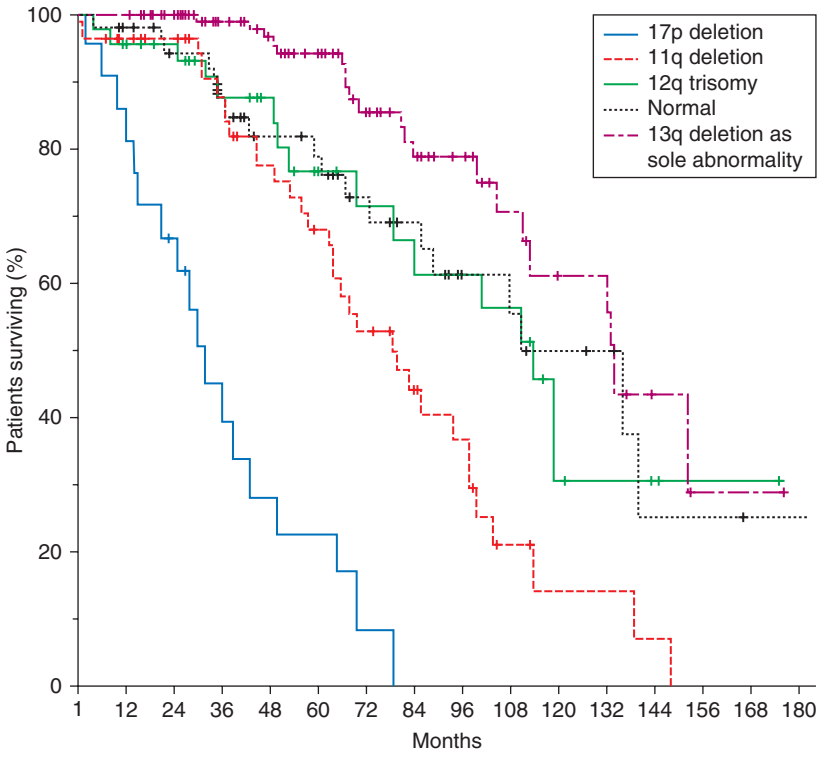
Fitting with the role of BCR signaling in CLL, one of the most influential prognostic factors identified in this disease is the mutational status of the immunoglobulin heavy chain variable (IGHV) region. During normal B-cell maturation, the variable regions of the immunoglobulin heavy chain undergo somatic hypermutation. In CLL, ~60% of patients have IGHV that is ≥2% mutated from germline. This may indicate a more mature, postgerminal center progenitor, and is typically associated with a more indolent disease course. Conversely, ~40% of patients will have IGHV <2% mutated from germline, which is associated with more rapid progression of disease and short survival before the era of therapeutics that target BCR. Unfavorable biologic properties including enhanced telomerase activity, overexpression of activation-induced cytidine deaminase, increased nuclear factor-κB (NF-κB) activity, high-risk genomic mutations (e.g., *NOTCH1, SF3B1, TP53, ATM*), and clonal evolution are also associated with IGHV unmutated disease. In addition to the mutational status of IGHV, about 30% of CLL patients express "stereotyped" BCRs, where the stereotype subset predicts clinical course, with subsets 1 and 2 predicting higher-risk disease.

CYTOGENETIC ABNORMALITIES



Besides IGHV mutational status, recurrent cytogenetic abnormalities are the most robust prognostic factor clinically available in CLL. These abnormalities are typically identified by fluorescent in situ hybridization (FISH) analysis; however, stimulated metaphase karyotype has a role as well. The most well-characterized abnormalities include del(13)(q14.3), trisomy 12, del(11)(q22.3), and del(17)(p13.1) **(Fig. 112-2)**. The presence of sole del(13)(q14.3) is associated with more indolent disease, prolonged survival, and good response to traditional therapies. Usually this abnormality is not seen on banded karyotype analysis, and when present on karyotype, it indicates a larger deletion involving the retinoblastoma gene, which negates the favorable prognosis associated with this marker. Trisomy 12 has a more intermediate prognosis. The del(11)(q23.3) results in deletion of the *ATM* gene and is associated with bulky lymphadenopathy and aggressive disease in young patients, with inferior prognosis, and more rapid progression to symptomatic disease. The del(17)(p13.1) results in loss of one allele of the tumor suppressor TP53 and is associated with the poorest prognosis in CLL with rapid disease progression, poor response to traditional therapies, and shorter survival. Other abnormalities have been shown to be important in smaller studies but are not routinely performed at all centers. Finally, complex karyotype (three or more abnormalities) on stimulated metaphase karyotype analysis has significant adverse impact on time to treatment and overall survival, with data indicating that increasing complexity is even more deleterious to response and survival.

Clonal evolution, or acquisition of cytogenetic or molecular abnormalities, is common in CLL, especially in patients with IGHV unmutated CLL. Because the cytogenetics of patients can change even in the absence of therapy, it is recommended that FISH, with or without cytogenetics, is checked before every line of therapy, mostly to evaluate acquisition of del(17)(p13.1).

GENE MUTATIONS AND MIR ALTERATIONS

Compared with many other malignancies, the genome in CLL is relatively simple, with an average CLL genome carrying ~20 nonsynonymous alterations and ~5 structural abnormalities. And, unlike many other hematologic malignancies, there is no unifying genetic lesion, and most recurrent genetic driving mutations exist at frequencies of <5%. Whole genome and whole exome sequencing have identified the most common mutations in CLL to be in *SF3B1*, *NOTCH1*, *MYD88*, *ATM*, and *TP53* **(Table 112-1)**. Most of the identified mutations in these genes are common among different malignancies, and with the exception of *MYD88*, they are generally identified with much higher frequency in IGHV unmutated disease.

NOTCH1 mutations are present in ~15% of CLL patients and are commonly associated with trisomy 12. Although multiple different

No. at Risk

17p deletion	23	18	13	8	5	4	1	0	0	0	0	0	0	0	0	0

FIGURE 112-2 Outcomes among CLL patients with various cytogenetic abnormalities. *(From The New England Journal of Medicine, Genomic Aberrations and Survival in Chronic Lymphocytic Leukemia, H Dohner et al: 343: 1910. Copyright @2000 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

mutations are seen, most are located within the PEST (proline, glutamic acid, serine, and threonine) domain and result in constitutive NOTCH signaling. *NOTCH1* mutations have been associated with lower sensitivity to CD20 antibody therapy and increased risk of transformation to aggressive diffuse large B-cell lymphoma (DLBCL; Richter's transformation), although its relevance in the era of targeted therapies is less clear. *SF3B1* is a component of the RNA spliceosome and is mutated in 10–15% of CLL cases. Mutations appear to be associated with intermediate-risk disease, and functionally, *SF3B1* may be important in the response to DNA damage.

Mutations of the tumor suppressor *TP53* are found in ~5% of CLLs in previously untreated early-stage disease and up to 40% in later stages.

TABLE 112-1 Recurrent Mutations in CLL

GENE	FREQUENCY OF MUTATIONS (%)
SF3B1	8–14
TP53	5–13
NOTCH1	10–13
MYD88	4–8
ATM	8–11
BIRC3	<5
XPO1	<5
FBXW7	<5
POT1	<5
BRAF	<5
EGR2	<5
IKZF3	<5

Abbreviation: CLL, chronic lymphocytic leukemia.

Seventy percent of the time, these mutations coexist with del(17)(p13.1), effectively eliminating *TP53* function. As expected, and consistent with other malignancies, *TP53* mutations are associated with a poor prognosis and expected lack of response to DNA-damaging therapies.

ATM mutations, which are heterogeneous and occur throughout the gene, occur in 10–15% of CLL patients. *ATM* mutations often coexist with del(11)(q22.3), eliminating *ATM* on the alternate allele. Similar to *TP53*, mutations in *ATM* tend to result in impaired response to DNA damage, which can reduce responsiveness to chemotherapy.

In contrast to the aforementioned mutations, those in *MYD88* tend to occur in IGHV-mutated CLL and be associated with a more indolent prognosis. This gene is involved in Toll-like receptor signaling, and the most common mutation, L265P, results in constitutive activation and NF-κB activity.

Along with abnormalities in coding genes, it has become apparent that noncoding genes such as microRNAs are recurrently altered in CLL. The most common cytogenetic abnormality, del(13)(q14.3), results in loss of the miR15/16 cluster, which is important in the pathogenesis of CLL. In normal cells, miR15A/miR16A inhibits antiapoptotic gene expression (including *BCL2*, *CCND1*, *CCND3*, and *CDK6*), and this specific deletion allows for overexpression of these genes and thus increased cell survival. Loss of other miR expression such as miR-181a leads to overexpression of proteins such as the antiapoptotic genes *MCL1* and *TCL1*. Overexpression of miR-155, an onco-miR associated with B-cell transformation, has also been documented in the majority of CLL patients.

IMMUNOLOGY

CLL is characterized by dysregulation of the normal immune system in addition to the malignant immune cells. Besides numerical abnormalities due to bone marrow dysfunction, even in the early stages of disease, there are skewed ratios of immune cells and functional abnormalities.

Innate immune system defects associated with CLL include reduced complement proteins and activity, qualitative neutrophil defects, and functional defects of natural killer cells.

More focus has been placed on the impairments in the adaptive immune system in this disease. Within the CD4+ T-cell compartment, a qualitative defect is noted similar to chronic antigen stimulation inducing a phenotype of T-cell exhaustion typical of what is seen in chronic viral infections such as hepatitis. This has been demonstrated to lead to impaired T-cell cytotoxic capacity and reduced proliferative ability. Additionally, there are physical changes in the T-cell cytoskeleton that cause impaired immune synapse formation with antigen presenting cells. In addition to a lack of capacity to respond to pathogens, the T-cell defect in CLL also likely leads to tumor cell tolerance. During the course of the disease, the polarization of the CD4+ T cells shifts from a Th1 (cytotoxic) phenotype to a Th2 phenotype, which leads to expansion of immunosuppressive cytokines such as interleukin (IL) 10. Additionally, in the later stage of disease, T regulatory cells are expanded, which contributes to an immunosuppressive phenotype.

Other components of the immune microenvironment are altered as well to form a more supportive environment for the malignant cells. M2 monocytes have been shown to differentiate into a type of tumor-associated macrophage known as a *nurse-like cell* in CLL. These cells promote survival by secreting chemokines and cytokines that increase migration and activation.

The humoral immune system in CLL is also dysregulated, as is expected for a malignancy that results in very few normal B cells. Hypogammaglobulinemia is very common and affects all subclasses of immunoglobulins, occurring in ~85% of patients at some time in their disease course, and is more common as disease progresses. A correlation between low IgG and IgA and infection risk has been established, but isolated IgM reduction does not seem to be associated with excess infection risk. Also, CLL cells can secrete monoclonal IgM or IgG in a small number of cases, and this can correlate with disease progression.

CLINICAL PRESENTATION AND DIAGNOSIS OF CLL

CLINICAL PRESENTATION AND DIAGNOSIS

The presentation of CLL most commonly occurs as an incidental diagnosis made at the time of medical evaluation for another cause. In this regard, CLL is most commonly diagnosed on routine blood work demonstrating an elevated lymphocyte count in asymptomatic individuals, although some patients present with symptoms and require early therapy. When noting either an elevated total white blood cell (WBC) count with lymphocytic predominance or a normal WBC with a differential showing a lymphocytosis, the next step is to perform flow cytometry on the peripheral blood. In CLL, this will reveal the typical immunophenotype that includes the typical B-cell markers CD19, CD20, CD22, CD23, CD200, the T-cell marker CD5 (CD5 is also expressed on the B1 subset of B cells that typically has unmutated immunoglobulin and responds to antigens independent of cognate T-cell help), and dim surface immunoglobulin of either kappa or lambda type **(Table 112-2)**. Atypical phenotypes can be seen as well and usually can be differentiated on the basis of morphology, cytogenetics, or clinical presentation. In cases in which the clonal B-cell count based on flow cytometry is $\geq 5 \times 10^9$/L, no further workup is needed to confirm the diagnosis of CLL.

Some patients will present with a small clonal proliferation of CLL cells in the peripheral blood but will also have lymphadenopathy or splenomegaly. In these cases, the likely diagnosis is small lymphocytic lymphoma (SLL), a semantic designation from CLL that denotes a primarily tissue-based disease rather than bone marrow/blood-based disease. The genetic and molecular features of SLL are identical to those of CLL. The retention of the cells in tissues may be related to the expression of a particular adhesion molecule. Thus, SLL patients are managed identically to CLL patients, and often in the later stages of disease, these patients will have blood and bone marrow involvement as well.

MONOCLONAL B-CELL LYMPHOCYTOSIS

Patients who do not meet the diagnostic criteria for CLL based on quantification of clonal B cells in the peripheral blood and who do not have associated signs of CLL including lymphadenopathy, organomegaly, or cytopenias have a disorder known as monoclonal B-cell lymphocytosis (MBL), which is now thought to precede every case of CLL. Analogous to monoclonal gammopathy of uncertain significance (MGUS) in myeloma, not all MBL progresses to CLL. MBL is initially characterized by a CLL-like immunophenotype in ~75% of cases but can also be atypical (CD23 negative or bright CD20) or CD5 negative. More relevant for prognosis is characterization by count, with low-count MBL defining patients with $<0.5 \times 10^9$ clonal B cells/L and high-count MBL defining patients with $>0.5 \times 10^9$ but $<5 \times 10^9$/L. Patients with low-count MBL have a negligible rate of progression to CLL, whereas those with high count progress to overt CLL at a rate of 1–2% per year, warranting continued monitoring. Population-based studies have estimated the prevalence of MBL up to ~12% in the general population, where it is most common in elderly men. It is especially common in first-degree relatives of CLL patients, where the frequency is ~18%.

Although the risk of MBL progression is relatively low, it has become apparent that patients still experience complications that suggest an immune dysfunction in MBL that is similar to that seen with CLL. Rates of serious infections requiring hospitalization appear to be significantly increased in MBL, similar to the rates seen in CLL. In a case-control study, patients with MBL had a 16% chance of hospitalization over a 4-year time period, compared with 18.4% in patients with newly diagnosed CLL. Secondary cancers also appear to be increased in MBL. These data suggest that monitoring for patients with MBL should focus on vaccinations and age-appropriate cancer screening, as the probability of complications appears to be higher than the risk of progression in most of these patients. Follow-up for patients with MBL can occur with the primary care physician as this does not represent a malignancy, whereas CLL is mostly co-managed with both a primary care physician and a hematologist.

COMPLICATIONS OF CLL

A significant amount of morbidity and mortality related to CLL is due to complications of the disease. In general, complications besides disease progression include infections, secondary cancers, autoimmune complications, and transformation to a more aggressive clonally related lymphoma.

INFECTIONS

Infections are a leading cause of both disease-related morbidity and death in patients with CLL, with ~30–50% of deaths in CLL patient attributed to infection. Owing to the immune dysfunction associated with the disease, patients are at risk for both typical and atypical infections. Besides this baseline risk of infections, most CLL therapies, even targeted therapies, can increase infection risk. Viral prophylaxis

Abbreviation: CLL, chronic lymphocytic leukemia.

is also indicated for many patients when therapy is initiated (even with targeted agents) and for patients with a history of varicella-zoster to diminish reactivation and morbidity from this virus.

Because of the abnormalities in cellular and humoral immunity, vaccine responses in CLL are limited in many patients, especially in the later stages of disease. In one study, one dose of 13-valent pneumococcal vaccine produced an adequate immune response in only 58% of patients compared with 100% in age-matched controls. Vaccine efficacy can be improved in CLL patients by repeated booster vaccinations, vaccine adjuvants, and protein conjugation. Despite the known limitations, vaccination against influenza, COVID-19, varicella-zoster, pneumococcal pneumonia (Prevnar 20), and respiratory syncytial virus is recommended in CLL. The recombinant zoster vaccine has approximately a 60% response in previously untreated CLL, is safe, and should be considered for this patient group. Efficacy of the newer 20-valent pneumococcal vaccine in patients with CLL has not yet been reported. In contrast, live vaccines should be avoided in the setting of CLL because of the small risk of viral reactivation with an immunocompromised host.

Vaccine effectiveness in terms of humoral response is also decreased by most CLL therapies, although this can be overcome in some cases by booster vaccinations. When possible, receiving vaccinations before the initiation of therapy is recommended.

As discussed earlier, hypogammaglobulinemia is common in CLL and can be associated with significant risk for infections, primarily of mucocutaneous etiology such as sinusitis and bronchitis. In addition, women can have frequent urinary tract infections. While administration of prophylactic intravenous immunoglobulin (IVIg) has not been shown to improve survival, it has been shown to reduce the number of minor or moderate bacterial infections, and thus is indicated in patients with hypogammaglobulinemia who suffer from recurrent infections or have pulmonary bronchiectasis. It is also our practice to administer at least one dose of immunoglobulin to CLL patients who develop influenza with coexisting hypogammaglobulinemia to diminish risk of postinfluenza pneumococcal pneumonia. IVIg is also indicated in patients who have been hospitalized for a serious infection and in those whose IgG level is <300–500 mg/dL.

SECONDARY MALIGNANCIES

Multiple population-based studies have shown that patients with CLL are at an elevated risk of developing other cancers, with a rate up to three times that of the general population, even in the absence of cytotoxic chemotherapy. The most common types of cancers seen in CLL are skin, prostate, and breast cancers, although other cancers are seen as well. Skin cancers are particularly common, with a rate of 8- to 15-fold higher than the general population, and may behave more aggressively. All CLL patients should be counseled on the use of sunscreen while outdoors and should undergo preventative skin examinations at least yearly.

In one single-center study, older age at CLL diagnosis, male sex, high β_2-microglobulin, high lactate dehydrogenase (LDH), and chronic kidney disease were associated with excess risk of other cancers; other CLL-specific risk factors have not shown association with other cancer risk.

While cancer risk is higher, there are no specific recommendations for increased cancer screening in CLL patients. Age- and sex-appropriate screenings should be recommended. In addition, we extend screening beyond age 70–75 years for CLL patients based on the higher frequency of cancers.

Conflicting data exist regarding the risk of cancers after CLL-specific therapy. Chemoimmunotherapy, in particular alkylator-containing regimens, seems to be associated with an increased risk for secondary cancers. Secondary cancers are also seen in the setting of targeted therapies. Bruton tyrosine kinase (BTK) inhibitors appear to have a secondary cancer risk similar to what is seen in the CLL population in general, but potentially a higher rate of nonmelanoma skin cancers. Compared with chemoimmunotherapy, venetoclax plus obinutuzumab has been associated with a numerically but not statistically higher rate of secondary cancers at follow-up of 6 years.

AUTOIMMUNE COMPLICATIONS

Autoimmune complications are frequent in CLL. Most commonly, these include autoimmune cytopenias, but autoimmune complications of other organs including glomerulonephritis, vasculitis, and neuropathies have also been reported. Of the autoimmune cytopenias, the most common is autoimmune hemolytic anemia (AIHA), which is an antibody-mediated destruction of autologous red blood cells (RBCs). Second most common is immune thrombocytopenia (ITP), which shares some features with AIHA and has a similar mechanism targeting platelets. These two syndromes may occur in isolation, sequentially in the same patient, or present in combination as Evan's syndrome. Pure red cell aplasia (PRCA) and autoimmune granulocytopenia (AIG) are comparatively rare and can occur alone or in combination with other autoimmune cytopenias. It is difficult to tease out whether autoimmune cytopenias lead to worse prognosis in CLL because of various complicating factors. However, it is clear that these can lead to significant morbidity, both due to the process itself and due to therapies required for management.

AIHA usually presents as an isolated anemia with an elevated reticulocyte count and features of hemolysis including elevated bilirubin and LDH and low haptoglobin. Detection of a warm IgG antibody on the surface of RBCs with a Coombs test can help solidify the diagnosis, although Coombs-negative cases can occur. Immediate therapy is almost always necessary and consists of transfusion and immunosuppression. Glucocorticoids are often used for initial therapy, although in most cases, additional treatment is needed due to either poor response or recurrence with taper of steroid dosing. Rituximab can be successful, and therapy directed toward the underlying CLL is often effective in more resistant cases. Transfusion of blood in cases of robust AIHA must be initiated with caution as transfusion reactions can be seen due to poorly matched blood, but it should be pursued in those with severe, symptomatic anemia. Death from uncontrolled AIHA can occur in the absence of appropriate supportive care.

ITP can be more difficult to diagnose, as it may be difficult to differentiate from progression of disease due to the lack of laboratory tests that identify platelet destruction from this mechanism. Signs that point toward ITP include isolated thrombocytopenia and rapid decline in platelet levels in the absence of an alternative etiology. A bone marrow biopsy showing normal or increased megakaryocytes can be used to confirm the diagnosis but is often not necessary. In CLL, treatment for ITP is usually instituted when platelet levels drop to 20,000–30,000 or if there is evidence of bleeding complications or need for invasive procedures. Like AIHA, initial therapy consists of glucocorticoids and IVIg, with rituximab also being an effective method to induce long-term remissions. Also, the thrombopoietin receptor agonists romiplostim and eltrombopag are effective in secondary ITP. In many cases, ITP can be successfully treated without treating the underlying CLL. In cases in which anemia or thrombocytopenia appear, it is important to investigate the mechanism because the approach to therapy of autoimmune cytopenias in CLL differs from that for cytopenias due to marrow replacement.

RICHTER'S TRANSFORMATION

One of the most devastating complications of CLL is Richter's transformation, transformation of CLL to an aggressive lymphoma, most commonly DLBCL. The World Health Organization also recognizes Hodgkin's lymphoma (HL) as a variant of Richter's transformation; other aggressive lymphomas are rarely identified. Some older series have included prolymphocytic transformation in this category, although this has much less prognostic impact on long-term outcome. The prevalence of Richter's transformation is difficult to estimate based on previous studies, but one prospective observational study estimated a rate of 0.5% per year for DLBCL and 0.05% per year for HL. Risk factors for development include bulky lymphadenopathy, *NOTCH1* mutations, del(17)(p13.1), and a specific stereotyped IGVH usage. Lymphomas arising in the setting of CLL can either be clonally related or unrelated to the initial CLL, with prognosis significantly better for clonally unrelated lymphomas. In addition, patients with Hodgkin's transformation have improved outcome when treated with standard

Hodgkin's disease treatment. B-cell prolymphocytic leukemia (PLL) arising from CLL is currently classified as Richter's transformation as well; however, clinical features and therapy are quite different, so these two should be differentiated for therapeutic purposes.

Clinical signs of Richter's transformation include rapid progression in adenopathy, often in a specific area, and constitutional symptoms including fatigue, night sweats, fever, and weight loss. LDH is usually high. In suspected cases, the first step is ^{18}FDG-PET/CT (fluorodeoxyglucose–positron emission tomography combined with computed tomography) scan to localize an area for biopsy. Standardized uptake values (SUVs) <5 are consistent with CLL and can rule out Richter's transformation in many cases. SUVs >5 are suspicious for Richter's transformation, with SUVs ≥10 being very concerning. Excisional biopsy is the preferred mode of diagnosis, and fine-needle aspiration should be discouraged.

Therapy for DLBCL Richter's transformation usually involves combination chemoimmunotherapy. Outcomes are poor, with median survivals of 6–16 months in most series for clonally related Richter's versus ~5 years for clonally unrelated. This highlights an area of unmet need in CLL therapy and an area of active investigation. Intensive chemotherapy is ineffective for most patients and results in significant toxicity. For fit patients who achieve a response with therapy, stem cell transplantation has the possibility to induce long-term remissions and should be explored. In addition, chimeric antigen receptor (CAR) T-cell (CAR-T) therapy has shown promising results in small groups of patients and remains an area of active clinical investigation. Limited data using bispecific antibodies are also encouraging. Patients with Hodgkin's disease can be treated according to the algorithm for this disease, with many individuals being cured.

WORKUP OF CLL AND APPROACH TO THERAPY

WORKUP AND STAGING

Workup of a patient with new diagnosis of CLL based on typical immunophenotyping includes a detailed history of infectious disease; family history of CLL; and careful physical examination with attention to the lymph nodes, spleen, and liver. In patients desiring to know the expected natural history of their CLL, prognostic testing using FISH and stimulated karyotype and sequencing for *TP53* and IGHV mutation status can be performed. Imaging with CT scan is usually not necessary unless there are symptoms and concern for intraabdominal nodes out of proportion to peripheral nodes. Bone marrow biopsy is not undertaken until therapy is initiated, except in cases of unexplained cytopenias.

STAGING

There are two widely used staging systems in CLL: The Rai staging system is used more commonly in the United States, whereas the Binet system is more commonly used in Europe. Both characterize CLL on the basis of disease bulk and marrow failure **(Table 112-3)**. Both rely on physical examination and laboratory studies and do not require imaging or bone marrow analysis. While the initial staging systems could reliably predict survival in CLL, with the changes in therapy since the original description of the stages, the impact of initial stage on survival is not as clear. Cytogenetic and genomic testing can help refine outcome of these staging tests. An international collaboration integrated both clinical and genomic staging to better predict outcome at diagnosis and time of initial treatment, which led to development of the CLL International Prognostic Index **(Table 112-4)**. This index has been shown to be useful in prediction of both time to first treatment and outcome with chemoimmunotherapy. Validation in the setting of novel targeted therapies has not occurred.

TABLE 112-3 Staging of CLL

Rai Staging System	
Low risk (stage 0)	Lymphocytosis only
Intermediate risk (stage I/II)	Lymphocytosis with lymphadenopathy, with or without splenomegaly or hepatomegaly
High risk (stage III/IV)	Lymphocytosis with anemia or thrombocytopenia due to bone marrow involvement
Binet Staging System	
A	<3 areas of lymphadenopathy
B	≥3 areas of lymphadenopathy
C	Hemoglobin ≤10 g/dL and/or platelets <100,000/μL

Abbreviation: CLL, chronic lymphocytic leukemia.

TABLE 112-4 CLL International Prognostic Index

Risk Score		
VARIABLE	**ADVERSE FACTOR**	**RISK SCORE**
TP53 status	Deleted or mutated	4
IGHV mutational status	Unmutated	2
β_2-Microglobulin concentration	>3.5 mg/L	2
Clinical stage	Rai I–IV or Binet B–C	1
Age	>65 years	1
Implications of Risk Score		
RISK SCORE	**RISK CLASSIFICATION**	**5-YEAR SURVIVAL (TRAINING SET DATA)**
0-1	Low	93.2%
2-3	Intermediate	79.3%
4-6	High	63.3%
7-10	Very high	23.3%

CRITERIA FOR THE INITIATION OF THERAPY

Currently, a watchful waiting strategy is used for most patients with CLL, with therapy reserved for patients with symptomatic disease. This recommendation is based on multiple trials showing no survival advantage with earlier therapy, although this question continues to be a focus of active investigation.

With the exception of patients participating in early intervention studies in CLL, disease-related symptoms that require the initiation of therapy are outlined in **Table 112-5**. Except for the rare patient who presents with disease requiring urgent therapy, in most cases, these symptoms can be monitored over short periods to determine relatedness to CLL and need for therapy.

INITIAL THERAPY FOR CLL

Over the past decade, the initial therapy of CLL has dramatically changed. Whereas chemoimmunotherapy was once standard for all patients, now most patients are treated with oral therapies targeted

TABLE 112-5 Criteria for the Initiation of Therapy

Symptoms Indicating Need for Therapy in CLL
Evidence of progressive marrow failure (worsening of anemia or thrombocytopenia not due to autoimmune destruction)
Massive (≥6 cm below costal margin), progressive, or symptomatic splenomegaly
Massive (≥10 cm), progressive, or symptomatic lymphadenopathy
Progressive lymphocytosis with an increase of ≥50% over a 2-month period or lymphocyte doubling time <6 months
Autoimmune anemia or thrombocytopenia not responsive to standard therapy
Symptomatic or functional extranodal involvement
Constitutional symptoms (one or more of the following: unintentional weight loss ≥10% over 6 months, significant fatigue, fevers ≥100.5°F for 2+ weeks without infection, night sweats for >1 month without infection)

Abbreviation: CLL, chronic lymphocytic leukemia.

against BTK or BCL2 with an anti-CD20 monoclonal antibody. This continues to be an area of active investigation, with standards of care shifting rapidly. The major classes of these therapies will be outlined here.

BTK Inhibitors BTK is an attractive target in CLL because, unlike other kinases in the BCR pathway, BTK does not have natural redundancy and is relatively selective for B cells, so inhibition leads to a predominant B-cell–specific phenotype. The first-in-class covalent BTK inhibitor is ibrutinib, which is relatively selective for BTK but also inhibits a number of structurally similar kinases. As initial therapy, ibrutinib was initially compared with chlorambucil (RESONATE study), and there was an 84% lower risk of progression or death with ibrutinib, with 59% of ibrutinib-treated patients alive and progression-free at 7 years. Subsequent studies have compared ibrutinib alone or with the anti-CD20 antibody rituximab to standard chemoimmunotherapy with fludarabine plus cyclophosphamide plus rituximab (FCR) or bendamustine plus rituximab (BR) and shown superiority of targeted therapy to chemoimmunotherapy. Ibrutinib also has immune modulatory roles to expand and also enhance T-cell function that may improve CAR-T efficacy. Side effects noted to occur with this class of agents include arthralgias/myalgias, rash, diarrhea, dyspepsia, bruising/bleeding (particularly when on antiplatelet/anticoagulation therapy or with surgery), hypertension, atrial fibrillation, and ventricular arrhythmias.

Two second-generation covalent BTK inhibitors, acalabrutinib and zanubrutinib, were developed to be more specific for BTK than ibrutinib and consequentially show better tolerability. Two trials performed in relapsed/refractory CLL have positioned acalabrutinib and zanubrutinib as preferred BTK inhibitors compared with ibrutinib. Acalabrutinib was compared head-to-head with ibrutinib in previously treated patients with high-risk relapsed CLL in the ELEVATE-RR trial. Acalabrutinib was shown to be noninferior to ibrutinib in terms of efficacy and to have lower rates of atrial fibrillation, hypertension, myalgias/arthralgias, bruising, and skin and nail changes than reported with ibrutinib. Zanubrutinib was compared head-to-head with ibrutinib in the ALPINE trial, which enrolled patients with relapsed CLL without regard to risk status. In this study, zanubrutinib was shown to be superior to ibrutinib in terms of overall response rate and progression-free survival (PFS). Zanubrutinib was also associated with lower rates of atrial fibrillation but similar rates of other adverse events.

Because acalabrutinib and zanubrutinib are newer, follow-up is shorter than with ibrutinib, but all three covalent BTK inhibitors appear to be similarly active in the frontline setting. Acalabrutinib was studied in the treatment-naïve setting in the ELEVATE-TN trial, where acalabrutinib resulted in a 6-year PFS of 62% and acalabrutinib given with obinutuzumab resulted in a 4-year PFS of 78%. Zanubrutinib was studied in treatment-naïve CLL in the SEQUOIA study, where 2-year PFS was 85.5% for patients treated with zanubrutinib.

Importantly, with the follow-up that is available from frontline studies of covalent BTK inhibitors in CLL, traditional prognostic factors, including IGHV mutational status and FISH, have less impact on outcome. Indeed, age and performance status were the only variables that predicted survival in the ELEVATE-TN trial.

BCL2 Inhibitor Venetoclax is an orally bioavailable, selective allosteric inhibitor of the antiapoptotic protein BCL2, which is upregulated in CLL. Similar to the BTK inhibitors, phase 3 trials support the frontline use of venetoclax in combination with obinutuzumab (VO) compared with chemoimmunotherapy. The CLL14 study compared VO versus chlorambucil plus obinutuzumab in previously untreated patients with coexisting medical conditions. Unlike BTK inhibitors, which are continuously administered until disease progression, VO treatment is administered for a fixed duration of 1 year. Median PFS for VO was 76.2 months, compared with 36.4 months for patients treated with chlorambucil plus obinutuzumab. The CLL13/GAIA trial also studied VO, as well as VO plus ibrutinib (IVO) and venetoclax plus rituximab (VR), compared with effective chemoimmunotherapy regimens (FCR for younger patients and BR for older patients) in fit patients. At 4 years, VO and IVO showed superior PFS compared with chemoimmunotherapy (81.8% and 85.5%, respectively, vs 77.2%), but VR was not superior to chemoimmunotherapy. Side effects associated with venetoclax include tumor lysis syndrome, neutropenia, and nausea/vomiting/diarrhea. Importantly, genomic risk features including IGHV mutational status and FISH/cytogenetics appear to be more relevant to PFS with fixed-duration VO therapy as compared with indefinite BTK inhibitor therapy.

Targeted Therapy Combinations Due to synergy between BTK and BCL2 inhibition, there has been considerable interest in studies combining agents with these two mechanisms to allow for fixed-duration therapies. As described earlier, 1-year fixed-duration IVO was shown to be superior to chemoimmunotherapy in previously untreated fit patients in the CLL13/GAIA study. The GLOW study is a registration trial comparing ibrutinib plus venetoclax (IV) to chemoimmunotherapy in previously untreated older or unfit patients. In this trial with 1 year of IV, 42-month PFS was 74.6% for IV compared with 24.8% for chlorambucil plus obinutuzumab. Although this study led to regulatory approval of IV in Europe, it is not approved by the U.S. Food and Drug Administration (FDA). It is not yet clear whether IV or IVO is a more effective therapy than the other fixed-duration standard, VO. Current studies are also using more selective inhibitors of BTK in an attempt to improve efficacy and safety of these combinations.

Chemoimmunotherapy For the most part, targeted therapy has supplanted chemoimmunotherapy in CLL. However, long-term follow-up of studies of FCR has demonstrated that a subset of patients treated with this regimen can have durable responses over 20 years, with a likely cure of CLL. This group is composed almost exclusively of patients with mutated *IGVH* and favorable cytogenetics. However, despite the efficacy of this regimen, short- and long-term toxicities limit its adaptability to many patients with IGHV-mutated disease. Short-term toxicities are mostly related to myelosuppression and include neutropenia and infection. Long-term cytopenias are less common, but they do occur. Also, there is about a 3–5% risk of therapy-related myeloid neoplasm with this regimen that is almost always fatal. In the E1912 study of FCR versus ibrutinib plus rituximab (IR), at follow-up, there was no difference in PFS or overall survival between FCR and IR for patients with mutated IGHV, suggesting that a place for this regimen may remain in clinical practice. In addition, current studies are focused on limiting chemotherapy and/or adding novel agents in efforts to achieve cure but limit toxicity.

THERAPY OF RELAPSED CLL

Currently, the mainstays of treatment for relapsed CLL are the same classes as initial therapy, and the choice of second-line therapy is heavily dependent on the agent that was used in the frontline setting. The optimal sequencing of targeted agents in CLL has not been established; however, the available data suggest that the sequence of either BTK inhibitor and then BCL2 inhibitor and the reverse are both acceptable. In addition, some patients treated initially with venetoclax-based regimens can likely be successfully retreated with venetoclax. In a trial of venetoclax for patients who had relapsed after ibrutinib therapy, overall response rate (ORR) was 65%, with a median PFS of ~2 years, in a very heavily pretreated patient population. Retrospective data of a BTK inhibitor given after venetoclax suggest that this sequence is also effective, with an ORR of 84% and median PFS of 32 months. PI3K inhibitors also have activity in relapsed CLL; however, activity following both BTK and BCL2 inhibitors is likely minimal. In addition, many new agents are in development in CLL, including novel oral targeted therapies, antibodies, and immune-based treatments.

Noncovalent Inhibitors of BTK Despite the activity of covalent BTK inhibitors in CLL, a subset of patients will eventually relapse, and the primary mechanism of acquired resistance to ibrutinib, acalabrutinib, and zanubrutinib is acquisition of a mutation at the binding site of the drug (predominantly *BTK* C481S). Noncovalent BTK inhibitors

TABLE 112-6 Response Criteria in CLL

	LYMPHOCYTE COUNT	LYMPH NODES[a]	SPLEEN/LIVER SIZE[b]	BONE MARROW[c]	PERIPHERAL BLOOD COUNTS
CR	<4000/μL	None >1.5 cm	Not palpable	Normocellular, <30% lymphocytes, no B lymphoid nodules	• Platelet count >100,000/μL • Hemoglobin >11 g/dL • Neutrophils >1500/μL

have been developed to overcome this resistance mechanism by binding both reversibly and to alternative sites on BTK. Pirtobrutinib is the first in class of these agents and is an extremely selective inhibitor of BTK that has achieved accelerated approval by the U.S. FDA for use in patients who have been previously treated with both BTK and BCL2 inhibitors. This is based on the BRUIN study, where an overall response rate of 82.2% and median PFS of 19.6 months were seen in a heavily pretreated high-risk group of patients, with equivalent efficacy noted for patients with C481S mutations in *BTK*.

Immune Therapies Immune therapies in CLL are currently focused in the relapsed setting and include allogenic stem cell transplantation, CAR-T therapy, and bispecific antibodies.

Stem cell transplantation is a curative approach to CLL. Because most CLL patients are older and many have significant comorbidities, myeloablative transplants incur extensive morbidity and mortality, making them prohibitive in many individuals. Reduced-intensity conditioning (RIC) allogeneic transplants have been successfully incorporated into the treatment of patients up to ~75 years in age but still have a ≥50% frequency of chronic graft-versus-host disease. This is still considered a standard treatment in CLL but has fallen out of favor with the introduction of well-tolerated novel agents, as well as clinical trials of CAR-T therapy. CD19 CAR-T trials have not been as successful in CLL as they have in other B-cell malignancies, due to the immunosuppression associated with the disease. The most robust data have come with lisocabtagene maraleucel (liso-cel), where in the TRANSCEND CLL 004 trial, the ORR was 43%, with a median PFS of 11.9 months in patients previously treated with BTK inhibitors and venetoclax. Many current trials are focused on optimizing CD19 CAR-T by adding agents such as BTK inhibitors or PI3K inhibitors or modifying the CAR-T structure, and other studies are testing different targets outside of CD19. This area remains a focus of intense investigation in CLL.

ASSESSING RESPONSE TO THERAPY AND MINIMAL RESIDUAL DISEASE IN CLL

Following the completion of therapy or during therapy for indefinite targeted agents, response is initially assessed using physical examination and laboratory studies **(Table 112-6)**. If residual disease is not detected using these methodologies, CT scans are used to assess response. Bone marrow biopsies with flow cytometry are indicated if no disease is detected to confirm CR.

It has been established in various malignancies that complete tumor eradication is associated with longer survival. In CLL, if no malignant cells can be detected in the bone marrow down to a level of 1 CLL cell in 10^4 leukocytes (0.01%), the patient is said to be negative for minimal residual disease (MRD). Following combination chemoimmunotherapy, eradication of MRD correlates with long-term survival and potentially cure in a subset of patients receiving FCR chemoimmunotherapy. Undetectable MRD in blood or bone marrow is also associated with improvement in PFS in venetoclax-based regimens. However, eradication of MRD has not been shown to be a meaningful endpoint with BTK inhibitors as monotherapy. Higher sensitivity of 1 CLL in 10^6 leukocytes (0.0001%) can be obtained using next-generation sequencing methods such as ClonoSeq. Treatment of MRD-relapsing CLL is being explored as part of clinical trials.

CONCLUSION

CLL is treated only when it becomes symptomatic. At the time of therapy, FCR chemoimmunotherapy in a small subset of young patients with very good risk CLL is potentially curative. In the majority of patients with symptomatic CLL, targeted therapy directed at BTK and/or BCL2 can produce durable remissions and allow patients many years of disease-free survival.

113 Non-Hodgkin's Lymphoma

Caron A. Jacobson, Dan L. Longo

Non-Hodgkin's lymphomas (NHLs) are cancers of mature B, T, and natural killer (NK) cells. They were distinguished from Hodgkin's lymphoma (HL) upon recognition of the Reed-Sternberg (RS) cell and differ from HL with respect to their biologic and clinical characteristics. Whereas ~80–85% of patients with HL will be cured of their lymphoma by chemotherapy with or without radiotherapy, the prognosis and natural history of NHL tend to be more variable. NHL can be classified as either a mature B-NHL or a mature T/NK-NHL depending on whether the cancerous lymphocyte is a B, T, or NK cell, respectively. Within each category are lymphomas that grow quickly and behave aggressively, as well as lymphomas that are more indolent, or slow growing, in nature. For a list of the World Health Organization (WHO) classification of lymphoid neoplasms, see **Table 113-1**.

EPIDEMIOLOGY AND ETIOLOGY

In 2023, it is estimated that there will be 80,550 new cases of NHL in the United States, ~4% of all new cancers in both males and females, making it the seventh most common cause of cancer-related death in both women and men. The incidence is nearly 10 times the incidence of HL. There is a slight male-to-female predominance and a higher incidence for Caucasians than for African Americans. The incidence rises steadily with age, especially after age 40, but lymphomas are also among the most common malignancies in adolescent and young adult patients. The incidence of NHL has nearly doubled over the past 20–40 years and continues to rise by 1.5–2% each year. Patients with both primary and secondary immunodeficiency states are predisposed to developing NHL. These include patients with HIV infection, patients who have undergone organ transplantation, and patients with inherited immune deficiencies and autoimmune conditions. The 5-year survival rate for NHL is 74% and is higher for Caucasians than it is for African Americans.

The incidence of NHL and the patterns of expression of the various subtypes differ geographically and across age groups. T-cell lymphomas are more common in Asia than in Western countries, whereas certain subtypes of B-cell lymphomas such as follicular lymphoma (FL) are more common in Western countries. A specific subtype of NHL known as the angiocentric nasal T/NK-cell lymphoma has a striking geographic occurrence, being most frequent in southern Asia and parts of Latin America. Another subtype of NHL associated with infection by human T-cell lymphotropic virus (HTLV) 1 is seen particularly in southern Japan and the Caribbean (see **Chap. 207**). Likewise, there are differences in the age-dependent incidence of NHL by histologic subtype, with aggressive lymphomas like diffuse large B-cell lymphoma (DLBCL) and Burkitt's lymphoma (BL) being the most common entities in children, and DLBCL and indolent lymphomas including FL being the most common forms in adults. The relative frequencies of the various types of lymphoid malignancies, including HL, plasma cell disorders, and lymphoid leukemias, are shown in **Fig. 113-1.**

A number of environmental factors have been implicated in the occurrence of NHL, including infectious agents, chemical exposures, and medical treatments. Several studies have demonstrated an association between exposure to agricultural chemicals and an increased incidence of NHL. Patients treated for HL can develop NHL; it is unclear whether this is a consequence of the HL or its treatment, especially radiation.

Several NHLs are associated with infectious agents **(Table 113-2)**. Epstein-Barr virus (EBV) is associated with the development of BL in Central Africa and the occurrence of aggressive NHL in immunosuppressed patients in Western countries. The majority of primary central nervous system (CNS) lymphomas are associated with EBV. EBV infection is strongly associated with the occurrence of extranodal nasal NK/T-cell lymphomas in Asia and South America. HTLV-1 infects T cells and leads directly to the development of adult T-cell lymphoma (ATL) in a small percentage of patients infected as babies through ingestion of breast milk of infected mothers. The median age of patients with ATL is ~56 years; thus, HTLV-1 demonstrates a long latency from infection to oncogenesis **(Chap. 207)**. Infection with HIV predisposes to the development of aggressive B-cell NHL. This may be through overexpression of interleukin 6 by infected macrophages. Infection of the stomach by the bacterium *Helicobacter pylori* induces the development of gastric mucosa-associated lymphoid tissue (MALT) lymphomas. This association is supported by evidence that patients treated with antibiotics to eradicate *H. pylori* have regression of their MALT lymphoma. The bacterium does not transform lymphocytes to produce the lymphoma; instead, a vigorous immune response is made to the bacterium, and the chronic antigenic stimulation leads to the neoplasia. MALT lymphomas of the skin may be related to *Borrelia* species infections in Europe, those of the eyes to *Chlamydophila psittaci*, and those of the small intestine to *Campylobacter jejuni*. Chronic hepatitis C virus infection has been associated with the development of lymphoplasmacytic lymphoma and splenic marginal zone lymphoma (MZL). Human herpesvirus 8 is associated with primary effusion lymphoma in HIV-infected persons and multicentric Castleman's disease, a diffuse lymphadenopathy associated with systemic symptoms of fever, malaise, and weight loss.

In addition to infectious agents, a number of other diseases or exposures may predispose to developing lymphoma **(Table 113-3)**. Diseases of inherited and acquired immunodeficiency as well as autoimmune

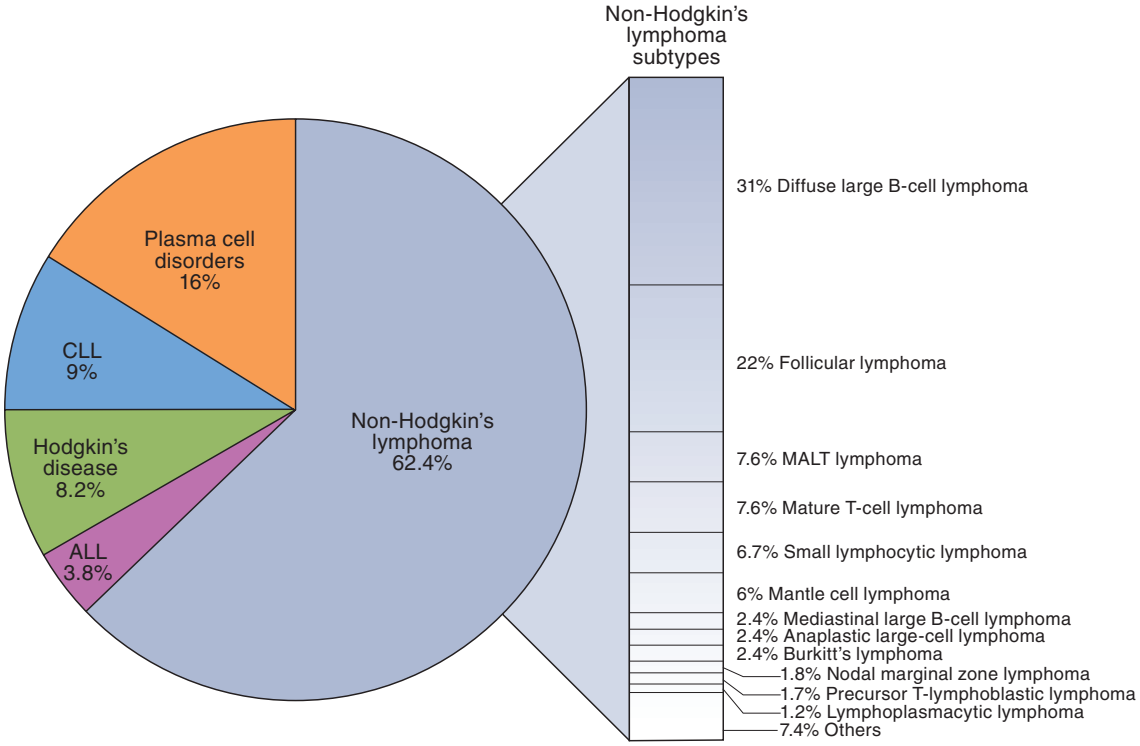

FIGURE 113-1 Relative frequency of lymphoid malignancies. ALL, acute lymphoid leukemia; CLL, chronic lymphocytic leukemia; MALT, mucosa-associated lymphoid tissue.

diseases are associated with an increased incidence of lymphoma. The association between immunosuppression and induction of NHLs is compelling because if the immunosuppression can be reversed, a percentage of these lymphomas regress spontaneously. The incidence of NHL is nearly a hundredfold increased for patients undergoing organ transplantation necessitating chronic immunosuppression and is greatest in the first year posttransplant. About 30% of these arise as a polyclonal B-cell proliferation that evolves into a clonal B-cell malignancy. The NHLs that occur in the context of immunosuppression or immunodeficiency, including HIV infection, are frequently associated with EBV. Histologically, DLBCLs are most frequently associated with immunosuppression and autoimmune diseases, although almost all histologies can be seen, especially MALT lymphomas in the context of autoimmune diseases such as Sjögren's syndrome and Hashimoto's thyroiditis. The rare inherited immunodeficiency diseases X-linked lymphoproliferative syndrome, Wiskott-Aldrich syndrome, Chédiak-Higashi syndrome, ataxia-telangiectasia, and common variable immunodeficiency syndrome are complicated by highly aggressive lymphomas. The elevated incidence of lymphoma in iatrogenic immunosuppression, AIDS, and autoimmune disease argues strongly for immune dysregulation contributing to the pathogenesis of some lymphomas. An increased risk of NHL has been observed in first-degree relatives with NHL, HL, or chronic lymphocytic leukemia (CLL). In large database studies, ~9% of patients with lymphoma or CLL have a first-degree relative with a lymphoproliferative disorder.

IMMUNOLOGY

All lymphoid cells are derived from a common hematopoietic progenitor that gives rise to lymphoid, myeloid, erythroid, monocyte, and megakaryocyte lineages. Through the ordered and sequential activation of a series of transcription factors, the cell first becomes committed to the lymphoid lineage and then gives rise to B and T cells.

About 90% of all lymphomas are of B-cell origin. A cell becomes committed to B-cell development when it expresses the master B lineage transcription factor PAX5, which ultimately results in a transcriptional program that leads to the rearrangement of its immunoglobulin genes, which involves chromosomal recombination as well as somatic hypermutation to create an immunoglobulin gene that is unique to that B cell. The sequence of cellular changes, including changes in

TABLE 113-3 Diseases or Exposures Associated with Increased Risk of Development of Malignant Lymphoma

Inherited immunodeficiency disease	Autoimmune disease
Klinefelter's syndrome	Sjögren's syndrome
Chédiak-Higashi syndrome	Celiac sprue
Ataxia-telangiectasia syndrome	Rheumatoid arthritis and systemic lupus erythematosus
Wiskott-Aldrich syndrome	Chemical or drug exposures
Common variable immunodeficiency disease	Phenytoin
Acquired immunodeficiency diseases	Dioxin, phenoxy herbicides
Iatrogenic immunosuppression	Radiation
HIV-1 infection	Prior chemotherapy and radiation therapy
Acquired hypogammaglobulinemia	Anti-TNF drugs

Abbreviations: HIV, human immunodeficiency virus; TNF, tumor necrosis factor.

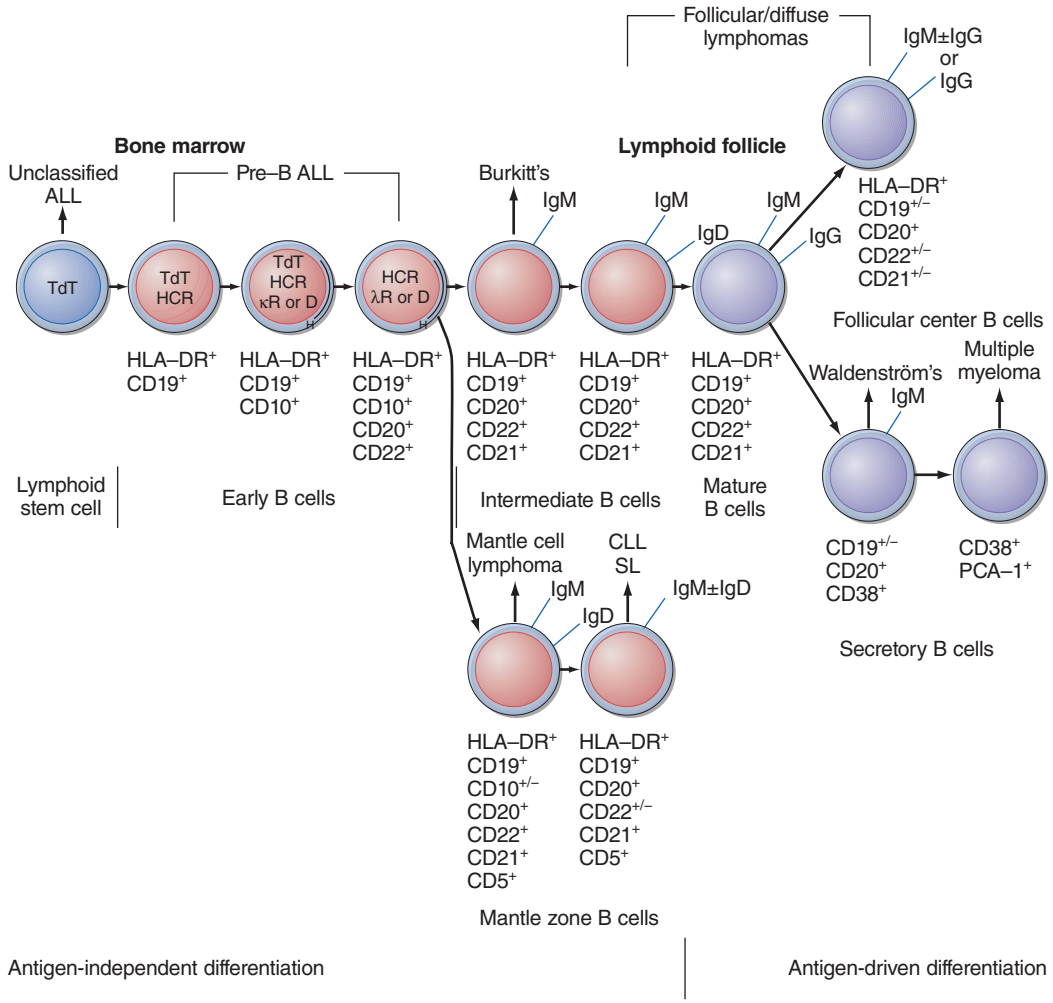

FIGURE 113-2 Pathway of normal B-cell differentiation and relationship to B-cell lymphomas. HLA-DR, CD10, CD19, CD20, CD21, CD22, CD5, and CD38 are cell markers used to distinguish stages of development. Terminal transferase (TdT) is a cellular enzyme. Immunoglobulin heavy chain gene rearrangement (HCR) and light chain gene rearrangement or deletion (κR or D, λR or D) occur early in B-cell development. The approximate normal stage of differentiation associated with particular lymphomas is shown. ALL, acute lymphoid leukemia; CLL, chronic lymphocytic leukemia; SL, small lymphocytic lymphoma.

cell-surface phenotype that characterizes normal B-cell development, is shown in Fig. 113-2. Most B-cell lymphomas arise following the process of immunoglobulin gene recombination and somatic hypermutation, which leads to class switching and affinity maturation of the mature immunoglobulin, respectively, suggesting that it is the error-prone nature of these genetic events that contributes to oncogenesis. Certainly the frequency of chromosomal translocations that result in the activation of an oncogene or the inactivation of a tumor-suppressor gene in B-cell NHL may be the result of these normal cellular processes gone awry (see below). In addition, the key roles of the transcription factors MYC and BCL6 and the antiapoptotic protein BCL2 in the process of B-cell development explain why the genes encoding these proteins are commonly mutated in B-cell lymphomas.

A cell becomes committed to T-cell differentiation upon migration to the thymus and rearrangement of T-cell receptor (TCR) genes. This requires the expression of the T-cell master regulatory transcription factor, NOTCH-1. As in B cells, the development of the mature TCR involves the rearrangement and recombination of the TCR loci, which is error-prone and potentially oncogenic. The sequence of the events that characterize T-cell development is depicted in Fig. 113-3.

Although lymphoid malignancies often retain the cell-surface phenotype of lymphoid cells at particular stages of differentiation, this information is of little clinical or prognostic consequence. The so-called stage of differentiation of a malignant lymphoma does not predict its natural history. The antigen footprint, or immunophenotype, of the cell, however, is valuable diagnostically as it allows for the distinguishing of specific NHL subtypes. It can be detected by flow cytometry of single-cell suspension from blood, bone marrow, body fluid, or disaggregated tissue using fluorescently labeled antibodies against these antigens or by immunohistochemical staining of paraffin-embedded tissue sections with enzyme-linked antibodies against these antigens followed by a colorimetric reaction.

As already mentioned, malignancies of lymphoid cells are associated with recurring genetic abnormalities including chromosomal translocations and genetic mutations that may in part be the result of aberrant immunoglobulin or TCR development. While specific genetic abnormalities have not been identified for all subtypes of lymphoid malignancies, it is presumed that they exist. As previously discussed, B cells are even more susceptible to acquiring mutations during their maturation in germinal centers; the generation of antibody of higher affinity requires the introduction of mutations into the variable region genes in the germinal centers. Given this, other nonimmunoglobulin genes, e.g., *bcl-6*, may acquire mutations as well. Likewise, many lymphomas contain balanced chromosomal translocations involving the antigen receptor genes; immunoglobulin genes on chromosomes 2, 14, and 22 in B cells; and T-cell antigen receptor genes on chromosomes 7 and 14 in T cells. The rearrangement of chromosome segments to generate mature antigen receptors must create a site of vulnerability to aberrant recombination. Examples of this type of event include the (8;14)(q24;q32) translocation in BL, involving the *MYC* proto-oncogene and the IgH gene; the (14;18)(q32;q32) translocation in FL, involving the *BCL2* proto-oncogene and the IgH gene; and the (11;14) (q13;q32) translocation in mantle cell lymphoma (MCL), involving the gene encoding cyclin D1 (*CCDN1*) and the IgH gene. Less commonly, chromosomal

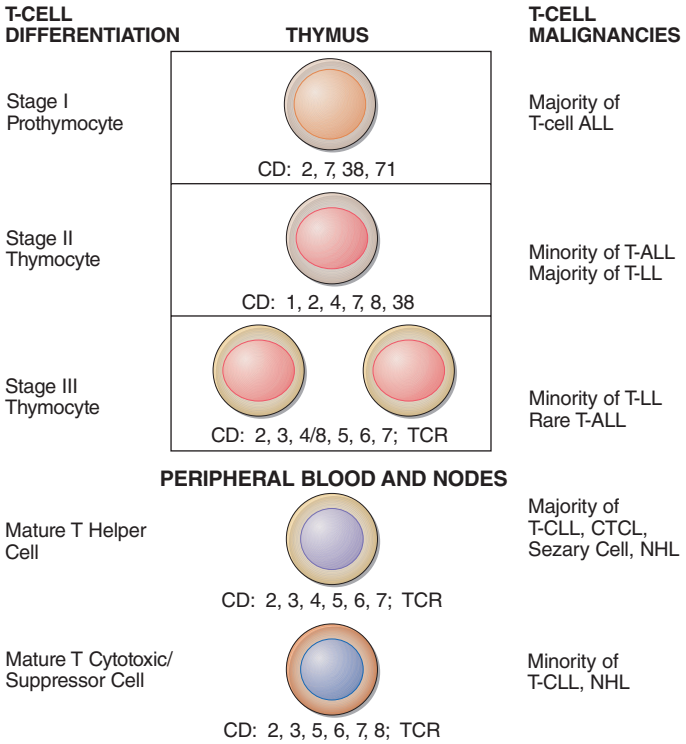

FIGURE 113-3 Pathway of normal T-cell differentiation and relationship to T-cell lymphomas. CD1, CD2, CD3, CD4, CD5, CD6, CD7, CD8, CD38, and CD71 are cell markers used to distinguish stages of development. T-cell antigen receptors (TCR) rearrange in the thymus, and mature T cells emigrate to nodes and peripheral blood. ALL, acute lymphoid leukemia; CTCL, cutaneous T-cell lymphoma; NHL, non-Hodgkin's lymphoma; T-ALL, T-cell ALL; T-CLL, T-cell chronic lymphocytic leukemia; T-LL, T-cell lymphoblastic lymphoma.

TABLE 113-4 Genetic Features of B- and T-Cell Lymphomas

GENETIC FEATURE	GENES	LYMPHOMA

translocations produce fusion genes that encode chimeric oncogenic proteins. Examples of this include the (2;5)(p23;q35) translocation involving the *ALK* and *NPM1* genes in anaplastic large-cell lymphoma (ALCL) and the t(11;18)(q21;q21) translocation involving the *API2* and *MLT* genes in MALT lymphoma. Table 113-4 presents the most common translocations and associated oncogenes for various subtypes of lymphoid malignancies.

Gene profiling using array technology allows the simultaneous assessment of the expression of thousands of genes. This technology provides the possibility to identify new genes with pathologic importance in lymphomas, the identification of patterns of gene expression with diagnostic and/or prognostic significance, and the identification of new therapeutic targets. Recognition of patterns of gene expression is complicated and requires sophisticated mathematical techniques. Early successes using this technology in lymphoma include the identification of previously unrecognized subtypes of DLBCL whose gene expression patterns resemble either those of follicular or germinal center B (GCB) cells or activated peripheral blood B cells (ABC). Patients whose lymphomas have a GCB-like pattern of gene expression have a considerably better prognosis than those whose lymphomas have a pattern resembling ABCs. This improved prognosis is independent of other known prognostic factors. These subcategories have been more specifically refined into five subcategories, using more advanced genetic sequencing techniques, that differ with respect to biology and driver genes, as well as prognosis, and may have important treatment implications in the future. Similar information is being generated in FL and MCL. The challenge remains to provide information from such techniques in a clinically useful time frame.

APPROACH TO THE PATIENT

Regardless of the type of lymphoid malignancy, the initial evaluation of the patient should include performance of a careful history and physical examination. These will help confirm the diagnosis, identify those manifestations of the disease that might require prompt attention, and aid in the selection of further studies to optimally characterize the patient's status to allow the best choice of therapy. It is difficult to overemphasize the importance of a carefully done history and physical examination. They might provide observations that lead to reconsidering the diagnosis, provide hints at etiology, clarify the stage, and allow the physician to establish rapport with the patient that will make it possible to develop and carry out a therapeutic plan.

The duration of symptoms and pace of symptomatic progression are important in distinguishing aggressive from more indolent lymphomas, as are the presence or absence of "B" symptoms, such as fevers, night sweats, or unexplained weight loss. Patients should be asked about localizing symptoms that may point toward lymphomatous involvement of specific sites, such as the chest, abdomen, or CNS. Comorbid diagnoses that may impact therapy or monitoring on therapy should be reviewed and acknowledged, including a history of diabetes or congestive heart failure. A physical examination should pay close attention to all the peripherally accessible sites of lymph nodes; the liver and spleen size; Waldeyer's ring; whether there is a pleural or pericardial effusion or abdominal ascites; whether there is an abdominal, testicular, or breast mass; and whether there is cutaneous involvement because all of these findings may influence further evaluation and disease management.

Laboratory studies should include a complete blood count, routine chemistries, liver function tests, and serum protein electrophoresis to document the presence of circulating monoclonal paraproteins. The serum β_2-microglobulin level and serum lactate dehydrogenase (LDH) are important independent prognostic factors in NHL. Staging of certain diseases may involve a bone marrow biopsy; results of other laboratory and staging studies may also warrant a marrow evaluation. A lumbar puncture for evaluation of lymphomatous involvement may be indicated in the setting of concerning neurologic signs or symptoms or diseases that are high

risk for CNS involvement. The latter may include disease involving the paranasal sinuses, testes, breast, kidneys, adrenal glands, and epidural space, as well as highly aggressive histologies like BL. Since HIV and hepatitis B and C infection can be risk factors for developing NHL, and since treatment for some NHLs can result in the potentially life-threatening reactivation of hepatitis B, patients with a new diagnosis of NHL should be screened for these viruses as well.

Lymphoma histology and clinical presentation dictate which imaging studies should be ordered. Chest, abdominal, and pelvic computed tomography (CT) scans are essential for accurate staging to assess lymphadenopathy for indolent lymphomas, whereas positron emission tomography (PET) using ^{18}F-fluorodeoxyglucose (FDG-PET) is useful for aggressive lymphomas, including BL, DLBCL, plasmablastic lymphoma, and the aggressive T-cell NHLs. FDG-PET is highly sensitive for detecting both nodal and extranodal sites involved by NHL. The intensity of FDG avidity, or standardized uptake value (SUV), correlates with histologic aggressiveness, and may be useful in cases when disease transformation of an indolent lymphoma to a diffuse aggressive lymphoma is suspected. PET scanning can also differentiate between treated disease and active disease at the end of therapy in patients with residual masses on CT scans. Consensus recommendations regarding PET scanning were published as a result of an International Harmonization Project and state that PET should only be used for DLBCL and HL, that scanning during therapy should only be done as part of clinical trials, and that the end-of-treatment scan should not be done before 3 weeks but preferably 6–8 weeks after chemotherapy and 8–12 weeks after radiation or chemoradiotherapy. There is no evidence that long-term follow-up should include PET scanning. More recently, though, PET scan results at the end of therapy for FL have been associated with prognosis, with patients with residual PET-avid disease at the end of treatment having a poorer prognosis than those who are PET negative, and so it may be used for this prognostic purpose. Finally, magnetic resonance imaging (MRI) is useful in detecting bone, bone marrow, and CNS disease in the brain and spinal cord. The staging evaluation is outlined in **Table 113-5**.

The Ann Arbor staging system developed in 1971 for HL was adapted for staging NHLs **(Table 113-6)**. This staging system focuses on the number of tumor sites (nodal and extranodal), location, and the presence or absence of systemic, or B, symptoms. Table 113-6 summarizes the essential features of the Ann Arbor system.

This anatomic based system is less useful in NHL, which disseminates widely, not in an ordered stepwise fashion. A majority of patients with NHL have advanced-stage disease at diagnosis. Apart from early-stage disease limited to a radiation field where local therapy with radiation is an option, all other disease is treated the same regardless of stage. Histology and clinical parameters at presentation are more important than stage with respect to prognosis. The International Prognostic Index (IPI) is perhaps the best predictor of outcome **(Table 113-7)**. The IPI was developed based on the analysis of >2000 patients with aggressive NHLs treated with an anthracycline-containing regimen. Age (≤60 vs >60), serum LDH (≤ normal vs > normal), performance status (0 or 1 vs 2–4), stage (I or II vs III or IV), and extranodal involvement (<1 site vs >1 site) were identified as independently prognostic for overall survival (OS). A point is awarded for each risk factor and then summed, defining four risk groups: low (0 or 1); low-intermediate (2); high-intermediate (3); and high (4–5). The 5-year OS rates for patients with scores of 0–1, 2, 3, and 4–5 were 73, 51, 43, and 26%, respectively. The age-adjusted IPI separates patients ≤60 from patients >60. For the age-adjusted IPI, only stage, LDH, and performance status were important. Younger patients with 0, 1, 2, or 3 risk factors had 5-year survival rates of 83, 69, 46, and 32%, compared to 56, 44, 37, and 21% for older patients. When factoring in the introduction and clinical benefit of rituximab, the 4-year progression-free survival rates are 94, 80, and 53% for 0–1, 2, or 3 or more risk factors, respectively.

The Follicular Lymphoma International Prognostic Index (FLIPI) is a similar predictive model for FL, derived from the analysis of >4000 patients. Age >60, stage III/IV disease, the

TABLE 113-6 Ann Arbor Staging for Lymphoma[a]

STAGE	DESCRIPTION
I	Involvement of a single lymph node region (I) or single extranodal site (IE)
II	Involvement of two or more lymph node regions or lymphatic structures on the same side of the diaphragm alone (II) or with involvement of limited, contiguous, extralymphatic organ or tissue (IIE)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may include the spleen (IIIS), or limited, contiguous, extralymphatic organ or tissue (IIIE), or both (IIIES)
IV	Diffuse or disseminated foci of involvement of one or more extralymphatic organs or tissues, with or without associated lymphatic involvement

[a]All stages are further subdivided according to the absence (A) or presence (B) of systemic B symptoms including fevers, night sweats, and/or weight loss (>10% of body weight over 6 months prior to diagnosis).

TABLE 113-7 International Prognostic Index for NHL

Five Clinical Risk Factors	
Age ≥60 years	
Serum lactate dehydrogenase levels elevated	
Performance status ≥2 (ECOG) or ≤70 (Karnofsky)	
Ann Arbor stage III or IV	
>1 site of extranodal involvement	
For Diffuse Large B-Cell Lymphoma	
0, 1 factor = low risk	35% of cases; 5-year survival, 73%
2 factors = low-intermediate risk	27% of cases; 5-year survival, 51%
3 factors = high-intermediate risk	22% of cases; 5-year survival, 43%
4, 5 factors = high risk	16% of cases; 5-year survival, 26%
For Diffuse Large B-Cell Lymphoma Treated With R-CHOP	
0 factor = good	10% of cases; 4-year survival, 94%
1, 2 factors = intermediate	45% of cases; 4-year survival, 80%
3, 4, 5 factors = poor	45% of cases; 4-year survival, 53%

Abbreviations: ECOG, Eastern Cooperative Oncology Group; NHL, non-Hodgkin's lymphoma; R-CHOP, rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone.

presence of >4 nodal sites, an elevated serum LDH concentration, and a hemoglobin <12 were identified as independent prognostic variables, and summation of each variable identified three risk groups. The median 10-year survival rates for patients with zero to one (low risk), two (intermediate risk), or three or more (high risk) of these adverse factors were 71, 51, and 36%, respectively. Similar disease-specific IPIs have been developed for MCL and peripheral T-cell lymphoma (PTCL) as well. These prognostic indices take into account the proliferative index and cell-surface markers, respectively.

Finally, as mentioned previously, gene expression profiling has identified DLBCLs with differential prognoses: GCB and ABC, where GCB-like DLBCL is associated with a significantly better OS. A more readily accessible immunohistochemical algorithm has been developed, based on the presence or absence of CD10, BCL6, and MUM1, that correlates closely with gene expression profiles and can differentiate the majority of GCB from non–GCB-like DLBCL. These profiles have prognostic importance but, to date, do not alter treatment recommendations for the primary treatment of DLBCL. Current clinical trials do stratify by DLBCL subtype, and it appears that agents like the Bruton tyrosine kinase (BTK) inhibitor ibrutinib and lenalidomide are most active in non-GCB DLBCL in the relapsed setting. Treatment may then be differentiated by these subtypes in the future.

CLINICAL FEATURES, TREATMENT, AND PROGNOSIS OF SPECIFIC NHL

MATURE B-CELL NEOPLASMS

B-cell NHLs can be characterized into two broad groups—those that behave aggressively, require immediate or urgent treatment with combination chemotherapy regimens, and are potentially curable; and those that are more indolent in nature, can be observed and treated only when they cause symptoms or signs of organ function impairment, are very responsive to therapy, but are not ultimately curable in the vast majority of cases. Among the aggressive diseases, the most common is DLBCL, and the most rapidly growing is BL. FL is the second most common NHL and the most common indolent NHL. Other indolent NHLs include MZL, lymphoplasmacytic lymphoma (LPL), and hairy cell leukemia (HCL). MCL is an intermediate-grade lymphoma that shares some characteristics with the aggressive lymphomas (fairly urgent need for treatment and aggressive upfront combination chemotherapy regimens), but like the indolent lymphomas, it is not readily curable with conventional-dose therapies.

Burkitt's Lymphoma Burkitt's lymphoma/leukemia (BL) is a rare disease in adults in the United States, making up <1% of NHL, but it makes up ~30% of childhood NHL. It is one of the fastest growing neoplasms, with a doubling time of <24 h. In general, it is a pediatric tumor that has three major clinical presentations. The endemic (African) form presents as a jaw or facial bone tumor that spreads to extranodal sites including ovary, testis, kidney, breast, and especially the bone marrow and meninges. The nonendemic form has an abdominal presentation with massive disease, ascites, and renal, testis, and/or ovarian involvement and, like the endemic form, also spreads to the bone marrow and CNS. Immunodeficiency-related cases more often involve lymph nodes and may present as acute leukemia. BL has a male predominance and is typically seen in patients <35 years of age.

On biopsy, there is a monotonous infiltration of medium-sized cells with round nuclei, multiple nucleoli, and basophilic cytoplasm with vacuoles. The proliferation rate is ~100%, and tingible body macrophages give rise to the classic "starry sky" appearance of this tumor (Fig. 113-4). Tumor cells are positive for B-cell antigens CD19 and CD20 and surface immunoglobulin. They are also uniformly positive for CD10 and BCL6 but negative for BCL2. Endemic BLs are EBV positive, whereas the majority of nonendemic BLs are EBV negative. BL is associated with a translocation involving MYC on chromosome 8q24 in >95% of the cases. The most common partners are chromosomes 14, 2, or 22, rearrangements that produce fusions of MYC with either the IgH (80%), kappa (15%), or lambda (5%) light chain genes, respectively.

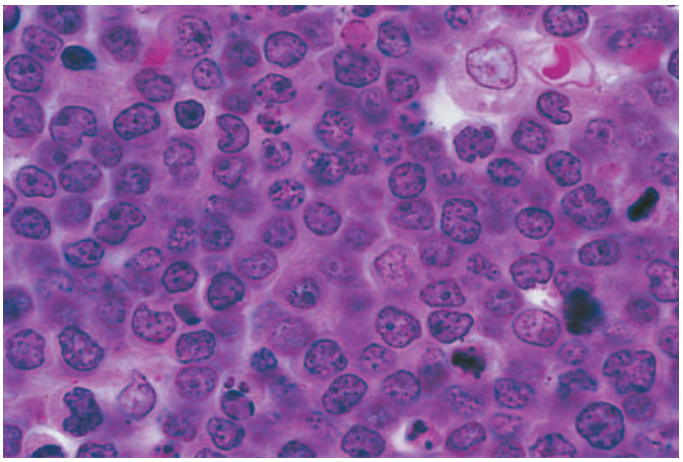

FIGURE 113-4 Burkitt's lymphoma. The neoplastic cells are homogeneous, medium-sized B cells with frequent mitotic figures, a morphologic correlate of high growth fraction. Reactive macrophages are scattered through the tumor, and their pale cytoplasm in a background of blue-staining tumor cells gives the tumor a so-called starry sky appearance.

While exquisitely chemosensitive, it is imperative that treatment for BL be initiated quickly given the rapid doubling time and high morbidity of this disease. There are several effective intensive combination chemotherapy regimens, all of which incorporate high doses of cyclophosphamide. Prophylactic therapy to the CNS is mandatory. Cure can be expected in 80–90% of patients when treated promptly and correctly. Modified Magrath and dose-adjusted EPOCH-R (rituximab, infusional etoposide/vincristine/doxorubicin, cyclophosphamide, prednisone) are highly effective regimens. Salvage therapy has been generally ineffective in patients whose disease progresses after upfront therapy, emphasizing the importance of the initial treatment approach and referral to a tertiary cancer center with experience treating this disease.

Diffuse Large B-Cell Lymphoma DLBCL is the most common histologic subtype of NHL diagnosed, representing about one-third of all cases. Previously felt to be "one disease," it is now recognized as a heterogeneous collection of multiple entities. It is slightly more common in Caucasians and men, and the median age at diagnosis is 64. The relative risk (RR) of DLBCL is higher among people with affected first-degree relatives (RR 3.5-fold), and patients with congenital or acquired immunodeficiency, patients on immunosuppression, and patients with autoimmune disorders also have a higher risk of developing DLBCL, often EBV-related. The majority of patients present with advanced-stage disease, with only 30–40% of patients having stage I or II disease; ~40% of patients will have "B" symptoms, and 50% of patients will have an elevated LDH. Up to 40% of patients will have involvement of non–lymph node sites including bone marrow, CNS, gastrointestinal tract, thyroid, liver, and skin. Patients with extensive bone marrow involvement or involvement of the testes, breast, kidney, adrenal gland, paranasal sinus, or epidural space are at increased risk of CNS dissemination.

The tumor consists of a diffuse proliferation of large, atypical lymphocytes with a high proliferative index (Fig. 113-5). These cells typically express the B-cell antigens CD19, CD20, and CD79a. Expression of CD10 and BCL6 is consistent with the tumor cell being of germinal center origin (GCB), while the expression of MUM1 corresponds with the non–germinal center or ABC subtype. BCL2 is overexpressed in anywhere from 25 to 80% of DLBCLs, whereas BCL6 is positive in more than two-thirds of cases, as the result of translocations, gain of copy number, or promoter mutations. MYC is rearranged in 10% of DLBCLs, and ~20% of MYC-rearranged cases have a concurrent BCL2 rearrangement, a combination referred to as "double-hit lymphoma." These double-hit lymphomas constitute one subtype of high-grade B-cell lymphoma (HGBL) and are associated with an extremely poor

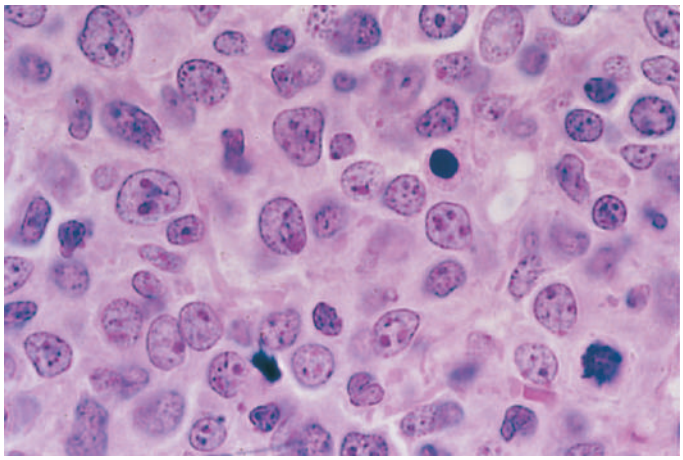

FIGURE 113-5 Diffuse large B-cell lymphoma. The neoplastic cells are heterogeneous but predominantly large cells with vesicular chromatin and prominent nucleoli.

prognosis with a median OS of only 12–18 months. The other subtype of HGBL is called HGBL not otherwise specified (NOS) and is defined based on blastoid or Burkitt-like morphologic features. Amplification and/or overexpression of MYC independent of rearrangements or amplification have also been described and are also associated with a poor, albeit better, prognosis.

Combination chemotherapy offers potentially curative therapy for DLBCL, regardless of the stage. The addition of the anti-CD20 antibody rituximab to cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) improved survival beyond CHOP alone and has been the standard first-line chemotherapy for this disease for decades. The combination of R-CHP (R-CHOP without vincristine) and the antibody-drug conjugate (ADC) polatuzumab was compared to R-CHOP in the randomized POLARIX study and demonstrated a progression-free survival benefit with polatuzumab–R-CHP, leading to the approval of this regimen as a new standard option for patients with IPI 2 or higher disease. For patients with early-stage disease localized to a radiation field, treatment options include full-course chemotherapy with R-CHOP every 3 weeks for six cycles or abbreviated chemotherapy for three to four cycles followed by involved field radiotherapy. The randomized FLYER studies compared four versus six cycles of R-CHOP chemotherapy for early favorable-risk DLBCL and showed no benefit to a more extended course of chemotherapy. For advanced-stage DLBCL, therapy is with a full course of chemotherapy. On average, ~65–70% of patients with DLBCL can be expected to be cured with this approach, and the likelihood of cure is predicted by the IPI, gene expression profile cell of origin, and/or MYC cytogenetics and expression. Several studies, other than the above mentioned POLARIX study, have investigated alternative anthracycline-containing chemotherapy regimens and/or consolidation autologous stem cell transplantation in first remission for higher-risk disease without improvement over R-CHOP alone. Dose-adjusted R-EPOCH is one such regimen. Although this regimen did not appear to be better than R-CHOP for DLBCL in one multicenter clinical trial, it is often used to treat primary mediastinal large B-cell lymphoma and double-hit DLBCL based on results from phase 2 and retrospective studies, respectively. CNS prophylaxis with either intrathecal chemotherapy or high-dose systemic methotrexate and leucovorin rescue offers unclear benefit to patients at high risk for CNS relapse and is increasingly not being used based on results of retrospective and observational studies.

Over one-third of patients will either have primary refractory disease or disease that relapses after first-line chemotherapy. These patients may still be cured with either salvage chemotherapy regimens followed by autologous stem cell transplantation (for patients relapsing >12 months from the completion of therapy) or CD19 chimeric antigen receptor (CAR) T cells (for patients with primary refractory or early relapsing disease or those who are not felt to be autologous stem cell transplantation candidates). However, patients with a poor performance status or certain comorbid conditions who are not candidates for such approaches are often managed with palliative intentions. Radiation to symptomatic areas of disease can be transiently helpful. Less intensive chemotherapy with drugs such as gemcitabine, cytarabine, or bendamustine can help control disease and symptoms for a limited period of time. Newer drugs including the CD79b ADC polatuzumab in combination with bendamustine and rituximab (BR), the high-affinity CD19 monoclonal antibody (mAb) tafasitamab in combination with lenalidomide, the CD19 ADC loncastuximab, and the CD20-CD3 bispecific antibodies epcoritamab and glofitamab have been approved for use in these palliative settings as well as for patients who relapse after CAR-T therapy or autologous stem cell transplantation. Some of these agents can be used as a bridge to a definitive allogeneic stem cell transplantation

For patients in whom more aggressive therapy is an option, treatment for late relapsing patients is with combination chemotherapy using various combinations of drugs primarily in order to identify patients with chemosensitive disease. Patients with chemosensitive disease have the greatest likelihood of benefiting from high-dose chemotherapy and autologous stem cell transplant, which improves response duration and survival over salvage chemotherapy alone and leads to long-term disease-free survival in ~40–50% of patients. The randomized ZUMA-7 and TRANSFORM studies of the CD19 CAR-T therapies axicabtagene ciloleucel (axi-cel) and lisocabtagene autoleucel (liso-cel) established both of these CAR-T therapies as the most effective option for patients with primary refractory or early (<12 months) relapsing disease over salvage chemotherapy and autologous stem cell transplantation.

For this therapy, T cells are collected from a patient and are then genetically modified to express a receptor that will bind to a surface antigen expressed on the patient's own tumor cells. In the case of B-cell malignancies, CD19 has been targeted most commonly. After infusion, autologous CAR-T cells home to sites of disease and persist over time. The CARs consist of an extracellular antigen recognition domain (typically a single-chain Fv variable fragment from a monoclonal antibody) linked via a transmembrane domain to an intracellular signaling domain (usually the CD3ζ endodomain), resulting in the redirection of T-cell specificity toward target antigen-positive cells, and one or more costimulatory domains including CD28, 4-1BB, or OX40 to enhance cytokine secretion and effector cell expansion and prevent activation-induced apoptosis and immune suppression by tumor-related metabolites. For late relapsing patients with chemorefractory disease, CAR-T therapies such as axi-cel, liso-cel, and tisagenlecleucel (tisa-cel) offer a potentially curative option in the third-line setting as well. In this setting, the response rate of CAR-T cells is >80%, with >50% of patients achieving a complete response. These responses appear to be durable, with 40% of patients in remission at long-term follow-up.

Other large B-cell lymphomas include intravascular large B-cell lymphoma, T-cell/histiocyte–rich large B-cell lymphoma, EBV-positive DLBCL of the elderly, and ALK-positive large B-cell lymphoma. Patients with the latter two diseases tend to have a poor prognosis, whereas the addition of rituximab to CHOP chemotherapy has dramatically improved outcomes with intravascular large B-cell lymphoma, and the outcomes in T-cell/histiocyte–rich large B-cell lymphoma are similar to DLBCL. R-CHOP remains the treatment of choice for each of these lymphomas.

Follicular Lymphoma FLs are the second leading NHL diagnosis in the United States and Europe and make up 22% of NHLs worldwide and at least 30% of NHLs diagnosed in the United States. This type of lymphoma can be diagnosed accurately on morphologic findings alone and has been the diagnosis in the majority of patients in therapeutic trials for "low-grade" lymphoma in the past.

Evaluation of an adequate biopsy by an expert hematopathologist is sufficient to make a diagnosis of FL. The tumor is composed of small cleaved and large cells in varying proportions organized in a follicular pattern of growth **(Fig. 113-6)**. Confirmation of B-cell immunophenotype (monoclonal immunoglobulin light chain, CD19, CD20, CD10, and BCL6 positive, and CD5 and CD23 negative) and the existence of t(14;18) and abnormal expression of BCL2 protein are confirmatory.

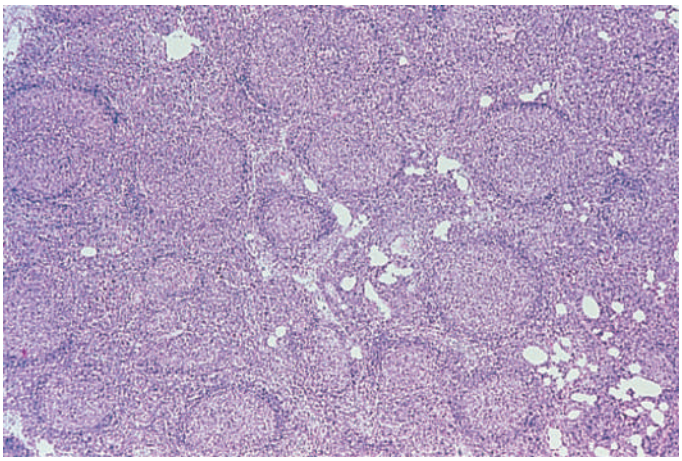

FIGURE 113-6 Follicular lymphoma. The normal nodal architecture is effaced by nodular expansions of tumor cells. Nodules vary in size and contain predominantly small lymphocytes with cleaved nuclei along with variable numbers of larger cells with vesicular chromatin and prominent nucleoli.

While >85% of FLs will harbor a t(14;18) and overexpress the anti-apoptotic protein BCL2, this genetic event is necessary but not sufficient for malignant transformation of the B lymphocytes, and multiple genetic events are required for the development of FL. Studies have identified the most common recurrent genetic events in FL, and they included mutations in several epigenetic modifying genes, including *MLL2, EZH2, CREBBP*, and *EP300*. The major differential diagnosis is between lymphoma and reactive follicular hyperplasia. The coexistence of DLBCL must be considered. Patients with FL are often subclassified, or graded, into those with predominantly small cells, those with a mixture of small and large cells, and those with predominantly large cells. The WHO classification adopted grading from I to III based on the number of centroblasts, or large cells, counted per high-power field (hpf): grade I, from 0 to 5 centroblasts/hpf; grade II, from 6 to 15 centroblasts/hpf; and grade III, >15 centroblasts/hpf. Grade III has been subdivided into grade IIIa, in which centrocytes predominate, and follicular large B-cell lymphoma (FLBCL), in which there are sheets of centroblasts. While this distinction cannot be made simply or very reproducibly, these subdivisions do have prognostic significance. Patients with FL with predominantly large cells have a higher proliferative fraction, progress more rapidly, and have a shorter OS with simple chemotherapy regimens. FLBCL is an aggressive disease and considered most similar to DLBCL and treated as such with curative intent.

The most common presentation for FL is with new, painless lymphadenopathy. Multiple sites of lymphoid involvement are typical, and unusual sites such as epitrochlear nodes are sometimes seen. However, essentially any organ can be involved, and extranodal presentations do occur. Most patients do not have an elevated LDH or fevers, night sweats, or weight loss, although histologic transformation to DLBCL does occur at a rate of ~3% per year and can be associated with these signs or symptoms. As discussed previously, prognosis is best predicted by the FLIPI. Staging is typically done with CT scans of the chest, abdomen, and pelvis, as well as the neck if neck disease is suspected, although PET/CT scans can be helpful in cases where disease transformation is suspected, as transformed disease will be more FDG avid than indolent disease, or for confirmation of early-stage disease, where definitive local therapy with radiation may be considered.

Although FL is highly sensitive to chemotherapy and radiotherapy, these therapies are usually not ultimately curative, except in the setting of early-stage disease. If the disease can be encompassed in a radiation field, involved field radiotherapy at a dose of 24–30 Gy may be curative, with 5-, 10-, and 15-year freedom from treatment failure rates of 72, 46, and 39%, and overall 5-, 10-, and 15-year survival rates of 93, 75, and 62%, respectively. If radiation therapy would not be tolerated or if a patient prefers not to receive radiation, observation is a reasonable alternative with a median time to treatment not reached at 7 years of follow-up in one study. Many of these patients are diagnosed incidentally or at a time when their lymphoma is not causing symptoms or signs of organ function impairment. Numerous studies have shown that treating patients with asymptomatic disease does not improve survival compared with a program of close observation, with treatment reserved for symptomatic disease progression or organ dysfunction. Thus, asymptomatic patients should be observed.

When systemic treatment is indicated, a variety of treatment options are available, including the use of the monoclonal antibody against CD20, rituximab, alone or in combination with chemotherapy or with the oral drug lenalidomide. Treatment decisions are often determined by the indication for treatment and/or by the volume of disease being treated. For patients requiring therapy for inflammatory or autoimmune phenomenon thought to be driven by FL or for patients with low-volume disease, single-agent rituximab is associated with a response rate of ~70% and a median response duration of >2 years. This response duration is improved with the addition of maintenance rituximab following a favorable response to rituximab induction therapy. For patients with a larger volume of disease at the time of treatment initiation, the addition of rituximab (R) to chemotherapy regimens such as CHOP or cyclophosphamide, vincristine, and prednisone (CVP) has improved survival in this disease. The combination of bendamustine and rituximab (BR) has been compared to R-CHOP and results in longer response duration and less toxicity. Thus, BR has become the standard of care for the first-line therapy of medium- to high-volume FL. Similarly, the addition of maintenance rituximab following a good response to R-CHOP or R-CVP improves response duration when used in newly treated FL patients. A newer anti-CD20 antibody, obinutuzumab, has been tested in combination with chemotherapy in a randomized trial against rituximab plus chemotherapy in previously untreated FL. The obinutuzumab combinations resulted in improvements in minimal residual disease (MRD) negativity as well as progression-free survival at the expense of more infection and infusion reactions. Based on these results, both rituximab plus chemotherapy and obinutuzumab plus chemotherapy are options for untreated FL in need of treatment. The superiority of one over the other has not been established. Finally, a randomized study has compared rituximab plus chemotherapy with either BR, R-CHOP, or R-CVP to rituximab plus lenalidomide, and results were similar in both arms, thus making the chemotherapy-free rituximab-lenalidomide regimen an option for the frontline treatment of FL.

In patients with FL, the disease nearly always recurs following therapy, after which retreatment is again reserved for symptomatic disease or disease interfering with organ function. Single-agent rituximab or alternative chemotherapy regimens, with both rituximab and obinutuzumab, can again be employed. Both autologous and allogeneic hematopoietic stem cell transplantations yield high complete response rates in patients with relapsed FL, and long-term remissions can occur in 40 and 60% of patients, respectively. The latter is associated with considerable treatment-related morbidity and mortality and so is usually reserved for patients with multiply relapsed FL that is no longer responsive to chemotherapy. More targeted oral therapies like lenalidomide and the EZH2 inhibitor tazemetostat are active in relapsed FL. The PI3 kinase inhibitors idelalisib, duvelisib, and copanlisib are active in FL but are no longer available given the lack of randomized confirmatory evidence to support their efficacy. The anti-CD19–directed CAR-T therapies axi-cel and tisa-cel have been approved for relapsed FL in the third-line setting and beyond, with complete responses seen in >80% of patients with multiply relapsed disease, and with many of those responses proving durable, albeit with limited follow-up. Longer follow-up is needed to determine if this may be a definitive treatment strategy for a subset of relapsed FL patients. The CD20-CD3 bispecific antibody mosunetuzumab has been approved for FL in the third-line setting and beyond as well and offers a highly effective and potentially less toxic option for patients compared with CAR-T therapy. On average, most patients will live with FL for 15–20 years, a number that is increasing given our improved understanding of the genetics and microenvironment of FL and the increasing number of drugs and therapies being tested in this disease. However, in addition to a high-risk FLIPI, patients who do not have a complete metabolic response by PET/CT scanning

to their primary therapy and patients who relapse within 2 years of the completion of their primary chemotherapy tend to do poorly with chemotherapy and should be considered for some of these non-chemotherapy options. Randomized trials comparing chemotherapy, lenalidomide-based therapy, and CAR-T therapy in the second-line setting for these refractory or early relapsing patients are underway.

Patients with FL have a high rate of histologic transformation to DLBCL (~3% per year). This is recognized ~40% of the time during the course of the illness by repeat biopsy and is present in almost all patients at autopsy. This transformation is usually heralded by rapid growth of lymph nodes—often localized—and the development of systemic symptoms such as fevers, sweats, and weight loss. When this happens in patients who have had previously untreated FL, treatment with R-CHOP chemotherapy, as for DLBCL, can be curative for the aggressive component while the FL may eventually recur. In patients with previously treated FL that transforms to DLBCL, prognosis is poor, and successful therapy with an aggressive combination chemotherapy regimen should be consolidated with an autologous stem cell transplant. CAR-T therapy and other therapies for relapsed/refractory DLBCL are options for chemorefractory transformations. Finally, as discussed previously, grade IIIb FL is more similar to DLBCL than it is to FL and should be treated as such.

Marginal Zone Lymphoma The second most common indolent B-cell NHL is MZL. There are three main types: splenic MZL, extranodal MZL of MALT, and nodal MZL.

Nodal MZL most closely resembles FL clinically, and much of the way we manage and treat it is based on studies done in FL. Tumor biopsies in this disease show parafollicular and perivascular infiltration by monocytoid-appearing atypical lymphocytes with folded nuclear contours that are positive for CD19, CD20, and CD79a but negative for CD10 and largely negative for CD5. Some cases can have plasmacytoid differentiation and can be associated with a monoclonal expression of kappa or lambda light chains and with small monoclonal immunoglobulin spikes. Treatment is often similar to that of FL, with the exception that the BTK inhibitors ibrutinib and zanubrutinib are highly active in this disease, while largely disappointing in FL, and are good treatment options for relapsed nodal MZL as well as other MZL subtypes. CAR-T therapy is not approved in MZL but has been tested in clinical trials with similar efficacy to what has been shown in FL.

Splenic MZL is largely a disease of older Caucasian patients; infection with hepatitis C is a risk factor for this disease, and treatment of hepatitis C can result in regression of the lymphoma. Patients present with a lymphocytosis with or without cytopenias and splenomegaly. Bone marrow involvement is common. Diagnosis can be made by flow cytometry of the peripheral blood; malignant lymphocytes will be positive for surface immunoglobulin, CD19, and CD20 and will generally lack CD5 and CD10. On peripheral smear, they have small nuclei and abundant cytoplasm with "shaggy" or villous projections. It can be differentiated from HCL by the absence of CD25, CD103, and annexin A1. Recurrent cytogenetic abnormalities include trisomy 3 and abnormalities of chromosome 7q. Therapy is indicated for symptomatic disease or significant cytopenias. Splenectomy is reasonable for selected patients with excellent relief of symptoms and cytopenias. Splenectomy is associated with an overall response rate of 85% and estimated progression-free survival and OS rates at 5 years of 58 and 77%, respectively. Single-agent rituximab can improve splenomegaly and cytopenias in >90% of patients. In a study of induction with weekly rituximab followed by maintenance, the response rate was 95%, with OS and progression-free survival rates at 5 years of 92 and 73%, respectively. Other options for therapy at relapse are similar to those used for FL and include retreatment with rituximab, alkylating agents, and purine analogues in combination with rituximab. The survival rate of patients is in excess of 70% at 10 years.

MALT lymphoma is an MZL lymphoma of extranodal tissue, most commonly the stomach, but other common sites include the skin, salivary glands, lung, small bowel, ocular adnexa, breasts, bladder, thyroid, dura, and synovium. It is associated with states of chronic inflammation due to either autoimmune diseases like Sjögren's syndrome or Hashimoto's thyroiditis or chronic infections with organisms such as *H. pylori* (gastric), *Borrelia burgdorferi* (skin), *C. psittaci* (conjunctiva), *C. jejuni* (intestines), and hepatitis C virus. The essential pathologic feature of MALT lymphoma is the presence of lymphoepithelial lesions, which result from invasion of mucosal glands and crypts by the neoplastic lymphocytes. These cells are positive for CD19, CD20, and CD79a and negative for CD5 and CD10. Recurrent cytogenetic abnormalities include t(11;18), t(14;18), t(1;14), t(3;14), and trisomy 8. The t(11;18) is most common, occurring in up to 50% of MALT lymphomas. It results in the fusion of the apoptosis inhibitor 2 (*API2*) gene and the *MALT1* gene, resulting in activation of nuclear factor-κB (NF-κB). Unlike other indolent B-cell lymphomas, MALT lymphomas present most commonly with stage I or II disease. In these cases, radiation therapy may be curative. Alternatively, patients may respond to antibiotics for the associated underlying infection. Treatment of symptomatic or organ-impairing relapsed, refractory, or advanced-stage disease is similar to approaches used in FL with chemotherapy, immunotherapy, or chemoimmunotherapy.

Lymphoplasmacytic Lymphoma About 1% of all NHLs will be LPLs, which are indolent B-cell NHLs with lymphoplasmacytic differentiation, most commonly associated with a monoclonal IgM paraprotein. Nearly all patients will have stage IV disease at diagnosis with bone marrow involvement. Patients with high levels of circulating IgM paraproteins constitute a specific entity known as Waldenström's macroglobulinemia and can have symptoms due to hyperviscosity as a result of the circulating IgM. Activating mutations in MYD88, an adaptor protein that is involved in signaling downstream of the Ig receptor leading to NF-κB activation, are present in >90% of cases. Tumor biopsies are notable for proliferation of small lymphocytes, lymphoplasmacytic cells, and plasma cells, and malignant lymphocytes are positive for CD19, CD20, and surface IgM but generally negative for CD5 and CD10. Like the other indolent NHLs, treatment is indicated for disease that causes symptoms or interferes with organ function; hyperviscosity related to elevated serum IgM and paraneoplastic neuropathy are additional indications for therapy. Single-agent rituximab may be useful for low-volume disease but can be associated with a transient rise in serum IgM concentrations that can cause or exacerbate hyperviscosity. Chemoimmunotherapy with regimens such as BR and rituximab, cyclophosphamide, and dexamethasone is active, as are myeloma therapies such as bortezomib. Ibrutinib and zanubrutinib in combination with rituximab are highly active in this disease and are options for both previously untreated and relapsed disease. Given that 85% of IgM remains intravascular, acute relief of hyperviscosity symptoms can be obtained by plasmapheresis. For recurrent disease, one can often use agents that were previously used. For patients with more refractory LPL, the mammalian target of rapamycin (mTOR) inhibitor everolimus and the bcl-2 inhibitor venetoclax are active. Selected patients with relapsed disease are considered for high-dose therapy with autologous or allogeneic stem cell transplantation. The results seen are similar to those of other indolent lymphomas.

Mantle Cell Lymphoma MCL composes ~6% of NHLs. It is an intermediate-grade lymphoma that, like the indolent B-cell NHLs, is not curable with conventional therapies but, like the aggressive lymphomas, often requires more aggressive chemoimmunotherapy regimens with or without an autologous stem cell transplant to achieve a reasonable response duration. This therapy is not curative, however, and median survival with this disease is on the order of 5–10 years. An exception to this is a more indolent SOX11 variant that often presents with circulating disease with splenomegaly but without significant lymphadenopathy and with a low Ki67 (<10%). This subset behaves more like the indolent B-cell NHLs and can be observed until treatment is indicated by symptoms or organ function impairment. Similarly, there is a blastic variant with a high Ki67 index that is associated with a poor prognosis and a median OS of only 18 months. For other patients, prognosis is best predicted by the biologic MCL International Prognostic Index (MIPI), which factors in age, performance status, LDH, white blood cell count, and Ki67 expression to determine a risk

group. This disease is more common in men, and the average age of diagnosis is 63. MCLs with a mutation in *TP53* or a complex karyotype are particularly high risk as well. Over two-thirds of patients will have stage IV disease, mostly with bone marrow and peripheral blood involvement, at the time of diagnosis. Another common extranodal site of involvement is the gastrointestinal tract, where diffuse lymphomatous polyposis may be seen.

The pathognomonic cytogenetic finding in MCL is t(11;14), which brings the gene for the cell cycle control protein cyclin D1 under the control of the immunoglobulin heavy chain gene promoter on chromosome 14. This translocation is present in >90% of cases. The remaining cases usually overexpress cyclin D2, cyclin D3, or cyclin E. Tumor cells also are positive for B-cell markers CD19 and CD20, as well as CD5. They usually lack CD10 and CD23.

Therapies for MCL are evolving. Patients with localized disease might be treated with combination chemotherapy followed by radiotherapy; however, these patients are exceedingly rare. Similarly, patients with the indolent variant can be observed until disease progresses to cause symptoms or signs of organ function impairment. For the usual presentation with disseminated disease, standard lymphoma treatments like R-CHOP have been unsatisfactory, with the minority of patients achieving complete remission. The addition of high-dose cytarabine to an R-CHOP–like backbone with or without consolidation autologous stem cell transplantation in first remission has improved progression-free survival, but it has not elicited cures in this disease. These include the Nordic regimens and R-HyperCVAD (rituximab, cyclophosphamide, vincristine, doxorubicin, dexamethasone, cytarabine, and methotrexate). BR has activity in this disease and is more effective and better tolerated than R-CHOP. Newer studies with short follow-up suggest that strategies that combine BR with cytarabine with or without autologous stem cell transplant may be effective and well tolerated. The SHINE study randomized patients to BR alone versus BR plus ibrutinib and showed a modest benefit with the addition of ibrutinib. It is not clear, however, if this benefit is greater than the sequencing of upfront BR followed by BTK inhibition at relapse. Maintenance rituximab, following a good response to induction chemotherapy or after autologous stem cell transplant, also improves outcomes over observation alone. Increasing evidence suggests that with modern induction therapies, high-dose chemotherapy and autologous stem cell rescue may no longer provide benefit in the frontline setting. The randomized European TRIANGLE study showed no benefit of autologous transplant when added to induction chemoimmunotherapy with ibrutinib followed by rituximab and ibrutinib maintenance. An ongoing randomized study in the United States is asking a similar question for patients who are treated with chemoimmunotherapy without upfront BTK inhibition. For relapsed disease, the BTK inhibitors ibrutinib, acalabrutinib, and zanubrutinib have single-agent activity with a response rate of almost 70% but a response duration of only 18–24 months. These drugs are being explored in combination with chemotherapy as well as with the BCL2 antagonist venetoclax. Anti-CD19–directed CAR-T therapies are approved for the treatment of relapsed/refractory MCL; two-thirds of patients who had progressed after chemoimmunotherapy (with or without an autologous stem cell transplant) and BTK inhibition have achieved complete responses, many of which are durable through limited follow-up. As in FL, longer follow-up is needed to determine if some of these patients may be cured, which would make this the only curative therapy for this disease outside of an allogeneic stem cell transplantation. The noncovalent BTK inhibitor pirtobrutinib has activity in MCL that has progressed on prior covalent BTK inhibitors and is now approved in this setting. Drugs such as lenalidomide, venetoclax, bortezomib, and temsirolimus can similarly induce transient partial responses. Appropriate patients who respond to salvage therapy, with the exception of CAR-T therapy, should be considered for allogeneic stem cell transplant, which can lead to long-term disease-free survival in 30–50% of patients.

MATURE (PERIPHERAL) T-CELL DISORDERS

Mature T-cell disorders include cutaneous lymphomas, such as mycosis fungoides, and the PTCLs, some of which are distinguished based on specific clinical presentations or contexts or by molecular or biologic features, but many of which fall into the category of PTCL not otherwise specified (NOS). T-cell NHLs are significantly rarer than B-cell NHLs, and as such, our understanding of their biology is less advanced and our therapies are less well developed. While some T-cell lymphomas, like mycosis fungoides, can behave indolently and some, like ALK-positive ALCL, can be cured with chemotherapy, the majority are associated with a poor prognosis. The advent of genomic technologies is enhancing our ability to understand the genetic and biologic basis of these neoplasms.

Mycosis Fungoides Mycosis fungoides is also known as cutaneous T-cell lymphoma. This lymphoma is more often seen by dermatologists than internists. The median age of onset is in the mid-fifties, and the disease is more common in males and in blacks.

Mycosis fungoides is an indolent lymphoma, with patients often having several years of eczematous or dermatitic skin lesions before the diagnosis is finally established. The skin lesions progress from patch stage to plaque stage to cutaneous tumors. Early in the disease, biopsies are often difficult to interpret, and the diagnosis may only become apparent by observing the patient over time. Adenopathy may reflect involvement with mycosis fungoides or be read as dermatopathic change. In advanced stages, the lymphoma can spread to lymph nodes and visceral organs. Patients with this lymphoma may develop generalized erythroderma and circulating tumor cells, called *Sézary's syndrome*.

Rare patients with localized early-stage mycosis fungoides can be cured with radiotherapy, often total-skin electron beam irradiation. More advanced disease has been treated with topical glucocorticoids, topical nitrogen mustard, phototherapy, psoralen with ultraviolet A (PUVA), extracorporeal photopheresis, retinoids (bexarotene), electron beam radiation, interferon, antibodies, fusion toxins, histone deacetylase inhibitors, brentuximab (for CD30+ disease), and systemic cytotoxic therapy. Mogamulizumab, an anti-CCR4 antibody, has activity in this disease and has been approved by the U.S. Food and Drug Administration for this indication. Unfortunately, these treatments are palliative.

Peripheral T-Cell Lymphoma, Not Otherwise Specified PTCLs include a number of entities, which constitute 15% of all NHLs in adults. PTCL NOS, which composes 6% of all NHLs, is the term used for cases that are not other entities defined in the WHO classification. Named varieties include ALCL, angioimmunoblastic T-cell lymphoma (AITL), hepatosplenic T-cell lymphoma, enteropathy-associated T-cell lymphoma, and subcutaneous panniculitis T-cell lymphoma. PTCL NOS is a disease of older individuals, with a median age at presentation of 65, and the majority of patients will have advanced-stage disease at diagnosis, with involvement of the bone marrow, liver, spleen, and skin being common. Associated "B" symptoms and pruritis are also common. These lymphomas can be associated with a reactive eosinophilia as well as hemophagocytic syndrome. The IPI has been applied to PTCL NOS and provides some assessment of outcomes, but even the low-risk group has a median OS of just >2 years.

This diagnostic category is a collection of heterogeneous lymphomas that vary widely and lack typical findings of other specific PTCL subgroups. Because of this heterogeneity, histology, immunophenotype, and genetics are variable. Often lymph nodes are effaced by atypical lymphoid cells of various sizes, sometimes associated with vascular proliferation or an infiltrate of eosinophils and/or macrophages. As most of these lymphomas behave aggressively, note is often made of mitotic and apoptotic figures as well as geographic necrosis. The cells often are positive for CD3, and the majority of PTCL NOS is positive for CD4 rather than CD8, but some are negative for both markers. There can be loss of more mature T-cell markers like CD5 and CD7, and this is associated with a more aggressive course. There are some recurrent translocations, including t(7;14), t(11;14), inv(14), and t(14;14), all of which involve the TCR genes.

The most common primary therapy for PTCL NOS involves a CHOP-like chemotherapy backbone—either CHOP alone or CHOP in combination with etoposide (CHOEP). The latter may provide the most benefit to younger patients and patients with more favorable disease risk factors. Brentuximab in combination with cyclophosphamide,

doxorubicin, and prednisone (CHP) has been tested in a randomized clinical trial against CHOP in CD30+ T-cell lymphomas; progression-free survival was improved with the brentuximab-containing arm, and this was most pronounced for patients with ALCL (see below). Autologous stem cell transplant has been investigated for patients in their first remission and does seem to improve progression-free survival in certain contexts. Drugs such as gemcitabine, bendamustine, and pralatrexate have activity in relapsed disease, as do the histone deacetylase inhibitors romidepsin and belinostat. The PI3 kinase inhibitor duvelisib is being investigated in these diseases with early signals of activity. All of these agents are associated with transient responses in a minority of patients. Patients should be considered for clinical trials. For patients who do achieve remission, reduced-intensity allogeneic stem cell transplantation can yield long-term nonrelapse survival rates of ~40–50%.

Angioimmunoblastic T-Cell Lymphoma AITL constitutes ~20% of T-cell NHLs and ~4% of all NHLs diagnosed. Patients present with a variety of signs and symptoms, most often including lymphadenopathy, hepatosplenomegaly, "B" symptoms, rash, polyarthritis, and hemolytic anemia. Over 80% of patients have advanced-stage disease at diagnosis, and bone marrow involvement is common. Polyclonal hypergammaglobulinemia is common, as are elevated LDH, eosinophilia, a positive Coombs test, and opportunistic infections.

On biopsy, lymph nodes are effaced by a polymorphous infiltrate of lymphocytes, ranging in size and shape, and of immunoblasts. The neoplastic lymphocytes are positive for CD3 as well as CXCL13, PD-1, CD10, and BCL6, most closely resembling CD4-positive follicular helper T cells. There is an expanded follicular dendritic cell network surrounding tumor cells. Scattered immunoblasts are often EBV positive and may give rise to secondary EBV-positive B-cell lymphomas at a later time. Genetic analysis of this disease has revealed recurrent mutations in *TET2* (76%), *DNMT3* (33%), and *IDH2* (20%).

A subset of AITL can remit with immunosuppression with agents like glucocorticoids or methotrexate. Most patients, however, will need combination chemotherapy with regimens like those used in PTCL NOS. Median response duration is short, and median OS is only 15–36 months. Treatment of relapsed disease is similar to that of relapsed PTCL NOS.

Anaplastic Large-Cell Lymphoma ALCL is the next most common T-cell lymphoma after AITL but is more common in children, accounting for up to 10% of pediatric lymphomas. Approximately 40–60% of cases harbor t(2;5), which fuses a portion of the nucleolar protein nucleophosmin-1 (*NPMI*) gene to a part of the anaplastic lymphoma kinase (*ALK*) gene, the product of which has constitutive tyrosine kinase activity. These patients have a much more favorable prognosis compared to ALK-negative ALCL, akin to that of DLBCL. There is an additional, more indolent and favorable subtype that occurs in the breast tissue of patients with breast implants, and there is a cutaneous variant. In general, this is a disease that is more common in men. ALK-positive disease is a disease of younger patients, with a median age at diagnosis of 34 years, whereas the median age at diagnosis of ALK-negative patients is 58. With the exception of the cutaneous variant and the variant associated with breast implants, most patients present with rapidly growing lymphadenopathy with or without extranodal involvement; "B" symptoms are common.

Most cases of ALCL involve large atypical lymphocytes with horseshoe-shaped nuclei with prominent nucleoli ("hallmark" cells). Tumor cells tend to be localized within the lymph node sinuses, and almost all are positive for CD30 but negative for CD15. A majority will also express CD3, CD25, CD43, and CD4. ALK-rearranged ALCL can be diagnosed by fluorescence in situ hybridization (FISH) cytogenetics for t(2;5) or by immunohistochemical staining for ALK.

ALCL is generally treated with CHOP, although like PTCL NOS, CHOEP may benefit younger patients, particularly with ALK-positive disease. Overall, ALCL has a better prognosis than PTCL, and this is particularly true for ALK-positive disease, which has an 8-year OS rate of 82%, versus 49% for ALK-negative disease. Relapsed ALK-positive ALCL is treated similarly to relapsed DLBCL, with salvage combination chemotherapy to identify chemotherapy sensitivity followed by autologous stem cell transplant. For patients with chemotherapy-insensitive disease or for ALK-negative disease, the conjugated anti-CD30 antibody to monomethyl auristatin E (MMAE)/brentuximab is highly active, with a response rate of 86% and a complete response rate of 57%. As mentioned earlier, brentuximab in combination with CHP chemotherapy is an approved frontline regimen for the treatment of CD30+ T-cell lymphomas, including ALCL. The ALK inhibitors, including crizotinib, are active in refractory ALK-positive ALCL with excellent outcomes.

Other PTCL Subtypes Enteropathy-associated T-cell lymphoma, hepatosplenic T-cell lymphoma, and subcutaneous panniculitis-like T-cell lymphoma are other less common PTCL subtypes. *Enteropathy-type intestinal T-cell lymphoma* is a rare disorder. Type I occurs in patients with a history of gluten-sensitive enteropathy and is associated with HLADQA1*0501, DQB1*0201; a gluten-free diet can prevent the development of this lymphoma. Type II is now referred to as monomorphic epitheliotropic intestinal T-cell lymphoma and is not associated with celiac disease. Patients are frequently cachectic and sometimes present with intestinal perforation. The prognosis is poor, with a median survival of 10 months. Therapy is often with combination chemotherapy, including high-dose methotrexate, and autologous stem cell transplant in first remission.

Hepatosplenic γδ T-cell lymphoma is a systemic illness that presents with sinusoidal infiltration of the liver, spleen, and bone marrow by malignant T cells. Tumor masses generally do not occur. The disease is associated with systemic symptoms and is often difficult to diagnose. Recurrent genetic events include isochromosome 7q and trisomy 8. Treatment outcome is poor, but regimens that include ifosfamide, such as ifosfamide, carboplatin, and etoposide (ICE) or ifosfamide, etoposide, and cytarabine (IVAC), are associated with better outcomes in small series of patients. Responding patients should be considered for allogeneic stem cell transplantation.

Subcutaneous panniculitis-like T-cell lymphoma is a rare disorder that is often confused with panniculitis. Patients present with multiple subcutaneous nodules, which progress and can ulcerate. There is a more indolent form that tends to express α/β TCRs and can be managed with immune suppression, whereas lymphomas that express γ/δ TCRs are more aggressive and are associated with a worse prognosis and coincident hemophagocytic syndrome. This is a disease of young men in their fifth and sixth decades of life. Patients with aggressive disease are managed with multiagent chemotherapy, and responding patients should be considered for allogeneic stem cell transplantation.

Adult T-Cell Leukemia/Lymphoma Adult T-cell leukemia/lymphoma (ATLL) is a disease that is most prevalent in Japan and the Caribbean basin **(Chap. 207)**. It is a neoplasm that is driven by HTLV-1, often contracted through the breast milk of infected mothers. The average age at diagnosis is 60, so there is a long latency between viral infection and viral transformation, and only 4% of infected patients will develop the disease. This suggests that HTLV-1 may not be sufficient to cause the malignant phenotype. There are four disease variants: acute (60% of patients), lymphomatous (20% of patients), chronic (15% of patients), and smoldering (5% of patients); prognosis varies across these groups, with median survival times of 6, 10, and 24 months, and not yet reached, respectively. Presentation depends on the subtype, but most commonly, patients present with circulating disease and bone marrow involvement, hypercalcemia, lytic bone lesions, lymphadenopathy, hepatosplenomegaly, skin lesions, and opportunistic infections.

The pathognomonic finding is the malignant "flower cell" that is positive for CD4 and CD25, as well as CD2, CD3, and CD5 but lacking CD7 **(Fig. 113-7)**. Combination chemotherapy is generally used, but for patients fortunate enough to respond, response durations are very short. Other active agents in this disease include the antiretroviral agent zidovudine, interferon α, arsenic and mogamulizumab, a humanized monoclonal antibody that blocks the CCR4 chemokine receptor. In any patients who do respond to therapy, allogeneic stem cell transplant should be considered.

Extranodal NK/T-Cell Lymphoma, Nasal Type Extranodal NK/T-cell lymphoma, nasal type, is a lymphoma that is associated with

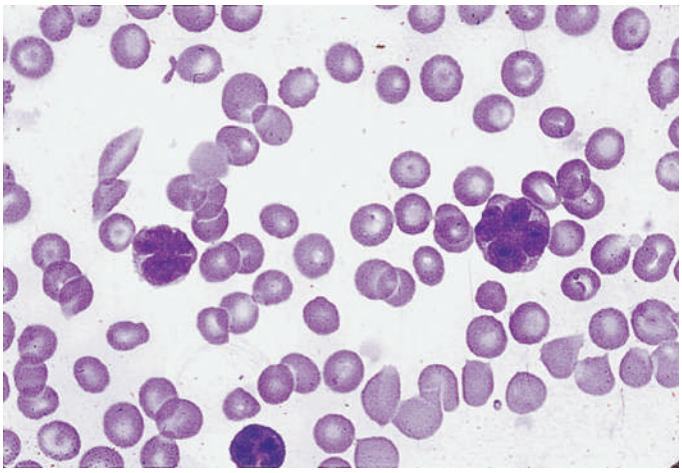

FIGURE 113-7 Adult T-cell leukemia/lymphoma. Peripheral blood smear showing leukemia cells with typical "flower-shaped" nucleus.

EBV infection in nearly all cases and more common in Asia and native populations in Peru. It usually presents with a mass and obstructive symptoms in the upper aerodigestive tract with occasional extranodal sites, but over two-thirds of patients will have localized disease. It is more common in men, and the median age at diagnosis is 60. This disease has its own prognostic score, which takes into account the presence or absence of "B" symptoms, disease stage, whether LDH is elevated, and whether there is lymph node involvement. EBV viral load at diagnosis and at the end of therapy is also predictive.

Treatment for early-stage disease is usually with combined-modality therapy of chemotherapy (commonly using etoposide, ifosfamide, cisplatin, and dexamethasone) and intensity-modulated radiation therapy (50–55 Gy), and patients with localized disease involving the nasal passages do quite well, with 3-year OS of ~85%. Patients with more advanced-stage disease do poorly, with disseminated extranodal relapse occurring frequently, and the median OS is only 4.3 months. The most commonly used treatment regimen is the SMILE regimen (dexamethasone, methotrexate, ifosfamide, L-asparaginase, and etoposide).

114 Hodgkin's Lymphoma

Caron A. Jacobson, Dan L. Longo

Hodgkin's lymphoma (HL) is a malignancy of mature B lymphocytes. It represents ~10% of all lymphomas diagnosed each year. The majority of HL diagnoses are classical HL (cHL), but there is a second subtype of HL, nodular lymphocyte-predominant HL (NLPHL). While this diagnosis does resemble cHL morphologically in certain respects, there is some evidence that it is more related to the indolent B-cell non-Hodgkin's lymphomas (NHLs) biologically than it is to cHL. The majority of this chapter will be specific to cHL, with a discussion of NLPHL at the end.

cHL is one of the success stories of modern oncology. Until the advent of extended-field radiotherapy in the mid-twentieth century, it was a highly fatal disease of young people. Radiation therapy cured some patients with early-stage disease, and the introduction of multiagent chemotherapy in the 1970s resulted in further improved cure rates, for both patients with early- and advanced-stage disease. Cure rates now are >85%. The new challenge in the treatment of HL is late therapy-related toxicity, including a high rate of secondary malignancies and cardiovascular disease. Current clinical trials are aimed at minimizing this risk while preserving efficacy.

EPIDEMIOLOGY AND ETIOLOGY

HL is of B-cell origin. The incidence of HL appears fairly stable, with an estimated 8830 new cases diagnosed in the United States in 2023. HL is more common in whites than in blacks and more common in males than in females. A bimodal distribution of age at diagnosis has been observed, with one peak incidence occurring in patients in their twenties and the other in those in their eighties. Some of the late age peak may be attributed to confusion among entities with similar appearance such as anaplastic large-cell lymphoma and T-cell/histiocyte–rich B-cell lymphoma. There are four distinct subtypes of cHL that are differentiated based on their histopathologic features **(Table 114-1)**: nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte-depleted. Patients in the younger age groups diagnosed in the United States largely have the nodular sclerosing subtype of HL. Elderly patients, patients infected with HIV, and patients in developing countries more commonly have mixed-cellularity HL or lymphocyte-depleted HL. Together, nodular sclerosis and mixed-cellularity types account for nearly 95% of cases. Infection by HIV is a risk factor for developing HL. In addition, an association between infection by Epstein-Barr virus (EBV) and HL has been suggested. A monoclonal or oligoclonal proliferation of EBV-infected cells in 20–40% of the patients with HL has led to proposals for this virus having an etiologic role in HL. However, the matter is not settled definitively. Viral oncogenesis appears to play a greater role in HIV-related cHL: EBV can be detected in nearly all cases of HIV-associated cHL, compared to only one-third of cases of non–HIV-associated cHL. Reed-Sternberg (HRS) cells are the malignant cells in HL. HRS cells in HIV-associated cHL express the EBV-transforming protein latent membrane protein 1 (LMP-1), and the EBV genomes from multiple disease sites in the same HIV-associated cHL patient are episomal and clonal, suggesting that EBV is directly involved in early lymphomagenesis.

Histologically, the HRS cell is diagnostic of cHL **(Fig. 114-1)**. These cells are large cells with abundant cytoplasm with bilobed and/or multiple nuclei. By immunohistochemistry, they are often PAX-5 positive but have low to no expression of other B-cell antigens like CD19 and CD20. They express CD15 and CD30 in 85 and 100% of cases, respectively. These cells, though, comprise <1% of the tumor cellularity, with the majority of the tumor made up of a surrounding inflammatory infiltrate of polyclonal lymphocytes, eosinophils, neutrophils, macrophages, plasma cells, fibroblasts, and collagen. The HRS cell interacts with its microenvironment via cell-cell contact and elaboration of growth factors and cytokines, which results in a surrounding cellular milieu that protects it from host immune attack. The surrounding environmental cells likewise support the HRS cells via cell-cell signaling and cytokine production, which provides signals

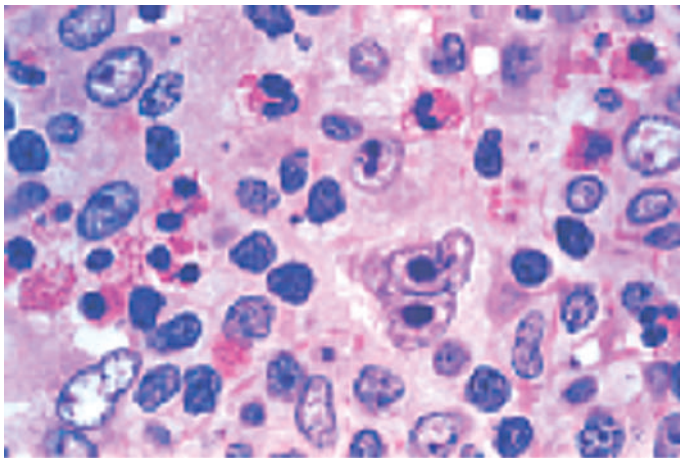

FIGURE 114-1 Hodgkin's disease: A classic Reed-Sternberg (RS) cell is present near the center of the field. RS cells are large cells with a bilobed nucleus and prominent nucleoli surrounded by a pleiomorphic cellular infiltrate. *(From DL Kasper: Harrison's Principles of Internal Medicine, 16th ed. New York, NY: McGraw-Hill; 2005, Fig. 97-11, p. 654.)*

that promote proliferation and survival of the HRS cell itself. Interestingly, 97% of HRS cells in cHL harbor genetic aberrations in the PD-L1 locus on chromosome 9p24.1, resulting in overexpression of PD-L1, the ligand for the inhibitory PD-1 receptor on immune cells. This is one mechanism whereby the HRS cell may be able to avoid immune destruction in its inflammatory microenvironment and may contribute to the generalized immune suppression in HL patients.

APPROACH TO THE PATIENT

Classical Hodgkin's Lymphoma

Most patients with cHL present with palpable lymphadenopathy that is nontender; in most patients, these lymph nodes are in the neck, supraclavicular area, and axilla. More than half of the patients will have mediastinal adenopathy at diagnosis, and this is sometimes the initial manifestation. Subdiaphragmatic presentation of cHL is unusual and more common in older males. One-third of patients present with fevers, night sweats, and/or weight loss, or "B" symptoms. Occasionally, HL can present as a fever of unknown origin. This is more common in older patients who are found to have mixed-cellularity HL in an abdominal site. Rarely, the fevers persist for days to weeks, followed by afebrile intervals and then recurrence of the fever. This pattern is known as *Pel-Ebstein* fever. HL can occasionally present with unusual manifestations. These include severe and unexplained itching, cutaneous disorders such as erythema nodosum and ichthyosiform atrophy, paraneoplastic cerebellar degeneration and other distant effects on the CNS, nephrotic syndrome, immune hemolytic anemia and thrombocytopenia, hypercalcemia, and pain in lymph nodes on alcohol ingestion.

Evaluation of patients with HL will typically begin with a careful history and physical examination. Patients should be asked about the presence or absence of "B" symptoms. Comorbid diagnoses that may impact therapy should be reviewed, including a history of pulmonary disease and congestive heart failure given the use of chemotherapy drugs that can cause both lung and heart toxicity. A physical examination should pay attention to the peripherally accessible sites of lymph nodes and to the liver and spleen size. Laboratory evaluation should include a complete blood count with differential; erythrocyte sedimentation rate (ESR); chemistry studies reflecting major organ function including serum albumin; and HIV and hepatitis virus testing. A positron emission tomography (PET)/computed tomography (CT) scan is used for staging and is more accurate than a bone marrow biopsy for evaluation of bone marrow involvement as the bone marrow involvement in cHL tends to be patchy and therefore potentially missed on a unilateral bone marrow biopsy. The initial evaluation of a patient with HL or NHL is similar. In both situations, the determination of an accurate anatomic stage is an important part of the evaluation. Staging is done using the Ann Arbor staging system **(Table 114-2)**.

TABLE 114-2 The Ann Arbor Staging System for Hodgkin's Lymphoma

STAGE	DEFINITION
I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer's ring)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (the mediastinum is a single site; hilar lymph nodes should be considered "lateralized" and, when involved on both sides, constitute stage II disease)
III	Involvement of lymph node regions or lymphoid structures on both sides of the diaphragm
III_1	Subdiaphragmatic involvement limited to spleen, splenic hilar nodes, celiac nodes, or portal nodes
III_2	Subdiaphragmatic involvement includes paraaortic, iliac, or mesenteric nodes plus structures in III_1
IV	Involvement of extranodal site(s) beyond that designated as "E"
	More than one extranodal deposit at any location
	Any involvement of liver or bone marrow
A	No symptoms
B	Unexplained weight loss of >10% of the body weight during the 6 months before staging investigation
	Unexplained, persistent, or recurrent fever with temperatures >38°C during the previous month
	Recurrent drenching night sweats during the previous month
E	Localized, solitary involvement of extralymphatic tissue, excluding liver and bone marrow

The diagnosis of HL is established by review of an adequate biopsy specimen by an expert hematopathologist. HL is a tumor characterized by rare neoplastic cells of B-cell origin (immunoglobulin genes are rearranged but not expressed) in a tumor mass that is largely polyclonal inflammatory infiltrate, probably a reaction to cytokines produced by the tumor cells. The differential diagnosis of a lymph node biopsy suspicious for HL includes inflammatory processes, mononucleosis, NHL, phenytoin-induced adenopathy, and nonlymphomatous malignancies.

Staging for cHL is anatomically based given the propensity of the disease to march from one lymph node group to the next group, often contiguous to the first. Staging is important for selecting therapy of appropriate duration and intensity, but the outcome of optimal therapy for all the stages is excellent. Patients are stratified based on whether they have early-stage disease (stage I or II) or advanced-stage disease (stage III or IV). Patients with early-stage disease have a better prognosis overall but are further classified as favorable or unfavorable based on a variety of factors. These factors vary from study to study but include bulky disease, number of lymph node areas involved, an elevated ESR (>30 if "B" symptoms are present; >50 if "B" symptoms are absent), and age. Prognosis in advanced-stage disease is best predicted by the International Prognostic Score (IPS), which ascribes 1 point for male sex, older age (>45 years), stage IV disease, serum albumin <4 g/dL, hemoglobin <10.5 g/dL, white blood cell count ≥15,000/μL, and a lymphocyte count <600/μL and/or <8% of white blood cell count. Five-year progression-free survival ranges from 88% for patients with no risk factors to 62% for patients with four or more factors, but very few patients have multiple risk factors.

TREATMENT

Classical Hodgkin's Lymphoma

The overwhelming majority of patients with HL will be cured with either chemotherapy alone or a combination of chemotherapy and radiation therapy. It has long been appreciated that patients

with advanced-stage disease do not benefit from the addition of radiation therapy to chemotherapy and are thus treated with chemotherapy alone. For early-stage disease, however, treatment with combined-modality therapy has been associated with a small decrease in risk of relapse but with an increased risk of late toxicity including secondary malignancies, thyroid disease, and premature cardiovascular disease and stroke resulting in minimal or no improvement in long-term survival. Much of this risk can be attributed to radiation therapy. Thus, investigation into the treatment of early-stage HL at present is aimed at trying to maximize treatment outcome without using radiotherapy. This is an area of controversy in the treatment of HL.

EARLY-STAGE DISEASE

The most common chemotherapy regimen used to treat early-stage HL in the United States is ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine). This regimen is given every other week, with each cycle including two treatments. In patients with low-risk, or favorable, disease, the use of four to six cycles of ABVD alone, without radiation therapy, results in progression-free and overall survival rates of 88–92% and 97–100%, respectively, at 5–7 years. This may be associated with a slightly increased risk of relapse when compared with abbreviated chemotherapy (ABVD for four cycles) followed by involved field radiation therapy (30 Gy), but with no difference in overall survival owing to the excellent salvage strategies used for relapsed HL and to the late toxicities seen following radiation therapy to the chest. German studies have examined a very abbreviated chemotherapy regimen (ABVD for two cycles) and low-dose radiation (20 Gy) for particularly good-risk disease with two or fewer lymph node areas involved and found that this was equally effective to standard combined-modality therapy of ABVD for four cycles and 30 Gy of radiation. However, long-term follow-up is not yet available to assess the impact of the lower radiotherapy dose on late toxicities. Finally, the use of an early interim PET/CT scan can aid decisions regarding the duration and extent of therapy. In one study, a negative PET/CT scan after three cycles of ABVD predicted for excellent outcomes with no additional therapy; in another, a negative PET/CT scan after two cycles of ABVD predicted for good outcomes with two additional cycles of ABVD alone, without radiation therapy.

For unfavorable-risk disease, the omission of radiation therapy following chemotherapy is associated with a more significant increased risk of relapse compared to favorable-risk disease, but again with no change in overall survival. For these patients, treatment options would include ABVD for four cycles followed by involved field radiation therapy or ABVD alone for six cycles. Treatment decisions are often based on the extent of the radiation field and the unfavorable risk factor, with patients with nonbulky disease being candidates for chemotherapy alone if radiation would be contraindicated for another reason. Combined modality therapy has typically been used for patients with bulky disease, although patients with bulky disease who have a negative PET/CT scan after chemotherapy may not benefit from additional radiation therapy.

Alternative chemotherapy regimens to ABVD have been developed and include the Stanford V regimen and escalated BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone). Neither of these regimens has resulted in improved outcomes in patients with early-stage disease.

ADVANCED-STAGE DISEASE

Patients with advanced-stage disease do not benefit from the addition of radiation therapy after a complete response to chemotherapy alone and should be treated with chemotherapy alone. The most common regimens used in the United States include ABVD or brentuximab vedotin plus doxorubicin, vinblastine, and dacarbazine (AVD) for six cycles. Brentuximab is an antibody-drug conjugate (ADC) that targets CD30 on the HRS cell and is conjugated to the microtubule inhibitor monomethyl auristatin E (MMAE). It was approved in the relapsed setting as a single agent and then was tested in phase 1 and 2 trials in combination with AVD chemotherapy for the upfront treatment of advanced-stage cHL. A phase 3 study, ESCHELON-1, randomized patients with advanced-stage cHL to either ABVD or brentuximab-AVD and demonstrated both a progression-free and overall survival benefit with brentuximab-AVD. Again, Stanford V and escalated BEACOPP have been evaluated in advanced-stage disease and are not associated with an improvement in overall survival but are associated with increased toxicity. The small fraction of patients who do not achieve complete remission with chemotherapy alone (partial responders with persistent PET scan positivity account for <10% of patients) may benefit from the addition of involved field radiotherapy.

Drugs that target the PD-1/PD-L1 axis have been developed for the treatment of relapsed HL based on the known genomic alterations leading to PD-L1 overexpression on the HRS cell (see "Relapsed Disease," below). In the setting of relapsed disease, these drugs, which include pembrolizumab and nivolumab, have very high response rates and are associated with durable responses. Phase 2 studies combining these drugs with either brentuximab (nivolumab) or ICE (nivolumab; ifosfamide, carboplatin, and etoposide) or GND (pembrolizumab; gemcitabine, vinorelbine, and doxorubicin) chemotherapy have demonstrated high complete response rates in order to get patients to autologous stem cell transplantation. A multicenter randomized trial comparing brentuximab-AVD to nivolumab-AVD in the upfront treatment of advanced-stage cHL has been presented, and there was a progression-free survival benefit with nivolumab-AVD and the regimen had an arguably more favorable toxicity profile. We await longer follow-up and U.S. Food and Drug Administration review of these results to determine if this study establishes a new standard of care for the upfront treatment of advanced-stage cHL.

RELAPSED DISEASE

Patients who relapse after primary therapy of HL can frequently still be cured. Patients who relapse after an effective chemotherapy regimen are usually not curable with subsequent chemotherapy administered at standard doses. Alternative salvage chemotherapy administered at standard doses, then, is given in order to document sensitivity to chemotherapy and to achieve maximum reduction of tumor mass. For patients who respond completely or nearly so, autologous stem cell transplantation can cure over half of patients. Standard salvage chemotherapy regimens have historically included ICE and GND. Newer combinations, including brentuximab with immune checkpoint inhibitors such as nivolumab, have also been tested with promising results for patients who have not seen brentuximab in the frontline setting. The combinations of ICE or GND with nivolumab or pembrolizumab, respectively, are similarly highly effective and lead to high complete remission rates and success in getting patients to definitive autologous stem cell transplantation. These novel combinations have largely replaced standard salvage chemotherapy approaches, as the chemotherapy/immunotherapy combinations appear to be more effective and are associated with higher rates of durable response after autologous stem cell transplantation, perhaps owing to the chemosensitizing effects that have been observed following immune checkpoint inhibition. Studies are ongoing to investigate whether autologous transplant is necessary for patients who have a favorable response to chemotherapy/immunotherapy combinations based on this observed phenomenon. For patients with early-stage disease who do not respond sufficiently to salvage chemotherapy, radiation therapy can be very effective to achieve a remission; whether to consolidate such a remission with an autologous stem cell transplant is debated. Brentuximab is also used as a maintenance therapy following successful autologous stem cell transplantation based on results of the AETHERA study, a randomized trial of brentuximab maintenance versus observation. Finally, anti-CD30 chimeric antigen receptor (CAR) T-cell therapy has been tested in multiply relapsed cHL with promising early results; these products are now being tested in multicenter phase 2 clinical trials.

SURVIVORSHIP

Because of the very high cure rate in patients with HL, long-term complications have become a major focus for clinical research. In fact, in some series of patients with early-stage disease, more patients died from late complications of therapy than from HL itself. This is particularly true in patients with localized disease. The most serious late side effects include second malignancies and cardiac injury. Patients are at risk for the development of acute leukemia in the first 10 years after treatment with combination chemotherapy regimens that contain alkylating agents plus radiation therapy. The risk for development of acute leukemia is greater after MOPP-like (mechlorethamine, vincristine, procarbazine, and prednisone) and BEACOPP-like regimens than with ABVD or brentuximab-AVD. The risk of development of acute leukemia after treatment for HL is also related to the number of exposures to potentially leukemogenic agents (i.e., multiple treatments after relapse) and the age of the patient being treated, with those aged >60 years at particularly high risk. The development of carcinomas as a complication of treatment for HL is a major problem. These tumors usually occur ≥10 years after treatment and are associated with use of radiotherapy. For this reason, young women treated with thoracic radiotherapy for HL should institute screening mammograms or breast MRI exams 5–10 years after treatment, and all patients who receive thoracic radiotherapy for HL should be discouraged from smoking. Mediastinal radiation also accelerates coronary artery disease, and patients should be encouraged to minimize risk factors for coronary artery disease such as smoking and elevated cholesterol levels. Cervical radiation therapy increases the risk of carotid atherosclerosis and stroke and thyroid disease, including cancer.

A number of other late side effects from the treatment of HL are well known. Patients who receive thoracic radiotherapy are at very high risk for the eventual development of hypothyroidism and should be observed for this complication; intermittent measurement of thyrotropin should be made to identify the condition before it becomes symptomatic. Lhermitte's syndrome occurs in ~15% of patients who receive thoracic radiotherapy. This syndrome is manifested by an "electric shock" sensation into the lower extremities on flexion of the neck. Because of the young age at which HL is often diagnosed, infertility is a concern for patients undergoing treatment for HL. Chemotherapy regimens containing alkylating agents induce permanent infertility in nearly all men. The risk of permanent infertility in women treated with alkylating agent–containing chemotherapy is age-related, with younger women more likely to recover fertility. Infertility is very rare after treatment with ABVD.

NODULAR LYMPHOCYTE-PREDOMINANT HODGKIN'S LYMPHOMA

NLPHL is now recognized as an entity distinct from cHL. Previous classification systems recognized that biopsies from a small subset of patients diagnosed as having HL contained a predominance of small lymphocytes and rare Reed-Sternberg–like cells; tumors had a nodular growth pattern and a clinical course that varied from that of patients with cHL. This is an unusual clinical entity and represents <5% of cases of HL and defines NLPHL.

NLPHL has a number of characteristics that suggest its relationship to NHL, rather than cHL, however. The HRS-like cell, or L&H (lymphocyte and histiocyte) or "popcorn" cell, is a clonal proliferation of B cells that are positive for B-cell markers CD45, CD79a, CD20, CD19, and BCL2. They do not express two markers normally found on HRS cells, CD30 and CD15. This lymphoma tends to have a chronic, relapsing course and sometimes transforms to diffuse large B-cell lymphoma, including a specific subtype of diffuse large B-cell lymphoma known as T-cell/histiocyte–rich B-cell lymphoma, which shares an immunophenotype with the L&H cell. This natural history most closely resembles that of the indolent B-cell NHLs outlined in **Chaps. 113** and **115**.

Patients with NLPHL are more commonly male (75%). Like cHL, the age distribution of patients with this disease has two peaks, but unlike cHL, these peaks include children and adults age 30–40 years, respectively. The majority of patients diagnosed have stage I or II disease (75%), with a minority having advanced-stage disease at diagnosis. "B" symptoms are uncommon.

Patients with early-stage disease at diagnosis should be treated with definitive radiotherapy. This is associated with a 15-year nonrelapse survival rate of 82%. The treatment of patients with advanced-stage NLPHL is controversial. Some clinicians favor no treatment of asymptomatic disease and merely close follow-up, akin to the indolent B-cell NHLs. For patients who need therapy due to symptoms or signs of organ function impairment, both cHL regimens and B-cell NHL regimens have been used, including ABVD and R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone). A single-institution experience with R-CHOP resulted in a 100% response rate in a small group of patients without a single relapse with 42 months of follow-up. Although this is short follow-up for an indolent disease, some believe R-CHOP may be curative in this disease and advocate treating patients with advanced-stage disease at diagnosis, regardless of symptoms or organ function.

115 Less Common Lymphoid and Myeloid Malignancies

Ayalew Tefferi, Dan L. Longo

The most common lymphoid malignancies are discussed in **Chaps. 111, 112, 113, 114, and 116**, myeloid leukemias in **Chaps. 109 and 110**, myelodysplastic syndromes (MDS) in **Chap. 107**, and myeloproliferative syndromes in **Chap. 108**. This chapter will focus on the more unusual forms of hematologic malignancy. The diseases discussed here are listed in **Table 115-1**. Each of these entities accounts for <1% of hematologic neoplasms.

RARE LYMPHOID MALIGNANCIES

All the lymphoid tumors discussed here are mature B-cell or T-cell natural killer (NK) cell neoplasms.

TABLE 115-1 Unusual Lymphoid and Myeloid Malignancies[a]

Lymphoid
Mature B-cell neoplasms
B-cell prolymphocytic leukemia
Splenic marginal zone lymphoma
Hairy cell leukemia
Nodal marginal zone B-cell lymphoma
Mediastinal large B-cell lymphoma
Intravascular large B-cell lymphoma
Primary effusion lymphoma
Lymphomatoid granulomatosis
Mature T-cell and natural killer (NK) cell neoplasms
T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Aggressive NK cell leukemia
Extranodal NK/T-cell lymphoma, nasal type
Enteropathy-type T-cell lymphoma
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Blastic NK cell lymphoma
Primary cutaneous CD30+ T-cell lymphoma
Angioimmunoblastic T-cell lymphoma
Myeloid
Chronic neutrophilic leukemia
Chronic eosinophilic leukemia/hypereosinophilic syndrome
Histiocytic and Dendritic Cell Neoplasms
Histiocytic sarcoma
Langerhans cell histiocytosis
Langerhans cell sarcoma
Interdigitating dendritic cell sarcoma
Follicular dendritic cell sarcoma
Mast cells
Mastocytosis
Cutaneous mastocytosis
Systemic mastocytosis
Mast cell sarcoma
Extracutaneous mastocytoma

[a]This list is not exhaustive. Many named entities are very rare and not discussed here. A complete listing is available in the online version of this chapter.

MATURE B-CELL NEOPLASMS

B-Cell Prolymphocytic Leukemia (B-PLL) This is a malignancy of medium-sized (about twice the size of a normal small lymphocyte), round lymphocytes with a prominent nucleolus and light blue cytoplasm on Wright's stain. It predominantly affects the blood, bone marrow (BM), and spleen and usually does not cause adenopathy. The median age of affected patients is 70 years, and men are more often affected than women (male-to-female ratio is 1.6). This entity is distinct from chronic lymphoid leukemia (CLL) and does not develop as a consequence of that disease.

Clinical presentation is generally from symptoms of splenomegaly or incidental detection of an elevated white blood cell (WBC) count. The clinical course can be rapid. The cells express surface IgM (with or without IgD) and typical B-cell markers (CD19, CD20, CD22). CD23 is absent, and about one-third of cases express CD5. The CD5 expression along with the presence of the t(11;14) translocation in 20% of cases leads to confusion in distinguishing B-PLL from the leukemic form of mantle cell lymphoma. No reliable criteria for the distinction have emerged, and gene expression studies suggest a close relationship between mantle cell lymphoma and B-PLL and significant differences with CLL. About half of patients have mutation or loss of p53, and deletions have been noted in 11q23 and 13q14. Nucleoside analogues like fludarabine and cladribine and combination chemotherapy (cyclophosphamide, doxorubicin, vincristine, and prednisone [CHOP]) have produced responses. CHOP plus rituximab may be more effective than CHOP alone, but the disease is sufficiently rare that large series have not been reported. Splenectomy can produce palliation of symptoms but appears to have little or no impact on the course of the disease. BM transplantation may be curative. Imatinib may also have activity.

Splenic Marginal Zone Lymphoma (SMZL) This tumor of mainly small lymphocytes originates in the marginal zone of the spleen white pulp, grows to efface the germinal centers and mantle, and invades the red pulp. Splenic hilar nodes, BM, and peripheral blood (PB) may be involved. The circulating tumor cells have short surface villi and are called villous lymphocytes. Table 115-2 shows differences in tumor cells of a number of neoplasms of small lymphocytes that aid in the differential diagnosis. SMZL cells express surface immunoglobulin and CD20 but are negative for CD5, CD10, CD43, and CD103. Lack of CD5 distinguishes SMZL from CLL, and lack of CD103 separates SMZL from hairy cell leukemia.

The median age of patients with SMZL is mid-fifties, and men and women are equally represented. Patients present with incidental or symptomatic splenomegaly or incidental detection of lymphocytosis in the PB with villous lymphocytes. Autoimmune anemia or thrombocytopenia may be present. The immunoglobulin produced by these cells contains somatic mutations that reflect transit through a germinal center, and ongoing mutations suggest that the mutation machinery has remained active. About 40% of patients have either deletions or translocations involving 7q21, the site of the *FLNC* gene (filamin Cγ, involved in cross-linking actin filaments in the cytoplasm). *NOTCH2* mutations are seen in 25% of patients. Chromosome 8p deletions may also be noted. The genetic lesions typically found in extranodal marginal zone lymphomas (e.g., trisomy 3 and t[11;18]) are uncommon in SMZL.

The clinical course of disease is generally indolent with median survivals exceeding 10 years. Patients with elevated lactate dehydrogenase (LDH) levels, anemia, and hypoalbuminemia generally have a poorer prognosis. Long remissions can be seen after splenectomy. Rituximab, ibrutinib, and PI3 kinase inhibitors are also active. A small fraction of patients undergo histologic progression to diffuse large B-cell lymphoma with a concomitant change to a more aggressive natural history. Experience with combination chemotherapy in SMZL is limited.

Hairy Cell Leukemia Hairy cell leukemia is a tumor of small lymphocytes with oval nuclei, abundant cytoplasm, and distinctive membrane projections (hairy cells). Patients have splenomegaly and diffuse BM involvement. While some circulating cells are noted, the clinical picture is dominated by symptoms from the enlarged spleen and pancytopenia. The mechanism of the pancytopenia is not completely clear and may be mediated by both inhibitory cytokines and

TABLE 115-3 Differential Diagnosis of "Dry Tap"—Inability to Aspirate Bone Marrow	
Dry taps occur in about 4% of attempts and are associated with:	
Metastatic carcinoma infiltration	17%
Chronic myeloid leukemia	15%
Myelofibrosis	14%
Hairy cell leukemia	10%
Acute leukemia	10%
Lymphomas, Hodgkin's disease	9%
Normal marrow	Rare

marrow replacement. The marrow has an increased level of reticulin fibers; indeed, hairy cell leukemia is a common cause of inability to aspirate BM or so-called "dry tap" (Table 115-3). Monocytopenia is profound and may explain a predisposition to atypical mycobacterial infection that is observed clinically. The tumor cells have strong expression of CD22, CD25, and CD103; soluble CD25 level in serum is an excellent tumor marker for disease activity. The cells also express tartrate-resistant acid phosphatase. The immunoglobulin genes are rearranged and mutated, indicating the influence of a germinal center. No specific cytogenetic abnormality has been found, but most cases contain the activating *BRAF* mutation V600E.

The median age of affected patients is mid-fifties, and the male-to-female ratio is 5:1. Treatment options are numerous. Splenectomy is often associated with prolonged remission. Nucleosides including cladribine and deoxycoformycin are highly active but are also associated with further immunosuppression and can increase the risk of certain opportunistic infections. However, after brief courses of these agents, patients usually obtain very durable remissions during which immune function spontaneously recovers. Interferon α is also an effective therapy but is not as effective as nucleosides. Chemotherapy-refractory patients have responded to vemurafenib, a BRAF inhibitor. Vemurafenib does not appear to be curative, but responses can be maintained with chronic treatment. More durable remissions occur when rituximab is added to vemurafenib.

Nodal Marginal Zone B-Cell Lymphoma This rare node-based disease bears an uncertain relationship with extranodal marginal zone lymphomas, which are often mucosa-associated and are called mucosa-associated lymphoid tissue (MALT) lymphomas, and SMZLs. Patients may have localized or generalized adenopathy. The neoplastic cell is a marginal zone B cell with monocytoid features and has been called monocytoid B-cell lymphoma in the past. Up to one-third of the patients may have extranodal involvement, and involvement of the lymph nodes can be secondary to the spread of a mucosal primary lesion. In authentic nodal primaries, the cytogenetic abnormalities associated with MALT lymphomas (trisomy 3 and t[11;18]) are very rare. The clinical course is indolent. Patients often respond to combination chemotherapy, although remissions have not been durable. Few patients have received CHOP plus rituximab, which is likely to be an effective approach to management.

Mediastinal (Thymic) Large B-Cell Lymphoma This entity was originally considered a subset of diffuse large B-cell lymphoma; however, additional study has identified it as a distinct entity with its own characteristic clinical, genetic, and immunophenotypic features. This is a disease that can be bulky in size but usually remains confined to the mediastinum. It can be locally aggressive, including progressing to produce a superior vena cava obstruction syndrome or pericardial effusion. About one-third of patients develop pleural effusions, and in 5–10% of cases, disease can disseminate widely to kidney, adrenal, liver, skin, and even brain. The disease affects women more often than men (male-to-female ratio is 1:2–3), and the median age is 35–40 years.

The tumor is composed of sheets of large cells with abundant cytoplasm accompanied by variable, but often abundant, fibrosis. It is distinguished from nodular sclerosing Hodgkin's disease by the paucity of normal lymphoid cells and the absence of lacunar variants of Reed-Sternberg cells. However, more than one-third of the genes that are expressed to a greater extent in primary mediastinal large B-cell lymphoma than in usual diffuse large B-cell lymphoma are also overexpressed in Hodgkin's disease, suggesting a possible pathogenetic relationship between the two entities that affect the same anatomic site. Tumor cells may overexpress *MAL*. The genome of tumor cells is characterized by frequent chromosomal gains and losses. The tumor cells in mediastinal large B-cell lymphoma express CD20, but surface immunoglobulin and human leukocyte antigen (HLA) class I and class II molecules may be absent or incompletely expressed. Expression of lower levels of class II HLA identifies a subset with poorer prognosis. The cells are CD5 and CD10 negative but may show light staining with anti-CD30. The cells are CD45 positive, unlike cells of classical Hodgkin's disease.

Methotrexate, leucovorin, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin (MACOP-B) and rituximab plus CHOP are effective treatments, achieving 5-year survival of 75–87%. Dose-adjusted therapy with prednisone, etoposide, vincristine, cyclophosphamide, and doxorubicin (EPOCH) plus rituximab has produced 5-year survival of 97%. A role for mediastinal radiation therapy has not been definitively demonstrated, but it is frequently used, especially in patients whose mediastinal area remains positron emission tomography–avid after 4–6 cycles of chemotherapy.

Intravascular Large B-Cell Lymphoma This is an extremely rare form of diffuse large B-cell lymphoma characterized by the presence of lymphoma in the lumen of small vessels, particularly capillaries. It is also known as malignant angioendotheliomatosis or angiotropic large-cell lymphoma. It is sufficiently rare that no consistent picture has emerged to define a clinical syndrome or its epidemiologic and genetic features. It is thought to remain inside vessels because of a defect in adhesion molecules and homing mechanisms, an idea supported by scant data suggesting absence of expression of β-1 integrin and ICAM-1. Patients commonly present with symptoms of small-vessel occlusion, skin lesions, or neurologic symptoms. The tumor cell clusters can promote thrombus formation. A subset of patients have tumors with *MYD88* or *CD79B* mutations. In general, the clinical course is aggressive and the disease is poorly responsive to therapy. Often a diagnosis is not made until very late in the course of the disease or at autopsy. Diagnosis may be revealed in random skin biopsies in settings where localized findings are limited.

Primary Effusion Lymphoma This entity is another variant of diffuse large B-cell lymphoma that presents with pleural effusions, usually without apparent tumor mass lesions. It is most common in the setting of immune deficiency disease, especially AIDS, and is caused by human herpes virus 8 (HHV-8)/Kaposi's sarcoma herpes virus (KSHV). It is also known as *body cavity–based lymphoma*. Some patients have been previously diagnosed with Kaposi's sarcoma. It can also occur in the absence of immunodeficiency in elderly men of Mediterranean heritage, similar to Kaposi's sarcoma but even less common.

The malignant effusions contain cells positive for HHV-8/KSHV, and many are also co-infected with Epstein-Barr virus. The cells are large with large nuclei and prominent nucleoli that can be confused with Reed-Sternberg cells. The cells express CD20 and CD79a (immunoglobulin-signaling molecule), although they often do not express immunoglobulin. Some cases aberrantly express T-cell markers such as CD3 or rearranged T-cell receptor genes. No characteristic genetic lesions have been reported, but gains in chromosome 12 and X material have been seen, similar to other HIV-associated lymphomas. The clinical course is generally characterized by rapid progression and death within 6 months. CHOP plus lenalidomide or bortezomib may produce responses. Highly active antiretroviral therapy for HIV should be maintained during treatment.

Lymphomatoid Granulomatosis This is an angiocentric, angiodestructive lymphoproliferative disease comprised by neoplastic Epstein-Barr virus–infected monoclonal B cells accompanied and outnumbered by a polyclonal reactive T-cell infiltrate. The disease is graded based on histologic features such as cell number and atypia in

the B cells. It is most often confused with extranodal NK/T-cell lymphoma, nasal type, which can also be angiodestructive and is Epstein-Barr virus–related. The disease usually presents in adults (males > females) as a pulmonary infiltrate. Involvement is often entirely extranodal and can include kidney (32%), liver (29%), skin (25%), and brain (25%). The disease often but not always occurs in the setting of immune deficiency.

The disease can be remitting and relapsing in nature or can be rapidly progressive. The course is usually predicted by the histologic grade. The disease is highly responsive to combination chemotherapy and is curable in most cases. Some investigators have claimed that low-grade disease (grade I and II) can be treated with interferon α.

MATURE T-CELL AND NK CELL NEOPLASMS

T-Cell Prolymphocytic Leukemia This is an aggressive leukemia of medium-sized prolymphocytes involving the blood, marrow, nodes, liver, spleen, and skin. It accounts for 1–2% of all small lymphocytic leukemias. Most patients present with elevated WBC count (often >100,000/μL), hepatosplenomegaly, and adenopathy. Skin involvement occurs in 20%. The diagnosis is made from PB smear, which shows cells about 25% larger than those in small lymphocytes, with cytoplasmic blebs and nuclei that may be indented. The cells express T-cell markers like CD2, CD3, and CD7; two-thirds of patients have cells that are CD4+ and CD8–, and 25% have cells that are CD4+ and CD8+. T-cell receptor β chains are clonally rearranged. In 80% of patients, inversion of chromosome 14 occurs between q11 and q32. Ten percent have t(14;14) translocations that bring the T-cell receptor alpha/beta gene locus into juxtaposition with oncogenes *TCL1* and *TCL1b* at 14q32.1. Chromosome 8 abnormalities are also common. Deletions in the *ATM* gene are also noted. Activating *JAK3* mutations have also been reported.

The course of the disease is generally rapid, with median survival of about 12 months. Responses have been seen with the anti-CD52 antibody alemtuzumab, nucleoside analogues, and CHOP chemotherapy. Histone deacetylase inhibitors like vorinostat and romidepsin may also have activity. Small numbers of patients with T-cell prolymphocytic leukemia have also been treated with high-dose therapy, and allogeneic BM transplantation after remission has been achieved with alemtuzumab or conventional-dose therapy.

T-Cell Large Granular Lymphocytic Leukemia T-cell large granular lymphocytic (LGL) leukemia is characterized by increases in the number of LGLs in the PB (2000–20,000/μL) often accompanied by severe neutropenia, with or without concomitant anemia. Pure red cell aplasia may occur in 15–20% of patients. Splenomegaly is seen in 25% of patients; adenopathy is generally absent. B symptoms are rare, but 20–30% of patients may have infections related to the severe neutropenia. Patients may have splenomegaly and frequently have evidence of systemic autoimmune disease, including rheumatoid arthritis, hypergammaglobulinemia, autoantibodies, and circulating immune complexes. BM involvement is mainly interstitial in pattern, with <50% lymphocytes on differential count. Usually the cells express CD3, T-cell receptors, usually TCRα/β, and CD8; NK-like variants may be CD3–. Like other T-cell neoplasms, loss of expression of CD5 and/or CD7 is common. The leukemic cells often express Fas and Fas ligand. The JAK/STAT pathway is often activated.

The course of the disease is generally indolent and dominated by the neutropenia. Paradoxically, immunosuppressive therapy with cyclosporine, methotrexate, or cyclophosphamide plus glucocorticoids can produce an increase in granulocyte counts. Nucleosides have been used anecdotally. Occasionally the disease can accelerate to a more aggressive clinical course.

Aggressive NK Cell Leukemia NK neoplasms are very rare, and they may follow a range of clinical courses from very indolent to highly aggressive. They are more common in Asians than whites, and the cells frequently harbor a clonal Epstein-Barr virus episome. The PB white count is usually not greatly elevated, but abnormal large lymphoid cells with granular cytoplasm are noted. The aggressive form is characterized by symptoms of fever and laboratory abnormalities of pancytopenia. Hepatosplenomegaly is common; node involvement is less common. Patients may have hemophagocytosis, coagulopathy, or multiorgan failure. Serum levels of Fas ligand are elevated.

The cells express CD2 and CD56 and do not have rearranged T-cell receptor genes. Deletions involving chromosome 6 are common. The disease can be rapidly progressive. Some forms of NK neoplasms are more indolent. They tend to be discovered incidentally with LGL lymphocytosis and do not manifest the fever and hepatosplenomegaly characteristic of the aggressive leukemia. The cells are also CD2 and CD56 positive, but they do not contain clonal forms of Epstein-Barr virus and are not accompanied by pancytopenia or autoimmune disease.

Extranodal NK/T-Cell Lymphoma, Nasal Type Like lymphomatoid granulomatosis, extranodal NK/T-cell lymphoma tends to be an angiocentric and angiodestructive lesion, but the malignant cells are not B cells. In most cases, they are CD56+ Epstein-Barr virus–infected cells; occasionally, they are CD56–Epstein-Barr virus–infected cytotoxic T cells. They are most commonly found in the nasal cavity. Historically, this illness was called lethal midline granuloma, polymorphic reticulosis, and angiocentric immunoproliferative lesion. This form of lymphoma is prevalent in Asia, Mexico, and Central and South America; it affects males more commonly than females. When it spreads beyond the nasal cavity, it may affect soft tissue, the gastrointestinal tract, or the testis. In some cases, hemophagocytic syndrome (HPS) may influence the clinical picture. Patients may have B symptoms. Many of the systemic manifestations of disease are related to the production of cytokines by the tumor cells and the cells responding to their signals. Deletions and inversions of chromosome 6 are common.

Many patients with extranodal NK/T-cell lymphoma, nasal type, have excellent antitumor responses with combination chemotherapy regimens, particularly those with localized disease. Radiation therapy is often used after completion of chemotherapy. Four risk factors have been defined, including B symptoms, advanced stage, elevated LDH, and regional lymph node involvement. Patient survival is linked to the number of risk factors: 5-year survival is 81% for zero risk factors, 64% for one risk factor, 32% for two risk factors, and 7% for three or four risk factors. Combination regimens without anthracyclines have been touted as superior to CHOP, but data are sparse. High-dose therapy with stem cell transplantation has been used, but its role is unclear.

Enteropathy-Type T-Cell Lymphoma Enteropathy-type T-cell lymphoma is a rare complication of longstanding celiac disease. It most commonly occurs in the jejunum or the ileum. In adults, the lymphoma may be diagnosed at the same time as celiac disease, but the suspicion is that the celiac disease was a longstanding precursor to the development of lymphoma. The tumor usually presents as multiple ulcerating mucosal masses but may also produce a dominant exophytic mass or multiple ulcerations. The tumor expresses CD3 and CD7 nearly always and may or may not express CD8. The tumor may express CD30, but therapies directed at CD30 have not been adequately tested. The normal-appearing lymphocytes in the adjacent mucosa often have a similar phenotype to the tumor. Most patients have the HLA genotype associated with celiac disease, HLA DQA1*0501 or DQB1*0201.

The prognosis of this form of lymphoma is typically poor (median survival is 7–11 months), but some patients have a good response to CHOP chemotherapy. Patients who respond can develop bowel perforation from responding tumor. If the tumor responds to treatment, recurrence may develop elsewhere in the celiac disease–affected small bowel.

An indolent form of T-cell or NK cell lymphoma occurs rarely that affects mainly the small intestine and presents with dyspepsia, vomiting, and diarrhea. The cells often contain genetic changes that result in JAK-STAT activation. The disease is most often chronic with little or no propensity to spread and develop aggressive growth. A variety of approaches have been tested; none are reliably curative.

Hepatosplenic T-Cell Lymphoma Hepatosplenic T-cell lymphoma is a malignancy derived from T cells expressing the gamma/delta

T-cell antigen receptor that affects mainly the liver and fills the sinusoids with medium-size lymphoid cells. When the spleen is involved, dominantly the red pulp is infiltrated. It is a disease of young people, especially young people with an underlying immunodeficiency or with an autoimmune disease that demands immunosuppressive therapy. The use of thiopurine and infliximab is particularly common in the history of patients with this disease. The cells are CD3+ and usually CD4– and CD8–. The cells may contain isochromosome 7q, often together with trisomy 8. The lymphoma has an aggressive natural history. Combination chemotherapy may induce remissions, but most patients relapse. Cytarabine/etoposide/platinum-based regimens appear more effective than CHOP-based regimens. Median survival is about 2 years. The tumor does not appear to respond to reversal of immunosuppressive therapy.

Subcutaneous Panniculitis-Like T-Cell Lymphoma Subcutaneous panniculitis-like T-cell lymphoma involves multiple subcutaneous collections of neoplastic T cells that are usually cytotoxic cells in phenotype (i.e., contain perforin and granzyme B and express CD3 and CD8). The rearranged T-cell receptor is usually alpha/beta-derived, but occasionally, the gamma/delta receptors are involved, particularly in the setting of immunosuppression. The cells are negative for Epstein-Barr virus. A history of autoimmune disease, particularly lupus erythematosus, in the patient or the family is present in almost one-third of patients. Patients may have an HPS in addition to the skin infiltration; fever and hepatosplenomegaly may also be present. Nodes are generally not involved. Patients frequently respond to combination chemotherapy, including CHOP. When the disease is progressive, the HPS can be a component of a fulminant downhill course. Effective therapy can reverse the HPS.

Blastic NK Cell Lymphoma The neoplastic cells express NK cell markers, especially CD56, and are CD3 negative. They are large blastic-appearing cells and may produce a leukemia picture, but the dominant site of involvement is the skin. Morphologically, the cells are similar to the neoplastic cells in acute lymphoid and myeloid leukemia. No characteristic chromosomal abnormalities have been described. The clinical course is rapid, and the disease is largely unresponsive to typical lymphoma treatments.

Primary Cutaneous CD30+ T-Cell Lymphoma This tumor involves the skin and is composed of cells that appear similar to the cells of anaplastic T-cell lymphoma. Among cutaneous T-cell tumors, ~25% are CD30+ anaplastic lymphomas. If dissemination to lymph nodes occurs, it is difficult to distinguish between the cutaneous and systemic forms of the disease. The tumor cells are often CD4+, and the cells contain granules that are positive for granzyme B and perforin in 70% of cases. The typical t(2;5) of anaplastic T-cell lymphoma is absent; indeed, its presence should prompt a closer look for systemic involvement and a switch to a diagnosis of anaplastic T-cell lymphoma. This form of lymphoma has sporadically been noted as a rare complication of silicone or saline breast implants. The natural history of breast implant–associated lymphoma is generally indolent. Cutaneous CD30+ T-cell lymphoma often responds to therapy. The anti-CD30 immunotoxin conjugate brentuximab vedotin is active. Radiation therapy can be effective, and surgery can also produce long-term disease control. Five-year survival exceeds 90%.

Angioimmunoblastic T-Cell Lymphoma Angioimmunoblastic T-cell lymphoma is a systemic disease that accounts for ~15% of all T-cell lymphomas. Patients frequently have fever, advanced stage, diffuse adenopathy, hepatosplenomegaly, skin rash, polyclonal hypergammaglobulinemia, and a wide range of autoantibodies including cold agglutinins, rheumatoid factor, and circulating immune complexes. Patients may have edema, arthritis, pleural effusions, and ascites. The nodes contain a polymorphous infiltrate of neoplastic T cells and non-neoplastic inflammatory cells together with proliferation of high endothelial venules and follicular dendritic cells (FDCs). The most common chromosomal abnormalities are trisomy 3, trisomy 5, and an extra X chromosome. Aggressive combination chemotherapy can induce regressions. The underlying immune defects make conventional lymphoma treatments more likely to produce infectious complications.

RARE MYELOID MALIGNANCIES

The World Health Organization (WHO) and the International Consensus Classification (ICC) systems use PB counts, PB smear analysis, BM morphology, and cytogenetic and molecular genetic tests in order to classify myeloid malignancies into several major categories **(Table 115-4)**. Among them, acute myeloid leukemia (AML) and AML-related disorders are discussed in **Chap. 109**, MDS and MDS/AML in **Chap. 107**, chronic myeloid leukemia (CML) in **Chap. 110**, and *JAK2* mutation–prevalent myeloproliferative neoplasms (MPN), including essential thrombocythemia, polycythemia vera, and primary myelofibrosis, in **Chap. 108**. In this chapter, we focus on some of the remaining myeloid neoplasms listed in Table 115-4, which are less frequent: (1) other MPNs including chronic neutrophilic leukemia (CNL), chronic eosinophilic leukemia, not otherwise specified (CEL-NOS), and MPN, unclassifiable (MPN-U); (2) MDS/MPN overlap including chronic myelomonocytic leukemia (CMML), atypical CML (aCML), MDS/MPN with mutated *SF3B1* and thrombocytosis, MDS/MPN with ring sideroblasts and thrombocytosis, not otherwise specified (MDS/MPN-RS-T-NOS), and MDS/MPN, not otherwise specified (MDS/MPN-NOS); (3) juvenile myelomonocytic leukemia (JMML); (4) transient myeloproliferative disorder (TMD); (5) hypereosinophilia including those associated with tyrosine kinase gene fusions (TKGFs) and hypereosinophilic syndrome (HES); (6) mastocytosis; and (7) histiocytic and dendritic cell neoplasms (hemophagocytic lymphohistiocytosis [HLH] is discussed in **Chap. 68**).

CHRONIC NEUTROPHILIC LEUKEMIA

CNL is a clonal proliferation of mature neutrophils with few or no circulating immature granulocytes. Other clinical features include hepatosplenomegaly and constitutional symptoms. The disease is molecularly characterized by activating mutations of the gene (*CSF3R*) encoding for the receptor for granulocyte colony-stimulating factor (G-CSF), also known as colony-stimulating factor 3 (CSF3). Patients with CNL might be asymptomatic at presentation but can also display constitutional symptoms, splenomegaly, anemia, and thrombocytopenia. A population-based study suggested an overall incidence of 0.1 cases/million individuals, using combined Surveillance, Epidemiology, and End Results and National Cancer Database data. CNL typically presents in elderly patients with a median age at diagnosis of 66.5 years (range, 15–86 years) and slight male preponderance (56–58% of cases). Median survival is ~2 years, and causes of death include transformation to acute leukemia, progressive disease associated with severe cytopenias, and marked treatment-refractory leukocytosis.

CSF3 is the main growth factor for granulocyte proliferation and differentiation. Accordingly, recombinant CSF3 is used for the treatment of severe neutropenia, including severe congenital neutropenia (SCN). Some patients with SCN acquire *CSF3R* mutations, and the frequency of such mutations is significantly higher (~80%) in patients who experience leukemic transformation. SCN-associated *CSF3R* mutations occur in the region of the gene coding for the cytoplasmic domain of CSF3R and result in truncation of the C-terminal–negative regulatory domain. In 2013, Maxson et al described a different class of *CSF3R* mutations in ~90% of patients with CNL; these were mostly membrane proximal, the most frequent being a C-to-T substitution at nucleotide 1853 (T618I). In a subsequent confirmatory study, *CSF3R* mutations were found to be specific to WHO-defined CNL. About 40% of the T618I-mutated cases also harbored *SETBP1* mutations. *CSF3R* T618I has been shown to induce lethal myeloproliferative disorder in a mouse model and to have in vitro sensitivity to JAK inhibition.

Diagnosis of CNL requires exclusion of the more common causes of neutrophilia including infections and inflammatory processes **(Table 115-5)**. In addition, one should be mindful of the association between some forms of metastatic cancer or plasma cell neoplasms with secondary neutrophilia. Neoplastic neutrophilia also occurs in other myeloid malignancies, which should be excluded during the

TABLE 115-4 International Consensus Classification of Myeloid Neoplasms

6. Acute myeloid leukemia (AML)
   a. AML diagnosis requiring ≥10% bone marrow (BM) or peripheral blood (PB) blasts
      i. Acute promyelocytic leukemia
      ii. Core binding factor AML
      iii. AML with *KMT2A* rearrangement
      iv. AML with *DEK::NUP214*
      v. AML with *MECOM* rearrangements
      vi. AML with *NPM1* mutation
      vii. AML with in-frame *bZIP CEBPA* mutations
      viii. AML with other rare recurring translocations
      ix. Myelodysplastic syndrome (MDS)/AML with *TP53* mutations
      x. MDS/AML with myelodysplasia-related mutations
      xi. MDS/AML with myelodysplasia-related karyotype
      xii. MDS/AML not otherwise specified (NOS)
   b. AML diagnosis requiring ≥20% BM or PB blasts
      i. AML with t(9;22)-*BCR::ABL1*
      ii. AML with *TP53* mutations, other than pure erythroid leukemia
      iii. AML with myelodysplasia-related gene mutations
      iv. AML with myelodysplasia-related karyotype
      v. AML NOS
7. AML-related disorders
   a. Pure erythroid leukemia (PEL; *TP53* mutated)
   b. Myeloid sarcoma
   c. Blastic plasmacytoid dendritic cell neoplasm
   d. Acute leukemia of ambiguous lineage
   e. Acute undifferentiated leukemia
   f. Mixed phenotype acute leukemia
8. Myelodysplastic syndromes (MDS)
   a. MDS with mutated *TP53*
   b. MDS with excess blasts (5–9% BM or 2–9% PB)
   c. MDS without excess blasts (<5% BM and <2% PB)
      i. MDS with del(5q) [isolated or accompanied by only one other cytogenetic abnormality other than 7/del(7q); no multi-hit *TP53*]
      ii. MDS with *SF3B1* [variant allele frequency ≥10%/no *RUNX1* or multi-hit *TP53*; no del(5q), –7/del(7q), complex karyotype, or abnormal 3q26.2]
      iii. MDS, NOS–single-lineage dysplasia
      iv. MDS, NOS–multilineage dysplasia
      v. MDS, NOS without dysplasia
9. MDS/AML
   a. MDS/AML (BM/PB blasts 10–19%)
   b. MDS/AML with mutated *TP53*
10. Myeloproliferative neoplasms (MPN)
   a. Chronic myeloid leukemia
   b. Polycythemia vera
   c. Essential thrombocythemia
   d. Primary myelofibrosis (PMF)
      i. Early/prefibrotic PMF
      ii. Overt PMF
   e. MPN, unclassifiable (MPN-U)
   f. Chronic neutrophilic leukemia
   g. Chronic eosinophilic leukemia, NOS
11. MDS/MPN
   a. Chronic myelomonocytic leukemia (CMML) (≥0.5 × 10^9/L absolute and ≥10% PB monocytes)
      i. CMML-1 (<10% BM and <5% PB blasts)
      ii. CMML-2 (10–19% BM or 5–19% PB blasts)
   b. Atypical chronic myeloid leukemia
   c. MDS/MPN with mutated *SF3B1* and thrombocytosis
   d. MDS/MPN with ring sideroblasts and thrombocytosis, NOS
   e. MDS/MPN, NOS
      i. MDS/MPN with isolated isochromosome (17q)
12. Eosinophilic disorders
13. Mastocytosis
14. Hematologic neoplasms with germline predisposition
15. Pediatric myeloid malignancies
16. Premalignant clonal hematopoiesis

diagnostic workup (Table 115-5). Accordingly, the ICC diagnostic criteria for CNL are designed to exclude the possibilities of both secondary/reactive neutrophilia and leukocytosis associated with myeloid malignancies other than CNL (Table 115-5). The discovery of *CSF3R* mutations (see above) and their almost invariable association with ICC-defined CNL has allowed its incorporation in the ICC diagnostic criteria (Table 115-5). In general, the presence of a membrane proximal *CSF3R* mutation in a patient with predominantly neutrophilic granulocytosis should be sufficient for the diagnosis of CNL, regardless of the degree of leukocytosis. Unfortunately, several exclusionary criteria still need to be met for diagnosing CNL in the absence of *CSF3R* mutations (Table 115-5).

Current treatment in CNL is largely palliative and suboptimal in its efficacy. Several drugs alone or in combination have been tried, and none have shown remarkable efficacy. As such, allogeneic hematopoietic stem cell transplant (ASCT) is reasonable to consider in the presence of symptomatic disease, especially in younger patients. Otherwise, cytoreductive therapy with hydroxyurea is probably as good as anything, and a more intensive combination chemotherapy may not have additional value. However, response to hydroxyurea therapy is often transient, and some have successfully used interferon α as an alternative drug. JAK inhibitor therapy has emerged as an additional therapeutic option but is not necessarily superior to hydroxyurea (estimated response rate of 30%). It is thus recommended that CNL patients first and foremost be evaluated for eligibility and disposition for ASCT, with the remaining therapeutic agents being aimed at controlling myeloproliferation (targeting leukocytes <25–30 × 10^9/L) and alleviating symptoms.

CHRONIC EOSINOPHILIC LEUKEMIA, NOT OTHERWISE SPECIFIED

In a Mayo Clinic survey of 1416 patients with PB eosinophilia evaluated between 2008 and 2019, 17 patients (1.2%) fulfilled the ICC criteria for CEL-NOS (Table 115-5); median age was 63 years, with the vast majority of patients (88%) presenting with systemic symptoms. Organ involvement was a prominent feature including spleen, cardiac, pulmonary, and distal esophagus. Laboratory abnormalities included anemia, leukocytosis, and eosinophilia (median eosinophil count of 6.4 × 10^9/L; range, 2.0–53.1 × 10^9/L). The most common bone marrow abnormalities included abnormal eosinophils, abnormal and increased megakaryocytes, and fibrosis (18%). Cytogenetic abnormalities occurred in 88% of patients and included trisomy 8, complex karyotype, 13q–, 20q–, and chromosome 1 abnormalities. All seven patients with next-generation sequencing studies harbored one or more mutations including *ASXL1* (43%) and *IDH1* (29%). Half of patients treated with hydroxyurea-based regimens responded with a persistent decline in eosinophil count for a median duration of 18 months. One-third of patients treated with prednisone responded, with a median duration of response at 13 months. Three patients were treated with imatinib, of whom two had normalization of eosinophil count. At a median follow-up of 13 months, nine patients had died, including three who underwent leukemic transformation.

MYELOPROLIFERATIVE NEOPLASM, UNCLASSIFIABLE

The category of MPN-U includes MPN-like neoplasms that cannot be clearly classified as one of the other subcategories of MPN listed in Table 115-1. Examples include patients presenting with unusual thrombosis or unexplained organomegaly with normal blood counts but found to carry MPN-characteristic mutations such as *JAK2* and *CALR* or display bone marrow morphology that is consistent with MPN. It is possible that some cases of MPN-U represent earlier disease stages in polycythemia vera (PV) or essential thrombocythemia (ET), which, however, fail to meet the threshold hemoglobin levels or platelet counts that are required per WHO diagnostic criteria. Specific treatment interventions might not be necessary in asymptomatic patients with MPN-U, whereas patients with arterial thrombotic complications might require cytoreductive and aspirin therapy and those with venous thrombosis might require systemic anticoagulation.

TABLE 115-5 International Consensus Classification (ICC) Diagnostic Criteria for Chronic Neutrophilic Leukemia (CNL), Atypical Chronic Myeloid Leukemia (aCML), and Chronic Myelomonocytic Leukemia (CMML)

VARIABLES	CNL[a]	aCML	CMML
PB leukocyte count	≥13 × 10^9/L[d]	≥13 × 10^9/L	
PB segmented neutrophils/bands	≥80%		
PB neutrophil precursors[b]	<10%	≥10%	
PB blasts	Usually absent[e]	<20%	<20%
PB monocyte count	<10% of leukocytes	No or minimal monocytosis	≥0.5 × 10^9/L[g] Persistent and lasting for at least 3 months
Cytopenia[h]		Yes	Yes
Dysgranulopoiesis		Yes	
PB basophil/eosinophil percentage		<10%	
PB monocyte percentage		<10%	≥10%
BM	Hypercellular ↑ Neutrophils, number and % <5% blasts Normal neutrophilic maturation	Hypercellular ↑ Granulocyte proliferation Granulocytic dysplasia ± erythroid/megakaryocyte Dysplasia <20% blasts	Hypercellular due to myeloproliferation and increased monocytes and lacking diagnostic features of AML, MPN, or other conditions associated with monocytosis
BCR-ABL1	No	No	No
Tyrosine kinase gene fusions[f]	No	No	No
CSF3R T618I or other activating CSF3R mutation or persistent neutrophilia, splenomegaly, no identifiable cause of reactive neutrophilia,[c] if plasma cell neoplasm is present, need demonstration of clonality of myeloid cells by cytogenetic or molecular studies	Yes

Evidence for reactive leukocytosis or monocytosis	No	No	No

[a]Diagnosis requires meeting all criteria. [b]Neutrophil precursors include myeloblasts, promyelocytes, myelocytes, and metamyelocytes. [c]Causes of reactive neutrophilia include plasma cell neoplasms, solid tumor, infections, and inflammatory processes. [d]≥25 × 10^9/L in cases lacking *CSF3R* T618I or another activating *CSF3R* mutation. [e]10–19% blasts constitute accelerated phase and ≥20% blast phase. [f]Tyrosine kinase gene fusions involve *PDGFRA*, *PDGFRB*, *FGFR1*, *ABL1*, *JAK2*, and *FLT3*. [g]PB monocytes ≥1 × 10^9/L in cases without evidence of clonality; the latter is signified by abnormal karyotype or a myeloid neoplasm associated mutation with ≥10% variant allele frequency. [h]Hemoglobin <12 g/dL in females and <13 g/dL in males, absolute neutrophil count <1.8 × 10^9/L, and/or platelets <150 × 10^9/L, that is not explained by another condition.

Abbreviations: AML, acute myeloid leukemia; BM, bone marrow; CML, chronic myeloid leukemia; ET, essential thrombocythemia; MDS, myelodysplastic syndromes; MPN, myeloproliferative neoplasms; PB, peripheral blood; PMF, primary myelofibrosis; PV, polycythemia vera.

CHRONIC MYELOMONOCYTIC LEUKEMIA

CMML is classified under the ICC category of MDS/MPN neoplasms and is defined by sustained (>3 months) PB monocytosis (≥0.5 × 10^9/L; monocytes ≥10% of leukocyte count), consistent BM morphology, <20% BM or PB blasts (including promonocytes), and cytogenetic or molecular evidence of clonality. The median age at CMML diagnosis is ~73–75 years, with a male preponderance (1.5–3:1). The exact incidence of CMML remains unknown but is estimated at 4 cases per 100,000 persons per year. Clinical presentation is variable and depends on whether the disease presents with MDS-like (MDS-CMML) or MPN-like (MP-CMML) phenotype, based on the presence or absence of leukocyte count of ≥13 × 10^9/L; the former is associated with cytopenias and the latter with splenomegaly and features of myeloproliferation such as fatigue, night sweats, weight loss, and cachexia. About 20% of patients with CMML experience unique symptoms including systemic inflammatory syndromes (e.g., arthritis, pericardial effusion, pleural effusion, ascites), autoimmune diseases, leukemia cutis, and lysozyme-induced nephropathy.

During the diagnostic workup of CMML, it is important to first exclude reactive causes of monocytosis, including tuberculosis, fungal infections, subacute bacterial endocarditis, viral and protozoal infections, connective tissue diseases, sarcoidosis, lipid storage disorders, postsplenectomy state, and the recovery phase of an acute infection or BM regeneration after chemotherapy. Other myeloid neoplasms in the differential diagnosis include CML (*BCR::ABL1*-defined) and other fusion gene-associated entities including those with rearrangements of *PDGFRA*, *PDGFRB*, *FGFR1, JAK2, FLT3,* and *ABL1*. Similarly, it should be noted that monocytosis can be associated with MPN such as primary myelofibrosis (PMF) and PV, where its presence adversely impacts survival. BM examination often shows morphologic dysplasia in at least one hematopoietic lineage and granulocytic and monocytic proliferation. On immunophenotyping, the abnormal cells often express myelomonocytic antigens such as CD13 and CD33, with variable expression of CD14, CD64, CD68, and CD163. Monocytic-derived cells are almost always positive for the cytochemical nonspecific esterases (e.g., butyrate esterase), while normal granulocytic precursors are positive for lysozyme and chloroacetate esterase. In CMML, it is common to have a hybrid cytochemical staining pattern with cells expressing both chloroacetate and butyrate esterases simultaneously (dual esterase staining).

Based on flow cytometric expression of CD14/CD16, monocytes can be classified into classical MO1 (CD14+/CD16–), intermediate MO2 (CD14+/CD16+), and nonclassical MO3 (CD14–/CD16+) fractions, with MO1 constituting the major monocyte population (85%) in healthy conditions. CMML patients have a characteristic increase in classical monocytes, distinguishing CMML from other causes of reactive and clonal monocytosis. Almost all patients with CMML harbor somatic mutations that are neither specific nor disease-defining, including (1) mutations in epigenetic control of transcription, such as histone modification (*EZH2*, *ASXL1*, *UTX*), and DNA methylation (*TET2*, *DNMT3A*, *IDH1*, *IDH2*); (2) mutations in the spliceosome machinery (*SF3B1*, *SRSF2*, *U2AF1*, *ZRSR2, PRPF8*); (3) mutations in genes that regulate cell signaling (*JAK2*, *KRAS*, *NRAS*, *CBL*, *PTPN11*, *NF1*, *FLT3*); (4) mutations in transcription factors and nucleosome

assembly regulators (*RUNX1*, *GATA2*, *SETBP1*); and (5) mutations in DNA damage response genes such as *TP53* and *PHF6*. Of these, those involving *TET2* (~60%), *SRSF2* (~50%), *ASXL1* (~40%), and the oncogenic *RAS* pathway (~30%) are the most frequent, with only frameshift and nonsense *ASXL1* mutations consistently and independently adversely impacting survival. Clonal cytogenetic abnormalities are seen in about a third of patients with CMML and include trisomy 8 and abnormalities of chromosome 7.

Several risk models serve similar purposes in identifying high-risk patients who are considered for ASCT earlier than later. Risk factors in the Mayo Molecular Model (MMM) include presence of truncating *ASXL1* mutations, absolute monocyte count >10 × 10^9/L, hemoglobin <10 g/dL, platelet count <100 × 10^9/L, and the presence of circulating immature myeloid cells. The resulting four-tiered risk categorization includes high (three or more risk factors), intermediate-2 (two risk factors), intermediate-1 (one risk factor), and low (no risk factors); the corresponding median survivals are 16, 31, 59, and 97 months, respectively. ASCT is the only treatment modality that secures cure or long-term survival and is appropriate for MMM high/intermediate-2 risk disease. In one of the largest retrospective cohorts involving 513 CMML patients (median age, 53 years), the European Group for Blood and Marrow Transplantation reported a 4-year relapse-free survival rate of 27% and an overall survival rate of 33%. At present, for younger patients with higher risk disease and an acceptable comorbidity index, ASCT is the preferred treatment modality. Drug therapy is currently not disease-modifying and includes hydroxyurea and hypomethylating agents; a phase 3 study (DAKOTA) comparing hydroxyurea and decitabine in high-risk MP-CMML showed similar overall survival at 23.1 versus 18.4 months, respectively, despite response rates being higher for decitabine (56 vs 31%).

ATYPICAL CHRONIC MYELOID LEUKEMIA

aCML is formally classified under the MDS/MPN category of myeloid malignancies and is characterized by left-shifted granulocytosis and dysgranulopoiesis. Diagnostic criteria are listed in Table 115-2 and include leukocyte count of ≥13 × 10^9/L, dysgranulopoiesis, cytopenia, ≥10% immature granulocytes, <20% PB or BM myeloblasts, <10% PB monocytes, <10% PB eosinophilia, absence of otherwise specific mutations such as *BCR::ABL1* or TKGFs (involving *PDGFRA, PDGFRB, FGFR1, JAK2, ABL1*, or *FLT3*; **Table 115-6**), and not meeting WHO criteria for CML, PMF, PV, or ET. The BM in aCML is hypercellular with granulocyte proliferation and dysplasia with or without erythroid or megakaryocytic dysplasia. The differential diagnosis of aCML includes CML, which is distinguished by the presence of *BCR::ABL1*; CNL, which is distinguished by the absence of dysgranulopoiesis and presence of *CSF3R* mutations; and CMML, which is distinguished by the presence of monocytosis (absolute monocyte count ≥0.5 × 10^9/L).

The molecular pathogenesis of aCML is incompletely understood; about one-fourth of patients express *SETBP1* mutations, which are, however, also found in several other myeloid malignancies, including CNL and CMML. *SETBP1* mutations in aCML were prognostically detrimental and mostly located between codons 858 and 871; similar mutations are seen with Schinzel-Giedion syndrome (a congenital disease with severe developmental delay and various physical stigmata including midface retraction, large forehead, and macroglossia). A somatic missense mutation in ethanolamine kinase 1 (*ETNK1* N244S) was described in 9% of patients with aCML but was also seen in 14% of patients with CMML, 6% of patients with mastocytosis (especially in association with eosinophilia), and rarely in other MPNs.

In a series of 55 patients with WHO-defined aCML, median age at diagnosis was 62 years, with female preponderance (57%); splenomegaly was reported in 54% of the patients, red cell transfusion requirement in 65%, abnormal karyotype in 20% (20q– and trisomy 8 being the most frequent), and leukemic transformation in 40%. Median survival was 25 months. Outcome was worse in patients with marked leukocytosis, transfusion requirement, and increased immature cells in the PB. In a more recent Mayo Clinic study of 25 molecularly annotated and strictly WHO-defined aCML patients, median age was 70 years and 84% were male. Cytogenetic abnormalities were seen in 36% and gene mutations in 100%. Mutational frequencies were as follows: *ASXL1* 28%, *TET2* 16%, *NRAS* 16%, *SETBP1* 12%, *RUNX1* 12%, *ETNK1* 8%, and *PTPN11* 4%. Median survival was 10.8 months, and at last follow-up (median, 11 months), 17 (68%) deaths and 2 (8%) leukemic transformations were documented. In multivariable analysis, advanced age, low hemoglobin, and *TET2* mutations were shown to carry independent prognostic significance; other mutations, including *ASXL1* and *SETBP1* lacked prognostic significance. Conventional chemotherapy is largely ineffective in the treatment of aCML. Similarly, treatment response to the JAK1/2 inhibitor ruxolitinib has not been impressive. However, a favorable experience with ASCT was reported in nine patients; after a median follow-up of 55 months, the majority of the patients remained in complete remission.

MDS/MPN WITH MUTATED SF3B1 OR WITH RING SIDEROBLASTS, BOTH ASSOCIATED WITH THROMBOCYTOSIS OR NOT OTHERWISE SPECIFIED

The ICC classifies patients with morphologic and laboratory features that resemble both MDS and MPN as "MDS/MPN overlap." This category is broad and is distinguished from MPN by the presence of "cytopenia." Leukocytosis is also part of the definition for the subcategories of MDS/MPN, including MDS/MPN with mutated *SF3B1* (MDS/MPN-T-*SF3B1*), MDS/MPN with ring sideroblasts and thrombocytosis, NOS (MDS/MPN-RS-T-NOS), and MDS/MPN-NOS. Diagnostic criteria for MDS/MPN-T-*SF3B1* include thrombocytosis (≥450 × 10^9/L), anemia, blasts <1% in PB and <5% in BM, presence of *SF3B1*

TABLE 115-6 Primary Eosinophilia Classification

Abbreviations: ABL1 (e.g., *ETV6::ABL1*); BM, bone marrow; *FGFR1* (e.g., *ZMYM2::FGFR1*); *FLT3* (*ETV6::FLT3*); *JAK2* (*PCM1::JAK2*); M/LN-eo-TK, myeloid/lymphoid neoplasms with eosinophilia and TKGF; PB, peripheral blood; TKGF, tyrosine kinase gene fusions, often involving *PDGFRA* (e.g. *FIP1L1::PDGFRA*) or *PDGFRB* (e.g., *ETV6::PDGFRB*).

(variant allele frequency [VAF] >10%), and not otherwise classified as another myeloid neoplasm; corresponding criteria for MDS/MPN-RS-T-NOS also include thrombocytosis and anemia and absence of excess blasts but, in addition, require presence of ≥15% BM ring sideroblasts and absence of *SF3B1* mutation. The term MDS/MPN-NOS is reserved for MDS/MPN that does not meet criteria for either of the aforementioned MDS/MPN entities despite displaying thrombocytosis (≥450 × 10^9/L) or leukocytosis (≥13 × 10^9/L).

JUVENILE MYELOMONOCYTIC LEUKEMIA

JMML is primarily a disease of early childhood and is now considered a unique clonal disorder of childhood, separated from MDS/MPN. Both CMML and JMML feature leukocytosis, monocytosis, and hepatosplenomegaly. Additional characteristic features in JMML include thrombocytopenia and elevated fetal hemoglobin. Myeloid progenitors in JMML display granulocyte-macrophage colony-stimulating factor (GM-CSF) hypersensitivity that has been attributed to dysregulated RAS/MAPK signaling. The latter is believed to result from mutually exclusive mutations involving *RAS*, *PTPN11*, and *NF1*. A third of patients with JMML that is not associated with Noonan syndrome carry *PTPN11* mutations, while the incidence of *NF1* in patients without neurofibromatosis type 1 and *RAS* mutations is ~15% each. In general, ~85% of JMML cases have one of the classical RAS pathway mutations (*PTPN11*, *NRAS*, *KRAS*, *NF1*, or *CBL*); in addition, a myriad of other mutations, such as *ASXL1*, *RUNX1*, *SETBP1*, *JAK3*, and *CUX1*, among others, have recently been reported. Taken together, it is currently believed that almost all patients with JMML harbor mutations in the RAS pathway; clonal disorders that mimic JMML but do not harbor a RAS pathway mutation are classified as JMML-like neoplasms.

The 2022 ICC diagnostic criteria for JMML require the presence of PB monocyte count ≥1 × 10^9/L, <20% blasts in PB or BM, splenomegaly, and absence of *BCR::ABL1*. Diagnosis also requires the presence of one of the following: (1) somatic mutations of *PTPN11*, *KRAS*, *NRAS,* or *RRAS*; (2) germline *NF1* mutation and loss of heterozygosity of *NF1* or clinical diagnosis of neurofibromatosis type 1; and (3) germline mutation and loss of heterozygosity of *CBL*. Drug therapy is relatively ineffective in JMML, and the treatment of choice is ASCT, which results in a 5-year survival of ~50%.

TRANSIENT MYELOPROLIFERATIVE DISORDER

TMD, also referred to as transient abnormal myelopoiesis (TAM), constitutes an often but not always transient phenomenon of abnormal megakaryoblast proliferation, which occurs in ~10% of infants with Down syndrome. TMD is usually recognized at birth and either undergoes spontaneous regression (75% of cases) or progresses to acute megakaryoblastic leukemia (AMKL; 25% of cases). Almost all patients with TMD and TMD-derived AMKL display somatic *GATA1* mutations. TMD-associated *GATA1* mutations constitute exon 2 insertions, deletions, or missense mutations, affecting the N-terminal transactivation domain of GATA-1 and resulting in loss of full-length (50 kD) GATA-1 and its replacement with a shorter isoform (40 kD) that retains friend of GATA-1 (FOG-1) binding. In contrast, inherited forms of exon 2 *GATA1* mutations produce a phenotype with anemia, whereas exon 4 mutations that affect the N-terminal, FOG-1-interactive domain produce familial dyserythropoietic anemia with thrombocytopenia or X-linked macrothrombocytopenia.

HYPEREOSINOPHILIA

Eosinophilia refers to a PB absolute eosinophil count (AEC) that is above the upper normal limit of the reference range. The term *hypereosinophilia* (HE) is used when the AEC is ≥1500 × 10^9/L. The ICC recommends both BM and PB examination for diagnostic evaluation of HE. The former should include cytogenetic and molecular analysis as well as immunohistochemistry for mast cells (CD117, tryptase, CD25), and the latter should include lymphocyte flow cytometry with T-cell panel, TCR gene rearrangement studies, and serum tryptase. The most frequent causes of HE include infections, especially those related to tissue-invasive helminths, allergic/vasculitic diseases, drugs, and metastatic cancer. Primary HE is the focus of this chapter and is considered when a cause for secondary eosinophilia is not readily apparent.

In the presence of normal BM morphology and absence of genetic abnormalities, the two major diagnostic possibilities are lymphocytic variant HE and idiopathic HE (Table 115-3); the former is characterized by the presence of an abnormal T-cell phenotype or clone. Both conditions might be associated with tissue/organ dysfunction due to eosinophilic infiltrates, in which case their nomenclature is modified into lymphocytic variant hypereosinophilic syndrome and idiopathic hypereosinophilic syndrome (iHES), respectively. In the presence of a TKGF, a diagnosis of myeloid/lymphoid neoplasm with eosinophilia and TKGF is considered (Table 115-3). The genes involved in TKGF-associated HE are listed in Table 115-6: *PDGFRA*, *PDGFRB*, *FGFR1*, *ABL*, *JAK2*, and *FLT3*. Once the latter possibility is excluded, other ICC-defined myeloid or lymphoid neoplasms (e.g., systemic mastocytosis, acute myeloid or lymphoblastic leukemia, CML, MPN or MDS/MPN, Hodgkin's and non-Hodgkin's lymphoma) must be considered and excluded. CEL-NOS is considered in the presence of cytogenetic abnormalities, excess blasts, or morphologic evidence of dysplasia, including that of megakaryocytes.

The diagnostic workup for HE that is not associated with morphologically overt myeloid malignancy should start with PB mutation screening for *PDGFRA* and *PDGFRB* mutations using fluorescence in situ hybridization (FISH) or reverse transcriptase polymerase chain reaction. If mutation screening is negative, a BM examination with cytogenetic and molecular studies is indicated. In this regard, one must first pay attention to the presence or absence of TKGF or associated cytogenetic abnormalities (Table 115-6). CEL-NOS is a subset of clonal eosinophilia that is neither molecularly defined nor classified as an alternative clinicopathologically assigned myeloid malignancy. We prefer to use the term strictly in patients with an HES phenotype who also display either a clonal cytogenetic/molecular abnormality, excess blasts in the BM or PB, or abnormal BM morphology (Table 115-6).

HYPEREOSINOPHILIA ASSOCIATED WITH TYROSINE KINASE GENE FUSIONS

Both platelet-derived growth factor receptors α (*PDGFRA*; located on chromosome 4q12) and β (*PDGFRB*; located on chromosome 5q31-q32) are involved in MPN-relevant activating mutations. Clinical phenotype in both instances includes prominent blood eosinophilia and excellent response to imatinib therapy. In regard to *PDGFRA* mutations, the most popular is *FIP1L1-PDGFRA*, a karyotypically occult del(4)(q12), which was described in 2003 as an imatinib-sensitive activating mutation. Functional studies have demonstrated transforming properties in cell lines and the induction of MPN in mice. Cloning of the *FIP1L1-PDGFRA* fusion gene identified a novel molecular mechanism for generating this constitutively active fusion tyrosine kinase, wherein an ~800 kb interstitial deletion within 4q12 fuses the 5′ portion of *FIP1L1* to the 3′ portion of *PDGFRA*. *FIP1L1-PDGFRA* occurs in a very small subset of patients who present with the phenotypic features of either systemic mastocytosis (SM) or HES, but the presence of the mutation reliably predicts complete hematologic and molecular response to imatinib therapy.

In a retrospective survey of 151 patients with *FIP1L1-PDGFRA*–associated eosinophilia (143 males; mean age at diagnosis, 49 years), organopathy involved the spleen (44%), skin (32%), lungs (30%), heart (19%), and CNS (9%); none of 31 patients initially treated with corticosteroids achieved complete hematologic remission, whereas all 148 patients treated with imatinib achieved complete hematologic responses and also molecular responses, when evaluated. Treatment discontinuation was documented in 46 patients followed by a 57% relapse rate; the 1-, 5-, and 10-year overall survival rates in imatinib-treated patients were 99%, 95%, and 84%, respectively. Other studies have confirmed the possibility of treatment-free remissions in some patients after imatinib discontinuation. Infrequent occurrence of *FIP1L1-PDGFRA*–mutated AML associated with eosinophilia has also been shown to respond to low-dose imatinib therapy (100 mg/d).

The association between eosinophilic myeloid malignancies and *PDGFRB* rearrangement was first characterized and published in 1994 when fusion of the tyrosine kinase encoding region of *PDGFRB* to the *ets*-like gene, *ETV6* (*ETV6-PDGFRB*, t(5;12)(q33;p13), was

demonstrated. The fusion protein was transforming to cell lines and resulted in constitutive activation of PDGFRB signaling. Since then, several other *PDGFRB* fusion transcripts with similar disease phenotypes have been described, cell line transformation and MPD induction in mice have been demonstrated, and imatinib therapy was effective when employed.

The 8p11 myeloproliferative syndrome (EMS) (also known as human stem cell leukemic/lymphoma syndrome) constitutes a clinical phenotype with features of both lymphoma and eosinophilic MPN and is characterized by a fusion mutation that involves the gene for fibroblast growth factor receptor 1 (*FGFR1*), which is located on chromosome 8p11 [e.g., *ZMYM2*::*FGFR1*, t(8;13)(p11.1;q12.1)]; disease phenotypes include T-cell acute lymphoblastic leukemia, large B-cell lymphoma, and MPN-like disease with HE. In EMS, both myeloid and lymphoid lineage cells exhibit the 8p11 translocation, thus demonstrating the stem cell origin of the disease. The disease features several 8p11-linked chromosome translocations, and some of the corresponding fusion *FGFR1* mutants have been shown to transform cell lines and induce EMS- or CML-like disease in mice depending on the specific *FGFR1* partner gene (*ZNF198* or *BCR*, respectively). Consistent with this laboratory observation, some patients with *BCR-FGFR1* mutation manifest a more indolent CML-like disease. The mechanism of *FGFR1* activation in EMS is similar to that seen with *PDGFRB*-associated MPN; the tyrosine kinase domain of *FGFR1* is juxtaposed to a dimerization domain from the partner gene. EMS is an aggressive disease often requiring combination chemotherapy followed by ASCT. Pemigatinib, which targets FGFR1/2/3, has been introduced and shown to induce hematologic and cytogenetic response in >70% of patients with *FGFR1*-rearranged myeloid/lymphoid neoplasms.

The 2022 ICC includes a number of other subcategories of myeloid/lymphoid neoplasms with eosinophilia and TKGFs (M/LN-eo-TK): (1) *ETV6*::*ABL1*, t(9;12)(q34.1;p13.2), phenotypically similar to CML and treated the same way with imatinib or similar tyrosine kinase inhibitors (TKIs) with good response; (2) *PCM1*::*JAK2* or *BCR*::*JAK2* or other *JAK2* partners, t(8;9)(p22;p24.1), phenotypically similar to MPN or MDS/MPN with >90% response rate to ruxolitinib but not durable and requiring bridging to ASCT; and (3) *ETV6*::*FLT3*, t(12;13)(p13.2;q12.2), phenotypically similar to lymphoblastic leukemia or lymphoma, CEL, or MDS/MPN, with some responses seen with *FLT3* inhibitor therapy.

HYPEREOSINOPHILIC SYNDROME

Blood eosinophilia that is neither secondary nor clonal is operationally labeled as being "idiopathic." HES is a subcategory of idiopathic eosinophilia with persistent increase of the AEC to $\geq 1.5 \times 10^9$/L and presence of eosinophil-mediated organ damage, including cardiomyopathy, gastroenteritis, cutaneous lesions, sinusitis, pneumonitis, neuritis, and vasculitis. In addition, some patients manifest thromboembolic complications, hepatosplenomegaly, and either cytopenia or cytosis.

BM histologic and cytogenetic/molecular studies should be examined before a working diagnosis of HES is made. Additional blood studies that are currently recommended during the evaluation of HES include serum tryptase (an increased level suggests mastocytosis and warrants molecular studies to detect *FIP1L1-PDGFRA*), T-cell immunophenotyping, and T-cell receptor antigen gene rearrangement analysis (a positive test suggests an underlying clonal or phenotypically abnormal T-cell disorder). In addition, initial evaluation in HES should include echocardiogram and measurement of serum troponin levels to screen for myocardial involvement by the disease.

Initial evaluation of the patient with eosinophilia should include tests that facilitate assessment of target organ damage, including complete blood count, chest x-ray, echocardiogram, and serum troponin level. Increased level of serum cardiac troponin has been shown to correlate with the presence of cardiomyopathy in HES. Typical echocardiographic findings in HES include ventricular apical thrombus, posterior mitral leaflet or tricuspid valve abnormality, endocardial thickening, dilated left ventricle, and pericardial effusion.

In a Mayo Clinic study of 98 consecutive patients with idiopathic eosinophilia, including HES, median age was 53 years (55% male), and overt organ involvement was seen in >80% of the cases, including 54% involving organs other than the skin. The frequencies of cardiac involvement, hepatosplenomegaly, and increased serum tryptase and interleukin (IL) 5 levels were 8%, 4%, 24%, and 31%, respectively. The study also revealed that 11% of the affected patients harbored pathogenetic mutations including *TET2*, *ASXL1*, and *KIT*; the presence of such mutations did not appear to influence phenotype, and the number of informative cases was too small to assess prognostic relevance. Instead, the study identified anemia and presence of cardiac involvement or hepatosplenomegaly as risk factors for survival.

Glucocorticoids are the cornerstone of therapy in HES. Treatment with oral prednisone is usually started at 1 mg/kg per day and continued for 1–2 weeks before the dose is tapered slowly over the ensuing 2–3 months. If symptoms recur at a prednisone dose level of >10 mg/d, either hydroxyurea or interferon α is used as steroid-sparing agent. In patients in whom usual therapy fails as outlined above, mepolizumab or alemtuzumab might be considered. Mepolizumab is a monoclonal antibody that targets IL-5, which is a well-recognized growth factor for eosinophils. Alemtuzumab targets the CD52 antigen, which has been shown to be expressed by eosinophils but not by neutrophils. In a recently reported placebo-controlled phase 3 study, HES patients received subcutaneous mepolizumab (300 mg) every 4 weeks, in addition to their preprotocol therapy, and experienced significantly fewer disease flare-ups or treatment discontinuations (28 vs 56% for placebo), without excess adverse events. Mepolizumab was U.S. Food and Drug Administration approved for use in HES on September 25, 2020. In a smaller phase 2 study, benralizumab (monoclonal antibody targeting the receptor for IL-5; 30 mg given subcutaneously every 4 weeks) was also shown to reduce eosinophil count more efficiently compared to placebo (90 vs 30%).

MASTOCYTOSIS

SM is characterized by proliferation of neoplastic mast cells (MCs) in BM and/or other extracutaneous organs and is distinguished from cutaneous mastocytosis (CM; skin involvement only) and mast cell sarcoma (MCS; high-grade focal MC tumor). According to the ICC and WHO-proposed fifth edition (WHO5) classification systems (Table 115-4), SM is subclassified into indolent (ISM), smoldering (SSM), aggressive (ASM), SM with associated myeloid (SM-AMN, per ICC) or hematologic (SM-AHN, per WHO5) neoplasm, and mast cell leukemia (MCL). WHO5 also includes an additional "low-grade" SM subtype, namely BM mastocytosis (BMM); the latter is described as consisting of (1) absence of skin lesions, (2) absence of B findings, and (3) serum tryptase level <125 ng/mL. The ICC considers BMM as a clinicopathologic variant and not an SM subtype. Both ICC and WHO5 have also refined their diagnostic criteria for SM in general. Diagnosis per ICC requires the presence of a major criterion (multifocal aggregates of ≥15 MCs) or, in its absence, the presence of at least three minor criteria, including (1) BM biopsy or extracutaneous organ section with >25% MCs with atypical morphology; (2) MC expression of CD25, CD2, and/or CD30; (3) *KIT* D816V or other activating *KIT* mutation; and (4) increased serum tryptase >20 ng/mL (needs to be adjusted in the presence of hereditary α-tryptasemia); in addition, presence of myeloid/lymphoid neoplasm with eosinophilia with TKGRs must be excluded. SM diagnosis per WHO5 requires the presence of the major criterion as well as one other minor criterion or at least three minor criteria.

The term *advanced SM* (AdvSM) includes ASM, SM-AMN/AHN, and MCL; AdvSM is distinguished from non-AdvSM by the presence of either an associated myeloid/hematologic neoplasm (e.g., AML, CMML, MDS, MPN) or organopathy resulting from MC infiltration. MC-associated organopathy is defined by the presence of one or more C findings: (1) ≥1 cytopenia (hemoglobin <10 g/dL, absolute neutrophil count $<1 \times 10^9$/L, or platelet count $<100 \times 10^9$/L); (2) palpable hepatomegaly with abnormal liver function tests, ascites, or portal hypertension; (3) palpable splenomegaly with thrombocytopenia attributed to hypersplenism; (4) MC infiltration of the gastrointestinal system with resultant malabsorption with weight loss; and (5) large osteolytic lesions with or without pathologic fractures.

The ICC system requires the AHN component in SM-AHN to be of myeloid lineage, resulting in a revised nomenclature (i.e., SM-AMN). By contrast, WHO5-defined SM-AHN allows the AHN component to be of either myeloid or lymphoid lineage. Additional divergence between ICC and WHO5 concerns the definition of MCL; both systems require the presence of ≥20% MCs in BM aspirate, but ICC criteria require, in addition, immature cytomorphology (i.e., promastocytes, metachromatic blast-like cells, or multinucleated or highly pleomorphic MC) of the excess MCs; furthermore, ICC no longer differentiates between leukemic (≥10% circulating MC) versus aleukemic MCL variants. Both the ICC and WHO5 use similar B findings to distinguish indolent from smoldering SM, with the latter requiring the presence of two or more B findings, including (1) MCs >30% of BM cellularity on BM biopsy *and* serum tryptase >200 ng/mL; (2) cytopenia not meeting criteria for C findings or cytosis; and (3) palpable hepatomegaly without liver function impairment or splenomegaly without thrombocytopenia or >1 cm lymphadenopathy on palpation or imaging; in addition, *KIT* D816V VAF ≥10% qualifies as a B finding, per WHO5.

In a study of 329 patients with AdvSM, including WHO5 subcategories of SM-AHN (64%), ASM (30%), and MCL (6%) or ICC subcategories of SM-AMN (64%), ASM (33%), and MCL (3%), multivariable analysis that included the Mayo Alliance risk factors for survival in SM (age >60 years, anemia, thrombocytopenia, increased alkaline phosphatase) revealed more accurate survival prediction with the ICC versus WHO5 classification order: (1) survival was significantly worse with ICC-defined MCL versus WHO5-defined MCL with otherwise mature MC cytomorphology; (2) prognostic distinction was confirmed for ICC-defined MCL versus ICC-defined SM-AMN but not for WHO5-defined MCL versus WHO-defined SM-AHN; (3) survival was similar between WHO5-defined MCL with mature cytomorphology versus ICC-defined SM-AMN; and (4) ICC-defined SM-AMN but not WHO-defined SM-AHN with lymphoid lineage was prognostically distinct from ASM. Accordingly, our views on the classification of AdvSM are in line with those of the ICC system. We believe that these details are therapeutically relevant considering the emergent nature of ICC-defined MCL and the fact that SM-AMN, as opposed to SM-AHN, carries a prognostically worse designation that might require therapeutic intervention with ASCT sooner than later.

Currently available drugs for treatment include KIT inhibitors (KITi), which exhibit remarkable activity in reducing MC and mutant *KIT* burden but have not been shown to extend survival. On the other hand, we are impressed by the remarkable activity of currently available KITi on the MC component of SM, with the caveat that such drugs are expensive, have significant side effects, and need long-term use. The first step in treatment decision-making is to identify whether the AMN component takes priority over the SM component of the disease, for treatment purposes. High-grade AMNs, including AML, high-/very-high-risk MDS or CMML, or those with >10% BM blasts, likely take precedence in this regard. Accordingly, in a fit patient with SM-AML or SM-high/very-high-risk MDS, intensive remission induction therapy or hypomethylating agent (HMA) therapy can be considered. If the SM is incidentally diagnosed or is associated with minimal symptoms, we generally limit SM therapy to supportive/symptomatic care, including with antihistamine and/or antileukotriene agents or cromolyn, as well as taking precautions for anaphylaxis prevention/treatment. For SM with significantly high MC or symptom burden, concurrent MC cytoreduction can be considered, particularly for those with relapsed/refractory disease, although there are no clear protocols in this regard.

ASCT has an important role in the treatment of SM-high-grade AMN, although there is no consensus regarding optimal timing, debulking strategy, and so on; overall survival appears to be most favorable for SM-AMN patients compared to other subgroups, and survival was superior in those receiving myeloablative versus reduced-intensity conditioning, thereby indicating the need for effective cytoreduction prior to stem cell transplantation. For SM-AMN patients with a low-grade AMN, such as PV or ET, or low-risk MDS, conventional therapy for the AMN including therapeutic phlebotomies, low-dose aspirin, hydroxyurea or interferon α, or erythropoiesis-stimulating agents is pursued. If the SM disease component does not warrant cytoreduction (e.g., no C findings), supportive/symptomatic care, as described earlier, is pursued, along with intermittent monitoring of disease status. If MC cytoreduction is warranted, monotherapy with a TKI or cladribine can be pursued, depending on individual risk, benefit considerations, treatment availability, cost considerations, and so on.

We find cladribine, midostaurin, and avapritinib to be reasonable drug considerations for AdvSM as well as MCL. While avapritinib has theoretical advantages over midostaurin, including a more potent inhibitory effect on *KIT* D816V and proven efficacy in patients previously treated with midostaurin, we are agnostic regarding the choice of TKI given the lack of head-to-head comparison; instead, we recommend an individualized approach to TKI selection that weighs drug accessibility/affordability, comorbid conditions, risk tolerance for anticipated adverse events, and provider/center experience with the particular TKI. We continue to utilize cladribine as a reasonable alternative to TKI therapy, based on decades-long experience, long-term safety record, and qualitatively better toxicity profile that is mostly limited to cytopenias, as opposed to cognitive impairment and other side effects with avapritinib and intolerance due to diarrhea with midostaurin. For ASM patients who exhibit disease progression and/or leukemic transformation despite adequate TKI dosing or cladribine, we recommend ASCT as salvage therapy. We consider "true" MCL an oncologic emergency, and collaboration with an experienced hematopathologist to expeditiously confirm the diagnosis is critical, as is expedited molecular testing for *KIT* D816V and other AMN-relevant mutations.

DENDRITIC AND HISTIOCYTIC NEOPLASMS

Dendritic cell (DC) and histiocyte/macrophage neoplasms are extremely rare. DCs are antigen-presenting cells, whereas histiocyte/macrophages are antigen-processing cells. BM myeloid stem cells (CD34+) give rise to monocyte (CD14+, CD68+, CD11c+, CD1a–) and DC (CD14–, CD11c+/–, CD1a+/c) precursors. Monocyte precursors, in turn, give rise to macrophages (CD14+, CD68+, CD11c+, CD163+, lysozyme+) and interstitial DCs (CD68+, CD1a–). DC precursors give rise to Langerhans cell DCs (Birbeck granules, CD1a+, S100+, langerin+) and plasmacytoid DCs (CD68+, CD123+). Follicular DCs (CD21+, CD23+, CD35+) originate from mesenchymal stem cells. Dendritic and histiocytic neoplasms are operationally classified into macrophage/histiocyte-related and DC-related. The former includes histiocytic sarcoma/malignant histiocytosis and the latter Langerhans cell histiocytosis, Langerhans cell sarcoma, interdigitating DC sarcoma, and follicular DC sarcoma.

Histiocytic Sarcoma/Malignant Histiocytosis Histiocytic sarcoma represents malignant proliferation of mature tissue histiocytes and is often localized. Median age at diagnosis is estimated at 46 years with slight male predilection. Some patients might have a history of lymphoma, MDS, or germ cell tumors at time of disease presentation. The three typical disease sites are lymph nodes, skin, and the gastrointestinal system. Patients may or may not have systemic symptoms including fever and weight loss, and other symptoms include hepatosplenomegaly, lytic bone lesions, and pancytopenia. Immunophenotype includes presence of histiocytic markers (CD68, lysozyme, CD11c, CD14) and absence of myeloid or lymphoid markers. Prognosis is poor, and treatment is often ineffective. The term *malignant histiocytosis* refers to a disseminated disease and systemic symptoms. Lymphoma-like treatment induces complete remissions in some patients, and median survival is estimated at 2 years. In one of the largest series of histiocytic sarcoma, 330 cases were included with median age of 61 years (59% male). In the latter study, the most common sites of presentation were skin, connective tissue, lymph nodes, gastrointestinal tract, and hematopoietic system; median overall survival was 6 months, and treatment included systemic chemotherapy, radiotherapy, and surgery. Factors associated with poor outcome included older age, high comorbidity index, and disease involving the hematopoietic and reticuloendothelial system.

Langerhans Cell Histiocytosis Langerhans cells (LCs) are specialized DCs that reside in mucocutaneous tissue and upon activation

become specialized for antigen presentation to T cells. LC histiocytosis (LCH; also known as histiocytosis X) represents neoplastic proliferation of LCs (S100+, CD1a+, and Birbeck granules on electron microscopy). LCH incidence is estimated at 5 per million, and the disease typically affects children, with a male predilection. Presentation can be either unifocal (eosinophilic granuloma) or multifocal. The former usually affects bones and less frequently lymph nodes, skin, and lung, while the latter is more disseminated. Unifocal disease often affects older children and adults, while multisystem disease affects infants. LCH of the lung in adults is characterized by bilateral nodules. Prognosis depends on organs involved. Only 10% of patients progress from unifocal to multiorgan disease. LCH of the lung might improve upon cessation of smoking. Approximately 55% of patients with LCH harbor *BRAF* V600E gain-of-function mutations, which indicates high-risk disease and resistance to first-line therapy, while responses to targeted therapy with vemurafenib have been reported. Other forms of treatment for LCH include combination chemotherapy and MEK inhibitors in *BRAF* wild-type but with other MAPK pathway mutations. Unfortunately, such targeted therapy has not secured long-lasting treatment-free remissions.

In one retrospective study, 33 adult patients with LCH were studied including 21 with single-system LCH, 10 with multisystem LCH, and 2 with pulmonary LCH. Patients with single-system unifocal involvement were successfully treated with local therapies such as surgery and radiotherapy. Most of the multisystem LCH patients and patients with single-system multifocal involvement were treated with systemic chemotherapy. Cladribine was the first choice in 10 of 11 patients who received chemotherapy. Among all patients, the overall response rate (ORR) was 97%. Among those who had cladribine in the first line, the ORR was 81%. All these patients achieved a complete remission and were alive at the last visit. The median follow-up was 38 months (range, 2–183 months). The median progression-free survival (PFS) has not yet been reached. Ten-year PFS was 90.9%. Expert consensus recommendations for treatment include local therapies for unifocal disease, smoking cessation as first-line therapy for pulmonary LCH, and systemic therapy for multifocal and multisystem disease; the latter might include cladribine, cytarabine, and targeted therapy with BRAF and MEK inhibitors.

In one study, 26 adult patients with non-LCH, including 17 with Erdheim-Chester disease (ECD), 3 with Rosai-Dorfman disease (RDD), 5 with ECD/RDD, and 1 with ECD/LCH, were treated with the MEK inhibitor trametinib; the most common treatment-related toxicity was rash (27%), whereas the response rate of the 17 evaluable patients was 71%, including 73% without a detectable *BRAF* V600E; median time-to-treatment failure was 37 months; most patients harbored mutations in *BRAF* (either classic *BRAF* V600E or other *BRAF* alterations) or alterations in other genes involved in the MAPK pathway (e.g., *MAP2K*, *NF1*, *GNAS*, or *RAS*).

Langerhans Cell Sarcoma Langerhans cell sarcoma (LCS) also represents neoplastic proliferation of LCs with overtly malignant morphology. The disease can present de novo or progress from antecedent LCH. There is a female predilection, and median age at diagnosis is estimated at 41 years. Immunophenotype is similar to that seen in LCH, and liver, spleen, lung, and bone are the usual sites of disease. Prognosis is poor, and treatment is generally ineffective.

Interdigitating Dendritic Cell Sarcoma Interdigitating DC sarcoma (IDCS), also known as reticulum cell sarcoma, represents neoplastic proliferation of interdigitating DCs. The disease is extremely rare and affects elderly adults with no sex predilection. Typical presentation is asymptomatic solitary lymphadenopathy. Immunophenotype includes S100+ and negative for vimentin and CD1a. Prognosis ranges from benign local disease to widespread lethal disease.

Follicular Dendritic Cell Sarcoma Follicular dendritic cells (FDCs) reside in B-cell follicles and present antigen to B cells. FDC neoplasms (FDCNs) are usually localized and often affect adults. FDCN might be associated with Castleman's disease in 10–20% of cases, and increased incidence in schizophrenia has been reported. Cervical lymph nodes are the most frequent site of involvement in FDCNs, and other sites include maxillary, mediastinal, and retroperitoneal lymph nodes; oral cavity; the gastrointestinal system; skin; and breast. Sites of metastasis include lung and liver. Immunophenotype includes CD21, CD35, and CD23. Clinical course is typically indolent, and treatment includes surgical excision followed by regional radiotherapy and sometimes systemic chemotherapy.

Hemophagocytic Lymphohistiocytosis **(see Chap. 68)** Hemophagocytic lymphohistiocytosis (HLH) represents nonneoplastic proliferation and activation of macrophages and cytotoxic lymphocytes that induce cytokine-mediated bone marrow suppression, features of intense phagocytosis in bone marrow and liver, and multiorgan dysfunction including cytopenias, coagulopathy, and fever. HLH may result from genetic (primary) or acquired (secondary) disorders of macrophages. The former entail genetically determined inability to regulate macrophage proliferation and activation and might include alterations in familial HLH genes, including those of perforin (*PRF1*, *UNC13D*, *STXBP2*, and *STX11*), granule/pigment abnormality genes (*RAB27A*, *LYST*, and *AP3B1*), or X-linked lymphoproliferative disease genes (*SH2D1A* and *XIAP*). Acquired HLH is often precipitated by viral infections, including Epstein-Barr virus. HLH might also accompany certain malignancies such as T-cell lymphoma and autoimmune diseases, ASCT, and chimeric antigen receptor (CAR) T-cell therapy. In a recent population-based study from Sweden, the annual incidence of malignancy-associated HLH had increased 10-fold and was at least 0.71 per 100,000 adults from 2012 to 2018, and early survival improved significantly, likely due to increased awareness and more HLH-directed therapy. Regardless of the cause, the common tissue/organ-damaging pathway involves excessive inflammatory cytokine release, including IL-6, IL-2, IL-1, interferon γ, and tumor necrosis factor (TNF).

Clinical presentation of HLH includes fever, severe constitutional symptoms, enlarged lymph nodes, hepatosplenomegaly, neurologic dysfunction, and abnormalities in multiple organ function tests. Diagnosis is accomplished by either detection of HLH-related mutations or meeting five of the following eight conventional criteria: (1) hemophagocytosis in the bone marrow/spleen/lymph nodes; (2) serum ferritin ≥500 μg/L; (3) hypofibrinogenemia (fibrinogen ≤1.5 g/L) or hypertriglyceridemia (triglycerides ≥3 mmol/L); (4) low NK cell activity; (5) elevated soluble IL-2 receptor (CD25) ≥2400 U/mL; (6) bi- or tri-cytopenia (platelets $<100 \times 10^9$/L, hemoglobin <9 g/dL, absolute neutrophil count $<1 \times 10^9$/L); (7) splenomegaly palpable >3 cm below left costal margin; and (8) fever. Clinical course is often fulminant and fatal with reported 1-year survival rates of <30% in patients with hematologic malignancy. Current therapeutic approaches for primary or secondary HLH include the so-called HLH-94 protocol, which consists of weekly treatments with etoposide and dexamethasone, stem cell transplant, emapalumab (a monoclonal antibody that binds and neutralizes interferon γ and is approved in primary HLH), and the JAK1/2 inhibitor ruxolitinib. The latter has recently been shown to increase survival rate in affected patients to >80%.

116 Plasma Cell Disorders

Nikhil C. Munshi, Dan L. Longo, Kenneth C. Anderson

The *plasma cell disorders* are monoclonal neoplasms related to each other by virtue of their development from common progenitors in the late B-lymphocyte lineage. Multiple myeloma (MM), Waldenström's macroglobulinemia, primary amyloidosis **(Chap. 117)**, and the heavy chain diseases comprise this group and may be designated by a variety of synonyms such as *monoclonal gammopathies, paraproteinemias, plasma cell dyscrasias*, and *dysproteinemias*. Mature B lymphocytes destined to produce IgG bear surface immunoglobulin molecules of both μ and γ heavy chain isotypes with both isotypes having identical idiotypes (variable regions). Under normal circumstances, maturation to antibody-secreting plasma cells and their proliferation is stimulated by exposure to the antigen for which the surface immunoglobulin is specific; however, in the plasma cell disorders, the control over this process is lost. The clinical manifestations of all the plasma cell disorders relate to the expansion of the neoplastic cells, to the secretion of cell products (immunoglobulin molecules or subunits, lymphokines), and to some extent to the host's response to the tumor. Normal development of B lymphocytes is discussed in **Chap. 360** and depicted in **Fig. 113-2**.

Three categories of structural variation are present among immunoglobulin molecules that form antigenic determinants, and these are used to classify immunoglobulins. *Isotypes* are those determinants that distinguish among the main classes of antibodies of a given species and are the same in all normal individuals of that species. Therefore, isotypic determinants are, by definition, recognized by antibodies from a distinct species (heterologous sera) but not by antibodies from the same species (homologous sera). There are five heavy chain isotypes (M, G, A, D, E) and two light chain isotypes (κ, λ). *Allotypes* are distinct determinants that reflect regular small differences between individuals of the same species in the amino acid sequences of otherwise similar immunoglobulins. These differences are determined by allelic genes; by definition, they are detected by antibodies made in the same species. *Idiotypes* are the third category of antigenic determinants. They are unique to the molecules produced by a given clone of antibody-producing cells. Idiotypes are formed by the unique structure of the antigen-binding portion of the molecule.

Antibody molecules **(Fig. 116-1)** are composed of two heavy chains (~50,000 molecular weight [mol wt]) and two light chains (~25,000 mol wt). Each chain has a constant portion (limited amino acid sequence variability) and a variable region (extensive sequence variability). The light and heavy chains are linked by disulfide bonds and are aligned so that their variable regions are adjacent to one another. This variable region forms the antigen recognition site of the antibody molecule; its unique structural features form idiotypes that are reliable markers for a particular clone of cells because each antibody is formed and secreted by a single clone. Because of the mechanics of the gene rearrangements necessary to specify the immunoglobulin variable regions (VDJ joining for the heavy chain, VJ joining for the light chain), a particular clone rearranges only one of the two chromosomes to produce an immunoglobulin molecule of only one light chain isotype and only one allotype (allelic exclusion) (Fig. 116-1). After exposure to antigen, the variable region may become associated with a new heavy chain isotype (class switch). Each clone of cells performs these sequential gene arrangements in a unique way. This results in each clone producing a unique immunoglobulin molecule. In most plasma cells, light chains are synthesized in slight excess, secreted as free light chains, and cleared by the kidney, but <10 mg of such light chains are excreted per day.

Electrophoretic analysis permits separation of components of the serum proteins **(Fig. 116-2)**. The immunoglobulins move heterogeneously in an electric field and form a broad peak in the gamma region. There is a sharp spike in this region called an *M component* (M for monoclonal) in the sera of patients with plasma cell tumors. Less commonly, the M component may appear in the β_2 or α_2 globulin region. The monoclonal antibody must be present at a concentration of at least 5 g/L (0.5 g/dL) to be accurately quantitated by this method. This corresponds to ~10^9 antibody producing cells. Confirmation of the type of immunoglobulin and that it is truly monoclonal is determined by immunoelectrophoresis that reveals a single heavy and/or light chain type. Hence, immunoelectrophoresis and electrophoresis provide qualitative and quantitative assessment of the M component, respectively. The amount of M component in the serum is a reliable measure of the tumor burden and an excellent tumor marker to manage therapy, yet it is not specific enough to be used to screen asymptomatic patients. In addition to the plasma cell disorders, M components may be detected in other lymphoid neoplasms such as chronic lymphocytic leukemia (CLL) and lymphomas of B- or T-cell origin; nonlymphoid neoplasms such as chronic myeloid leukemia, breast cancer, and colon cancer; a variety of nonneoplastic conditions such as cirrhosis, sarcoidosis, parasitic diseases, Gaucher's disease, and pyoderma gangrenosum; and a number of autoimmune conditions, including rheumatoid arthritis, myasthenia gravis, and cold agglutinin disease. Monoclonal proteins are also observed in immunosuppressed patients after organ transplant and, rarely, allogeneic transplant. At least two very rare skin diseases—lichen myxedematosus (also known as papular mucinosis) and necrobiotic xanthogranuloma—are associated with a monoclonal gammopathy. In papular mucinosis, highly cationic IgG is deposited in the dermis of patients. This organ specificity may reflect the specificity of the antibody for some antigenic component of the dermis. Necrobiotic xanthogranuloma is a histiocytic infiltration of the skin, usually of the face, that produces red or yellow nodules that can enlarge to plaques. Approximately 10% progress to myeloma. Five percent of patients with sensory motor neuropathy also have a monoclonal paraprotein.

The nature of the M component is variable in plasma cell disorders. It may be an intact antibody molecule of any heavy chain subclass, or it may be an altered antibody or fragment. Isolated light or heavy chains may be produced. In some plasma cell tumors such as extramedullary or solitary bone plasmacytomas, less than one-third of patients will have an M component. In ~20% of myelomas, only light chains are produced and, in most cases, are secreted in the urine as Bence Jones proteins. The frequency of myelomas of a particular heavy chain class is roughly proportional to the serum concentration, and therefore, IgG myelomas are more common than IgA and IgD myelomas. In ~1% of patients with myeloma, biclonal or triclonal gammopathy is observed.

MULTIPLE MYELOMA

DEFINITION

MM represents a malignant proliferation of plasma cells derived from a single clone. The tumor, its products, and the host response to it result in a number of organ dysfunctions and symptoms, including bone pain or fracture, renal failure, susceptibility to infection, anemia, hypercalcemia, and occasionally clotting abnormalities, neurologic symptoms, and manifestations of hyperviscosity.

ETIOLOGY

The cause of myeloma is not known. Myeloma occurred with increased frequency in those exposed to the radiation of nuclear warheads in World War II after a 20-year latency. Myeloma has been seen more commonly than expected among farmers, wood workers, leather workers, and those exposed to petroleum products. A variety of recurrent chromosomal alterations have been found in patients with myeloma: hyperdiploidy (trisomies involving one or more of chromosomes 3, 5, 7, 9, 11, 15, 19, or 21) is observed in half of the patients, while the other half have translocations involving the 14q32 chromosome with variable partners including t(11;14)(q13;q32), t(4;14)(p16;q32), and t(14;16). Other frequent abnormalities include 13q14 deletion, 1q amplification or 1p deletion, and 17p13 deletions. Evidence is strong that errors in switch recombination—the genetic mechanism to change antibody heavy chain isotype—participate in the early transformation process. However, no single common molecular pathogenetic pathway has yet

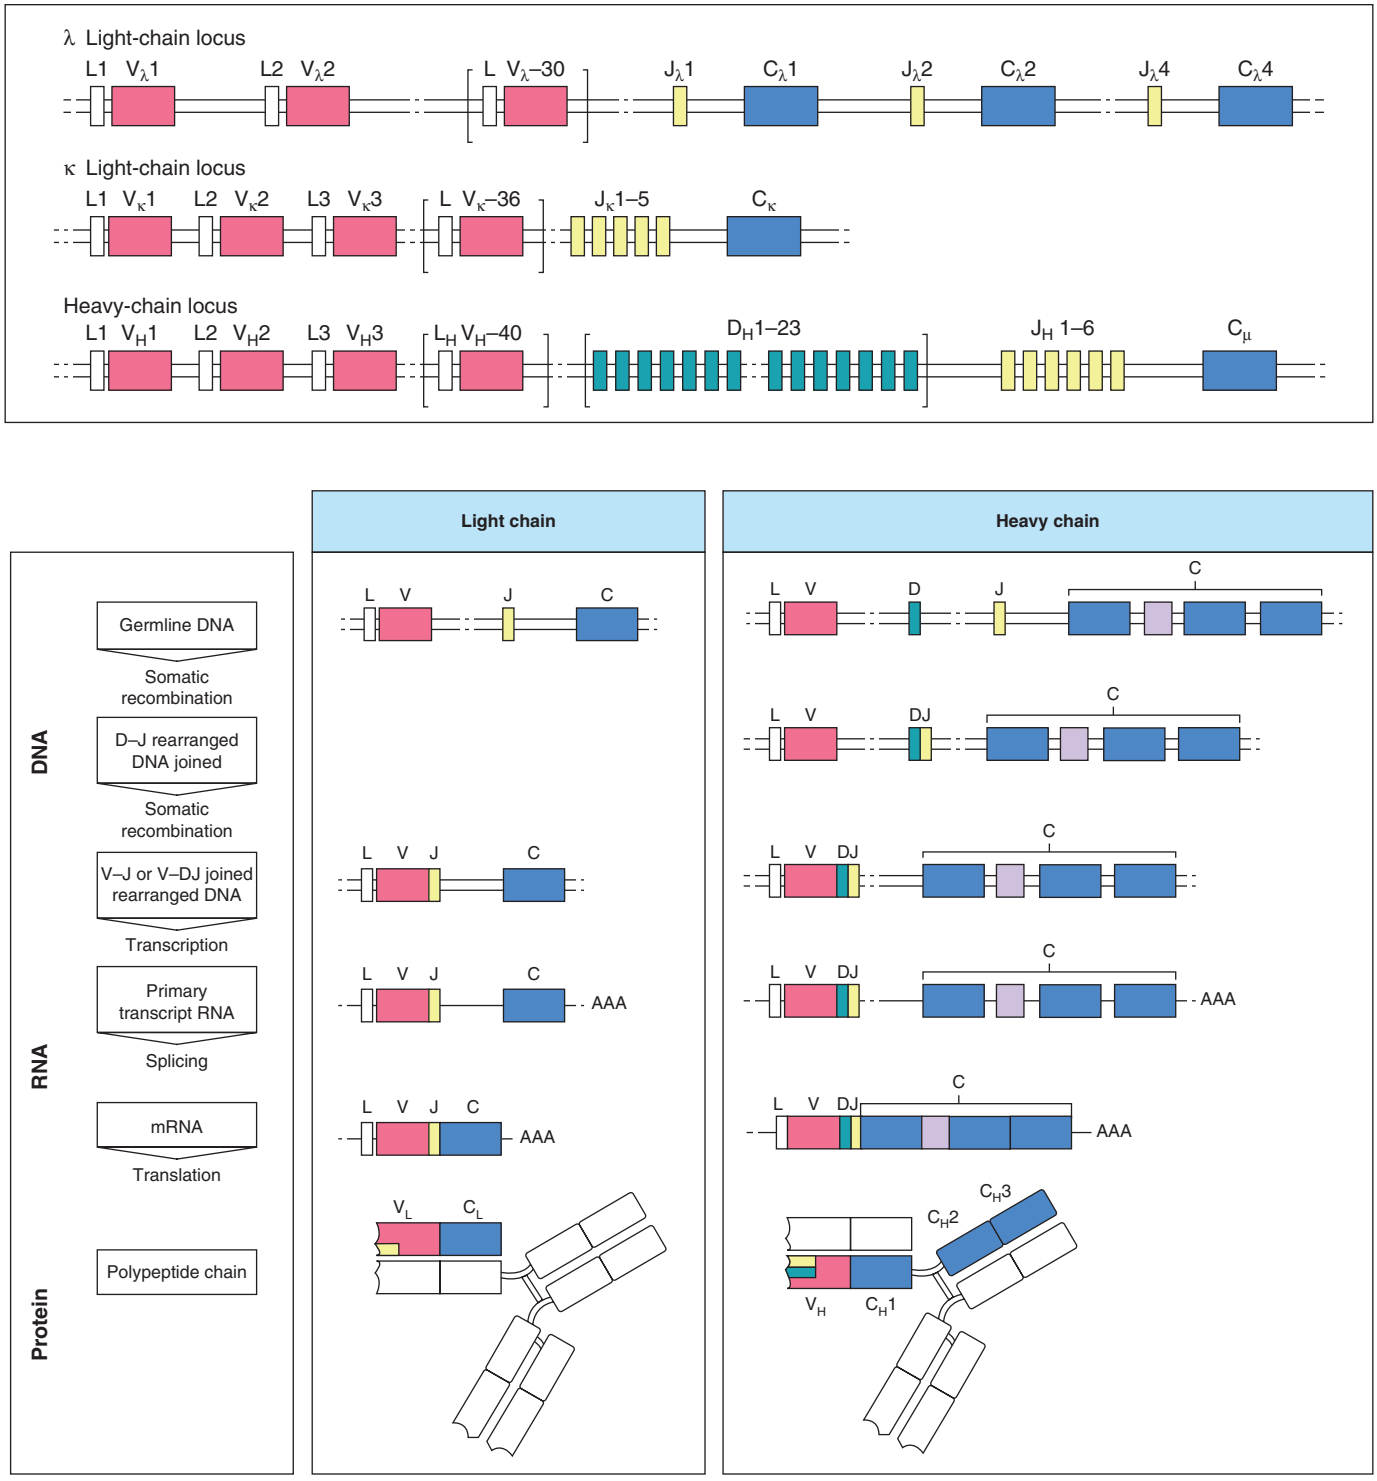

FIGURE 116-1 Immunoglobulin genetics and the relationship of gene segments to the antibody protein. The *top* portion of the figure is a schematic of the organization of the immunoglobulin genes, λ on chromosome 22, κ on chromosome 2, and the heavy chain locus on chromosome 14. The heavy chain locus is >2 megabases, and some of the D region gene segments are only a few bases long, so the figure depicts the schematic relationship among the segments, not their actual size. The *bottom* portion of the figure outlines the steps in going from the noncontiguous germline gene segments to an intact antibody molecule. Two recombination events juxtapose the V-D-J (or V-J for light chains) segments. The rearranged gene is transcribed, and RNA splicing cuts out intervening sequences to produce an mRNA, which is then translated into an antibody light or heavy chain. The sites on the antibody that bind to antigen (the so-called CDR3 regions) are encoded by D and J segments for heavy chains and the J segments for light chains. *(Adapted from Janeway's Immunobiology, 8th ed by Kenneth Murphy. emerged. Genome sequencing efforts have allowed for characterization of critical genes, pathways, and clonal heterogeneity in myeloma. The median number of mutations per transcribed genome in myeloma is ~58, and within the whole genome, it is >7000. A very heterogeneous mutational landscape with no unifying mutation has been observed. The most frequently mutated genes are *KRAS* and *NRAS* (~20% each), followed by *TP53, DIS3, FAM46C,* and *BRAF*, all mutated in 5–10% of patients. All other mutations were observed in <5% of the patients. These results are now being applied to develop new targeted personalized therapies in myeloma. Evidence of complex clusters of subclonal variants is present at diagnosis, and additional mutations are acquired over time, indicative of genomic evolution that may drive disease progression. Interleukin (IL) 6 may play a role in driving myeloma cell proliferation. It remains difficult to distinguish benign from malignant

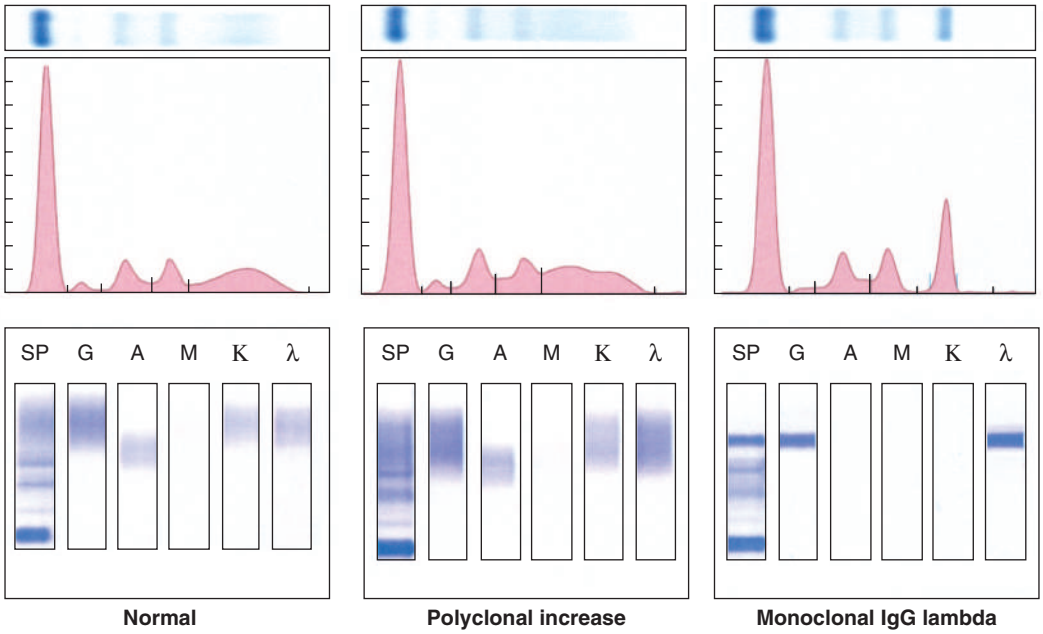

FIGURE 116-2 Representative patterns of serum electrophoresis and immunofixation. The *upper panels* represent agarose gel, middle panels are the densitometric tracing of the gel, and *lower panels* are immunofixation patterns. The panel on the *left* illustrates the normal pattern of serum protein on electrophoresis. Because there are many different immunoglobulins in the serum, their differing mobilities in an electric field produce a broad peak. In conditions associated with increases in polyclonal immunoglobulin, the broad peak is more prominent (*middle panel*). In monoclonal gammopathies, the predominance of a product of a single cell produces a "church spire" sharp peak, usually in the γ globulin region (*right panel*). The immunofixation (*lower panel*) identifies the type of immunoglobulin. For example, normal and polyclonal increases in immunoglobulins produce no distinct bands; however, the *right panel* shows distinct bands in IgG and lambda protein lanes, confirming the presence of IgG lambda monoclonal protein. *(Courtesy of Dr. Neal I. Lindeman.)*

plasma cells based on morphologic criteria in all but a few cases (Fig. 116-3).

INCIDENCE AND PREVALENCE

In 2024 in the United States, 35,780 new cases of myeloma were estimated to be diagnosed, and 12,540 people were estimated to die from the disease. Myeloma increases in incidence with age. The median age at diagnosis is 69 years; it is uncommon under age 40. Males are more commonly affected than females, and blacks have nearly twice the incidence of whites. In 2021, myeloma accounted for 1.8% of all malignancies, with incidence rates per 100,000 of 8.1 and 5.1 in white and 17.1 and 13.0 in black men and women, respectively.

GLOBAL CONSIDERATIONS

The incidence of myeloma is highest in blacks and Pacific Islanders; intermediate in Europeans and North American whites; and lowest in people from developing countries including Asia. The higher incidence in more developed countries may result from the combination of a longer life expectancy and more frequent medical surveillance. Incidence of MM in other ethnic groups including native Hawaiians, female Hispanics, American Indians from New Mexico, and Alaskan natives is higher relative to U.S. whites in the same geographic area. Chinese and Japanese populations have a lower incidence than whites. Immunoproliferative small-intestinal disease (IPSID) with α heavy chain disease is most prevalent in the Mediterranean area. Despite these differences in prevalence, the characteristics, response to therapy, and prognosis of myeloma are similar worldwide.

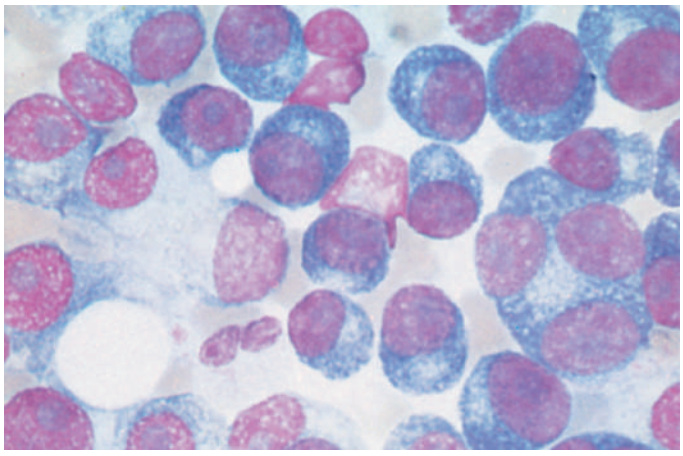

FIGURE 116-3 Multiple myeloma (marrow). The cells bear characteristic morphologic features of plasma cells: round or oval cells with an eccentric nucleus composed of coarsely clumped chromatin, a densely basophilic cytoplasm, and a perinuclear clear zone containing the Golgi apparatus. Binucleate and multinucleate malignant plasma cells can be seen.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

MM cells bind via cell-surface adhesion molecules to bone marrow stromal cells (BMSCs) and extracellular matrix (ECM), which triggers MM cell growth, survival, drug resistance, and migration in the bone marrow milieu (Fig. 116-4). These effects are due both to direct MM cell–BMSC binding via adhesion molecules and to induction of various cytokines, including IL-6, insulin-like growth factor type 1 (IGF-1), and vascular endothelial growth factor (VEGF). Growth, drug resistance, and migration are mediated via Ras/Raf/mitogen-activated protein kinase, PI3K/Akt, and protein kinase C signaling cascades, respectively. Other cellular elements in the bone marrow microenvironment also significantly impact MM cell growth and survival, especially interactions with endothelial cells and osteoclasts. Immune cells such as plasmacytoid dendritic cells (pDC), myeloid-derived suppressor cells (MDSC), and T helper 17 (T_H17) cells are increased in number and support myeloma growth, while antimyeloma immune responses, especially T helper and cytotoxic cells, B cells, and natural killer T cells, are suppressed.

Bone pain is the most common symptom in myeloma, affecting nearly 70% of patients. The bone lesions of myeloma are caused by the proliferation of tumor cells, activation of osteoclasts that destroy bone, and suppression of osteoblasts that form new bone. The increased osteoclast activity is mediated by osteoclast activating factors (OAFs) produced by the myeloma cells (mediated by several cytokines, including IL-1, lymphotoxin, VEGF, receptor activator of nuclear factor-κB [RANK] ligand, macrophage inhibitory factor [MIP]-1α, and tumor

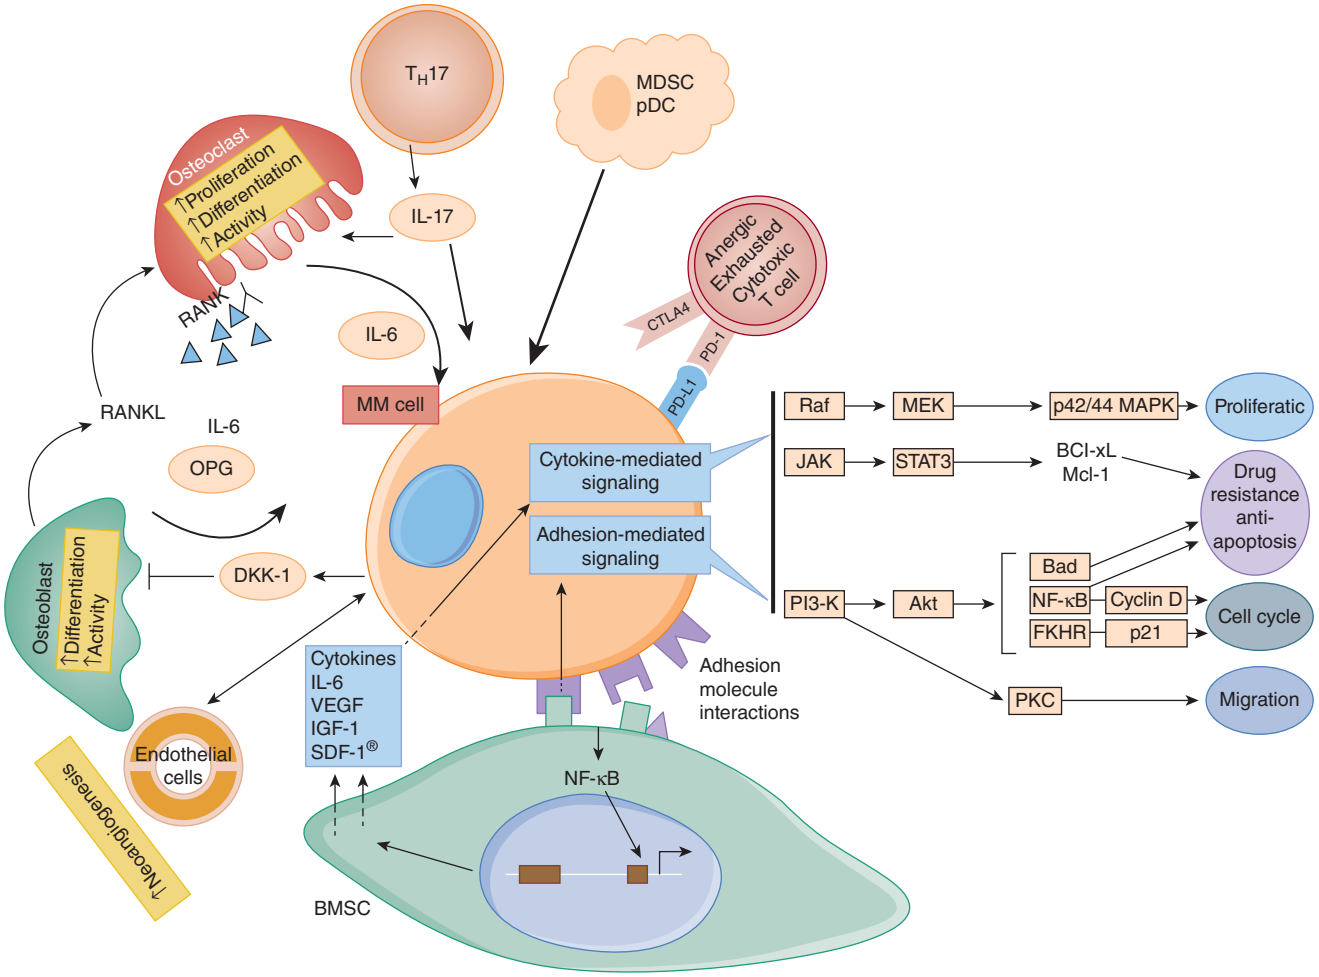

FIGURE 116-4 Pathogenesis of multiple myeloma. Multiple myeloma (MM) cells interact with bone marrow stromal cells (BMSCs) and extracellular matrix proteins via adhesion molecules, triggering adhesion-mediated signaling as well as cytokine production. This triggers cytokine-mediated signaling that provides growth, survival, and antiapoptotic effects as well as development of drug resistance. Additional bidirectional interactions lead to inhibition of osteoblast and increase in osteoclast activity, which leads to bone-related issues in myeloma. Similar interactions with immune microenvironment lead to augmentation of tumor-promoting immune responses and suppression of tumor protective immune responses, overall allowing myeloma cell growth. *(Adapted from G Bianchi, NC Munshi: Blood 125: 3049, 2015.)*

necrosis factor [TNF]). The bone lesions are lytic in nature **(Fig. 116-5)** and are rarely associated with osteoblastic new bone formation due to their suppression by dickkopf-1 (DKK-1) produced by myeloma cells. Therefore, radioisotopic bone scan is less useful in diagnosis than is plain radiography. The bony lysis results in substantial mobilization of calcium from bone, and serious acute and chronic complications of hypercalcemia may dominate the clinical picture (see below). Localized bone lesions may cause pathological fracture or the collapse of vertebrae, leading to spinal cord compression. The next most common clinical problem in patients with myeloma is susceptibility to bacterial infections. The most common infections are pneumonias and pyelonephritis, and the most frequent pathogens are *Streptococcus pneumoniae, Staphylococcus aureus*, and *Klebsiella pneumoniae* in the lungs and *Escherichia coli* and other gram-negative organisms in the urinary tract. In ~25% of patients, recurrent infections are the presenting features, and >75% of patients will have a serious infection at some time in their course. The susceptibility to infection has several contributing causes. First, patients with myeloma have diffuse hypogammaglobulinemia if the M component is excluded. The hypogammaglobulinemia is related to both decreased production and increased destruction of normal antibodies. The large M component results in fractional catabolic rates of 8–16% instead of the normal 2%. Moreover, some patients generate a population of circulating regulatory cells in response to their myeloma that can suppress normal antibody synthesis. These patients have very poor antibody responses, especially to polysaccharide antigens such as those on bacterial cell walls. Various abnormalities in T-cell function are also observed including decreased T_H1 response, increase in T_H17 cells producing proinflammatory cytokines, and aberrant T regulatory cell function. Granulocyte lysozyme content is low, and granulocyte migration is not as rapid as normal in patients with myeloma, probably the result of a tumor product. There are also a variety of abnormalities in complement functions in myeloma patients. All these factors contribute to the immune deficiency in these patients. Some commonly used therapeutic agents may significantly affect immune function; e.g., dexamethasone suppresses immune responses and increases susceptibility to bacterial and fungal infection, B-cell maturation antigen (BCMA)–targeting chimeric antigen receptor T (CAR-T) cells and bispecific antibodies can eliminate plasma cells inducing hypogammaglobulinemia, and bortezomib predisposes to herpesvirus reactivation.

Renal failure occurs in nearly 25% of myeloma patients, and some renal pathology is noted in >50%. Of many contributing factors, hypercalcemia is the most common cause of renal failure. Glomerular deposits of amyloid, hyperuricemia, recurrent infections, frequent use of nonsteroidal anti-inflammatory agents for pain control, use of iodinated contrast dye for imaging, bisphosphonate use, and occasional infiltration of the kidney by myeloma cells all may contribute to renal dysfunction. However, tubular damage associated with the excretion of light chains is common. Normally, light chains are filtered, reabsorbed in the tubules, and catabolized. With the increase in the amount of light chains presented to the tubule, the tubular cells become overloaded with these proteins, and tubular damage results either directly from light chain toxic effects or indirectly from the release of intracellular lysosomal enzymes. The earliest manifestation of this tubular damage is the adult Fanconi's syndrome (a type 2 proximal renal tubular acidosis), with loss of glucose and amino acids, as well as defects in the ability of the kidney to acidify and concentrate the urine.

FIGURE 116-5 Bony lesions in multiple myeloma (MM). ***A.*** The skull demonstrates the typical "punched out" lesions characteristic of MM. The lesion represents a purely osteolytic lesion with little or no osteoblastic activity (*above*). ***B.*** Positron emission tomography/computed tomography showing multiple fluorodeoxyglucose (FDG)-avid lesions in skeleton (*left panel*) with their resolution on achieving complete response (CR) (*right panel*). *(Part A courtesy of Dr. Geraldine Schechter; with permission. Part B courtesy of Dr. Sundar Jagannath; with permission.)*

The proteinuria is not accompanied by hypertension, and the protein is nearly all light chains. Generally, very little albumin is in the urine because glomerular function is usually normal. When the glomeruli are involved, nonselective proteinuria is also observed. Patients with myeloma also have a decreased anion gap [i.e., $Na^+ - (Cl^- + HCO_3^-)$] because the M component is cationic, resulting in retention of chloride. This is often accompanied by hyponatremia that is felt to be artificial (pseudohyponatremia) because each volume of serum has less water as a result of the increased protein. Renal dysfunction due to light chain deposition disease, light chain cast nephropathy, and amyloidosis is partially reversible with effective therapy. Myeloma patients are susceptible to developing acute renal failure if they become dehydrated.

Normocytic and normochromic anemia occurs in ~80% of myeloma patients. It is usually related to the replacement of normal marrow by expanding tumor cells, to the inhibition of hematopoiesis by factors produced by the tumor, to reduced production of erythropoietin by the kidney, and to the effects of long-term therapy. In addition, mild hemolysis may contribute to the anemia. A larger than expected fraction of patients may have megaloblastic anemia due to either folate or vitamin B_{12} deficiency. Granulocytopenia and thrombocytopenia are rare except when therapy-induced. Clotting abnormalities may be seen due to the failure of antibody-coated platelets to function properly; the interaction of the M component with clotting factors I, II, V, VII, or VIII; antibody to clotting factors; or amyloid damage of endothelium. Deep venous thrombosis is also observed with the use of thalidomide, lenalidomide, or pomalidomide. Raynaud's phenomenon and impaired circulation may result if the M component forms cryoglobulins, and hyperviscosity syndromes may develop depending on the physical properties of the M component (most common with IgM, IgG3, and IgA paraproteins). Hyperviscosity is defined based on the relative viscosity of serum as compared with water. Normal relative serum viscosity is 1.8 (i.e., serum is normally almost twice as viscous as water). Symptoms of hyperviscosity occur at a level greater than 4 centipoises (cP), which is usually reached at paraprotein concentrations of ~40 g/L (4 g/dL) for IgM, 50 g/L (5 g/dL) for IgG3, and 70 g/L (7 g/dL) for IgA; however, chemico-physical properties of the paraproteins may cause it at lower levels.

Although neurologic symptoms occur in a minority of patients, they may have many causes. Hypercalcemia may produce lethargy, weakness, depression, and confusion. Hyperviscosity may lead to headache, fatigue, shortness of breath, exacerbation or precipitation of heart failure, visual disturbances, ataxia, vertigo, retinopathy, somnolence, and coma. Bony damage and collapse may lead to cord compression, radicular pain, and loss of bowel and bladder control. Infiltration of peripheral nerves by amyloid can be a cause of carpal tunnel syndrome and other sensorimotor mono- and polyneuropathies. Neuropathy associated with monoclonal gammopathy of undetermined significance (MGUS) and myeloma is more frequently sensory than motor neuropathy and is associated with IgM more than other isotypes. In >50% of patients with neuropathy, the IgM monoclonal protein is directed against myelin-associated globulin (MAG). Sensory neuropathy is also a side effect of therapy, specifically thalidomide and bortezomib.

Many of the clinical features of myeloma, e.g., cord compression, pathologic fractures, hyperviscosity, sepsis, and hypercalcemia, can present as medical emergencies. Despite the widespread distribution of plasma cells in the body, tumor expansion is dominantly within bone and bone marrow and, for reasons unknown, rarely causes enlargement of spleen, lymph nodes, or gut-associated lymphatic tissue.

DIAGNOSIS AND STAGING

The diagnosis of myeloma requires marrow plasmacytosis (>10%), a serum and/or urine M component, and at least one of the myeloma-defining events detailed in **Table 116-1**. Bone marrow plasma cells are CD138+ and either monoclonal kappa or lambda light chain positive. The most important differential diagnosis in patients with myeloma involves their separation from individuals with MGUS or smoldering multiple myeloma (SMM). MGUS is vastly more common than myeloma, occurring in 1% of the population aged >50 years and in up to 10% of individuals aged >75 years. The diagnostic criteria for MGUS, SMM, and myeloma are described in Table 116-1. Although ~1% of patients per year with MGUS go on to develop myeloma, all cases of myeloma are preceded by MGUS. Non-IgG subtype, abnormal kappa/lambda free light chain ratio, and serum M protein >15 g/L (1.5 g/dL) are associated with higher incidence of progression of MGUS to myeloma. Absence of all three features predicts a 5% chance of progression, whereas higher-risk MGUS with the presence of all three features predicts a 60% chance of progression over 20 years. The features

TABLE 116-1 Diagnostic Criteria for Multiple Myeloma, Myeloma Variants, and Monoclonal Gammopathy of Undetermined Significance

Monoclonal Gammopathy of Undetermined Significance (MGUS)
Serum monoclonal protein (non-IgM type) <30 g/L
Clonal bone marrow plasma cells <10%[a]
Absence of myeloma-defining events or amyloidosis that can be attributed to the plasma cell proliferative disorder
Smoldering Multiple Myeloma (Asymptomatic Myeloma)
Both criteria must be met: • Serum monoclonal protein (IgG or IgA) ≥30 g/L or urinary monoclonal protein ≥500 mg per 24 h and/or clonal bone marrow plasma cells 10–60% • Absence of myeloma-defining events or amyloidosis
Symptomatic Multiple Myeloma

Clonal bone marrow plasma cells or biopsy-proven bony or extramedullary plasmacytoma[a] and any one or more of the following myeloma-defining events:
• Evidence of one or more indicators of end-organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically:
  • Hypercalcemia: serum calcium >0.25 mmol/L (>1 mg/dL) higher than the upper limit of normal or >2.75 mmol/L (>11 mg/dL)
  • Renal insufficiency: creatinine clearance <40 mL/min[b] or serum creatinine >177 μmol/L (>2 mg/dL)
  • Anemia: hemoglobin value of >20 g/L below the lower limit of normal, or a hemoglobin value <100 g/L
  • Bone lesions: one or more osteolytic lesions on skeletal radiography, CT, or PET-CT[c]
  • Any one or more of the following biomarkers of malignancy:
  • Clonal bone marrow plasma cell percentage[a] ≥60%
  • Involved: uninvolved serum free light chain ratio[d] ≥100
  • >1 focal lesion on MRI studies[e]

Nonsecretory Myeloma
No M protein in serum and/or urine with immunofixation[f] Bone marrow clonal plasmacytosis ≥10% or plasmacytoma[a] Myeloma-related organ or tissue impairment (end-organ damage, as described above)
Solitary Plasmacytoma
Biopsy-proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells Normal bone marrow with no evidence of clonal plasma cells[a] Normal skeletal survey and MRI (or CT) of spine and pelvis (except for the primary solitary lesion) Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, or bone lesions (CRAB) that can be attributed to a lymphoplasma cell proliferative disorder
POEMS Syndrome
All of the following four criteria must be met: 1. Polyneuropathy 2. Monoclonal plasma cell proliferative disorder 3. Any one of the following: (a) sclerotic bone lesions; (b) Castleman's disease; (c) elevated levels of vascular endothelial growth factor (VEGF) 4. Any one of the following: (a) organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy); (b) extravascular volume overload (edema, pleural effusion, or ascites); (c) endocrinopathy (adrenal, thyroid, pituitary, gonadal, parathyroid, and pancreatic); (d) skin changes (hyperpigmentation, hypertrichosis, glomeruloid hemangiomata, plethora, acrocyanosis, flushing, and white nails); (e) papilledema; (f) thrombocytosis/polycythemia[g]

[a]Clonality should be established by showing κ/λ light chain restriction on flow cytometry, immunohistochemistry, or immunofluorescence. Bone marrow plasma cell percentage should preferably be estimated from a core biopsy specimen; in case of a disparity between the aspirate and core biopsy, the highest value should be used. [b]Measured or estimated by validated equations. [c]If bone marrow has <10% clonal plasma cells, more than one bone lesion is required to distinguish from solitary plasmacytoma with minimal marrow involvement. [d]These values are based on the serum Freelite assay (The Binding Site Group, Birmingham, United Kingdom). The involved free light chain must be ≥100 mg/L. [e]Each focal lesion must be ≥5 mm in size. [f]A small M component may sometimes be present. [g]These features should have no other attributable causes and have temporal relation with each other.

Abbreviations: CT, computed tomography; MRI, magnetic resonance imaging; PET-CT, ^{18}F-fluorodeoxyglucose positron emission tomography with computed tomography; POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes.

responsible for higher risk of progression from SMM to MM are bone marrow plasmacytosis >10%, abnormal kappa/lambda free light chain ratio, and serum M protein >30 g/L (3 g/dL). Patients with only one of these three features have a 25% chance of progression to MM in 5 years, whereas patients with high-risk SMM with all three features have a 76% chance of progression. Two important variants of myeloma are solitary bone plasmacytoma and solitary extramedullary plasmacytoma. These lesions are associated with an M component in <30% of the cases, they may affect younger individuals, and both are associated with median survivals of ≥10 years. Solitary bone plasmacytoma is a single lytic bone lesion without marrow plasmacytosis. Extramedullary plasmacytomas usually involve the submucosal lymphoid tissue of the nasopharynx or paranasal sinuses without marrow plasmacytosis. Both tumors are highly responsive to local radiation therapy. If an M component is present, it should disappear after treatment. Solitary bone plasmacytomas may recur in other bony sites or evolve into myeloma. Extramedullary plasmacytomas rarely recur or progress.

LABORATORY INVESTIGATION

Serum protein electrophoresis and measurement of serum immunoglobulins and free light chains are useful for detecting and characterizing M spikes, supplemented by immunoelectrophoresis, which is especially sensitive for identifying low concentrations of M components not detectable by protein electrophoresis. A 24-h urine specimen is necessary to quantitate Bence Jones protein (immunoglobulin light chain) excretion. The serum M component is IgG in 53% of patients, IgA in 25%, and IgD in 1%; 20% of patients will have only light chains in serum and urine. Dipsticks for detecting proteinuria are not reliable at identifying light chains, and the heat test for detecting Bence Jones protein is falsely negative in ~50% of patients with light chain myeloma. Fewer than 1% of patients have no identifiable M component; these patients usually have light chain myeloma in which renal catabolism has made the light chains undetectable in the urine. In most of these patients, light chains can now be detected by serum free light chain assay. Mass spectrometry has been investigated to accurately

assess M protein. IgD myeloma may also present with light chain disease. About two-thirds of patients with serum M components also have urinary light chains. The light chain isotype may have an impact on disease behavior. Whether this is due to some genetically important determinant of cell proliferation or because lambda light chains are more likely to cause renal damage and form amyloid than are kappa light chains is unclear. About half of patients with IgM paraproteins develop hyperviscosity compared with only 2–4% of patients with IgA and IgG M components. Among IgG myelomas, it is the IgG3 subclass that has the highest tendency to form both concentration- and temperature-dependent aggregates, leading to hyperviscosity and cold agglutination at lower serum concentrations. A standard workup directed at detecting monoclonal plasma cells and myeloma-defining events as well as prognosis is detailed in **Table 116-2**.

A complete blood count with differential may reveal anemia. Erythrocyte sedimentation rate is elevated. Rare patients (~1%) may have plasma cell leukemia with >2000 plasma cells/μL. This may be seen in disproportionate frequency in IgD (12%) and IgE (25%) myelomas. Serum calcium, urea nitrogen, creatinine, and uric acid levels may be elevated. Serum alkaline phosphatase is usually normal even with extensive bone involvement because of the absence of osteoblastic activity. It is also important to quantitate serum β_2-microglobulin and albumin (see below).

Chest and bone radiographs may reveal lytic lesions or diffuse osteopenia. Magnetic resonance imaging (MRI) offers a sensitive means to document extent of bone marrow infiltration and cord or root compression in patients with pain syndromes. ^{18}F-fluorodeoxyglucose (^{18}F-FDG) positron emission tomography (PET)/computed tomography (CT) is a valuable tool to assess bone damage and detect extramedullary sites of the disease (Fig. 116-5). The use of ^{18}F-FDG PET/CT is now considered standard to distinguish between smoldering and active MM and to confirm a suspected diagnosis of solitary plasmacytoma. It is also a valuable tool to evaluate response in patients with oligo- or nonsecretory myeloma.

TABLE 116-2 Standard Investigative Workup in Multiple Myeloma (MM)

Investigations to Evaluate for Clonal Plasma Cells
Bone marrow aspirate and biopsy (fine-needle aspiration of plasmacytoma if indicated) • Histology • Clonality by kappa/lambda immunostaining by flow cytometry or immunohistochemistry
Investigations to Evaluate Clonal Paraprotein
Serum protein electrophoresis and immunofixation
Quantitative serum immunoglobulin levels (IgG, IgA, and IgM)
24-h urine protein electrophoresis and immunofixation
Serum free light chain and ratio
Immunofixation for IgD or IgE in select cases
Investigation to Evaluate End-Organ Damage
Hemogram to assess for anemia.
Chemistry panel for renal function and calcium
Skeletal survey or PET/CT scan to evaluate bone lesions
PET/CT or MRI if smoldering MM or solitary plasmacytoma
Investigation for Risk Stratification
β_2-Microglobulin and serum albumin for ISS stage
DNA-sequencing or if not available Fluorescent in situ hybridization for hyperdipoidy, del17p, t(4;14); t(11;14), t(14;16), t(14;20), amp1q34, and del1p and p53 mutation on bone marrow sample
LDH
Specialized Investigation in Selected Cases
Abdominal fat pad for amyloid
Serum viscosity if IgM component or high IgA levels or serum M component >7 g/dL
Myd88 and *CXCR4* mutation analysis if IgM component

Abbreviations: CT, computed tomography; ISS, International Staging System; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PET/CT, positron emission tomography/computed tomography.

PROGNOSIS

Serum β_2-microglobulin is the single most powerful predictor of survival and can substitute for staging. β_2-Microglobulin is the light chain of the class I major histocompatibility antigens (HLA-A, -B, -C) on the surface of every cell. Combination of serum β_2-microglobulin and albumin levels forms the basis for a three-stage International Staging System (ISS) **(Table 116-3)** that predicts survival. With the use of high-dose therapy and the newer agents, the Durie-Salmon staging system is unable to predict outcome and is no longer used. High labeling index, circulating plasma cells, performance status, and high levels of lactate dehydrogenase are also associated with poor prognosis.

With low proliferative activity of plasma cells, karyotype is now not recommended in myeloma. Fluorescent in situ hybridization (FISH) has become a standard investigative technique, and the current recommendation suggests switching to DNA sequencing-based methods. Chromosome 17p deletion with 20% clonality or *TP53* mutation, and translocations t(4;14), (14;16), or t(14;20) associated with del 1p or amp1q changes along with high β2-microglobulin with normal renal function are considered prognostic for high-risk disease, as described in Table 116-3. Chromosome 13q deletion and t(11;14) are not considered predictors of high-risk myeloma.

TREATMENT

Multiple Myeloma

MGUS, SMM, AND SOLITARY PLASMACYTOMA

No specific intervention is indicated for patients with MGUS. Follow-up once a year or less frequently is adequate except in higher-risk MGUS, where serum protein electrophoresis, complete blood count, creatinine, and calcium should be repeated every 6 months. A patient with MGUS and severe polyneuropathy is considered for therapeutic intervention if a causal relationship can be assumed, especially in the absence of any other potential causes for neuropathy. Therapy can include plasmapheresis and occasionally rituximab in patients with IgM MGUS or myeloma-like therapy

TABLE 116-3 Risk Stratification in Myeloma

METHOD	STANDARD RISK (75–80%) (EXPECTED SURVIVAL 8–10+ YEARS)	HIGH RISK (20–25%) (EXPECTED SURVIVAL 3–4 YEARS)
DNA sequencing or FISH if sequencing not available	t(11;14)	del(17p) (20% cutoff) and/or TP53 mut
	del(13)	t(4;14)/t(14;16)/t(14;20) with 1q gain and/or 1p del
	Hyperdiploidy	Del 1p + 1q gain or biallelic del 1p
Biochemical assessment		β_2M >5.5 with normal creatinine

INTERNATIONAL STAGING SYSTEM (ISS)		
INTERNATIONAL STAGING SYSTEM (ISS)	**STAGE**	**MEDIAN SURVIVAL, MONTHS**
β_2M <3.5, ALB ≥3.5	I (28%)	62
β_2M <3.5, ALB <3.5 ***or*** β_2M <3.5, ALB ≥3.5 *or* β_2M = 3.5–5.5	II (39%)	44
β_2M >5.5 *or* β_2M <3.5, ALB <3.5 *or* β_2M = 3.5–5.5	III (33%)	29

[a]Percentage of patients presenting at each stage.

Abbreviations: β_2M, serum β_2-microglobulin in mg/L; ALB, serum albumin in g/dL; FISH, fluorescent in situ hybridization; LDH, lactate dehydrogenase.

in those with IgG or IgA disease. A subset of patients with MGUS develop renal dysfunction usually based on renal damage from the monoclonal antibody. The damage may affect the glomeruli, tubules, or vessels. No consensus exists on management, but lowering the level of the monoclonal antibody with bortezomib has had some advocates.

About 10% of patients have SMM and will have an indolent course demonstrating only slow progression of disease over many years. For patients with SMM, no specific therapeutic intervention is indicated in general. But early intervention with lenalidomide alone or in combination with dexamethasone has been shown to prevent progression from high-risk SMM to active MM. At present, patients with SMM only require antitumor therapy when myeloma-defining events are identified.

Patients with solitary bone plasmacytomas and extramedullary plasmacytomas may be expected to enjoy prolonged disease-free survival after local radiation therapy at a dose of ~40 Gy. Occult marrow involvement may occur at low incidence in patients with solitary bone plasmacytoma. Such patients are usually identified because their serum M component falls slowly or disappears initially after local therapy, only to return after a few months. These patients respond well to systemic therapy.

SYMPTOMATIC MM

Patients with symptomatic myeloma require therapeutic intervention. In general, such therapy has two purposes: (1) systemic therapy to control myeloma; and (2) supportive care to control symptoms of the disease, its complications, and adverse effects of therapy. Therapy can significantly prolong survival and improve the quality of life for myeloma patients.

The therapy of myeloma includes an initial induction regimen followed by consolidation and/or maintenance therapy and, on subsequent progression, management of relapsed disease. All agents available for use at various stages of the therapy and their doses, schedules, and combinations are detailed in **Table 116-4**. Therapy is partly dictated by the patient's age and comorbidities, which may

TABLE 116-4 Standard Therapeutic Agents in Myeloma

CLASS	AGENT	STANDARD DOSAGE AND ADMINISTRATION	COMBINATION	MYELOMA INDICATION
Immunomodulatory drugs (IMiD)	Thalidomide (T)	Oral 50–200 mg qd	TD, VTD	Newly diagnosed and relapsed
	Lenalidomide (R)	Oral 5–25 mg daily × 21 days q 4 weeks	RD, RVD, DaRD, ERD, KRD, IRD, DaRVD	Newly diagnosed, maintenance, and relapsed
	Pomalidomide (P)	Oral 2–4 mg daily × 21 days q 4 weeks	PD, KPD, DaPD	Relapsed
Proteasome inhibitors (PI)	Bortezomib (V)	IV or SC 1.3 mg/m^2 days 1, 4, 8, 11 OR days 1, 8, 15	VD, VTD, VRD, DaVD, VCD DaRVD	Newly diagnosed and relapsed
	Carfilzomib (K)	IV 20–56 mg/m^2 days 1, 2, 8, 9, 15, 16 q 4 weeks	KD, KRD, KPD, Da KD, Da KRD, IsaKD	Newly diagnosed and relapsed
	Ixazomib (I)	Oral 4 mg days 1, 8, 15	IRD	Relapsed, maintenance
Antibodies	Daratumumab (Da)	IV or SC 16 mg/kg per week for 8 weeks then every 2 weeks for 16 weeks and then every 4 weeks thereafter	Dara, DaRD, DaVD, DaPD, DaKD	Newly diagnosed, maintenance, and relapsed
	Elotuzumab (E)	IV 10 mg/kg days 1, 8, 15, and 22 for first two cycles, then on days 1 and 15; along with RD	ERD, EPD	Relapsed
	Isatuximab (Isa)	IV 10 mg/kg weekly for 4 weeks and then every 2 weeks	IsaPD, IsaKD	Relapsed
	Belantamab mafodotin	IV 2.5 mg/kg once every 3 weeks		Relapsed or refractory—4 prior lines of therapy
Selective inhibitor of nuclear export (SINE)	Selinexor (S)	Oral 80 mg on days 1 and 3 of each week	SVD	Relapsed
Histone deacetylase inhibitor	Panobinostat (Pa)	Oral 20 mg once every other day for 3 doses/week for 2 weeks every 21 days	PaVD	Relapsed
Alkylating agents	Melphalan (M)	Oral 0.25 mg/kg per day for 4 days (with P) every 4–6 weeks	MP, MPT, MPR, MPV, DaMPV, high-dose M	Newly diagnosed and relapsed conditioning
	Cyclophosphamide	IV—300–500 mg/m^2 weekly × 2 q 4 weeks Oral—50 mg qd × 21 days	VCD	Newly diagnosed and relapsed
	Bendamustine (B)	IV 70–90 mg days 1, 2 OR days 1, 8 q 4 weeks	BD or BVD	Relapsed
	Melflufen (Me)	IV 40 mg day 1 (with D 40 mg on days 1, 8, 15, and 22) q 28 days	MeD	Relapsed or refractory—4 prior lines of therapy
Glucocorticoid	Dexamethasone (D) Prednisone (P)	Oral 10–40 mg q week Oral 1 mg/kg		All stages
Cellular therapy	Idecabtagene vicleucel (Ide-cel)	IV 450 × 10^6 cells	None	At least two prior lines of therapy that includes an PI, IMiD and anti-CD38 antibody
	Ciltacabtagene autoleucel (Cilta-cel)	IV	None	At least one prior line of therapy, including PI and IMiD and who are refractory to lenalidomide
Bispecific antibodies	Teclistamab Anti-BCMA–anti-CD3	Step-up doses of 0.06 mg and 0.3 mg per kilogram SC days 1, 4 and 1.5 mg per kilogram of body weight day 8 and q week	None	Relapsed or refractory—4 prior lines of therapy with prior exposure to PI, IMiD, and anti-CD38 antibody
	Elranatamab Anti-BCMA–anti-CD3	Step-up doses of 12 and 32 mg on days 1, 4 and 76 mg SC day 8 and then q week for 25 weeks and then q 2 weeks	None	
	Talquetamab Anti-GPRC5D–anti-CD3	Two step-up doses during first week and then every week or every other week regimen	None	

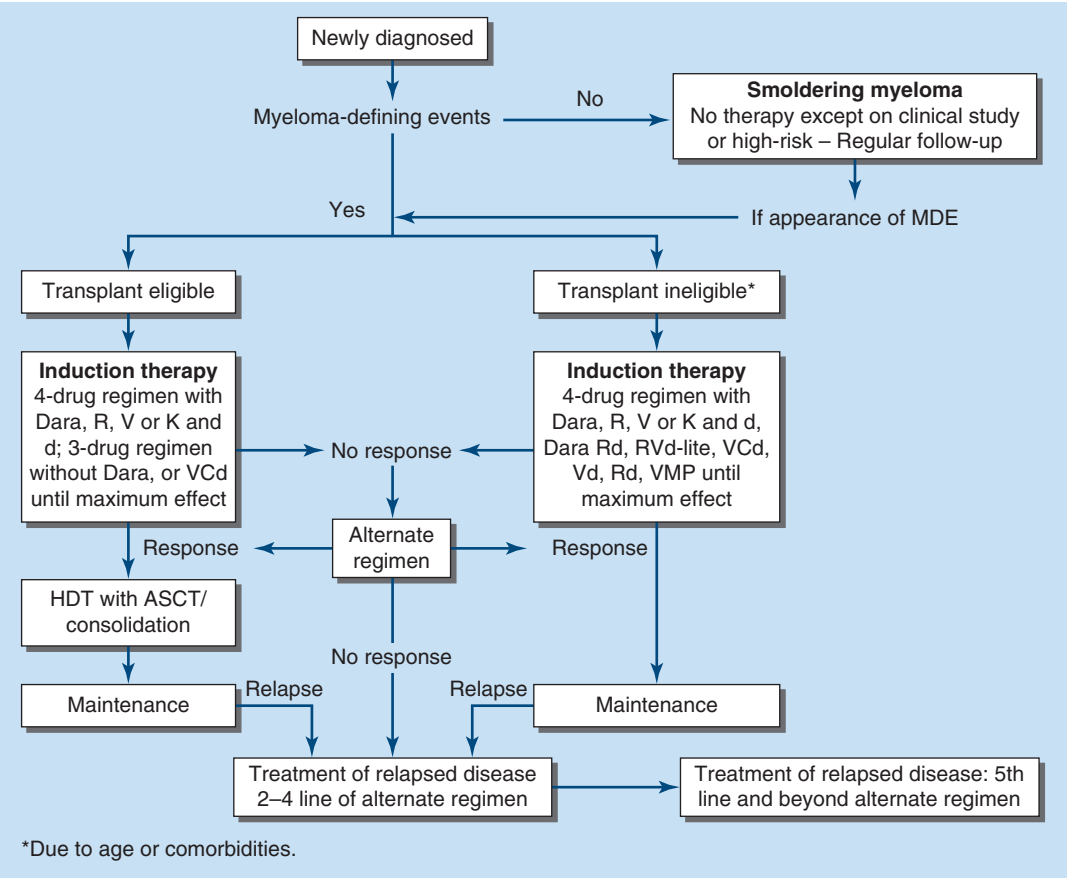

FIGURE 116-6 Treatment algorithm for multiple myeloma. *Alternate regimen* indicates combinations including daratumumab, elotuzumab, panobinostat, carfilzomib, ixazomib, pomalidomide, or other agents. ASCT, autologous stem cell transplantation; C, cyclophosphamide; D, dexamethasone; HDT, high-dose therapy; M, melphalan; MDE, myeloma-defining events; P, prednisone; R, lenalidomide; RVD-lite, weekly regimen; V, bortezomib.

affect a patient's ability to undergo high-dose therapy and transplantation (Fig. 116-6).

Three important classes of agents approved for treatment of newly diagnosed MM are immunomodulatory agents, proteasome inhibitors, and antibodies targeting CD38. The combination of lenalidomide with a proteasome inhibitor (bortezomib or carfilzomib) and dexamethasone achieves close to a 100% response rate and a >50% complete response (CR) rate, making this combination one of the preferred induction regimens in transplant-eligible patients. Other similar three-drug combinations (bortezomib, thalidomide, and dexamethasone or bortezomib, cyclophosphamide, and dexamethasone) also achieve >90% response rate. Addition of a fourth agent, daratumumab or isatuximab, an anti-CD38 antibody, is providing even deeper responses and such four-drug regimens as induction therapy are becoming standard of care. Usually between four and six cycles of these combination regimens are utilized to achieve initial deep cytoreduction before consideration of high-dose therapy with autologous stem cell transplantation.

In patients who are not transplant candidates due to physiologic age >70 years, significant cardiopulmonary problems, or other comorbid illnesses, the same three-drug combinations described above are considered standard of care as induction therapy with age- and frailty-guided dose and schedule modifications. Combination of daratumumab with lenalidomide and dexamethasone (DRd) and modified lenalidomide-bortezomib-dexamethasone (RVD lite) combination achieve high overall response rates (93 and 86%, respectively) and CR rates (47 and 32%, respectively). The four-drug combinations used in younger patients are also utilized in healthy older patients with excellent response. In the past, the combination of melphalan with prednisone (MP) alone or with thalidomide or bortezomib has been utilized effectively, but with the availability of newer agents and combinations, MP-based combinations are now not utilized.

HIGH-DOSE THERAPY WITH AUTOLOGOUS STEM CELL TRANSPLANTATION

High-dose therapy (HDT) and consolidation/maintenance are standard practice in the majority of eligible patients. In patients who are transplant candidates and receiving lenalidomide, stem cells should be collected within 6 months because the continued use of lenalidomide may compromise the ability to collect adequate numbers of stem cells. Randomized studies comparing standard-dose therapy to high-dose melphalan therapy with hematopoietic stem cell support have shown that HDT can achieve higher overall response rates, with up to 25–40% additional CRs and prolonged progression-free and overall survival; however, few, if any, patients are cured. Although two successive HDTs (tandem transplantations) are more effective than single HDT, the benefit is only observed in the subset of patients who do not achieve a complete or very good partial response to the first transplantation, which is a rare subset. Moreover, a randomized study failed to show any significant difference in overall survival between early transplantation after induction therapy versus delayed transplantation at relapse. These data allow an option to delay transplantation, especially with the availability of newer agents and combinations. Allogeneic transplantations may also produce high response rates, but with significant toxicities. Nonmyeloablative allogeneic transplantation can reduce toxicity but is recommended only under the auspices of a clinical trial to exploit an immune graft-versus-myeloma effect while avoiding attendant toxicity. Due to effective cellular therapies, allogeneic transplantation is very rarely used.

Maintenance therapy prolongs remissions following standard-dose regimens as well as HDT. Several phase 3 studies have demonstrated improved progression-free survival, and one study showed prolonged overall survival in patients receiving lenalidomide compared to placebo as maintenance therapy after HDT. In nontransplant candidates, two phase 3 studies showed prolonged

progression-free survival with lenalidomide maintenance after MP plus lenalidomide or lenalidomide plus dexamethasone induction therapy. Although concern arises regarding an increased incidence of second primary malignancies in patients receiving lenalidomide maintenance, its benefits in reducing the risk of progressive disease and death from myeloma far outweigh the small increased risk of second cancers. In patients with high-risk cytogenetics, lenalidomide and bortezomib or an oral proteasome inhibitor, ixazomib, show promise as maintenance combination therapy after transplantation. A phase 3 study has also demonstrated the benefit of maintenance therapy with daratumumab after HDT.

RELAPSED DISEASE

Relapsed myeloma can be treated with a number of agents including lenalidomide and/or bortezomib, if previously not used. The second-generation proteasome inhibitor carfilzomib and immunomodulatory agent pomalidomide have shown efficacy in relapsed and refractory MM, even MM refractory to lenalidomide and bortezomib. An oral proteasome inhibitor, ixazomib, has also been approved in combination with lenalidomide and dexamethasone as an all-oral regimen for relapsed MM. Four antibodies are approved for treatment of relapsed MM. Daratumumab targeting CD38 achieves high response rates and improved progression-free survival as a single agent with further improvement in response and survival when added to bortezomib and dexamethasone or lenalidomide and dexamethasone. A formulation of daratumumab for subcutaneous administration provides decreased toxicity and improved convenience. Isatuximab, another antibody targeting CD38, achieves high response rates and improved progression-free survival in combination with pomalidomide or carfilzomib and dexamethasone. Elotuzumab, which targets SLAMF7, has shown significant activity in combination with lenalidomide and dexamethasone in relapsed/refractory myeloma but not as a single agent. Finally, belantamab mafodotin, an antibody-drug conjugate, targets B-cell maturation antigen (BCMA), which is expressed mainly on normal plasma cells and myeloma cells and delivers auristatin, a microtubule inhibitor, to the tumor cells and achieves responses in relapsed/refractory myeloma. The drug has a unique ophthalmologic toxicity that requires close monitoring. Its efficacy increases significantly when combined with pomalidomide or proteasome inhibitor.

Panobinostat, a histone deacetylase inhibitor, in combination with bortezomib and dexamethasone has been approved for treatment of relapsed/refractory myeloma based on superior response and progression-free survival compared to bortezomib and dexamethasone alone. Two additional newer agents have unique mechanisms of action: selinexor is a first-in-class exportin inhibitor that blocks export of proteins from the cell nucleus, and melflufen is an alkylating agent conjugated to a peptide to improve specific delivery to myeloma cells that express aminopeptidase required for cleaving of the peptide to deliver the drug intracellularly in myeloma cells. Both agents have been approved based on their effectiveness in relapsed/refractory myeloma.

Immunotherapeutic Approaches Two cellular therapies, both targeting BCMA, are approved for relapsed myeloma. The anti-BCMA CAR transduced T cell, idecabtagene vicleucel (Ide-cel), is approved after at least two prior lines of therapy that includes an immunomodulatory agent, a proteasome inhibitor, and an anti-CD38 monoclonal antibody, whereas ciltacabtagene autoleucel (Cilta-cel) is approved for patients who have received at least one prior line of therapy, including a proteasome inhibitor and an immunomodulatory agent and who are refractory to lenalidomide. In patients with advanced myeloma with a median of six prior lines of treatment, 81% of patients receiving target dose of Ide-cel responded, and a CR rate of 33% was observed. Cilta-cel in a similar patient population achieved 98% overall response with 82% achieving CR. Cytokine release syndrome and neurotoxicity remain primary toxicities requiring close monitoring and aggressive management.

Three bispecific antibodies are also approved for treatment of relapsed and refractory myeloma after four prior lines of therapies. Bispecific antibodies can bind to two different cell surface targets through two distinct binding domains. One domain binds to CD3 on human lymphocytes, while the other domain binds to a cell surface target specific for myeloma cells, bringing the T cells closer and leading to myeloma cell death. Two bispecific antibodies, teclistamab and elranatamab, target BCMA, whereas talquetamab targets a novel cell surface target on myeloma cells, G protein–coupled receptor class C group 5 (GPRC5D). In patients with relapsed refractory myeloma, these antibodies result in a 60–70% response rate, with a quarter of the patients achieving CR. Bispecific antibodies are associated with toxicities including cytokine release syndrome, neurotoxicity, and significant susceptibility to infectious complications. Incorporation of the large number of active agents at various stages of treatment, including in newly diagnosed patients, is improving survival as well as quality of life.

THERAPY ENDPOINT

Improvement in the serum M component may lag behind the symptomatic improvement due to longer serum half-life (~3 weeks) of the immunoglobulin. The fall in M component depends on the rate of tumor kill and the fractional catabolic rate of immunoglobulin. Serum and urine light chains with a functional half-life of ~6 h may fall much quicker within the first week of treatment. Because urine light chain levels may relate to renal tubular function, they are not a reliable measure of tumor cell kill in patients with renal dysfunction. Achieving CR, defined as disappearance of serum and urine monoclonal protein with normal bone marrow by light microscopy, has been a standard goal of therapy. However, sequencing or multicolor flow cytometry–based assessment of minimal residual disease (MRD) in bone marrow to measure the presence of one myeloma cell in a million cells is being considered as an important new endpoint, both in newly diagnosed and relapsed patients. Absence of MRD at this sensitivity predicts for both longer progression-free survival and longer overall survival. Although patients may not achieve complete remission, clinical responses may last for long periods of time in small numbers of patients.

The median overall survival of patients with myeloma is 8+ years, with subsets of younger patients surviving >10 years. The major causes of death are progressive myeloma, renal failure, sepsis, or therapy-related myelodysplasia. Nearly a quarter of patients die of myocardial infarction, chronic lung disease, diabetes, or stroke, which are all intercurrent illnesses related more to the age of the patient group than to the tumor.

SUPPORTIVE THERAPY

Herpes zoster prophylaxis is indicated if bortezomib is used, and neuropathy attendant to bortezomib can be decreased both by its subcutaneous administration and by administration on a weekly schedule. Lenalidomide use requires prophylaxis for deep-vein thrombosis (DVT) with either aspirin or, if patients are at a greater risk of DVT, warfarin, low-molecular-weight heparin, or direct-acting anticoagulants DOACs. Patients receiving anti-BCMA CAR-T cell therapy or bi-specific antibodies may need supplementation with intravenous γ globulin due to induction of prolonged hypogammaglobulinemia.

Supportive care directed at the anticipated complications of the disease may be as important as primary antitumor therapy. Hypercalcemia generally responds well to bisphosphonates, glucocorticoid therapy, hydration, and natriuresis and rarely requires calcitonin as well. Bisphosphonates (e.g., pamidronate 90 mg or zoledronate 4 mg initially once a month for 12–24 months and later every 2–3 months) reduce osteoclastic bone resorption and preserve performance status and quality of life, decrease bone-related complications, and may also have antitumor effects. Osteonecrosis of the jaw and renal dysfunction can occur in a minority of patients receiving bisphosphonate therapy. Denosumab is an alternative agent administered intravenously at 120 mg monthly and achieves

a similar level of effect as bisphosphonates to prevent bone-related complications in myeloma. Treatments aimed at strengthening the skeleton such as fluorides, calcium, and vitamin D, with or without androgens, have been suggested but are not of proven efficacy. Kyphoplasty or vertebroplasty should be considered in patients with painful collapsed vertebra. Iatrogenic worsening of renal function may be prevented by maintaining a high fluid intake to prevent dehydration and enhance excretion of light chains and calcium. In the event of acute renal failure, plasmapheresis is ~10 times more effective at clearing light chains than peritoneal dialysis; however, its role in reversing renal failure remains controversial. Importantly, reducing the protein load by effective antitumor therapy with agents such as bortezomib may result in improvement in renal function in over half of the patients. Use of lenalidomide in renal failure is possible but requires dose modification because it is renally excreted. Urinary tract infections should be watched for and treated early. Plasmapheresis may be the treatment of choice for hyperviscosity syndromes. Although the pneumococcus is a dreaded pathogen in myeloma patients, pneumococcal polysaccharide vaccines may not elicit an antibody response. The pneumococcal conjugate vaccines are more protective. Prophylactic administration of intravenous γ globulin preparations is used in the setting of recurrent serious infections and in patients receiving CAR-T therapy or bispecific antibodies. Routine chronic oral antibiotic prophylaxis is not warranted. Patients receiving bortezomib or CD38-directed therapies receive prophylaxis against herpes zoster. Patients with myeloma and even SMM and MGUS may be at a higher risk of developing COVID-19 and thus are encouraged to have vaccination for prevention and, if positive for infection, to receive antiviral therapy for COVID-19. Patients developing neurologic symptoms in the lower extremities, severe localized back pain, or problems with bowel and bladder control may need emergency MRI and local radiation therapy and glucocorticoids if cord compression is identified. In patients in whom neurologic deficit is increasing or substantial, emergent surgical decompression may be necessary. Most bone lesions respond to analgesics and systemic therapy, but certain painful lesions may respond more promptly to localized radiation. The anemia associated with myeloma may respond to erythropoietin along with hematinics (iron, folate, cobalamin). The pathogenesis of the anemia should be established and specific therapy instituted, whenever possible.

WALDENSTRÖM'S MACROGLOBULINEMIA

In 1948, Waldenström described a malignancy of lymphoplasmacytoid cells that secreted IgM. In contrast to myeloma, the disease was associated with lymphadenopathy and hepatosplenomegaly, but the major clinical manifestation was hyperviscosity syndrome. The disease resembles the related diseases CLL, myeloma, and lymphocytic lymphoma. It originates from a post–germinal center B cell that has undergone somatic mutations and antigenic selection in the lymphoid follicle and has the characteristics of an IgM-bearing memory B cell. Waldenström's macroglobulinemia (WM) and IgM myeloma follow a similar clinical course, but therapeutic options are different. The diagnosis of IgM myeloma is usually reserved for patients with lytic bone lesions and predominant infiltration with CD138+ plasma cells usually with t(11;14) translocation in the bone marrow. Such patients are at greater risk of pathologic fractures than patients with WM.

A familial occurrence is common in WM, but its molecular bases are yet unclear. A distinct *MYD88* L265P somatic mutation is present in >90% of patients with WM and the majority of IgM MGUS. Other commonly occurring mutations include *CXCR4* (30–40%), *ARID1A* (17%), and *CD79B* (8–15%). Presence of *MYD88* mutation status is now used as a diagnostic test to discriminate WM from marginal zone lymphomas (MZLs), IgM-secreting myeloma, and CLL with plasmacytic differentiation. This mutation also explains the molecular pathogenesis of the disease with involvement of Toll-like receptor (TLR) and interleukin 1 receptor (IL-1R) signaling leading to activation of IL-1R–associated kinase (IRAK) 4 and IRAK1 followed by nuclear factor-κB (NF-κB) activation. *MYD88* mutation also triggers Bruton's tyrosine kinase (BTK) and hemopoietic cell kinase (HCK)-mediated growth and survival signaling, which are now important therapeutic targets in WM. *CXCR4* mutations induce AKT and extracellular regulated kinase 1/2 (ERK1/2) signaling. This pathway can lead to development of drug resistance in the presence of its ligand CXCL12.

The disease is similar to myeloma in being slightly more common in men and occurring with increased incidence with increasing age (median age 64 years). The IgM in some patients with macroglobulinemia may have specificity for myelin-associated glycoprotein (MAG), a protein that has been associated with demyelinating disease of the peripheral nervous system and may be lost earlier and to a greater extent than the better-known myelin basic protein in patients with multiple sclerosis. Sometimes patients with macroglobulinemia develop a peripheral neuropathy, and half of these patients are positive for anti-MAG antibody. The neuropathy may precede the appearance of the neoplasm. The whole process may begin with a viral infection that may elicit an antibody response that cross-reacts with a normal tissue component.

Like myeloma, the disease involves the bone marrow, but unlike myeloma, it does not cause bone lesions or hypercalcemia. Bone marrow shows >10% infiltration with lymphoplasmacytic cells (surface IgM+, CD19+, CD20+, and CD22+, rarely CD5+, but CD10− and CD23−) with an increase in number of mast cells. Like myeloma, an M component is present in the serum in excess of 30 g/L (3 g/dL), but unlike myeloma, the size of the IgM paraprotein results in little renal excretion, and only ~20% of patients excrete light chains. Therefore, renal disease is not common. The light chain isotype is kappa in 80% of the cases. Patients present with weakness, fatigue, and recurrent infections similar to myeloma patients, but epistaxis, visual disturbances, and neurologic symptoms such as peripheral neuropathy, dizziness, headache, and transient paresis are much more common in macroglobulinemia. Presence of *MYD88* and *CXCR4* mutations also affects disease presentation. Presence of *CXCR4* mutations is associated with higher bone marrow disease burden and higher incidence of hyperviscosity. Patients with wild-type *MYD88* show lower bone marrow disease burden.

Physical examination reveals adenopathy and hepatosplenomegaly, and ophthalmoscopic examination may reveal vascular segmentation and dilation of the retinal veins characteristic of hyperviscosity states. Patients may have a normocytic, normochromic anemia, but rouleaux formation and a positive Coombs test are much more common than in myeloma. Malignant lymphocytes are usually present in the peripheral blood. About 10% of macroglobulins are cryoglobulins. These are pure M components and are not the mixed cryoglobulins seen in rheumatoid arthritis and other autoimmune diseases. Mixed cryoglobulins are composed of IgM or IgA complexed with IgG, for which they are specific. In both cases, Raynaud's phenomenon and serious vascular symptoms precipitated by the cold may occur, but mixed cryoglobulins are not commonly associated with malignancy. Patients suspected of having a cryoglobulin based on history and physical examination should have their blood drawn into a warm syringe and delivered to the laboratory in a container of warm water to avoid errors in quantitating the cryoglobulin.

TREATMENT

Waldenström's Macroglobulinemia

A diagnosis of WM requires lymphoplasmacytic infiltrate of any level in the bone marrow and an IgM monoclonal paraprotein of any size. Treatment is usually not initiated unless the disease is symptomatic or increasing anemia, hyperviscosity, lymphadenopathy, or hepatosplenomegaly is present. Control of serious hyperviscosity symptoms such as an altered state of consciousness or paresis can be achieved acutely by plasmapheresis because 80% of the IgM paraprotein is intravascular. The median survival of affected individuals is ~50 months. However, many patients with WM have indolent disease that does not require therapy. Pretreatment

parameters including older age, male sex, general symptoms, and cytopenias define a high-risk population. BTK inhibitors (ibrutinib), alkylating drugs (bendamustine and cyclophosphamide), and proteasome inhibitors (bortezomib, carfilzomib, and ixazomib), alone or more frequently in combination with rituximab, are considered as first-line therapy for symptomatic patients with WM. Ibrutinib targets the constitutively activated BTK. In patients with one prior line of therapy, the overall response to ibrutinib was 91%. Best responses to ibrutinib are observed in patients with mutated *MYD88* and wild-type *CXCR4* status, while delayed and lower response rates to ibrutinib are observed in patients with mutated *CXCR4*. At first relapse, in patients with an initial durable response, either the previous regimen or another primary therapy regimen can be used. The therapeutic choice is dependent upon the genomic features, drug availability, and the patient's clinical profile.

Rituximab can produce an IgM flare, so either plasmapheresis should be used before rituximab or its use should be initially withheld in patients with high IgM levels. Fludarabine (25 mg/m^2 per d for 5 days every 4 weeks) is also an effective single agent. With identification of the *MYD88* mutation, novel BTK inhibitors (acalabrutinib, zanubrutinib, and tirabrutinib), inhibitors targeting IRAK1/4, and the BCL2 antagonist venetoclax are being explored for the treatment of WM. HDT plus autologous transplantation has been utilized in the past, but it is now not recommended due to the availability of other effective agents.

POEMS SYNDROME

The features of this syndrome are *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein, and *s*kin changes (POEMS). Diagnostic criteria are described in Table 116-1. Patients usually have a severe, progressive sensorimotor polyneuropathy associated with sclerotic bone lesions from myeloma. Polyneuropathy occurs in ~1.4% of myelomas, but the POEMS syndrome is only a rare subset of that group. Unlike typical myeloma, hepatomegaly and lymphadenopathy occur in about two-thirds of patients, and splenomegaly is seen in one-third. The lymphadenopathy frequently resembles Castleman's disease histologically, a condition that has been linked to IL-6 overproduction. The endocrine manifestations include amenorrhea in women and impotence and gynecomastia in men. Hyperprolactinemia due to loss of normal inhibitory control by the hypothalamus may be associated with other central nervous system manifestations such as papilledema and elevated cerebrospinal fluid pressure and protein. Type 2 diabetes mellitus occurs in about one-third of patients. Hypothyroidism and adrenal insufficiency are occasionally noted. Skin changes are diverse: hyperpigmentation, hypertrichosis, skin thickening, and digital clubbing. Other manifestations include peripheral edema, ascites, pleural effusions, fever, and thrombocytosis. Not all the components of POEMS syndrome may be present initially.

The pathogenesis of the disease is unclear, but high circulating levels of the proinflammatory cytokines IL-1, IL-6, VEGF, and TNF have been documented, and levels of the inhibitory cytokine transforming growth factor β are lower than expected. Treatment of the myeloma may result in an improvement in the other disease manifestations.

Patients are often treated similarly to those with myeloma. Plasmapheresis does not appear to be of benefit in POEMS syndrome. Patients presenting with isolated sclerotic lesions may have resolution of neuropathic symptoms after local therapy for plasmacytoma with radiotherapy. Similar to MM, novel agents and HDT with autologous stem cell transplantation have been pursued in selected patients and have been associated with prolonged progression-free survival.

HEAVY CHAIN DISEASES

The heavy chain diseases are rare lymphoplasmacytic malignancies. Their clinical manifestations vary with the heavy chain isotype. Patients have absence of light chain and secrete a defective heavy chain that usually has an intact Fc fragment and a deletion in the Fd region. Gamma, alpha, and mu heavy chain diseases have been described, but no reports of delta or epsilon heavy chain diseases have appeared. Molecular biologic analysis of these tumors has revealed structural genetic defects that may account for the aberrant chain secreted.

GAMMA HEAVY CHAIN DISEASE (FRANKLIN'S DISEASE)

This disease affects individuals of widely different age groups and countries of origin. It is characterized by lymphadenopathy, fever, anemia, malaise, hepatosplenomegaly, and weakness. It is frequently associated with autoimmune diseases, especially rheumatoid arthritis. Its most distinctive symptom is palatal edema, resulting from involvement of nodes in Waldeyer's ring, and this may progress to produce respiratory compromise. The diagnosis depends on the demonstration of an anomalous serum M component (often <20 g/L [<2 g/dL]) that reacts with anti-IgG but not anti–light chain reagents. The M component is typically present in both serum and urine. Most of the paraproteins have been of the γ_1 subclass, but other subclasses have been seen. The patients may have thrombocytopenia, eosinophilia, and nondiagnostic bone marrow that may show increased numbers of lymphocytes or plasma cells that do not stain for light chain. Patients usually have a rapid downhill course and die of infection; however, some patients have survived 5 years with chemotherapy. Therapy is indicated when symptomatic and involves chemotherapeutic combinations used in low-grade lymphoma. Rituximab has also been reported to show efficacy.

ALPHA HEAVY CHAIN DISEASE (SELIGMANN'S DISEASE)

This is the most common of the heavy chain diseases. It is closely related to a malignancy known as Mediterranean lymphoma, a disease that affects young persons in parts of the world where intestinal parasites are common, such as the Mediterranean, Asia, and South America. The disease is characterized by an infiltration of the lamina propria of the small intestine with lymphoplasmacytoid cells that secrete truncated alpha chains. Demonstrating alpha heavy chains is difficult because the alpha chains tend to polymerize and appear as a smear instead of a sharp peak on electrophoretic profiles. Despite the polymerization, hyperviscosity is not a common problem in alpha heavy chain disease. Without J chain–facilitated dimerization, viscosity does not increase dramatically. Light chains are absent from serum and urine. The patients present with chronic diarrhea, weight loss, and malabsorption and have extensive mesenteric and paraaortic adenopathy. Respiratory tract involvement occurs rarely. Patients may vary widely in their clinical course. Some may develop diffuse aggressive histologies of malignant lymphoma. Chemotherapy may produce long-term remissions. Rare patients appear to have responded to antibiotic therapy, raising the question of the etiologic role of antigenic stimulation, perhaps by some chronic intestinal infection. Chemotherapy plus antibiotics may be more effective than chemotherapy alone. IPSID is recognized as an infectious pathogen–associated human lymphoma associated with *Campylobacter jejuni*. It involves mainly the proximal small intestine, resulting in malabsorption, diarrhea, and abdominal pain. IPSID is associated with excessive plasma cell differentiation and produces truncated alpha heavy chain proteins lacking the light chains as well as the first constant domain. Early-stage IPSID responds to antibiotics (30–70% complete remission). Most untreated IPSID patients progress to lymphoplasmacytic and immunoblastic lymphoma. Patients not responding to antibiotic therapy are considered for treatment with combination chemotherapy used to treat low-grade lymphoma.

MU HEAVY CHAIN DISEASE

The secretion of isolated mu heavy chains into the serum appears to occur in a very rare subset of patients with CLL. The only features that may distinguish patients with mu heavy chain disease are the presence of vacuoles in the malignant lymphocytes and the excretion of kappa light chains in the urine. The diagnosis requires ultracentrifugation or gel filtration to confirm the nonreactivity of the paraprotein with the light chain reagents because some intact macroglobulins fail to interact with these serums. The tumor cells seem to have a defect in

the assembly of light and heavy chains because they appear to contain both in their cytoplasm. Such patients are not treated differently from other patients with CLL **(Chap. 107)**.

117 Amyloidosis

John L. Berk, Vaishali Sanchorawala

GENERAL PRINCIPLES

Amyloidosis is the term for a group of protein misfolding disorders characterized by the extracellular deposition of insoluble polymeric protein fibrils in tissues and organs. A robust cellular machinery exists to chaperone proteins during the process of synthesis and secretion, to ensure that they achieve correct tertiary conformation and function, and to eliminate proteins that misfold. However, genetic mutation, incorrect processing, and other factors may favor misfolding, with consequent loss of normal protein function and intracellular or extracellular aggregation. Many diseases, ranging from cystic fibrosis to Alzheimer's disease, are now known to involve protein misfolding. In the amyloidoses, the aggregates are typically extracellular, and the misfolded protein subunits assume a common antiparallel, β-pleated sheet–rich structural conformation that leads to the formation of higher-order oligomers and then fibrils with unique staining properties. The term *amyloid* was coined around 1854 by the pathologist Rudolf Virchow, who thought that these deposits resembled starch (Latin *amylum*) under the microscope.

Amyloid diseases, defined by the biochemical nature of the protein composing the fibril deposits, are classified according to whether they are systemic or localized, whether they are acquired or inherited, and their clinical patterns **(Table 117-1)**. The standard nomenclature is *AX*, where *A* indicates amyloidosis and *X* represents the protein present in the fibril. This chapter focuses primarily on the systemic forms. *AL* amyloidosis refers to amyloid composed of immunoglobulin light chains; this disorder, formerly termed *primary systemic amyloidosis*, arises from a clonal B-cell or plasma cell disorder and can be associated with myeloma or lymphoma. *ATTR* amyloidosis, the most prevalent of the *familial amyloidoses*, refers to amyloid derived from wild-type or mutated transthyretin (TTR), the transport protein for thyroid hormone and retinol-binding protein. *AA* amyloid is composed of the acute-phase reactant protein serum amyloid A (SAA) and occurs in the setting of chronic inflammatory or infectious diseases; for this reason, this type was formerly known as *secondary amyloidosis*. $A\beta_2M$ amyloid results from misfolded β_2-microglobulin, occurring in individuals with long-standing renal disease who have undergone dialysis, typically for years. *A*β, the most common form of localized amyloidosis, is found in the brain of patients with Alzheimer's disease after abnormal proteolytic processing and aggregation of polypeptides derived from the amyloid precursor protein.

Diagnosis and treatment of the amyloidoses rest upon the histopathologic identification of amyloid deposits and immunohistochemical, biochemical, or genetic determination of amyloid type **(Fig. 117-1)**. In the systemic amyloidoses, the clinically involved organs can be biopsied, but amyloid deposits may be found in any tissue of the body. Historically, blood vessels of the gingiva or rectal mucosa were often examined, but the most easily accessible tissue—positive in more than 80% of patients with systemic amyloidosis—is abdominal fat. After local anesthesia, fat is aspirated with a 16-gauge needle from the subcutaneous layer of the abdominal wall. Fat globules expelled onto a glass slide can be stained for amyloid by Congo red dye, thus avoiding a surgical procedure. If this material is negative, more invasive biopsies of the involved organ like kidney, heart, liver, tongue, or gastrointestinal tract can be considered in patients in whom amyloidosis is suspected. The regular β-sheet structure of amyloid deposits exhibits a unique "green" birefringence by polarized light microscopy when stained with Congo red dye; other regular protein structures (e.g., collagen) appear white under these conditions. The 10-nm-diameter fibrils can also be visualized by electron microscopy of paraformaldehyde-fixed tissue. Once amyloid is found, the precursor protein type must be determined by immunohistochemistry, immunoelectron microscopy, or extraction and biochemical analysis employing mass spectrometry; gene sequencing is used to identify mutants causing hereditary amyloidosis. However, a mass spectrometry–based analysis of the amyloid-containing tissues is now considered the best approach, with a reported sensitivity of 88% and specificity of 96%, which are higher than immunochemical techniques, and this technique does not require a large panel of antisera to identify non-AL amyloidosis. The patient's history, physical findings, and clinical presentation, including age and ethnic origin, organ system involvement, underlying diseases, and family history, may provide helpful clues as to the type of amyloidosis. However, there can be considerable overlap in clinical presentations, and accurate typing of the amyloidogenic protein is essential to guide appropriate therapy and offer genetic counseling as appropriate.

The mechanisms of fibril formation and tissue toxicity remain controversial. The "amyloid hypothesis," as it is currently understood, proposes that precursor proteins undergo a process of reversible unfolding or misfolding; misfolded proteins form oligomeric aggregates, higher-order polymers, and then fibrils that deposit in tissues. Accumulating evidence suggests that the oligomeric intermediates may constitute the most toxic species. Oligomers are more capable than fibrils of interacting with cells and inducing formation of reactive oxygen species and stress signaling. Ultimately, the fibrillar tissue deposits are likely to interfere with normal organ function. However, direct proteotoxicity of the soluble oligomers also can lead to organ dysfunction. A more sophisticated understanding of the mechanisms leading to amyloid formation and cell and tissue dysfunction will continue to provide new targets for therapies.

The clinical syndromes of the amyloidoses are associated with relatively nonspecific alterations in routine laboratory tests. Blood counts are usually normal, although the erythrocyte sedimentation rate is

TABLE 117-1 Amyloid Precursor Proteins and Their Clinical Syndromes

DESIGNATION	PRECURSOR	CLINICAL SYNDROME	CLINICAL INVOLVEMENT
Systemic Amyloidoses			
AL	Immunoglobulin light chain	Primary or myeloma-associated[a]	Any
AH	Immunoglobulin heavy chain	Rare variant of primary or myeloma-associated	Any
AA	Serum amyloid A protein	Secondary; reactive[b]	Renal, heart, other
$A\beta_2M$	β_2-Microglobulin	Hemodialysis-associated	Synovial tissue, bone
ATTR	Transthyretin	Familial (mutant) Age-related (wild type)	Cardiac, peripheral and autonomic nerves, soft tissues, spine, bladder
AApoAI	Apolipoprotein AI	Familial	Hepatic, renal
AApoAII	Apolipoprotein AII	Familial	Renal
AGel	Gelsolin	Familial	Cornea, cranial nerves, skin, renal
AFib	Fibrinogen Aα	Familial	Renal, vascular
ALys	Lysozyme	Familial	Renal, hepatic
ALECT2	Leukocyte chemotactic factor 2	Undefined	Renal
Localized Amyloidoses			
Aβ	Amyloid β protein	Alzheimer's disease; Down's syndrome	Central nervous system
ACys	Cystatin C	Cerebral amyloid angiopathy	Central nervous system, vascular
APrP	Prion protein	Spongiform encephalopathies	Central nervous system
AIAPP	Islet amyloid polypeptide (amylin)	Diabetes-associated	Pancreas
ACal	Calcitonin	Medullary carcinoma of the thyroid	Thyroid
AANF	Atrial natriuretic factor	Atrial fibrillation	Cardiac atria
APro	Prolactin	Endocrinopathy	Pituitary
ASgl	Semenogelin I	Age-related; incidental autopsy or biopsy finding	Seminal vesicles

[a]Localized AL deposits can occur in skin, conjunctiva, urinary bladder, and the tracheobronchial tree. [b]Secondary to chronic inflammation or infection or to a hereditary periodic fever syndrome such as familial Mediterranean fever.

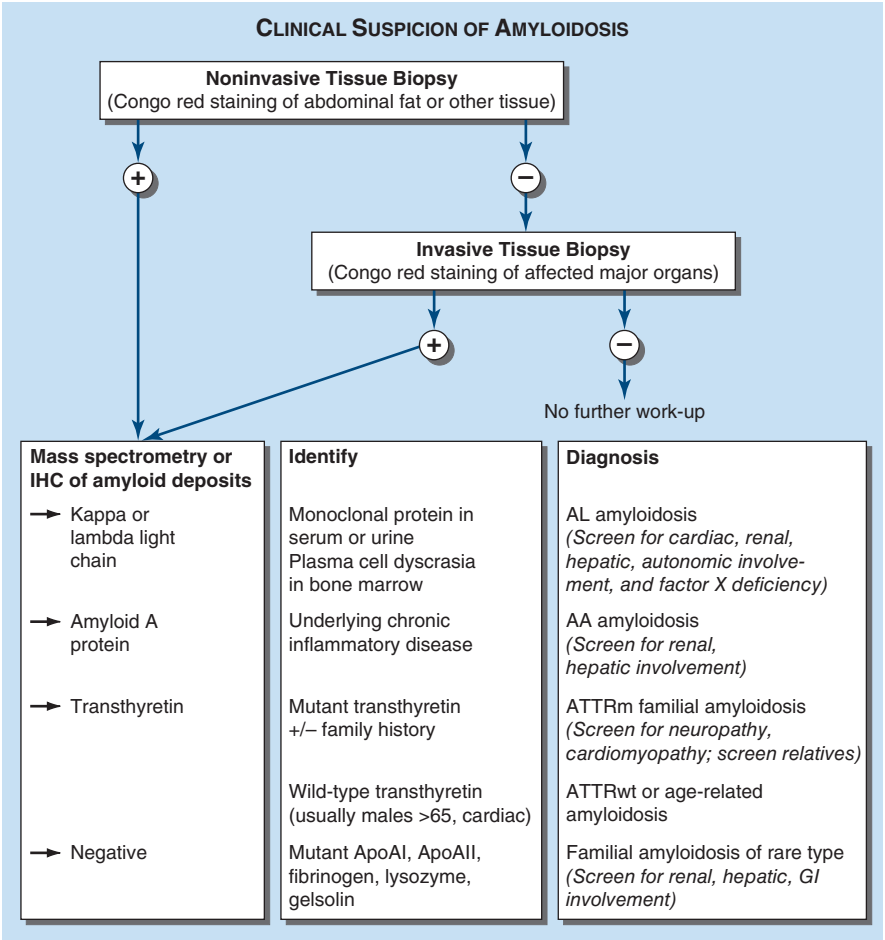

FIGURE 117-1 Algorithm for the diagnosis of amyloidosis and determination of type. Clinical suspicion: unexplained nephropathy, cardiomyopathy, neuropathy, enteropathy, arthropathy, and macroglossia. ApoAI, apolipoprotein AI; ApoAII, apolipoprotein AII; GI, gastrointestinal; IHC, immunohistochemistry.

frequently elevated. Patients with glomerular kidney involvement generally have proteinuria, often in the nephrotic range, leading to hypoalbuminemia that may be severe; patients with serum albumin levels <2 g/dL generally have pedal edema or anasarca. Amyloid cardiomyopathy is characterized by concentric ventricular hypertrophy and diastolic dysfunction associated with elevation of brain natriuretic peptide (BNP) or *N*-terminal pro–brain natriuretic peptide (NT-proBNP) as well as troponin. These cardiac biomarkers can be used for disease staging, prognostication, and disease activity monitoring in patients with AL amyloidosis. Notably, renal insufficiency can falsely elevate levels of these biomarkers. Biomarkers of cardiac remodeling—that is, matrix metalloproteinases and tissue inhibitors of metalloproteinases—are altered in the serum of patients with amyloid cardiomyopathy. Electrocardiographic and echocardiographic features of amyloid cardiomyopathy are described below. Patients with liver involvement, even when advanced, usually develop cholestasis with an elevated alkaline phosphatase concentration with minimal alteration of the aminotransferases and preservation of synthetic function. In AL amyloidosis, endocrine organs may be involved, and hypothyroidism, hypoadrenalism, or even hypopituitarism can occur. Although none of these findings is specific for amyloidosis, the presence of abnormalities in multiple organ systems should raise suspicions of the diagnosis.

AL AMYLOIDOSIS

Etiology and Incidence AL amyloidosis is most frequently caused by a clonal expansion of

bone marrow plasma cells that secrete a monoclonal immunoglobulin light chains forming amyloid fibrils and deposits in tissues. Whether the clonal plasma cells produce a light chain that misfolds and leads to AL amyloidosis or a light chain that folds properly, allowing the cells to inexorably expand over time and develop into multiple myeloma (Chap. 116), may depend upon primary sequence of the clonal light chain or other genetic or epigenetic factors. AL amyloidosis can occur with multiple myeloma or other B lymphoproliferative diseases, including non-Hodgkin's lymphoma (Chap. 113) and Waldenström's macroglobulinemia (Chap. 116). AL amyloidosis is the most common type of systemic amyloidosis diagnosed in North America. Its incidence has been estimated at 8–12 cases per 100,000 population; however, ascertainment continues to be inadequate, and the true incidence may be much higher. AL amyloidosis, like other plasma cell disorders, usually occurs after age 40 and is often progressive and fatal if untreated.

Pathology and Clinical Features Amyloid deposits are usually widespread in AL amyloidosis and can be present in the interstitium of any organ outside the central nervous system. The amyloid fibril deposits are composed of full-length 23-kDa monoclonal immunoglobulin light chains as well as fragments. Accessory molecules co-deposited with light chain fibrils (as well as with other amyloid fibrils) include serum amyloid P component, apolipoproteins e and A-IV, glycosaminoglycans, and metal ions. Although all kappa and lambda light chain subtypes have been identified in AL amyloid fibrils, lambda subtypes predominate.

AL amyloidosis is often a rapidly progressive disease that presents as a pleiotropic set of clinical syndromes, recognition of which is key for initiation of the appropriate workup. Nonspecific symptoms of fatigue and weight loss are common; however, the diagnosis is rarely considered until symptoms referable to a specific organ develop. The kidneys are a frequently involved organ and are affected in 60–70% of patients. Renal amyloidosis usually manifests as proteinuria, often in the nephrotic range and associated with hypoalbuminemia, secondary hypercholesterolemia and hypertriglyceridemia, and edema or anasarca. In some patients, interstitial rather than glomerular amyloid deposition can produce azotemia without proteinuria. The heart is the other commonly affected organ (70–80% of patients), and cardiac involvement is the leading cause of death from AL amyloidosis. Early on, the electrocardiogram may show low voltage in the limb leads with a pseudo-infarct pattern. Echocardiographic features of disease include concentrically thickened ventricles and diastolic dysfunction with an abnormal global longitudinal strain pattern; a "sparkly" appearance has been described but is often not seen with modern high-resolution echocardiographic techniques. Poor atrial contractility occurs even in sinus rhythm, and patients with cardiac amyloidosis are at risk for development of atrial thrombi and thromboembolic complications. Cardiac magnetic resonance imaging (MRI) can show increased wall thickness and characteristic delayed gadolinium enhancement of the subendocardium. Nervous system symptoms include peripheral sensorimotor neuropathy and/or autonomic dysfunction manifesting as gastrointestinal motility disturbances (early satiety, diarrhea, constipation), dry eyes and mouth, impotence, orthostatic hypotension, and/or neurogenic bladder. Macroglossia (Fig. 117-2*A*), a pathognomonic sign of AL amyloidosis, is seen in only ~10% of patients. Liver involvement causes cholestasis and hepatomegaly. The spleen is frequently involved, and there may be functional hyposplenism in the absence of significant splenomegaly. Many patients experience "easy bruising" due to amyloid deposits in capillaries or deficiency of clotting factor X due to binding to amyloid fibrils; cutaneous ecchymoses appear, particularly around the eyes, producing another uncommon but pathognomonic finding, the "raccoon-eye" sign (Fig. 117-2*B*). Other findings include nail dystrophy (Fig. 117-2*C*), alopecia, and amyloid arthropathy with thickening of synovial membranes in the wrists and shoulders. The presence of a multisystemic illness or general fatigue along with any of these clinical syndromes should prompt a workup for amyloidosis.

Diagnosis Identification of an underlying clonal plasma cell or B lymphoproliferative process and a clonal light chain are key to the diagnosis of AL amyloidosis. Serum protein electrophoresis and urine protein electrophoresis, although of value in multiple myeloma, are *not* useful screening tests if AL amyloidosis is suspected because the clonal light chain or whole immunoglobulin often is not present in sufficient amounts to produce a monoclonal "M-spike" in the serum or light chain (Bence Jones) protein in the urine. However, more than 90% of patients with AL amyloidosis have serum or urine monoclonal light chain or whole immunoglobulin detectable by immunofixation electrophoresis of serum (SIFE) or urine (UIFE) (Fig. 117-3*A*) or by nephelometric measurement of serum "free" light chains (i.e., light chains circulating in monomeric form rather than in an immunoglobulin tetramer with heavy chain). Examining the ratio as well as the absolute amount of serum-free light chains is essential, as renal insufficiency reduces light chain clearance, nonspecifically elevating both isotypes. In addition, an increased percentage of plasma cells in the bone marrow—typically 5–30% of nucleated cells—is found in ~90% of patients. Kappa or lambda clonality should be demonstrated by flow cytometry, immunohistochemistry, or in situ hybridization for light chain mRNA (Fig. 117-3*B*). More sensitive mass spectrometry–based assays can have higher levels of detection for low concentration of monoclonal protein.

A monoclonal serum protein by itself is not diagnostic of amyloidosis, since monoclonal gammopathy of uncertain significance is common in older patients (Chap. 116). However, when monoclonal gammopathy of uncertain significance is found in patients with biopsy-proven amyloidosis, the AL type should be ruled out. Similarly, patients thought to have "smoldering myeloma" because of a modest elevation of bone-marrow plasma cells should be screened for AL amyloidosis if

O'Hara; with permission.)*

they have signs or symptoms of renal, cardiac, or neurologic disease. Accurate tissue amyloid typing is essential for appropriate treatment. Immunohistochemical staining of the amyloid deposits is useful if they selectively bind one light chain antibody in preference to the other; some AL deposits bind antibodies nonspecifically. Commercial antibodies used for immunohistochemistry may not be accurate in amyloid typing. Immunoelectron microscopy is more reliable; laser capture microdissection and tandem mass spectrometry–based typing of the amyloid precursor protein have become the diagnostic standard. In ambiguous cases, other forms of amyloidosis should be thoroughly excluded with appropriate genetic and other testing.

Staging System and Risk Stratification The current staging systems for systemic AL amyloidosis are based on the biomarkers of plasma cell dyscrasia and cardiac and renal involvement. The Mayo 2004 staging system is based on the levels of NT-proBNP and cardiac troponins and was modified by European investigators to identify and classify very-high-risk patients. This cardiac staging system is the most widely used to determine patient management. This staging system was modified (Mayo 2012) to include clonal burden, assessed by dFLC (difference between involved and uninvolved circulating free light chain) concentration, which has independent ability to predict survival. Boston University investigators introduced a staging system incorporating BNP and troponin I that also is able to predict survival. Patients with AL amyloidosis with a very low (<50 mg/L) dFLC level have a significantly better outcome irrespective of cardiac stage. A renal staging system based on 24-h urine protein excretion and estimated glomerular filtration rate (eGFR) predicting the progression to dialysis at 2 years has also been developed and validated. Several other biomarkers have been shown to predict outcomes and survival but have not been incorporated in staging systems yet.

TREATMENT

AL Amyloidosis

Extensive multisystemic involvement typifies AL amyloidosis, and historically, the median survival without treatment was usually only ~1–2 years from the time of diagnosis. Marked progress in the outcome and survival has taken place over the past four decades with advent of new therapies, increased awareness, and accurate diagnosis. Current therapies target the clonal bone marrow plasma cells, using approaches employed for multiple myeloma. High-dose intravenous (IV) melphalan followed by autologous stem cell transplantation (HDM/SCT) produces complete hematologic responses in ~40% of treated patients, as determined by loss of clonal plasma cells in the bone marrow and disappearance of the amyloidogenic monoclonal light chain, as determined by SIFE/UIFE and free light chain quantitation. Six to 12 months after achieving a hematologic response, improvements in organ function and quality of life may occur. Hematologic responses appear to be more durable after HDM/SCT than in multiple myeloma, with remissions continuing in some patients beyond 15 years without additional treatment. Unfortunately, only ~20–30% of all AL amyloidosis patients are suitable for aggressive treatment, and even at specialized treatment centers, transplantation-related morbidity and mortality rates are higher than those for other hematologic diseases because of impaired organ function at initial presentation. Amyloid cardiomyopathy, poor nutritional and performance status, and multiorgan disease contribute to excess morbidity and mortality. A bleeding diathesis resulting from adsorption of clotting factor X to amyloid fibrils also increases mortality rates; however, this syndrome occurs in only 5–10% of patients. A randomized multicenter trial conducted in France compared oral melphalan and dexamethasone with HDM/SCT and failed to show a benefit of dose-intensive treatment, although the transplantation-related mortality rate in this study was very high. It has become clear that careful selection of patients and expert peritransplantation management are essential in reducing transplantation-related complications.

The best therapy for those who are not eligible to receive SCT is based on a U.S. Food and Drug Administration–approved therapy of CyBorD (cyclophosphamide, bortezomib [a proteasome inhibitor], and dexamethasone) with daratumumab. Patient characteristics should be considered when choosing a regimen; for example, treatment with bortezomib plus oral melphalan and dexamethasone (MDex) can overcome the effects of both gain of 1q21 (which confers a poorer outcome with oral melphalan) and t(11;14) (which confers a poorer outcome with bortezomib). Transplant-ineligible patients in whom bortezomib is contraindicated due to preexisting peripheral neuropathy can be treated with MDex or combinations based on immunomodulatory drugs (e.g., lenalidomide or pomalidomide). High-risk patients represent ~15–20% of all individuals with AL amyloidosis and are a challenge owing to advanced cardiac stage (IIIb) or severe heart failure (New York Heart Association class III or IV) as they are excluded from most of the clinical trials.

Novel antifibril monoclonal antibodies are currently undergoing clinical trials in combination with treatments directed against the plasma cell dyscrasia (CyBorD plus daratumumab [anti-CD38]) in patients with newly diagnosed AL amyloidosis. Clinical trials are essential in improving therapy for this rare disease.

Supportive care is important for patients with any type of amyloidosis. For nephrotic syndrome, diuretics and support stockings

can ameliorate edema; angiotensin-converting enzyme inhibitors should be used with caution and have not been shown to slow renal disease progression. Effective diuresis can be facilitated with albumin infusions to raise intravascular oncotic pressure. Congestive heart failure due to amyloid cardiomyopathy is best treated with diuretics; it is important to note that digitalis, calcium channel blockers, and beta blockers are relatively contraindicated as they can interact with amyloid fibrils and produce heart block and worsening heart failure. Amiodarone has been used for atrial and ventricular arrhythmias. Automatic implantable defibrillators appear to have reduced effectiveness due to the thickened myocardium, but they may benefit some patients. Atrial ablation is an effective approach for atrial fibrillation. For conduction abnormalities, ventricular pacing may be indicated. Atrial contractile dysfunction is common in amyloid cardiomyopathy and associated with increased thromboembolic complications, prompting considerations of anticoagulation even in the absence of atrial fibrillation. Autonomic neuropathy can be treated with α agonists such as midodrine to support postural blood pressure; gastrointestinal dysfunction may respond to motility or bulk agents. Nutritional supplementation, either oral or parenteral, is also important.

In localized AL amyloidosis, amyloid deposits can be produced by clonal plasma cells infiltrating local sites in the airways, bladder, skin, or lymph nodes (Table 117-1). These deposits may respond to surgical intervention or elimination of the responsible plasma cell clone by low-dose radiation therapy (typically only 20 Gy); systemic treatment generally is not appropriate. Patients should be referred to a center familiar with management of these rare manifestations of amyloidosis.

AA AMYLOIDOSIS

Etiology and Incidence AA amyloidosis can occur in association with almost any chronic inflammatory state (e.g., rheumatoid arthritis, inflammatory bowel disease, ankylosing spondylitis, familial Mediterranean fever [Chap. 381], or other periodic fever syndromes) or chronic infections such as tuberculosis, osteomyelitis, or subacute bacterial endocarditis. In the United States and Europe, AA amyloidosis has become less common, occurring in fewer than 2% of patients with these diseases, presumably because of advances in anti-inflammatory and antimicrobial therapies. It has also been described in association with Castleman's disease, lymphomas, and renal cell carcinoma, emphasizing the diagnostic importance of computed tomography (CT) scanning to look for such tumors as well as serologic and microbiologic studies. In up to 20% of patients, AA amyloidosis can also be seen without any identifiable underlying disease.

Pathology and Clinical Features Organ involvement in AA amyloidosis usually begins in the kidneys. Hepatomegaly, splenomegaly, and autonomic neuropathy can also occur as the disease progresses; cardiomyopathy is a late manifestation in ~10–25% of patients. The symptoms and signs of AA disease cannot be reliably distinguished from those of AL amyloidosis. AA amyloid fibrils are usually composed of an 8-kDa, 76-amino-acid *N*-terminal portion of the 12-kDa precursor protein SAA. This acute-phase protein is synthesized in the liver and transported by high-density lipoprotein (HDL3) in the plasma. Several years of an underlying inflammatory disease causing chronic elevation of SAA levels usually precede fibril formation, although infections can lead to AA amyloid deposition more rapidly.

TREATMENT

AA Amyloidosis

Primary therapy for AA amyloidosis consists of treatment of the underlying inflammatory or infectious disease. Treatment that suppresses or eliminates the inflammatory state or infection decreases the circulating levels of SAA, slowing the rate of amyloid fibril formation. For familial Mediterranean fever, colchicine at a dose of 1.2–1.8 mg/d is the standard treatment. However, colchicine has not been helpful for AA amyloidosis of other causes or for other amyloidoses. Tumor necrosis factor and interleukin 1 and interleukin 6 antagonists can effectively interrupt cytokine signaling that drives many inflammatory syndromes, inhibiting hepatic SAA production and limiting AA amyloid deposition. Development of a fibril-specific agent (eprodisate) that interferes with the interaction of serum amyloid A protein and glycosaminoglycans to prevent or disrupt fibril formation failed in phase 3 trials.

ATTR AND OTHER HEREDITARY AMYLOIDOSES

The familial amyloidoses are autosomal dominant diseases in which mutated or variant plasma proteins misfold or aggregate to form beta-sheet rich amyloid deposits. These diseases are rare, with an estimated case incidence of <1/100,000 population in the United States, although founder effects in remote areas of Portugal, Sweden, and Japan produce a higher local prevalence of disease. The most prevalent form of hereditary amyloidosis arises from mutation of the abundant liver-derived plasma protein transthyretin (TTR, also known as *prealbumin*) and is termed ATTR variant (ATTRv) amyloid. More than 130 TTR mutations typically conferring one-amino-acid substitutions have been described, with most inducing clinical ATTR amyloid disease. Toxic TTR oligomers and ATTR amyloid deposits target peripheral and autonomic nervous systems and the heart. One TTR variant, V122I, occurs in nearly 4% of the African-American and Afro-Caribbean populations and is associated with late-onset cardiac amyloidosis. The actual incidence and penetrance of disease in the African-American population are the subject of ongoing research, but consideration of V122I ATTR amyloidosis is warranted in African-American patients who present with concentric cardiac hypertrophy and evidence of diastolic heart failure, particularly in the absence of a history of hypertension or valvular disease. Other familial amyloidoses, caused by variant apolipoproteins AI or AII, gelsolin, fibrinogen Aα, or lysozyme, are reported with lower prevalence worldwide. New amyloidogenic serum proteins continue to be identified periodically, including leukocyte chemotactic factor LECT2, which is a cause of renal amyloidosis in Hispanic and Pakistani populations. Although the clustering of ALECT2 cases suggests heritability, no LECT2 gene-coding sequence variations have been identified.

Normal (wild-type) transthyretin can also misfold and aggregate to form ATTR amyloid, principally expressed in men beginning in the seventh decade with increasing prevalence with age. Formerly termed senile systemic amyloidosis, ATTRwt amyloid is reported at autopsy in 25% of hearts from male patients who are 80 years and older. Although it is unclear why a wild-type protein becomes amyloidogenic, aging inefficiencies of intracellular quality-assurance mechanisms (termed the unfolded protein response) likely predispose to secretion of proteins prone to misaggregation. Due to the numbers of aging men globally, ATTRwt is the most prevalent and rapidly growing form of amyloidosis in the world today. Data to date characterize ATTRwt amyloidosis as a disease of aging, not inheritance.

Clinical Features and Diagnosis ATTRv amyloidosis has varied presentations predicted by the specific TTR mutation. Consequently, kindreds typically express similar disease timing and clinical course. Apparent sporadic presentations (no recognized family history) often reflect incomplete penetrance of the TTR mutation and not a spontaneous event. ATTRv amyloidosis presents as familial amyloidotic polyneuropathy (nerve damage) or familial amyloidotic cardiomyopathy (heart damage), although the majority of cases exhibit multiorgan disease. Peripheral neuropathy begins as a length-dependent small-fiber sensorimotor neuropathy first exhibited in the feet with ascending progression to the upper extremities. Autonomic neuropathy manifests as smooth muscle dysmotility (dysphagia, diarrhea, urinary retention), vascular dysregulation (orthostatic hypotension, erectile dysfunction), and anhidrosis. Soft tissue disease (carpal tunnel syndrome, tendinopathy, and spinal stenosis) commonly precedes nerve or heart manifestations of disease by one to two decades, particularly in ATTRwt amyloid patients who frequently report bicipital, patellar, or Achilles tendon rupture. Less common expressions of ATTRv include vitreous

opacities and leptomeningeal amyloid deposition from variant protein produced by the retinal epithelium and choroid plexus, respectively. ATTR amyloid involvement of the heart is clinically better tolerated than AL amyloid cardiomyopathy as reflected by both the time from heart failure presentation to death in untreated cases of ATTR (median 42–48 months) versus AL (median 6 months) amyloidosis, and the dramatically greater burden of disease by echocardiographic measures at symptomatic presentation.

Typical syndromes associated with non-ATTR forms of hereditary (AF) disease include renal amyloidosis with mutant fibrinogen, lysozyme, or apolipoproteins; hepatic amyloidosis with apolipoprotein AI; and amyloidosis of cranial neuropathy with corneal lattice dystrophy pathognomonic of gelsolin (Finnish) amyloidosis. Patients with AF amyloidosis can present with clinical syndromes that mimic those of patients with AL disease. Rarely, AF carriers can develop AL disease or AF patients may have monoclonal gammopathy without AL. Thus, it is important to screen for plasma cell disorders and for protein mutations in patients with amyloidosis. Although mass spectrometry often detects amino acid sequence variations, it is not designed to definitively identify specific protein variations; DNA sequencing is the diagnostic standard for AF mutations.

TREATMENT

ATTR Amyloidosis

Untreated, survival after onset of ATTR disease is 4–15 years depending on whether the disease affects primarily the heart or nervous system, respectively. To date, therapeutic strategies used to control ATTR amyloidosis include: (1) orthotopic liver transplantation (OLT) to replace the factory of the mutated protein (only applicable to ATTRv); (2) stabilization of circulating TTR tetramers, preventing TTR monomer release and amyloid fibril formation; and (3) TTR gene silencing (RNA interference or antisense oligonucleotide agents), suppressing hepatic TTR production and subsequent ATTR fibril formation. After nearly 30 years as the principal treatment, OLT is now rarely employed, limited to patients with ATTRv amyloid, early peripheral neuropathy (V30M ATTR), and minimal systemic amyloid burden. Patients with more extensive amyloid (late V30M and non-V30M TTR mutations) who undergo OLT often suffer posttransplant disease progression due to allograft wild-type ATTR complexing on preexisting amyloid deposits. The TTR small-molecule thyroxine mimetic agents, diflunisal and tafamidis, bind to the kinetically stable tetrameric TTR conformation, limiting release and misfolding of monomeric protein, which is the critical step in TTR amyloidogenesis. International phase 3 randomized controlled trials demonstrate that TTR stabilizers slow but infrequently stop progression of ATTR polyneuropathy (diflunisal) and cardiomyopathy (tafamidis). TTR gene silencers (patisiran, inotersen, vutrisiran, eplontersen) more reliably halt neurologic disease progression by minimizing production of the amyloidogenic protein by the liver. Indeed, 35–60% of treated patients with familial amyloid polyneuropathy exhibit improved sensory nerve deficits, a novel finding. Therapeutic drug trials are underway to examine the safety, tolerability, and effectiveness of TTR gene silencers for ATTR cardiomyopathy. Preliminary data suggest TTR gene silencers may promote heart remodeling and improve systolic function in patients with wild type and variant ATTR amyloid cardiomyopathy.

Future clinical trials are set to examine the applicability of (1) one-time CRISPR/cas9 gene editing or (2) ATTR amyloid-depleting antibodies in patients with either ATTR polyneuropathy or cardiomyopathy. These antibodies are designed to recognize and bind nonnative (misfolded) TTR epitopes, mobilizing macrophages and monocytes to disrupt existing amyloid deposits. Whether disrupting amyloid deposits renews heart and nerve function will be determined by the outcome of these pivotal trials.

The extraordinary pace of drug development harnessing cutting-edge science in this orphan disease has extended survival and improved quality of life. Ironically, these advances expose previously unrecognized leptomeningeal (brain) and vitreous (eye) ATTR disease due to their occurrence late in disease, highlighting the unmet need for effective amyloid treatments that penetrate the blood-brain barrier.

$A\beta_2M$ AMYLOIDOSIS

$A\beta_2M$ amyloid is composed of β_2-microglobulin, the invariant chain of class I human leukocyte antigens, and produces rheumatologic manifestations in patients undergoing long-term hemodialysis and, rarely, in patients with a hereditary form of disease. β_2-Microglobulin is excreted by the kidney, and levels become elevated in end-stage renal disease. The molecular mass of β_2M is 11.8 kDa—above the cutoff of some dialysis membranes. The incidence of this disease appears to be declining with the use of newer membranes in high-flow dialysis techniques. $A\beta_2M$ amyloidosis usually presents as carpal tunnel syndrome, persistent joint effusions, spondyloarthropathy, or cystic bone lesions. Carpal tunnel syndrome is often the first symptom. In the past, persistent joint effusions accompanied by mild discomfort were found in up to 50% of patients who had undergone dialysis for >12 years. Involvement is bilateral, and large joints (shoulders, knees, wrists, and hips) are most frequently affected. The synovial fluid is noninflammatory, and β_2M amyloid can be found if the sediment is stained with Congo red. Although less common, visceral β_2M amyloid deposits do occasionally occur in the gastrointestinal tract, heart, tendons, and subcutaneous tissues of the buttocks. There are no proven specific therapies for $A\beta_2M$ amyloidosis, but cessation of dialysis after renal allografting may lead to symptomatic improvement.

SUMMARY

A diagnosis of amyloidosis should be considered in patients with unexplained nephropathy, cardiomyopathy (particularly with diastolic dysfunction), neuropathy (either peripheral or autonomic), enteropathy, or the pathognomonic soft tissue findings of macroglossia or periorbital ecchymoses. Pathologic identification of amyloid fibrils can be made with Congo red staining of aspirated abdominal fat or of an involved-organ biopsy specimen. Accurate typing by a combination of immunologic, biochemical, and genetic testing is essential in selecting appropriate therapy (Fig. 117-1). Systemic amyloidosis should be considered a treatable condition, as anti–plasma cell chemotherapy is highly effective in AL disease and targeted therapies are being developed for AA and ATTR disease. The combination of precursor and end-organ amyloid therapeutics potentially provides not only disease control but also functional and quality-of-life improvements for patients with amyloidosis. Tertiary referral centers can provide specialized diagnostic techniques and access to clinical trials for patients with these rare diseases.

118 Transfusion Therapy and Biology

Pierre Tiberghien, Olivier Garraud, Jacques Chiaroni

Transfusion encompasses the use of blood components (BCs) to prevent or treat anemia, hemorrhage, and bleeding disorders. Occasionally, BCs may be used to treat infection or relapse of malignant blood diseases after allogeneic hematopoietic transplantation. BCs comprise mainly red blood cell concentrates (RBCCs), platelet concentrates (PCs), and plasma for transfusion use as opposed to plasma fractionated into medicinal products (such as immunoglobulin, albumin, and clotting factors). Alongside transfusion safety, ensuring BC quality, assessing in vivo efficacy, and promoting evidence-based transfusion practices are critical aspects of transfusion medicine.

Donor medicine does not fall within the scope of this chapter. While particularly safe, blood donations can cause adverse reactions, among which are fainting reactions and iron deficiency. These reactions require preventive approaches and appropriate treatment when needed.

BLOOD COMPONENTS

BC collection and manufacturing processes are described in Table 118-1. BCs are collected as whole blood or directly as components by apheresis. The vast majority of BCs are homologous. Autologous BCs, collected ahead of planned surgery, are now exceptional as they present little to no advantage over homologous BCs. Nevertheless, such donation may still be of benefit in the presence of a rare blood group phenotype.

All BCs comply with common quality and performance standards and guidelines. Quality assurance encompasses well-defined processing steps and stringent BC quality controls as defined by health authorities. Reporting of adverse reactions and events associated with blood collection, BC processing, and transfusion is highly recommended.

With the obvious exception of granulocyte concentrates and mononuclear cells, most BCs are now leukocyte-reduced, and universal prestorage leukocyte reduction has been recommended. These BCs contain $<1–5.10^6$ donor leukocytes and are associated with reduced incidence of febrile nonhemolytic transfusion reactions (FNHTRs), infections with intracellular pathogens such as cytomegalovirus (CMV), alloimmunization, and immunomodulation.

BCs may undergo additional processing steps. These include irradiation to prevent graft-versus-host disease (GVHD) in immunosuppressed patients, pathogen reduction to further reduce the risk of transfusion-transmitted infections, plasma reduction in patients with severe allergic reactions to BCs, or the manufacturing of specific units for young children, neonates, or intrauterine transfusion.

BC constituents undergo centrifugation and filtration and are placed in contact with needles, plastic tubing, and bags, as well as anticoagulants and various additive solutions. BCs are subjected to gas exchanges that are significantly different from aerobic breathing and are maintained at temperatures that are not physiologic, such as 22°C or 4°C. Any of these elements may contribute to so-called "storage lesions" and to the presence of bioactive molecules such extracellular vesicles and cell-free mitochondrial DNA in the BC. The clinical impact of such lesions is still under investigation with currently no consensus on this issue.

Furthermore, plasma present in BCs contains donor antibodies (Abs). When directed toward antigens (Ags) present in the recipient, such as blood group or tissue (human leukocyte antigen [HLA]) Ags, such Abs may result in adverse events. RBCCs bring only a limited amount of donor plasma (10–30 mL), unlike PCs and obviously plasma. The use of platelet additive solution can replace two-thirds of plasma in PCs, while still leaving the equivalent of one plasma unit of 200 mL per transfused PC.

BLOOD GROUP ANTIGENS AND ANTIBODIES

Red blood cells (RBCs), as well as other blood constituents such as platelets and neutrophils, express allogeneic determinants. Transfusion may therefore result in alloimmunization and the production of alloantibodies (alloAbs). These alloAbs comprise anti-RBC Abs, anti-HLA, anti-human platelet Ag (HPA) Abs, and anti-human neutrophil Ag (HNA) Abs. Anti-RBC immunization may result in hemolysis, whereas anti-HLA or anti-HPA Abs may result in complications such as fever and platelet transfusion refractoriness. Furthermore, anti-HLA and anti-HNA immunization in the donor may result in a severe lung disorder called transfusion-related acute lung injury (TRALI). The Abs against red cell Ags may be IgM or IgG immunoglobulin classes. Some IgG or IgM can activate complement, and some IgG, crossing the placental barrier, may induce hemolytic disease of the fetus and newborn.

Erythrocyte blood groups refer to antigenic molecules that are expressed on the surface of RBC and other cells, genetically transmitted, and recognized by specific Abs. The polymorphism of such molecules explains their immunizing potential in situations such as transfusion, pregnancy, and transplantation. Blood groups can also interact with the environment and with infectious pathogens, leading to individual susceptibilities. For example, malaria is less severe in type O than non-O patients. Currently, ~390 different blood group Ags have been described, classified within ~45 different systems. Blood group Ags belong to two broad categories based on their biochemical nature: carbohydrate blood groups and protein blood groups. RBC Ags may be the target of autoantibodies (autoAbs) generating autoimmune hemolytic anemia. Some of them, mostly IgG, are active at 37°C, called "warm autoAbs," and are most often directed against Rh Ags, whereas others, most often IgM, are active at 4°C, called "cold autoAbs," and may be directed against ABO, HI, I, i, P, and other Ags.

Carbohydrate blood groups are headed by the **ABO system**, which comprises two main Ags, A and B, encoded by two alleles, which are the *A* and *B* alleles, respectively. In addition to these active alleles, there is an inactive allele: *O*. Depending on the genotype, four different phenotypes are produced (Table 118-2). Other carbohydrate systems (H, P1PK, Lewis, I, GLOB and SID) share many characteristics with the ABO system. The *A* allele encodes the A enzyme, which binds the A-type sugar (GalNac) A to the H substrate (expressed by action of the H enzyme encoded by the *H* allele, which happens to be inactive in the Bombay phenotype); sugars are attached to protein substrates on the surface of the RBC and so forth.

Carbohydrate Ags are ubiquitously distributed in the body. The ABO Ags, expressed on endothelial cells, are genuine "tissue" groups and may be involved in graft rejection. These Ags are not specific to humans but are shared by many species including viruses and bacteria. The presence of A and B Ags in the environment and, in particular, on the bacteria of the microbiota explains the synthesis of so-called "natural" or "regular" Abs, aside from any transfusion or pregnancy. Such Abs have a major hemolytic capacity as they bind complement and activate its cascade up to the membrane attack complex. This imposes donor-recipient stringent compatibility rules for RBCCs and whole blood transfusion and, albeit less stringently, for plasma and PC transfusion.

Protein blood groups are headed by the **Rh system** for RBCs (Table 118-3). As these Ags are specific to humans, the occurrence of immunization can only occur upon allogeneic stimulation. Abs directed against Ags of RBC groups other than ABO must be detected before RBCC transfusion or transplantation and during pregnancy. Of the 45 RBC group systems described, five (Rh, Kell, Duffy, Kidd, and MNS) are routinely investigated due to the clinical significance of Abs and their frequency. Testing for all five types ensures routine transfusion compatibility of 95%.

The Rh system comprises nearly 56 Ags, the most immunogenic of which is the D Ag (RH1). The Rh system has two *RH*D* and *RH*CE* genes located on chromosome 1. The *RH*D* gene codes for the RhD protein expressing the D Ag (RH1) present in 85%, 93%, and >99%

TABLE 118-1 Blood Components: Collection and Manufacturing Processes

BLOOD OR APHERESIS COLLECTION AND INITIAL PROCESSING	BLOOD COMPONENT	ADDITIONAL COMPONENT PROCESSING (OPTIONAL TO MANDATORY)	RATIONALE	VOLUME AND CONTENT	STORAGE CONDITIONS AND DURATION
Whole blood collection: Separation into RBCC and platelet-rich plasma (PRP) by slow centrifugation, followed by high-speed centrifugation of the PRP to yield one unit of platelets (most often subsequently pooled) and one unit of plasma. *or* Separation into a RBCC, a plasma, and a "buffy coat" containing leukocytes and platelets by high-speed centrifugation, followed by pooling and slow-speed centrifugation of the buffy coat to produce a pooled platelet unit. Alternatively, the buffy coat may undergo high-speed centrifugation to produce a granulocyte unit that will be subsequently pooled. Apheresis collection: Various apheresis devices allow for the collection of BCs either as individual BCs such as plasma or PC (possibly double, such as double RBCC) or combined BCs, such as PC and plasma, or RBCC, platelets, and plasma.	RBCC from whole blood or from apheresis	Leukocyte reduction Deleukocytation to <1–5.10^6 leukocytes per unit (highly recommended): initial whole blood filtration or RBC elective filtration (highly recommended)	Reduction of fever and chills Reduction of intracellular pathogens (including CMV) Reduction of alloimmunization	250–300 mL (including additive solution, no more than 40–50 mL of plasma) Hemoglobin: 22–40 g/dL Hematocrit: 50–70% Hemolysis ≤0.8% at issuing	4 +/– 2°C Duration depends on the additive solution: 25–42 days After irradiation: 24 h After plasma reduction: 24 h to 10 days depending on reduction methodology
		Irradiation: X-ray or gamma, ~25–35 Gy; most often units not older than 28 days after collection	GVHD prevention in immunosuppressed patients or intrafamily transfusions		
		Plasma reduction	Prevention of allergic reactions in patients with prior severe transfusion reactions	Lesser volume, 10% reduction in RBC content	
		Pediatric preparation	Adjustment to low-weight recipients	Adjusted content	
		Cryopreservation (glycerol)	Most often to ensure availability of RBCCs with a rare blood group for immunized "public-negative" recipients or recipients with complex alloimmunizations[a]	Same Hb content Hematocrit: 40–80% Glycerol ≤1 g	N2 or –80°C electric freeze drying N2: unlimited; –80°C: 30 years 7 days after thawing in suitable additive solutions, 24 h without additive solution
	PC from whole blood (individual units or pools of 4–6 units of ABO identical units) or from apheresis	Suspension in a platelet additive solution (PAS). PAS contains ingredients such as acetate, potassium, phosphate, and magnesium to sustain platelet storage	Reduction of fever and chills Plasma orientation toward fractionation	From 100 to 700 mL ≥2.10^{11} platelets pH ≥6.4	At 20–24°C and under permanent motion: 3–7 days *or* At 4°C without motion: up to 14–21 days If irradiated: <24 h
		Leukocyte reduction (<1–5.10^6 leukocytes per unit) (highly recommended): initial whole blood filtration or PC elective filtration	Reduction of fever and chills Reduction of intracellular pathogens (including CMV infections) Reduction of alloimmunization		
		Pathogen reduction: Most often nucleic acid cross-linker and/or UV illumination	Reduction of transfusion-transmitted infections Prevention of GVHD		
		Volume reduction	Prevention of allergic reactions in patients with prior severe reactions		
		Irradiation: X-ray or gamma, ~25–35 Gy; in general, on bags no older than 3 days after collection	Prevention of GVHD		
		Pediatric	Volume and content adjustment		
		Cryopreservation (DMSO)	To ensure continuous availability in remote locations To ensure availability of platelets with rare HPA groups		6 h after thawing (depending on cryopreservation procedure, may be resuspended in plasma)
	Plasma from whole blood or from apheresis	Cryopreservation at –18°C (most often)	Shelf-life extension	200–300 mL Coagulation factors, including fibrinogen (≥2 g/L), factor VIII (≥0.5 IU/mL), protein C and S, antithrombin	1–2 years if cryopreserved Up to 28 days if kept unfrozen

(*Continued*)

TABLE 118-1 Blood Components: Collection and Manufacturing Processes (Continued)

BLOOD OR APHERESIS COLLECTION AND INITIAL PROCESSING	BLOOD COMPONENT	ADDITIONAL COMPONENT PROCESSING (OPTIONAL TO MANDATORY)	RATIONALE	VOLUME AND CONTENT	STORAGE CONDITIONS AND DURATION
		Leukocyte reduction (<1–5.10^6 leukocytes per product): Initial whole blood filtration and/or plasma elective filtration	Reduction of fever and chills Reduction of intracellular pathogens (including CMV) Reduction of alloimmunization		
		Pathogen reduction: Nucleic acid cross-linker and/or UV illumination or solvent detergent treatment (most often on pooled products)	Reduction of transfusion-transmitted infections		
		Lyophilization	To facilitate transportation and storage, as well as immediate availability, in remote locations		
	Granulocyte concentrates from whole blood (pools of 10–20 ABO-identical units) or from apheresis[b]	Irradiation (mandatory)	Prevention of GVHD	≤650 mL ≤2.10^{10} granulocytes	Room temperature ≤24 h after the end of collection
	Whole blood	Leukocyte reduction with a platelet-sparing device	Reduction of posttransfusion fever and chills Reduction of intracellular pathogens (including CMV) Reduction of alloimmunization	~520 mL (including additive solution)	At 2–4°C 21–35 days
	Peripheral blood mononuclear cells (apheresis)	May undergo cryopreservation (N2)	Increased practicability Repeated administration	Number of cells adjusted for a predetermined number of T lymphocytes 10^5–10^7 CD3+ cells/recipient kg	N2: unlimited Never frozen or thawed: <6 h
	Cryoprecipitate (collected after thawing and centrifugation of plasma)	Resuspension in plasma (10–15 mL) and cryopreservation	N/A	Cold-insoluble plasma proteins (fibrinogen, factor VIII, von Willebrand factor)	12 months After thawing, may be stored at 20–24°C for up to 6 h

[a]Antigen frequency below 1% to 1/1000 of the population and contraindication for using regular blood units, depending on country-specific regulations. [b]Granulocyte collection by apheresis requires donor preadministration of steroids and/or hematopoietic growth factor and exposure to heparin and hydroxyethyl starch during the apheresis procedure.

Abbreviations: BC, blood component; CMV, cytomegalovirus; DMSO, dimethyl sulfoxide; GVHD, graft-versus-host disease; Hb, hemoglobin; HPA, human platelet antigen; N2, nitrogen gas; N/A, not applicable; RBC, red blood cell; RBCC, red blood cell concentrate; PC, platelet concentrate; UV, ultraviolet.

of individuals of Caucasian, African, and Asian ancestry, respectively. The *RH*CE* gene codes for RhCE proteins expressing C (RH2) and/or c (RH4), and E (RH3) and/or e (RH4) Ags. The presence of the D Ag confers Rh "positivity," while its absence confers Rh "negativity." The *RH*D* and *RH*CE* genes determine eight main haplotypes (*DCe, DcE, Dce, DCE, dce, dCe, dcE,* and *dCE*) whose frequencies differ considerably among different geographical populations. The high diversity of the Rh Ags includes weak and/or partial expression. Identifying individuals (especially young females of childbearing potential and multitransfused patients) with a weak or partial D Ag is important to adequately select D-positive or -negative RBCs. Molecular biology is now routinely applied to resolve such situations.

TABLE 118-2 ABO Blood Groups and Antibodies: Transfusion Compatibility

GENOTYPE(S)	ENZYME(S)/IMMUNODOMINANT SUGAR(S)	PHENOTYPE	NATURAL ANTIBODIES	TRANSFUSION COMPATIBILITY REQUIREMENTS		
				RBCC	PC[a]	PLASMA
A/A or A/O	"A" transferase/N-acetylgalactosamine (GalNac)	A	Anti-B	A or O	A, O^b, B^b, or AB^b	A or A,B
B/B or B/O	"B" transferase/galactose (Gal)	B	Anti-A	B or O	B, O, A^b, or AB^b	B or A,B
A/B	"A" transferase and "B" transferase GalNac and Gal	A,B	None	A,B or A or B or O	A,B, O^b, or A^b or B^b	A,B
O/O	Inactive Unconverted H antigen	O	Anti-A and Anti-B	O	O, A, B, or A,B	A or B or A,B or O

[a]Order of priority. [b]Without high-titer anti-A and/or anti-B antibody.

Abbreviations: PC, platelet concentrate; RBCC, red blood cell concentrate.

TABLE 118-3 Red Blood Cell Group Systems and Antibodies: Clinical Significance and Transfusion Recommendations

ISBT NO./ SYSTEM	SYMBOL/GENE(S)	ANTIGENS (NO.)	MAIN ANTIBODIES (ANTI-)	HEMOLYSIS CHARACTERISTICS		RBCC TRANSFUSION RECOMMENDATIONS
				TRANSFUSION	HDFN	
1/ABO	ABO/*ABO*	4	A, B	None to severe; immediate and/or delayed	None to moderate (rarely severe)	Ab-negative RBCC
2/MNS	MNS/*GYPA, GYPB, (GYPE)*	49	M	None (except in extremely rare cases if active at 37°C)	None (except in extremely rare cases if active at 37°C)	Compatible RBCC (negative IAT at 37°C) Ag-negative red cells in the case of sickle cell disease
			N	None (may be clinically significant in the case of the rare N–S–s–U– phenotype)	None	Compatible RBCC (negative IAT at 37°C) Ag-negative RBCC in the case of N–S–s–U– phenotype
			S, s	None to moderate (rare)	None to severe (rare)	Ag-negative RBCC
			U	Mild to severe	Mild to severe (one reported case requiring an intrauterine transfusion)	Ag-negative RBCC
3/P1PK	P1PK/*A4GALT*	3	P1	None to moderate; delayed (rare)	None	Compatible RBCC (negative IAT at 37°C)
			P1, Pk, P (Tj^a)	None to severe	None to severe	Ag-negative RBCC
4/Rh	RH/*RHD, RHCE*	55	D, C, E, c, e	Mild to severe; immediate or delayed	Mild to severe	Ag-negative RBCC
6 /Kell	KEL/*KEL*	36	K	Mild to severe; delayed	Mild to severe (rare)	Ag-negative RBCC
7/Lewis	LE/*FUT3*	6	Le^a, Le^b	None (rare cases of hemolytic reactions)	None	Compatible RBCC (negative IAT at 37°C)
8/Duffy	FY/*ACKR1*	5	Fy^a, Fy^b	Mild to severe (rare); immediate/delayed	Mild to severe (rare)	Ag-negative RBCC
			Fy3, Fy5	Mild to moderate; immediate (rare)/delayed	Mild (rare) (no data for anti-Fy5)	Ag-negative RBCC
9/Kidd	JK/*SLC14A1*	3	Jk^a, Jk^b	None to severe; immediate or delayed	Mild to moderate (rare)	Ag-negative RBCC
			Jk3	None to severe; immediate or delayed	None to mild	Ag-negative RBCC
18/H	H/*FUT1*	1	H (Bombay)	None to severe; immediate/ delayed	Not none	Ag-negative RBCC
20/Globoside	GLOB/*B3GALNT1*	2	P	None to severe	None to mild	Ag-negative RBCC

Abbreviations: Ab, antibody; Ag, antigen; HDFN, hemolytic disease of the fetus and newborn; IAT, indirect antiglobulin test (indirect Coombs test); ISBT, International Society of Blood Transfusion; RBCC, red blood cell concentrate.

The **Kell system** comprises 38 Ags, one of which is routinely determined: the K antigen (KEL1); 9% and 2% of individuals of Caucasian and African ancestry are K positive (KEL:1), respectively, whereas 91% and 98%, respectively, are K negative (KEL:–1). The immunogenicity of Kell is third behind the ABO and Rh systems. The Kell protein is linked to another blood group protein called Kx. The rare absence of this protein (controlled by a gene on X) is associated with a weak KEL Ag, acanthocytosis, shortened RBC survival, and a progressive form of muscular dystrophy that includes cardiac defects. This rare condition is called the McLeod phenotype.

The **Duffy system** (FY) comprises five Ags, two of which are routinely tested: the Fy^a Ag (FY1), coded by the Fy^a allele, and the Fy^b Ag (FY2), coded by the Fy^b allele. Depending on the combination of alleles, three common phenotypes are expected: Fy (a+b+), which has the two alleles Fy^a and Fy^b; Fy (a+b–), which has only the Fy^a allele in a double dose; and Fy (a–b+), which has only a double dose of the Fy*b* allele. A particular phenotype characterized by the absence of the Fy^a and Fy^b Ags, the Fy(a–b–) phenotype, is exclusive (with some exceptions) to individuals of African ancestry where it can reach frequencies of 70–100% depending on the population. It is linked to the presence of a double dose of a silent *FY*0* allele. This distribution may be related to the fact that the Fy Ags serve as receptors for *Plasmodium vivax* and therefore the Fy(a–b–) phenotype. However, these individuals may develop Abs against two high-frequency Ags (FY3 and FY5) after transfusion or pregnancy. They may also have low a granulocyte count but are not associated with any disease.

The **Kidd system** (JK) comprises three Ags, two of which are routinely tested: the Jk^a Ag (JK1), coded by the Jk^a allele, and the Jk^b Ag (JK2), coded by the Jk^b allele. Depending on the combinations of alleles, three common phenotypes are seen: Jk(a+b+) displaying the two alleles Jk^a and Jk^b, Jk(a+b–) displaying only the Jk^a allele in a double dose, and Jk(a–b+) displaying only a double dose of the Jk^b allele. A particular phenotype is characterized by the absence of the Jk^a and Jk^b Ags: the Jk(a–b–) phenotype found in Polynesian populations. It is linked to the presence of a double dose of a silent *JK*0* allele. These people may develop Abs against the high-frequency anti-JK3 Ag after transfusion or pregnancy.

The **MNS system** comprises 50 Ags, four of which are routinely tested. Two genes (*GYPA, GYPB*) encode two pairs of so-called "antithetical" Ags. The M (MNS1) and N (MNS2) pair Ags encoded by the *M* and *N* alleles, respectively, are branched on the glycophorin A molecule. Their combination will determine whether or not they are present. M+ and N+ subjects have both alleles; an M+, N– subject is homozygous for the *M* allele; and an M–, N+ subject is homozygous for the *N* allele. The same holds true for the other pair of Ags, S (MNS3) and s (MNS4) expressed on glycophorin B. Therefore, an M+, N–, S–, s+ subject (in international nomenclature, this is written as MNS:1,–2,–3,5) will be homozygous for the *M* and s alleles. A rare phenotype, S–s–, found exclusively in individuals of African ancestry, can develop an Ab against the high-frequency U Ag (MNS5) after transfusion or pregnancy.

RARE RBC PHENOTYPES

Some patients present with rare genotype/phenotype assortments, and their RBCs display so-called private Ags or, conversely, lack public Ags (i.e., widely shared Ags) toward which the patient may develop

an immune response when exposed to these Ags. Public-negative immunized individuals are virtually impossible to transfuse using conventional blood bank resources and require access to designated blood banks that have access to rare blood programs. Their primary responsibility is to identify and collect blood from donors exhibiting particular Ag displays on their RBCs or platelets that are uncommon in the given jurisdiction. Specific ethnic populations may be targeted, as some may display genotype specificities, such as the Bombay group in southwestern Indians. Several hemoglobinopathies, such as sickle cell disease, are more common in individuals of African ancestry. Such patients may display RBC phenotypes that are uncommon in countries in the Northern Hemisphere, resulting in difficulties adequately identifying donors to match the need, as a last resort, for highly valued cryopreserved BCs.

CLINICAL INDICATIONS AND EFFICACY ASSESSMENT OF BLOOD COMPONENTS

BCs are life-saving therapies but also scarce resources. Furthermore, transfusion may result in well-identified adverse reactions as well as more ill-defined adverse reactions, including inflammation and therapeutic inefficacy. As highlighted in patient blood management programs, transfusion should be considered within a multidisciplinary approach that includes optimization of hematopoiesis and minimization of blood loss during surgical interventions. Clinical indications of BCs as well as means to assess therapeutic efficacy are detailed in **Table 118-4**.

ADVERSE REACTIONS TO BLOOD COMPONENTS

Adverse reactions to transfused BCs are most commonly non-life-threatening, although serious reactions can present with mild symptoms. Transfused patients should be closely monitored for warning signs suggestive of adverse reactions, as described in **Table 118-5**. When an adverse reaction is suspected, the transfusion must be stopped while the recipient's clinical status is assessed, and supportive care is initiated as needed. An average of 37 transfusion-associated fatalities with possible to definite imputability were reported yearly to the U.S. Food and Drug Administration (FDA) between 2017 and 2021 among ~15 million transfused BCs. Most frequent causes of death were transfusion-associated circulatory overload (TACO) (32%), followed by TRALI (21%), hemolysis (21%), and microbial contamination (13%).

Adverse reactions to BCs may result in immune and nonimmune mechanisms. Immune-mediated reactions are often due to recipient or donor alloimmunization and the presence of preformed recipient or donor Abs. Nonimmune causes of reactions are from the physical or chemical properties of BCs or from pathogens present in the BC.

IMMUNE-MEDIATED ADVERSE REACTIONS

Hemolytic Transfusion Adverse Reactions Immune-mediated acute hemolysis occurs when the recipient preformed Abs lyse transfused donor RBCs and may occur during or 24 h after transfusion. The anti-A or anti-B Abs are responsible for most of the most severe reactions, which can be fatal. However, alloAbs directed against other RBC Ags (i.e., Rh, Kell, and Duffy) are also responsible for severe hemolytic reactions. Such dramatic reactions are usually caused by a failure in product or patient identification, erroneous blood grouping, or unidentified anti-RBC alloimmunization in the recipient. Hemolysis, most often of lesser severity, may also occur upon transfusion of BCs containing incompatible plasma with a large amount of alloAbs directed against the recipient's RBCs. This may typically occur after transfusion of a PC containing ABO-incompatible plasma. Estimated frequencies of acute and chronic hemolytic adverse reactions are 1–10 and 5–40 per 10^5 transfused BCs, respectively.

Mechanisms of transfusion hemolytic reactions are described in **Fig. 118-1.**

Prevention of hemolytic reactions relies on **pretransfusion testing** of potential recipients. Testing will include determination of the ABO D phenotype (and anti-ABO Abs) as well as additional typing for the other main Rh Ags (CcEe), K Ag of the Kell system, and more rarely, Duffy (Fy^a and Fy^b), Kidd (Jk^a and Jk^b), and MNS (S and s) Ags, depending on the clinical setting. These determinations are most often performed by serology. However, molecular typing is increasingly being used to predict RBC phenotype and facilitate the selection of a compatible component. Special care must be taken to verify the patient's identity and apply adequate tube labeling. A double ABO determination performed separately may be considered, especially in the absence of a systematic crossmatch.

Testing will also include the screening and identification of alloAbs directed against RBC Ags other than ABO. This screen is performed by mixing patient serum with type O RBCs expressing Ags from most blood group systems and whose extended phenotype is known. The specificity of the alloAb is identified by correlating the presence or absence of Ag with the induced—or not—agglutination. Special attention should be paid to patients receiving monoclonal Ab treatment that may bind to erythrocytes in vivo (such as anti-CD38 IgG treatment for multiple myeloma) and therefore interfere with alloAb screening. Such interference may be offset by sample dithiothreitol pretreatment.

Crossmatching between the recipient plasma/serum and the selected RBCs may be performed, especially when the recipient is alloimmunized against RBC or is frequently transfused, as well as in specific clinical settings such as sickle cell disease, even if the Ab screening is negative.

The selection of a compatible BC should consider pretransfusion testing as well as the recipient's clinical status. In the case of D-negative patients, every attempt must be made to provide Rh-negative RBCC to prevent anti-D alloimmunization. In an emergency, D-positive RBCC can be safely transfused to a D-negative patient who lacks anti-D. However, an estimated 20–22% of RBCC recipients will become alloimmunized and produce anti-D Abs after transfusion with D-positive RBCs. Such alloimmunization can occur after PC transfusion, although at a much lower frequency (~1%). Whenever possible, females with childbearing potential (to include prepubertal girls) should be transfused with D- and K-compatible RBCCs and D-compatible PCs to prevent alloimmunization and protect a future fetus/newborn from an alloimmune-mediated hemolytic disease. D-negative females with childbearing potential who are transfused with BCs containing D-positive RBCs should receive anti-D Ab to prevent allosensitization.

Hemolysis, most often of lesser severity, may also occur after transfer of alloAbs directed against the recipient's RBC Ags. Such ABO "plasmatic" incompatibility, called "minor ABO incompatibility," will occur mainly with PC transfusions, where platelets are suspended in ~100–300 mL of plasma (depending on whether part of the plasma is substituted by additive solution). BCs containing plasma with high-titer anti-A/B Ab may induce a hemolytic reaction. When the transfusion of ABO-identical (vs ABO-compatible) PCs is not feasible, PCs provided by donors with low-titer anti-A/B only should be preferred. While there is no universal definition of high-titer Abs, a threshold titer of 1/64 (as assessed by hemagglutination) may be appropriate. The use of an additive solution in PCs substantially mitigates this risk. Lastly, ABO plasmatic incompatibility can lead to the formation of immune complexes with soluble A and/or B Ags and ensuing inflammation and platelet activation.

Acute hemolytic reactions may present with hypotension, tachypnea, tachycardia, fever (+1–2°C), chills, chest and back pain, hemoglobinuria, and hemoglobinemia. In the most severe cases, disseminated intravascular coagulation (DIC), acute renal failure, shock, and death may occur.

Delayed hemolytic reactions, with icterus and persisting or worsening anemia as the main clinical manifestations, result from an anamnestic response. Such reactions may occur in patients previously sensitized to RBC Ags who have a negative alloAb screen at the time of transfusion due to low Ab levels. The alloAb is detectable 1–2 weeks after the transfusion.

Diagnosis of transfusion-associated hemolysis relies on persistent and/or worsening anemia, depleted plasma haptoglobin levels,

TABLE 118-4 Blood Components: Clinical Use

COMPONENT	THERAPEUTIC INDICATION	GOAL	DONOR/RECIPIENT COMPATIBILITY	DOSAGE	EFFICACY EVALUATION
RBCC	Transfusion: Anemia and/or tissue ischemia (treatment or prevention) Hb below a given threshold (to be considered in relation with clinical symptoms): <7 g/dL for patients hemodynamically stable, except for patients undergoing orthopedic surgery, cardiac surgery, or with preexisting cardiovascular disease (<8 g/dL) as well as for patients with acute coronary disease (<9–10 g/dL). Such thresholds do not apply to neonates and patients with severe thrombocytopenia and chronic transfusion-dependent anemia. Not recommended: nutritional anemia (iron, vitamin B_{12}, or folate deficiency)	Improve systemic and tissue oxygenation	ABO compatible (cellular) and ABO identical when achievable. RhD compatibility in young and childbearing-age females, and if multitransfused RhC/c/E/e; Kell-compatible RBCCs if multitransfused whenever possible. Additional compatibility may be required depending on the clinical setting and screening results.	1 unit at a time (250–350 mL, including additive solution), repeated per clinical status and Hb level	Reduction of anemia-related symptoms, clinical improvement Increased Hb (+1 g/dL) and hematocrit (+3%)
	RBC exchange: Anemia/sickle cell crisis in hemoglobinopathies (sickle cell disease, thalassemia)	Replace altered RBCs with donor RBCs and compensate for hemolysis, prevention of sickle cell occlusive crisis		25–30 mL/kg	Sickle cell disease: reduced percentage of HbS
PC (from pooled whole blood–derived platelets or single donor apheresis), maintained at room temperature (most often) or at 4°C	Thrombocytopenia-related bleeding disorders: Treatment (cold or room temperature PC) or prevention (room temperature PC) Platelet level below a given threshold: ≤5000/μL in the absence of fever or infection, ≤10,000/μL to 20,000/μL if fever or infection; ≤50,000/μL if surgery, DIC, endoscopy, invasive procedures; ≤80,000/μL if neurosurgery, eye surgery, or ECMO Acute hypovolemic coagulopathy (see below) Immune thrombocytopenia, thrombotic microangiopathy, and heparin-induced thrombocytopenia: Not recommended	Correct impaired primary hemostasis, including vessel healing Cold stored platelets, despite lower in vivo survival, have maintained and possibly improved hemostatic capacity compared with room temperature stored platelets	ABO identical preferable; if not, ABO compatible (cellular) with low-titer anti-A/B Ab; RhD compatible preferred in premenopausal women HLA compatible (negative lymphocyte crossmatch) or HLA identical in case of refractoriness related to the presence of anti-HLA Ab HPA compatible in thrombocytopenic neonates to HPA immunized mother (fetal neonatal alloimmune thrombocytopenia)	$0.5–0.7 \times 10^{10}$ platelets/kg (apheresis or pooled whole blood–derived PCs)	Prevention and/or resolution of bleeding CCI[a] >7.5 to 10 within 1 h and > 4.5 to 5 within 24 h after transfusion (not applicable to cold/cryopreserved platelets)
Plasma (thawed frozen, never frozen and maintained at 4°C or at room temperature, freeze-dried)	Transfusion: Coagulation factor–related bleeding disorders Acute hypovolemic coagulopathy (see below) Infectious disease (convalescent plasma containing pathogen-specific Abs): Argentina hemorrhagic fever, viral respiratory infections (experimental) Plasma exchange (plasma or combined plasma and albumin):	Correct impaired hemostasis by providing missing elements of coagulation or fibrinolysis cascade, as well as elements to heal injured vessel endothelium Provide Abs against relevant pathogens	ABO compatible (plasma)	10–15 mL/kg Not determined	Reduced bleeding disorder Infection resolution
	Pathogenic Ab removal and supplementation of lacking enzyme (e.g., thrombotic thrombocytopenic microangiopathy or Guillain-Barré syndrome) Pathogenic Ab removal (e.g., anti-HLA Ab prior to kidney transplantation)	Deplete pathogenic elements in the blood (autoantibodies such as anti-ADAMTS-13 Ab in case of TTP, excess cholesterol, etc.); plasma may also bring anti-inflammatory and/or immunomodulatory factors such as immunoglobulin	ABO compatible (plasma)	45–60 mL/kg	Improved disease-specific symptomatology (i.e., apyrexia and platelet recovery in case of TTP) Reduced antibody levels (e.g., anti-HLA antibodies prior to organ transplantation)

(*Continued*)

Whole blood	Acute hypovolemic coagulopathy requiring massive transfusion	Balanced provision of blood components maintained at 4°C and without an additive solution and related dilution	ABO-identical or group O with low-titer anti-A/B Ab	Repeated per clinical status	Normovolemia; bleeding resolution
Multicomponent (RBCC, PC, and plasma)	Acute hypovolemic coagulopathy requiring massive transfusion	Appropriate ratio is under investigation; a ratio of 1 RBCC/1 plasma/0.25 PC (platelet content of a whole blood) is currently favored	Standard RBCC, PC, and plasma compatibility	1 RBCC/1 plasma/0.25 PC ratio, repeated per clinical status	Normovolemia; bleeding resolution
Granulocyte concentrates (apheresis or a pool of whole blood–derived granulocytes)	Severe refractory bacterial or fungal infection (mainly soft tissues and lung) in patients with neutropenia (<100/μL) or with dysfunctional granulocytes (CGD). Neutropenia can be acquired (chemotherapy) or congenital. Formal proof of efficacy is lacking.	Correct impaired granulocyte function in relation to granulocytopenia or granulocyte dysfunction	ABO compatible	$1–2 \times 10^{10}$, repeated per clinical status	Infection resolution (or stabilization until recovery from neutropenia)
Donor mononuclear cells	Relapse of malignant hemopathy after allogeneic hematopoietic cell transplantation	Graft-versus-leukemia effect (and graft enhancement effect)	N/A	$10^5–10^7$ T lymphocytes/kg	Disease specific (remission)
Cryoprecipitate	Acute bleeding coagulopathy, type II (dysfunctional factor) or type III (absent factor) von Willebrand disease, hemophilia A in the absence of factor VIII concentrates	Provision of fibrinogen, factor VIII, von Willebrand factor, and factor XIII	ABO compatibility is not required	10–15 mL/unit, pool of 4–5 units	Increased plasma fibrinogen (0.3–1 g/L)

[a]CCI calculation:

$$\text{CCI} = \frac{\text{Posttransfusion count } (/\mu\text{L}) - \text{pretransfusion count } (/\mu\text{L})}{\text{Number of platelets transfused} \times 10^{11}} \times \text{Body surface area } (\text{m}^2)$$

Abbreviations: Ab, antibody; CCI, corrected count increment; CGD, chronic granulomatous disease; DIC, disseminated intravascular coagulation; ECMO, extracorporeal membrane oxygenation; Hb, hemoglobin; HLA, human leukocyte antigen; N/A, not applicable; RBC, red blood cell; RBCC, red blood cell concentrate, PC, platelet concentrate; TTP, thrombotic thrombocytopenic purpura.

TABLE 118-5 Transfusion Adverse Reactions: Main Warning Signs

Fever (≥38°C)	+1–2°C within 4 h	FNHTR Anti-HLA immunization and cognate Ag in the blood product TRALI (with dyspnea at the forefront)
	+1–2°C within 15 min +/–: • Chills • Dyspnea • Hypotension • Digestive disorders • Disseminated intravascular coagulation • Hemoglobinuria	Transfusion-transmitted bacterial infection Hemolysis
	>2°C	Transfusion-transmitted bacterial infection
Hypotension (≥30 mmHg decrease in systolic blood pressure)		Hemolytic shock Anaphylactic shock Septic shock TRALI (with dyspnea at the forefront)
Dyspnea		TRALI (within 6 h of transfusion) TACO (within 12 h of transfusion) Severe allergy (immediate; within 4 h)
Hemoglobinuria		Intravascular hemolysis • Immunologic • Mechanical • Toxic • Thermic
Rash	<2/3 of the body within 2–3 h >2/3 of the body during or within 2–3 h >2/3 of the body within 5 min Associated with dyspnea and shock	Minor allergy Severe allergy Anaphylaxis
Icterus		Delayed hemolysis
New alloantibody		Alloimmunization
Rash, diarrhea, and fever occurring 2 days to 6 weeks after transfusion		GVHD
Gum bleeding, purpura 5–12 days after transfusion		Posttransfusion purpura
Cardiac, hepatic, and/or renal insufficiency in frequently transfused patients		Posttransfusion iron overload
Top-down investigation after a blood donor is subsequently found to be infected Bottom-up investigation after another recipient of a same blood donation is found to be infected Infectious symptoms within 6 months		Transfusion-transmitted infection

Abbreviations: Ag, antigen; FNHTR, febrile nonhemolytic transfusion reaction; GVHD, graft-versus-host disease; HLA, human leukocyte antigen; TACO, transfusion-associated circulatory overload; TRALI, transfusion-related acute lung injury.

hemoglobinemia and hemoglobinuria, and elevated plasma lactate dehydrogenase and unconjugated bilirubin. The direct antiglobulin test (DAT, or direct Coombs test) that detects immunoglobulin, and possibly complement (C3d), on the surface of the recipient's RBC will most often be positive **(Fig. 118-2)**. Similarly, a positive indirect antiglobulin test (IAT, or indirect Coombs test) that detects anti-RBC alloAb in the serum will also be positive. An elution of the Ab on the surface of the RBC may allow for the identification of the culprit alloAb.

The management of an immune-mediated acute hemolytic transfusion reaction is mainly supportive. Prompt interruption of the transfusion, biological workup, and a thorough clerical check to prevent a possible second misidentified transfusion are crucial initial steps. Vigorous hydration with isotonic saline and diuretics to maintain urine output is recommended. Although often self-limiting, acute hemolysis may also require forced alkaline diuresis, correction of electrolyte abnormalities, and pressor support as needed. In patients with DIC and severe bleeding, PC, plasma, and cryoprecipitate or fibrinogen may be required. When transfusion of incompatible RBCCs is unavoidable, prophylaxis with steroids (100 mg of hydrocortisone) just before the transfusion and repeated 24 h later and polyvalent immunoglobulin (1.2–2.0 g/kg per day over 2–3 days, initiated just before the transfusion) have been successfully used to prevent or minimize acute and delayed hemolysis. Polyvalent immunoglobulin, anticomplement (C3) Ab, anti-B-cell Ab, or plasma exchange may be considered in case of severe posttransfusion hyperhemolysis in sickle cell patients.

Immune-mediated hemolysis may also occur after allogeneic hematopoietic transplantation (most often involving a peripheral blood stem cell graft) or, more seldomly, solid organ transplantation. Minor ABO incompatibility, with subsequent red cell destruction in the recipient, is the most common cause of clinically significant hemolysis in such cases. Viable donor B lymphocytes, called "passenger lymphocytes," transferred passively with the graft, may produce alloAbs (including anti-D or anti-A1 in an A2 donor) that target recipient red cells. Such hemolysis has been reported to develop 5–14 days after transplantation. Reduced-intensity conditioning regimens and cyclosporine as prophylaxis against GVHD or rejection have been associated with increased risk. Transfusing RBCs compatible with the graft donor and the use of GVHD prophylaxis able to target B cells (e.g., methotrexate) have significantly reduced the incidence of passenger lymphocyte syndrome. Allogeneic hematopoietic transplantation may also result in acute hemolysis due to incompatible donor-derived red cell (and precursor) destruction by the recipient alloAbs (i.e., major ABO incompatibility). Prolonged pure red cell aplasia may occur in such a situation. Graft deserythrocytation will reduce the risk of early acute hemolysis.

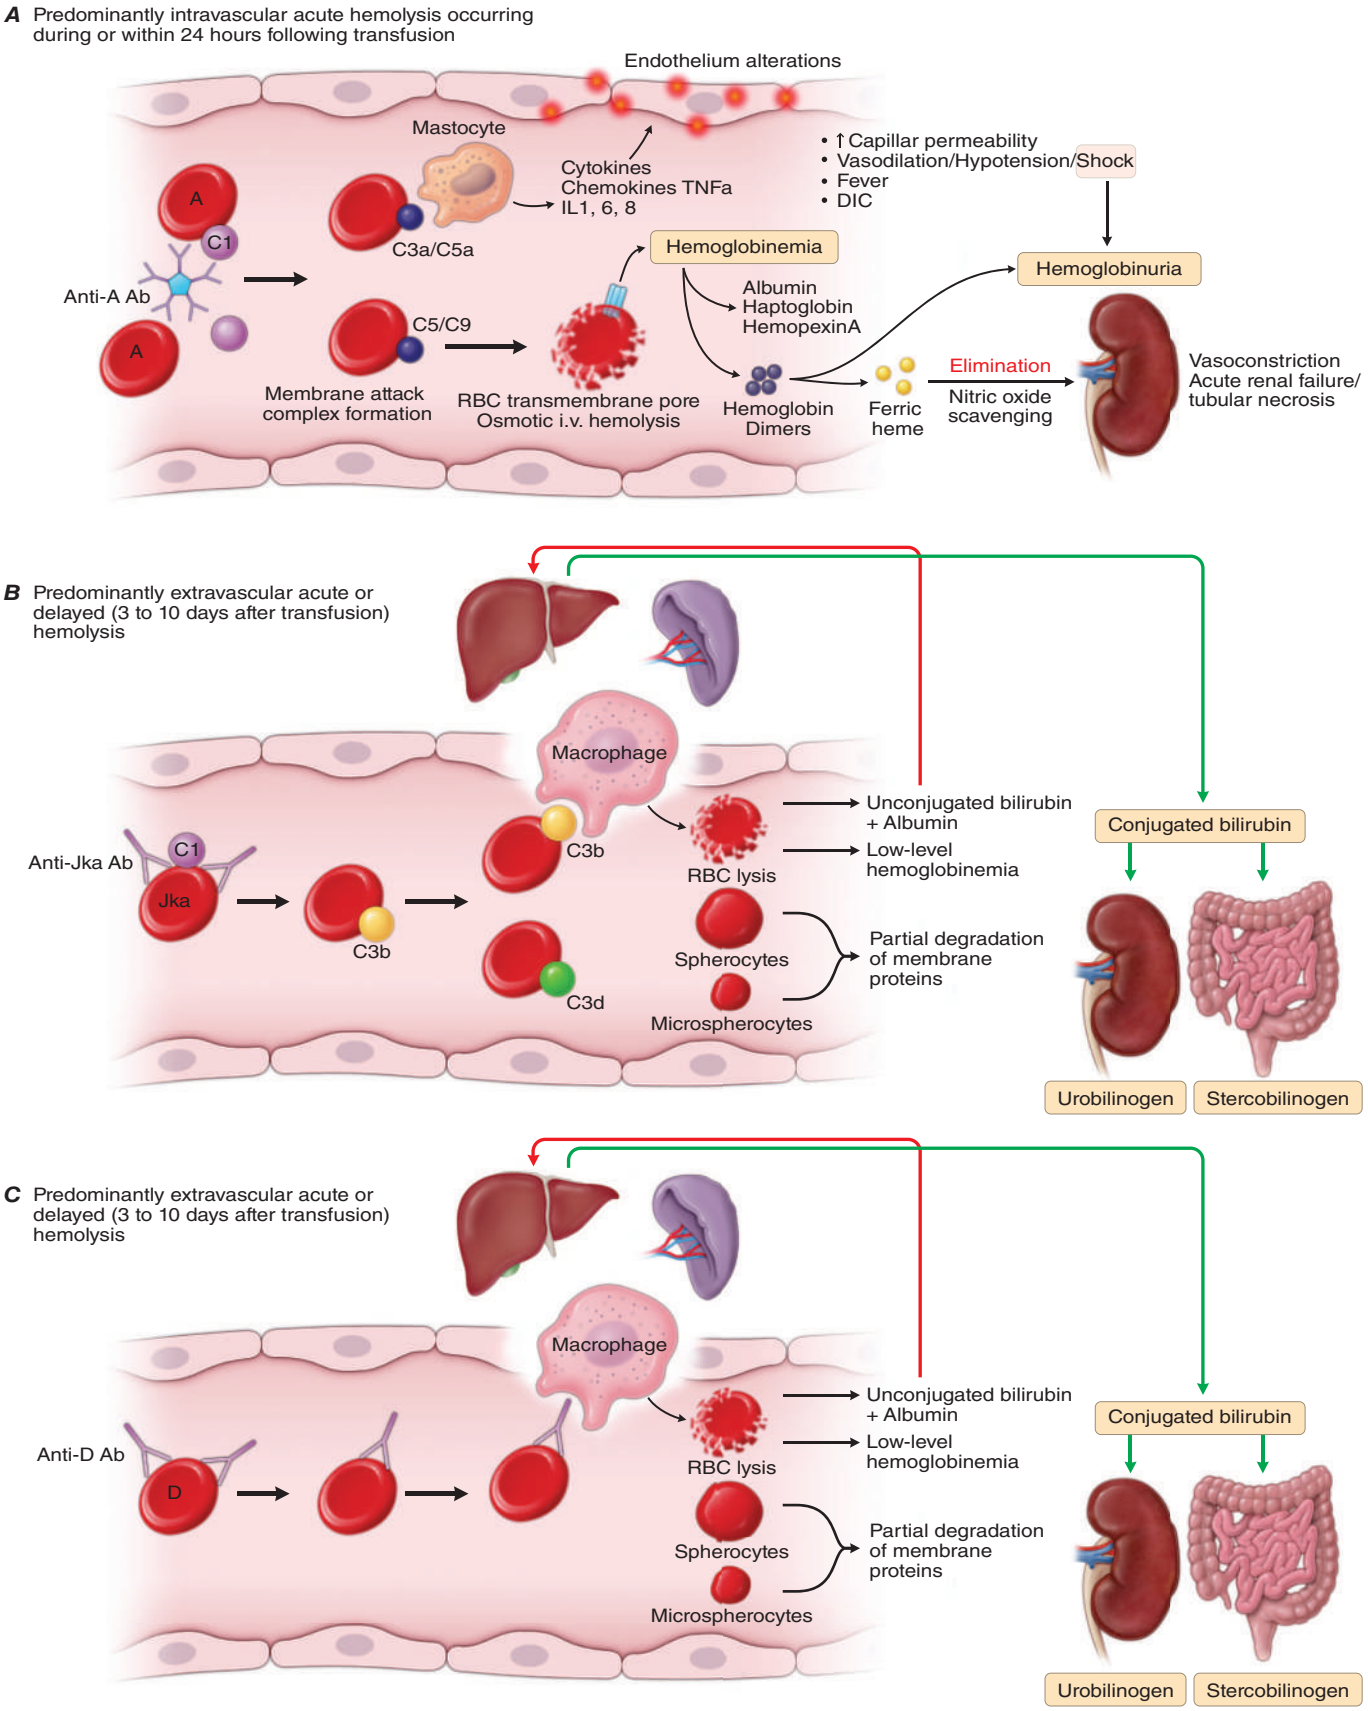

FIGURE 118-1 Mechanisms of transfusion hemolytic reactions. ***A.*** Acute responses will involve preexisting antibodies (Abs), naturally occurring anti-A/anti-B IgM or IgG directed against other RBC antigens (Ags) and resulting from prior sensitization. Upon interaction with cognate antigen on transfused red blood cells (RBCs), recipient allogeneic Ab (alloAb), mostly natural anti-A/anti-B IgM, may fix and activate complement up to C5/C9. Formation of membrane attack complex (MAC) will create pores in transfused RBCs with resulting intravascular hemolysis, release of toxic moieties including free hemoglobin responsible for end-organ damage including renal failure, and tissue factors contributing to occurrence of disseminated intravascular coagulation (DIC). ***B.*** Alternatively, complement activation may be incomplete, as typically observed in a delayed hemolytic transfusion reaction involving neoformed allogeneic IgG. In such cases, complement activation up to C3 results in C3b-mediated opsonization of RBCs, extravascular hemolysis, and clearance through immunophagocytosis. Anemia and jaundice will be the primary clinical manifestations. ***C.*** Lastly, alloAb may not fix complement while ensuring antibody-dependent cellular cytotoxicity (ADCC)–mediated phagocytosis of targeted RBC. *(Adapted from SR Panch et al: Hemolytic transfusion reactions. N Engl J Med 381:150, 2019.)*

FIGURE 118-2 Direct and indirect Coombs test. The direct Coombs/antiglobulin test detects the presence of Abs (or complement) on the surface of erythrocytes. The indirect Coombs/antiglobulin test detects Abs in the serum that may bind to donor erythrocytes. Abs, antibodies; RBC, red blood cell. *(Adapted from http://upload.wikimedia.org/wikipedia/commons/1/1c/coombs_test_schematic.png.)*

Polyvalent immunoglobulin may contain high titers of anti-A (mostly) and/or anti-B Abs and induce acute hemolysis, most often of limited severity. Such hemolysis is particularly described in group A or AB children receiving high-dose immunoglobulin, notably for Kawasaki's disease, as well as in adults treated for thrombotic thrombocytopenic purpura. A similar mechanism may lead to hemolysis after anti-D immunoglobulin treatment for immune thrombocytopenia in RhD-positive patients.

Nonimmune mechanisms of transfusion-associated hemolysis include thermal (overheated or cold BCs), osmotic (concurrent hypoosmotic perfusion), and mechanical (pressure related to high-flow transfusion filtering during cell saver processing) mechanisms.

Autoimmune and drug-induced hemolytic anemias may be exacerbated by transfusion and can therefore mimic hemolytic transfusion reactions. Transfusion of RBCs with enzymatic defects may mimic immune-mediated hemolysis as well. Notably, severe hemolytic reactions in patients receiving long-term transfusions for hemoglobinopathies (mainly sickle cell disease) can precipitate bystander hemolysis, in addition to clearing transfused red cells. The mechanisms of this hyperhemolytic transfusion reaction may be a mediated RBC hemolysis-related systemic inflammatory response and resulting lysis of red cell precursors by macrophages. This process may be immediate or delayed, with hemoglobin levels falling below the pretransfusion values, often to life-threatening levels. Further RBCC transfusion typically exacerbates ongoing hemolysis, with the exogenous (transfused) allogeneic Ags probably triggering further nonspecific hemolysis.

Febrile Nonhemolytic Transfusion Reaction The most frequent reaction associated with the transfusion of cellular BCs is FNHTR (up to 300 per 10^5 BCs). This reaction is characterized by chills and rigors and a ≥1°C rise in body temperature and is caused by proinflammatory cytokines in the BC or by recipient Abs directed against donor cell Ags present in the BC. FNHTR is diagnosed when other causes of fever, notably infection and hemolysis, have been excluded. Leukocyte reduction, especially prestorage, can prevent the occurrence of FNHTR. Moreover, the use of additive solutions decreases FNHTR frequency associated with PC transfusion. Premedication with antipyretics has generally proven ineffective at decreasing the rate of such reactions and may mask relevant clinical symptoms.

Allergic Reactions Most allergic transfusion reactions are mild and include rash, pruritus, urticaria, and localized edema. More rarely, allergic reactions may be severe to life-threatening with an anaphylactic reaction that can involve bronchospasm, respiratory distress, hypotension, nausea, vomiting, and shock. Frequencies of mild and severe allergic reactions are ~100 and ~5 per 10^5 BCs, respectively. Allergic reactions are related to plasma proteins found in transfused components. Mild reactions may be treated by temporarily stopping the transfusion and administering antihistamine drugs. Patients with a history of allergic transfusion reaction may be premedicated with an antihistamine, although there is no consensus on this issue. Cellular components can be washed to remove residual plasma for extremely sensitized patients. Most of the allergic presentation may not depend on preformed Abs and may be attributable to soluble mediators triggering histamine and serotonin release from platelets and leukocytes. An anaphylactic reaction may occur after the transfusion of only a few milliliters of the BC. Treatment includes stopping the transfusion, maintaining vascular access, and administering adrenaline (0.3–0.5 mg subcutaneously). Additional treatment with steroids, antihistamine drugs, and bronchodilators may also be required.

Patients who are IgA deficient (<1% of the population) may be sensitized to this immunoglobulin isotype and may be at risk of anaphylactic reactions associated with plasma transfusion. As a precaution, individuals with severe IgA deficiency should therefore receive, where available, IgA-deficient plasma and washed cellular BCs. Patients who have anaphylactic or repeated allergic reactions to BCs should be tested for IgA deficiency. It should be noted that the importance, or even the reality, of such a transfusion-related allergic risk is currently debated.

Graft-Versus-Host Disease GVHD is an extremely rare adverse reaction caused by transfusion, although it is a frequent complication of allogeneic hematopoietic transplantation. Transfusion-related GVHD is mediated by engrafted donor T lymphocytes in a recipient unable to reject such allogenic lymphocytes (as in severely immunosuppressed patients or patients homozygous for an HLA haplotype shared with the donor). Such donor T lymphocytes interact with host HLA Ags and mount an immune response, which is manifested clinically by the development, 5–10 days after transfusion, of cytopenia, fever, a characteristic skin rash, diarrhea, and liver function abnormalities. Transfusion-associated GVHD is highly resistant to treatment with immunosuppressive therapies as well as ablative therapy followed by allogeneic bone marrow transplantation and is fatal in >90% of cases. Prevention in at-risk patients relies on the irradiation of cellular BCs (minimum of 25 Gy) or treating BCs with pathogen reduction technology that will deplete all living cells in the component. At-risk patients include patients with inherited immune deficiency, patients undergoing autologous or allogeneic hematopoietic transplantation, patients treated with immunosuppressive drugs such as purine or pyrimidine analogues, anti-CD52 Ab, or antithymocyte globulin, fetuses receiving intrauterine transfusions, and recipients of BCs provided by a blood relative. Because granulocyte concentrates contain a large number of lymphocytes, they should always be irradiated.

Transfusion-Related Acute Lung Injury TRALI is characterized by the occurrence or worsening of hypoxia and noncardiogenic pulmonary edema with bilateral interstitial infiltrates on chest x-ray during or within 6 h after transfusion, although delayed cases may occur up to 72 h later. Frequency of TRALI is BC dependent and ranges, on average, from 0.5 to 10 per 10^5 BCs. TRALI may be difficult to distinguish from other causes of hypoxia, such as circulatory overload, and is among the most common causes of transfusion-related fatalities. Treatment is supportive only. TRALI usually results from the transfusion of donor plasma that contains high-titer anti-HLA class II Abs that bind recipient cognate Ag. Anti-HLA class I and anti-HNA Abs may also be involved. TRALI mediated by cytokines and chemokines in the absence of an HLA-mediated interaction may occur also. Leukocytes, especially when primed by either a bacterial moiety such as lipopolysaccharide or a cytokine/chemokine, aggregate in the pulmonary vasculature and release inflammatory mediators. The transfusion of plasma and PCs from male donors and nulliparous or parous female donors without anti-HLA Abs has significantly reduced the risk of TRALI where implemented. Recipient factors associated with an increased risk of TRALI include smoking, chronic alcohol use, shock, liver surgery (transplantation), cancer surgery, mechanical ventilation, and positive fluid balance.

Posttransfusion Purpura This rare reaction (~$1/10^5$ BCs) is defined as a thrombocytopenia-related bleeding disorder developing 5–12 days after PC (and more rarely RBCC) transfusion, predominantly in women. Platelet-specific alloAbs are found in the recipient, most frequently anti-HPA-1a in HPA-1a-negative alloimmunized individuals. The delayed thrombocytopenia is due to a secondary increased production of alloAbs. The mechanisms for the destruction of the patient's own platelets remain unclear. Management is mostly supportive but may require polyvalent immunoglobulin, glucocorticoids, or plasma exchange. Additional platelet transfusions may worsen the thrombocytopenia or be associated with poor increments. Prevention of recurrence includes use of washed BCs or BCs from HPA-compatible donors.

Alloimmunization/Platelet Refractoriness A recipient may become alloimmunized to a number of Ags on cellular blood elements and plasma proteins. AlloAbs to RBC Ags are detected during pretransfusion testing, and their presence may delay finding Ag-negative crossmatch-compatible products for transfusion. Women of childbearing age who are sensitized to RBC Ags (i.e., D, c, E, Kell, or Duffy) are at risk of bearing a fetus with hemolytic disease of the fetus or newborn. Ag matching is the only pretransfusion selection test to prevent RBC alloimmunization, which is found to occur with a frequency of

~100/10^5 RBCC transfusions. Alloimmunization to Ags on leukocytes and platelets, most often anti-HLA Abs, can result in refractoriness to PC transfusions (as defined by a low increase in platelet count after transfusion). Once alloimmunization has developed, HLA-compatible (crossmatched) PCs should be preferred if available. If not, repeated PCs at shortened intervals may be considered. Use of leukocyte-reduced cellular BCs will reduce the incidence of immunization. Transfusion refractoriness may also result from an anti-HPA alloimmunization, although less commonly. Recipient factors associated with platelet refractoriness include fever, splenomegaly, bleeding, DIC, and medications such as amphotericin B. Notably, cold-stored (and cryopreserved) PCs have been found to have preserved hemostatic function in acutely bleeding patients despite poor platelet increments.

Immunomodulation Transfusion of allogeneic blood may be associated with immunosuppression, as evidenced early on by the beneficial effect of pretransplant transfusion on kidney graft survival. The intensity of such an effect is debated and, if present, is most probably attenuated with leukoreduced BCs. Transfusion-related immunomodulation is indeed thought to be mainly mediated by donor leukocytes, whether transfused to the recipient or undergoing apoptosis during storage. However, leukoreduced RBCCs or PCs still release immunomodulatory mediators during storage. These mediators, along with the transfused RBCs or platelets, may exert various, possibly opposing, immune effects in vivo, including immunosuppression and inflammation.

NONIMMUNOLOGIC TRANSFUSION ADVERSE REACTIONS

Fluid Overload TACO is a common and underrecognized transfusion adverse reaction. Estimated frequencies vary from ~10 to 100 per 10^5 BCs. TACO is now the main cause of death from transfusion since the TRALI risk has been mitigated. Risk factors include older age, renal failure, preexisting fluid overload, cardiac dysfunction, administration of a large volume of BCs, and an excessive rate of transfusion in relation to the patient's hemodynamic tolerance. TACO results in dyspnea, hypoxia, bilateral and predominantly alveolar infiltrates on chest x-ray, frequent systolic hypertension, and elevated brain natriuretic peptide. Fever may also exist. Prevention involves identifying at-risk patients, close monitoring, a slow transfusion rate (1 RBCC over 3–4 h), and use of diuretics in hemodynamically stable patients with a history of TACO. Treatment requires stopping the transfusion and administrating oxygen and diuretics.

Massive Transfusion-Associated Reactions/Electrolyte and Cold Toxicity Reactions Reactions related to massive transfusion, i.e., transfusion of 50% of the patient's total blood volume over 3 h or >5–10 units of RBCCs (plus associated BCs), include citrate toxicity, hypothermia, hyperkalemia, and dilutional coagulopathy. Citrate, which is commonly used to anticoagulate BCs, chelates calcium. Hypocalcemia, manifested by circumoral paresthesia, and changes in cardiac function may result from multiple rapid transfusions. Although citrate is quickly metabolized to bicarbonate, calcium infusion (through a separate line) may be required. Rapid transfusion of BCs still at 4°C can result in hypothermia and cardiac dysrhythmias. Use of an inline warmer will prevent this complication. RBC leakage during storage, longer storage, and irradiation increase the concentration of potassium in the unit. Neonates and patients with renal failure or other comorbidities (e.g., hyperglycemia or hypocalcemia) are at risk of hyperkalemia and resulting acute cardiac toxicity. Treatment includes insulin, glucose, calcium gluconate, and furosemide, and prevention includes the use of washed or plasma-reduced RBCCs or a storage age of <7–10 days and the avoidance of RBCCs stored for >24 h after irradiation.

Iron Overload Each RBCC contains 200–250 mg of iron. In frequently transfused recipients, iron accumulation that is left untreated will affect endocrine, hepatic, and cardiac function. Death may occur from cardiac failure or arrhythmia. Iron overload can be assessed by means of serum ferritin measurements, magnetic resonance imaging, and liver biopsy. Prevention and treatment of this frequently underreported transfusion adverse event rely on careful monitoring and iron chelation.

Hypotensive Reactions Acute hypotensive transfusion reactions are defined as an abrupt drop in blood pressure of >30 mmHg early after the start of transfusion and resolving quickly once the transfusion is stopped, without further intervention. Respiratory, gastrointestinal, or mild allergic reactions may also be present. Estimated frequency is 1–10/10^5 BCs. These reactions may result from the generation of vasoactive kinins in the BCs and are more likely to occur in hypertensive patients taking angiotensin-converting enzyme (ACE) inhibitors who are therefore less able to metabolize bradykinin. Upon resolution, the same blood product should not be restarted. Switching from an ACE inhibitor to an alternative drug should be considered for patients requiring further transfusions.

Adverse Transfusion Reactions of Uncertain Imputability Necrotizing enterocolitis, which is common in preterm and very-low-birth-weight neonates, has been infrequently described with close temporal association with RBC transfusion. However, the causality of any association remains to be further ascertained, as does the efficacy of withholding feeds during transfusion to prevent such a complication. Posterior reversible encephalopathy syndrome is a rare syndrome characterized by acute reversible neurologic symptoms related to subcortical vasogenic brain edema. It has been described within 10 days after RBCC transfusion, mainly in women with severe (and long-standing) anemia. The prognosis is most often favorable, although irreversible neurologic disturbance has been described. Prevention may include avoiding rapid correction of chronic severe anemia. Again, causality remains to be established.

INFECTIOUS ADVERSE REACTIONS

Donor screening involves the selection of healthy donors without high-risk lifestyles, medical conditions, or exposure to transmissible pathogens. Tests are performed on donated blood to detect the presence of pathogens by testing for relevant Abs or Ags or by directly detecting infectious agents by nucleic acid amplification. Increasing sensitivity of testing methods has progressively narrowed the "window" period early on after infection during which a low-titer undetectable pathogen may be present in the blood and result in a transfusion-transmitted infection.

Transfusion-transmitted bacterial infection remains a significant concern, notably with PCs stored at room temperature, which allows for bacterial proliferation. However, some gram-negative bacteria such as *Yersinia* can grow at 4°C and therefore may be implicated in infections related to RBCC transfusion. Recipients of contaminated BCs may develop abrupt (during transfusion and up to several hours after) fever and chills, which can deteriorate to septic shock, DIC, and death. Endotoxin formed within the BC may be implicated. After sampling for bacterial culture, broad-spectrum antibiotics should be promptly initiated.

Pathogen reduction of PC and plasma, and perhaps soon of RBCCs as well, offers an additional means of reducing transfusion infection risks. Although effective for a wide range of pathogens, such processes are most often ineffective for bacterial spores and nonenveloped viruses such as hepatitis A virus, parvovirus B19, and hepatitis E virus. Postdonation information (i.e., fever occurring within 24 h after donation) allows the involved BCs to be quarantined and may provide an additional safety measure.

Transfusion-transmitted infections are increasingly rare. However, new or previously unidentified infectious risks may occur, as highlighted by the emergence of the transfusion-associated West Nile virus infection and babesiosis in early 2000 in the United States, as well as transfusion-associated hepatitis E in early 2010 in Europe. Such occurrences require active surveillance programs and the appropriate implementation of mitigation measures such as additional testing, pathogen reduction, and travel-related deferral criteria. Along with West Nile virus, a number of other arbovirus-related infections

TABLE 118-6 Infectious Transfusion Adverse Events

PATHOGEN		DONATION PREVALENCE (/10^4 BLOOD DONATIONS)	PREVENTION MEASURES (IN ADDITION TO DONOR DEFERRAL)	INFECTION PREVALENCE IN RECIPIENTS (/10^6 BLOOD PRODUCTS TRANSFUSED)
Bacteria	Pyogenic bacteria	PC: 10–20	Venipuncture sepsis, diversion of the initial 10–30 mL of blood, bacterial detection, pathogen reduction (for PC)	Sepsis: PC: 5–30; with bacterial detection: <1 to 10; with pathogen reduction: <1 RBCC: <0.2
	Treponema pallidum (syphilis)	~1[a]	Serology[b,c]	<0.01
Virus	HIV-1/2	~0.1	Serology, NAT (+/– p24 Ag)[b,c]	0.1–1[d]
	HBV	~0.5	Serology, NAT[b,c]	<0.5 (3 without NAT)[d]
	HCV	0.2–1.2	Serology, NAT[b,c]	<0.1–1[d]
	HTLV-1/2	0.05–0.1[a]	Serology, BC leukocyte reduction [b,c]	0.1–0.3[d]
	HEV	0–10 (in endemic regions)	NAT	Endemic regions: <0.1 with NAT; a transmission rate from infected donors of ~50% has been reported
	CMV	Undetermined	Serology, BC leukocyte reduction[b,c]	<0.1 in leukocyte-reduced BCs
	Parvovirus B19	~0.5 with viral DNA >10^6 IU/mL,[e] up to 100 overall	NAT	Most adults are immune to parvovirus B19; up to 0.12% in seronegative adults has been reported
	West Nile virus	Up to 3 in high season endemic regions[a]	NAT[b]	High season endemic regions: <1 with NAT
Parasite[f]	*Plasmodium* (malaria)	~4 (40–>50 in donors from endemic regions)[a]	Serology (NAT soon available)	<0.1 in nonendemic regions
	Babesia	~90 (in endemic regions)[a]	Serology (NAT implementation underway)	ND (0.04% donors may be within the serology window period)
	Trypanosoma cruzi (Chagas disease)	~0.14 in donors/mothers from endemic regions[a]	Serology, leukocyte reduction	ND

[a]As assessed based on seropositivity, i.e., including a varying percentage of individuals not harboring the pathogen in their blood. [b]Prevention measures may also include pathogen reduction (for PC and plasma), [c]Prevention measures may also include a quarantine of the (cryopreserved) BC pending a negative serology on a subsequent donation (for plasma), [d]Estimated residual risk. [e]Transfusion risk deemed as absent below this threshold, [f]Visceral leishmaniasis is a transfusion risk as well in endemic regions, a risk that may be mitigated by leukocyte reduction.

Note. Other pathogens associated with transfusion-transmitted infections at a very low frequency include arboviruses other than West Nile (dengue, Zika virus), hepatitis A, human herpesvirus-8, Japanese encephalitis virus, tick-borne encephalitis virus complex, and the prion responsible for variant Creutzfeldt-Jakob disease (4 cases in the United Kingdom, in the context of the bovine spongiform encephalopathy epidemic, before implementation of systematic leukocyte reduction).

Abbreviations: Ag, antigen; BC, blood component; CMV, cytomegalovirus; HBV, hepatitis B virus; HCV, hepatitis C virus; HEV, hepatitis E virus; HTLV, human T-cell leukemia virus; NAT, nucleic acid detection test; ND, not determined; PC platelet concentrate; RBCC, red blood cell concentrate.

possibly transmissible by blood transfusion are endemic or involved in epidemic outbreaks. Despite being possibly present in the blood at asymptomatic phases of the disease, documented cases of transfusion-transmitted infections involving these arboviruses have been very rare (Zika), often without a discernible clinical impact (Dengue), or absent (Chikungunya). Route of infection (i.e., intravenous vs mosquito bite), pathogen dose, storage conditions, recipient immune status, and ongoing treatments may all impact the ability of a pathogen in the donor to induce a disease in the recipient. Estimated frequencies of transfusion-relevant infections in donors and of transfusion-transmitted infections are reported in Table 118-6. Such frequencies depend heavily on variables such as local epidemiology, donor deferral rules, risk reduction measures, and data reporting, and may vary considerably.

ALTERNATIVES AND PERSPECTIVES

In addition to promoting appropriate transfusion indications, patient blood management programs have highlighted several transfusion-sparing strategies, such as the treatment of iron deficiency before surgery and minimization of blood loss. Antifibrinolytic agents such tranexamic acid (TXA) have been shown to be effective in preventing bleeding complications in various forms of hemorrhage. Erythropoietin stimulates erythrocyte production in patients with anemia from chronic renal failure and other conditions. Thrombopoietin receptor agonists may reduce platelet transfusion needs resulting from chemotherapy-induced thrombopenia. Bone marrow transplantation and gene therapy approaches, including CRISPR-Cas9-mediated gene editing, dramatically reduce the transfusion needs in patients with sickle cell or major thalassemia. Stem cell–derived blood cells such as RBCs or platelets may in the future become a suitable alternative to rare blood donors.

Importantly, issues surrounding transfusion safety now fully encompass transfusion efficacy. Linked large-scale databases pertaining to blood donors and transfused patients will also be instrumental in further assessing and understanding the basis of transfusion safety and efficacy. Optimal transfusion care will soon require consideration of new criteria in relation to donor, blood product, and/or recipient characteristics.

119 Hematopoietic Cell Transplantation

Frederick R. Appelbaum

Bone marrow transplantation was the original term used to describe the collection and transplantation of hematopoietic stem cells, but with the demonstration that peripheral blood and umbilical cord blood are also useful sources of stem cells, *hematopoietic cell transplantation* has become the preferred generic term for this process. Hematopoietic cell transplantation is used to treat patients with an abnormal but nonmalignant lymphohematopoietic system by replacing it with one from a normal donor. Hematopoietic cell transplantation is also used to treat malignancy by allowing the administration of higher doses of myelosuppressive therapy than would otherwise be possible and, in the setting of allogeneic hematopoietic cell transplantation, by conferring an immunologic graft-versus-tumor effect. The use of hematopoietic cell transplantation is increasing, as it becomes safer and applicable to more diseases and as donor availability expands.

The Worldwide Network for Blood and Marrow Transplantation (*http://www.wbmt.org*) estimates that worldwide more than 100,000 transplants were performed in 2022. The frequency of transplantation varied widely from country to country, with a close association of transplant rates with gross national income (GNI) per capita. However, even among countries with similar GNIs per capita, there are substantial differences between countries and regions regarding the frequency of transplantation, disease indications, and choice of donor type.

THE HEMATOPOIETIC STEM CELL

Several features of the hematopoietic stem cell (HSC) make transplantation clinically feasible, including its remarkable regenerative capacity, its ability to home to the marrow space following intravenous injection, and the ability of the stem cell to be cryopreserved **(Chap. 101)**. Transplantation of a single stem cell can replace the entire lymphohematopoietic system of an adult mouse. In humans, transplantation of a small percentage of a donor's bone marrow volume regularly results in complete and sustained replacement of the recipient's entire lymphohematopoietic system, including all red cells, granulocytes, B and T lymphocytes, and platelets, as well as cells comprising the fixed macrophage population, including Kupffer cells of the liver, pulmonary alveolar macrophages, osteoclasts, and Langerhans cells of the skin. Homing of HSCs to their marrow niche initially involves interactions between P- and E-selectins on marrow sinusoidal endothelium with integrins including VLA-4 on HSCs. Once tethered to the vascular endothelium, changes in integrin conformation result in tight adhesion following which stem cells migrate through the endothelium and extracellular matrix eventually reaching the stem cell niche. This last step is facilitated by CXCL12 produced by the niche stroma interacting with the chemokine CXCR4 on HSCs. Human hematopoietic stem cells can survive freezing and thawing with little, if any, damage, making it possible to remove and store a portion of the patient's own bone marrow for later reinfusion following treatment of the patient with high dose myelotoxic therapy.

CATEGORIES OF HEMATOPOIETIC CELL TRANSPLANTATION

Hematopoietic cell transplantation can be described according to the relationship between the patient and the donor and by the anatomic source of stem cells. In ~1% of cases, patients have identical twins who can serve as donors. With the use of syngeneic donors, there is no risk of graft-versus-host disease (GVHD), and unlike the use of autologous marrow, there is no risk that the stem cells are contaminated with tumor cells.

Allogeneic transplantation involves a donor and a recipient who are not genetically identical. Following allogeneic transplantation, immune cells transplanted with the stem cells or developing from them can react against the patient, causing GVHD. Alternatively, if the immunosuppressive preparative regimen used to treat the patient before transplant is inadequate, immunocompetent cells of the patient can cause graft rejection. The risks of these complications are influenced by the degree of matching between donor and recipient for human leukocyte antigen (HLA) molecules encoded by genes of the major histocompatibility complex.

HLA molecules are responsible for binding antigenic proteins and presenting them to T cells. The antigens presented by HLA molecules may derive from exogenous sources (e.g., during active infections) or may be endogenous proteins. If individuals are not HLA-matched, T cells from one individual will react strongly to the mismatched HLA, or "major antigens," of the second. Even if the individuals are HLA-matched, the T cells of the donor may react to differing endogenous or "minor antigens" presented by the HLA of the recipient. Reactions to minor antigens tend to be less vigorous. The genes of major relevance to transplantation include HLA-A, -B, -C, and -D; they are closely linked and therefore tend to be inherited as haplotypes, with only rare crossovers between them. Thus, the odds that any one full sibling will match a patient are one in four, and the probability that the patient has an HLA-identical sibling is $1 - (0.75)^n$, where n equals the number of siblings.

With conventional techniques, the risk of graft rejection is 1–3%, and the risk of severe, life-threatening acute GVHD is ~15% following transplantation between HLA-identical siblings. The incidence of graft rejection and GVHD increases progressively with the use of family member donors mismatched for one, two, or three antigens. Newer approaches to GVHD prophylaxis, including the use of posttransplant high-dose cyclophosphamide, have diminished the impact of HLA mismatching, making transplantation between donor/recipient pairs who share only one HLA haplotype possible. Since the formation of the National Marrow Donor Program and other registries, HLA-matched unrelated donors can be identified for many patients. The genes encoding HLA antigens are highly polymorphic, and thus the odds of any two unrelated individuals being HLA identical are extremely low, somewhat less than 1 in 10,000. However, by recruiting >40 million volunteer donors, HLA-matched donors can be found for ~60% of patients for whom a search is initiated, with higher rates among whites and lower rates among minorities and patients of mixed race. It takes, on average, 3–4 months to complete a search and schedule and initiate an unrelated donor transplant. With improvements in HLA typing and supportive care measures, survival following matched unrelated donor transplantation is essentially the same as that seen with HLA-matched siblings.

Allogeneic hematopoietic cell transplantation can be carried out across ABO blood barriers by removing isoagglutinins and/or incompatible red blood cells from the donor graft. However, depending on the direction of the mismatch, hemolysis of donor cells by persistent isoagglutinins in the host, or hemolysis of recipient red cells by isoagglutinins in the graft or developing from it may occur despite appropriate manipulation of the donor cell product.

Autologous transplantation involves the removal and storage of the patient's own stem cells with subsequent reinfusion after the patient receives high dose myeloablative therapy. Unlike allogeneic transplantation, there is no risk of GVHD or graft rejection with autologous transplantation. On the other hand, autologous transplantation lacks a graft-versus-tumor (GVT) effect, and the autologous stem cell product can be contaminated with tumor cells, which could lead to relapse. A variety of techniques have been developed to "purge" autologous products of tumor cells, but no prospective randomized trials have shown that any approach decreases relapse rates or improves disease-free or overall survival.

Bone marrow aspirated from the posterior and anterior iliac crests initially was the source of hematopoietic stem cells for transplantation. Typically, anywhere from 1.5 to 5×10^8 nucleated marrow cells per kilogram are collected for allogeneic transplantation. Several studies have found improved survival following both matched sibling and

unrelated transplantation by transplanting higher numbers of bone marrow cells.

Hematopoietic stem cells circulate in the peripheral blood but in very low concentrations. Following the administration of a myeloid growth factor such as granulocyte colony-stimulating factor (G-CSF) and during recovery from intensive chemotherapy, the concentration of hematopoietic progenitor cells in blood, as measured either by colony-forming units or expression of the CD34 antigen, increases markedly. This makes it possible to harvest adequate numbers of stem cells from the peripheral blood for transplantation. Donors are typically treated with 4 or 5 days of hematopoietic growth factor, following which stem cells are collected in one or two 4-h pheresis sessions. In the autologous setting, transplantation of $>2.5 \times 10^6$ CD34 cells per kilogram, a number that can be collected in most circumstances, leads to rapid and sustained engraftment in virtually all cases. In the 5–10% of patients who fail to mobilize enough CD34+ cells with growth factor alone, the addition of plerixafor, an antagonist of CXCR4, may be useful. Blocking CXCR4 allows more stem cells to escape the marrow. When compared to the use of autologous marrow, use of peripheral blood stem cells results in more rapid hematopoietic recovery. Although this more rapid recovery diminishes the morbidity rate of transplantation, no studies show improved survival.

In the setting of allogeneic transplantation, the use of growth factor–mobilized peripheral blood stem cells also results in faster engraftment than seen with marrow but at the cost of more chronic GVHD because of donor T-cell contamination. With matched sibling donors, the increased chronic GVHD is more than balanced by reductions in rates of relapse and nonrelapse mortality, resulting in improved overall survival. However, in the setting of matched unrelated donor transplantation, use of peripheral blood results in more chronic GVHD without a compensatory survival advantage. Nonetheless, because of ease of collection, peripheral blood continues to be the more commonly used source of stem cells.

Umbilical cord blood contains a high concentration of hematopoietic progenitor cells, allowing for its use as a source of stem cells for transplantation. Cord blood transplantation from family members has been used when the immediate need for transplantation precludes waiting the 9 or so months generally required for the baby to mature to the point of donating marrow. Use of cord blood results in slower peripheral count recovery than seen with marrow but a lower incidence of GVHD, perhaps reflecting the low number of T cells in cord blood. Multiple cord blood banks have been developed to harvest and store cord blood for possible transplantation to unrelated patients from material that would otherwise be discarded. Currently >800,000 units are cryopreserved and available for use. The advantages of unrelated cord blood are rapid availability and decreased immune reactivity allowing for the use of partially matched units, which is of particular importance for those without matched unrelated donors. The risks of graft failure and transplant-related mortality are related to the dose of cord blood cells per kilogram, which previously limited the application of single cord blood transplantation to pediatric and smaller adult patients. Subsequent trials have found that for patients without suitable single cord units, the use of double cord transplants diminishes the risk of graft failure and early mortality even though only one of the donors ultimately engrafts. Given the similar survival rates seen with cord blood, matched unrelated, and haploidentical family member donors, a source of allogeneic stem cells can now be found for almost every patient in need **(Table 119-1)**.

THE TRANSPLANT PREPARATIVE REGIMEN

The treatment regimen administered to patients immediately preceding transplantation is designed to eradicate the patient's underlying disease and, in the setting of allogeneic transplantation, immunosuppress the patient adequately to prevent rejection of the transplanted stem cells. The appropriate regimen therefore depends on the disease setting and graft source. For example, when transplantation is performed to treat severe combined immunodeficiency and the donor is a histocompatible sibling, no preparative regimen is needed because no host cells require eradication, and the patient is already too immune incompetent to reject the transplanted graft. For aplastic anemia, there is no large population of cells to eradicate, and high-dose cyclophosphamide plus antithymocyte globulin are sufficient to immunosuppress the patient adequately to accept the marrow graft. In the setting of thalassemia and sickle cell anemia, high-dose busulfan is frequently added to cyclophosphamide to eradicate hyperplastic host hematopoiesis. A variety of different regimens have been developed to treat malignant diseases. Most regimens include agents with high activity against the tumor in question at conventional doses and with myelosuppression as their predominant dose-limiting toxicity. Therefore, these regimens commonly include busulfan, cyclophosphamide, melphalan, thiotepa, carmustine, etoposide, and total-body irradiation in various combinations.

Although high-dose treatment regimens were the initial approach to transplantation for malignancies, the realization that much of the antitumor effect of transplantation derives from an immunologically mediated GVT response led investigators to ask if reduced-intensity conditioning regimens might be effective and more tolerable. Evidence for a GVT effect comes from studies showing that posttransplant relapse rates are lowest in patients who develop acute and chronic GVHD, higher in those without GVHD, and higher still in recipients of T cell–depleted allogeneic or syngeneic marrow. The demonstration that complete remissions can be obtained in many patients who have relapsed after transplant by simply administering viable lymphocytes from the original donor further strengthens the argument for a potent GVT effect. Accordingly, a variety of alternative regimens have been studied, ranging from nonmyeloablative, which are the very minimum required to achieve engraftment (e.g., fludarabine plus 200 cGy total-body irradiation) and would cause only transient myelosuppression if no transplant were performed, to so-called reduced-intensity regimens, which would cause significant but not necessarily fatal myelosuppression in the absence of transplantation (e.g., fludarabine plus melphalan). With the use of nonmyeloablative and reduced-intensity regimens, engraftment is readily achieved with less toxicity than seen with conventional transplantation. In general, relapse rates are higher following reduced-intensity conditioning, but transplant-related mortality is lower, favoring the use of reduced-intensity conditioning in older patients and those with significant comorbidities. High-dose regimens are favored in those felt able to tolerate the treatment, particularly if patients have any evidence of measurable disease at the time of transplantation.

THE TRANSPLANT PROCEDURE

Marrow is usually collected from the donor's posterior and sometimes anterior iliac crests, with the donor under general or spinal anesthesia. Typically, 10–15 mL/kg of marrow is aspirated, placed in heparinized media, and filtered through 0.3- and 0.2-mm screens to remove fat and bony spicules. The collected marrow may undergo further processing depending on the clinical situation, such as the removal of red cells to prevent hemolysis in ABO-incompatible transplants, the removal of donor T cells to prevent GVHD, or attempts to remove possible contaminating tumor cells in autologous transplantation. Marrow donation is safe, with only very rare complications reported.

Peripheral blood stem cells are collected by leukapheresis after the donor has been treated with hematopoietic growth factors or, in the setting of autologous transplantation, sometimes after treatment with a combination of chemotherapy and growth factors. Stem cells for transplantation are infused through a large-bore central venous

catheter. Such infusions are usually well tolerated, although occasionally patients develop fever, cough, or shortness of breath. These symptoms typically resolve with slowing of the infusion. When the stem cell product has been cryopreserved using dimethyl sulfoxide, patients sometimes experience short-lived nausea or vomiting due to the taste (and smell) of the cryoprotectant.

ENGRAFTMENT AND IMMUNE RECONSTITUTION

Peripheral blood counts reach their nadir several days to a week after transplant as a consequence of the preparative regimen; then cells produced by the transplanted stem cells begin to appear in the peripheral blood. The rate of recovery depends on the source of stem cells and use of posttransplant growth factors. If marrow is the source, recovery to 100 granulocytes/μL occurs on average by day 16 and to 500/μL by day 22. Use of G-CSF–mobilized peripheral blood stem cells speed the rate of recovery by ~1 week compared to marrow, whereas engraftment following cord blood transplantation is typically delayed by ~1 week. Use of a myeloid growth factor after transplant accelerates recovery by 3–5 days. Platelet counts usually recover shortly after granulocytes.

While granulocytes and other components of innate immunity recover rapidly after hematopoietic cell transplantation, adaptive immunity, which consists of cellular (T cell) and humoral (B cell) immunity, may take 1–2 years to fully recover. Survival and peripheral expansion of infused donor T cells is the dominant mechanism for T-cell recovery in the first months after hematopoietic cell transplantation and results in mostly CD8+ T cells with a limited repertoire. After several months, de novo generation of donor-derived CD4+ and CD8+ T cells becomes dominant, providing a more diverse T-cell repertoire. B-cell counts recover by 6 months after autologous hematopoietic cell transplantation and 9 months after allogeneic hematopoietic cell transplantation. In general, immune recovery occurs more rapidly after autologous than allogeneic hematopoietic cell transplantation and after receipt of unmodified grafts compared to the setting of in vivo or ex vivo T-cell depletion.

Following allogeneic transplantation, engraftment can be documented using fluorescence in situ hybridization of sex chromosomes if donor and recipient are sex-mismatched or by analysis of short tandem repeat polymorphisms after DNA amplification.

COMPLICATIONS FOLLOWING HEMATOPOIETIC CELL TRANSPLANTATION

Early Direct Chemoradiotoxicities The transplant preparative regimen may cause a spectrum of acute toxicities that vary according to the intensity of the regimen and the specific agents used but frequently include nausea, vomiting, and mild skin erythema (Fig. 119-1).

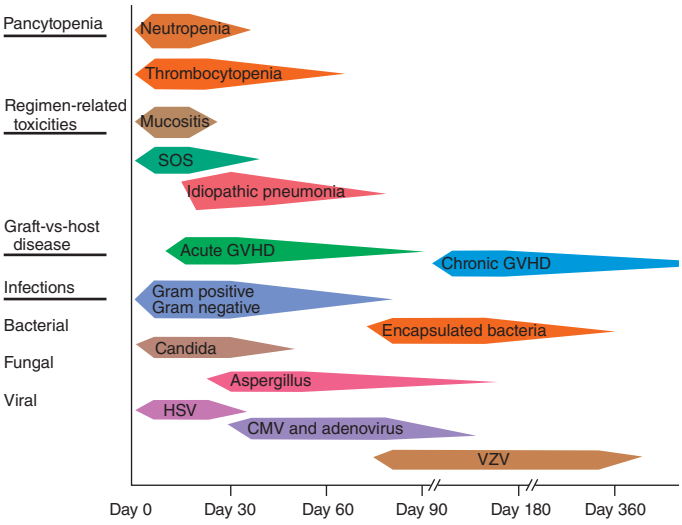

FIGURE 119-1 Major syndromes complicating marrow transplantation. CMV, cytomegalovirus; GVHD, graft-versus-host disease; HSV, herpes simplex virus; SOS, sinusoidal obstructive syndrome (formerly venoocclusive disease); VZV, varicella-zoster virus. The size of the shaded area roughly reflects the period of risk of the complication.

High-dose cyclophosphamide can result in hemorrhagic cystitis, which can usually be prevented by bladder irrigation or with the sulfhydryl compound mercaptoethanesulfonate (MESNA). Most high-dose preparative regimens will result in oral mucositis, which typically develops 5–7 days after transplant and often requires narcotic analgesia. Use of a patient-controlled analgesic pump provides the greatest patient satisfaction and results in a lower cumulative dose of narcotic. Keratinocyte growth factor (palifermin) can shorten the duration of mucositis by several days following autologous transplantation. Patients begin losing their hair 5–6 days after transplant and by 1 week are usually profoundly pancytopenic.

Depending on the intensity of the conditioning regimen, 3–10% of patients will develop sinusoidal obstruction syndrome (SOS) of the liver (formerly called venoocclusive disease), a syndrome that results from direct cytotoxic injury to hepatic-venular and sinusoidal endothelium, with subsequent deposition of fibrin and the development of a local hypercoagulable state. This chain of events leads to the clinical symptoms of tender hepatomegaly, ascites, jaundice, and fluid retention. These symptoms can develop any time during the first month after transplant, with the peak incidence at day 16. Predisposing factors include prior exposure to intensive chemotherapy, pretransplant hepatitis of any cause, and use of more intense conditioning regimens. The mortality rate of sinusoidal obstruction syndrome is ~30%, with progressive hepatic failure culminating in a terminal hepatorenal syndrome. Treatment of severe SOS with defibrotide, a polydeoxyribonucleotide, reduces mortality.

Although most pneumonias developing early after transplant are caused by infectious agents, in a small percentage of patients, a diffuse interstitial pneumonia will develop that is a result of direct toxicity of high-dose preparative regimens. Bronchoalveolar lavage usually shows alveolar hemorrhage, and biopsies are typically characterized by diffuse alveolar damage, although some cases may have a more clearly interstitial pattern. High-dose glucocorticoids or anti–tumor necrosis factor therapies are sometimes used as treatment, although randomized trials proving their utility have not been reported.

Transplant-associated thrombotic microangiopathy is seen in 5–10% of patients, appearing on average about 1 month after transplant. The syndrome is characterized by presence of schistocytes on peripheral smear, elevated lactate dehydrogenase, thrombocytopenia, and acute kidney injury and is the result of endothelial injury and complement activation. Since calcineurin and mTOR inhibitors are thought to contribute to the pathogenesis of the syndrome, changing immunosuppressive regimens is sometimes effective. Patients sometimes respond to eculizumab.

Late Direct Chemoradiotoxicities Two categories of chronic pulmonary disease occur in patients >3 months after hematopoietic cell transplantation. Cryptogenic organizing pneumonia is a restrictive lung disease characterized by dry cough, shortness of breath, and chest imaging showing a diffuse, fluffy infiltrate. Biopsy shows granulation tissue within alveolar spaces and small airways and no infectious agents. The disease responds well to corticosteroids and is entirely reversible. Bronchiolitis obliterans is an obstructive disease presenting with cough, progressive dyspnea, and radiologic evidence of air trapping. Pathology shows collagen and granulation tissue in and around bronchial structures and eventually obliteration of small airways. The disease is usually associated with chronic GVHD, and although it may respond to increasing immunosuppression, complete reversal is uncommon.

Other late complications of the preparative regimen include decreased growth velocity in children and delayed development of secondary sex characteristics. These complications can be partly ameliorated with the use of appropriate growth and sex hormone replacement. Most men become azoospermic, and most postpubertal women will develop ovarian failure, which should be treated. However, pregnancy is possible after transplantation, and patients should be counseled accordingly. Thyroid dysfunction, usually well compensated, is sometimes seen. Cataracts develop in 10–20% of patients and are most common in patients treated with total-body irradiation and

those who receive glucocorticoid therapy after transplant for treatment of GVHD. Aseptic necrosis of the femoral head is seen in 10% of patients and is particularly frequent following chronic glucocorticoid therapy. Both acute and late chemoradiotoxicities (except those due to glucocorticoids and other agents used to treat GVHD) are less frequent in recipients of reduced-intensity compared to high-dose preparative regimens.

Graft Failure Although complete and sustained engraftment is usually seen after transplant, occasionally marrow function either does not return or, after a brief period of engraftment, is lost. Graft failure after autologous transplantation can be the result of inadequate numbers of stem cells being transplanted, damage during ex vivo treatment or storage, or exposure of the patient to myelotoxic agents after transplant. Infections with cytomegalovirus (CMV) or human herpesvirus type 6 have also been associated with loss of marrow function. Graft failure after allogeneic transplantation can also be due to immunologic rejection of the graft by immunocompetent host cells. Such rejection is generally thought to be mostly T-cell–mediated, but the presence before hematopoietic cell transplantation of donor-specific HLA antibodies in the patient is associated with poor engraftment, leading to the recommendation for screening for donor-directed anti-HLA antibodies in recipients prior to transplant. Immunologically based graft rejection is more common following use of less immunosuppressive preparative regimens, in recipients of T-cell–depleted stem cell products, and in patients receiving grafts from HLA-mismatched donors or cord blood.

Treatment of graft failure involves removing all potentially myelotoxic agents from the patient's regimen and attempting a short trial of a myeloid growth factor. Persistence of lymphocytes of host origin in allogeneic transplant recipients with graft failure indicates immunologic rejection. Reinfusion of donor stem cells in such patients is usually unsuccessful unless preceded by a second immunosuppressive preparative regimen. Standard high-dose preparative regimens are tolerated poorly if administered within 100 days of a first transplant because of cumulative toxicities. However, reduced-intensity conditioning regimens have been effective in some cases.

Graft-Versus-Host Disease Acute GVHD occurs within the first 3 months after allogeneic transplant with a peak onset around 4 weeks and is characterized by an erythematous maculopapular rash; by persistent anorexia or diarrhea, or both; and by liver disease with increased serum levels of bilirubin, alanine and aspartate aminotransferase, and alkaline phosphatase. Because many conditions can mimic acute GVHD, the diagnosis usually requires skin, liver, or endoscopic biopsy for confirmation. In all these organs, endothelial damage and lymphocytic infiltrates are seen. In skin, the epidermis and hair follicles are damaged; in liver, the small bile ducts show segmental disruption; and in intestines, destruction of the crypts and mucosal ulceration may be noted. A commonly used rating system for acute GVHD is shown in Table 119-2. Grade I acute GVHD is of little clinical significance, does not affect the likelihood of survival, and does not require treatment. In contrast, grades II to IV GVHD are associated with significant symptoms and a poorer probability of survival and require aggressive therapy. The incidence of acute GVHD is higher in recipients of stem cells from mismatched or unrelated donors, in older patients, and in patients unable to receive full doses of drugs used to prevent the disease.

Historically, the standard approach to GVHD prevention was the administration of a calcineurin inhibitor (cyclosporine or tacrolimus) paired with an antimetabolite (most commonly methotrexate) following transplantation. Prospective randomized trials have demonstrated the benefit of adding a third drug, either mycophenolate mofetil, abatacept, or posttransplant cyclophosphamide, to the two-drug regimen. Other approaches include the addition of anti–T-cell immune globulin (ATG) to the GVHD prophylactic regimen or the removal of subsets or all T cells from the stem cell inoculum.

Despite prophylaxis, significant acute GVHD will develop in ~30% of recipients of stem cells from matched siblings. Factors associated with a greater risk of acute GVHD include HLA-mismatching between recipient and donor, patient and donor age, use of more intense preparative regimens, and use of multiparous women as donors. Presumably, multiparous women have more alloreactivity based on carriage of genetically disparate fetuses. Disruption of the intestinal microbiota leading to loss of diversity and overgrowth by a single taxon is associated with a higher risk of GVHD and transplant-associated mortality. Biomarkers, including ST2, REG32, and TNF R1, have been identified that predict the severity of acute GVHD. The disease is usually treated with prednisone at a daily dose of 1–2 mg/kg. Patients in whom the acute GVHD fails to respond to prednisone sometimes respond to the oral JAK2 inhibitor ruxolitinib.

Chronic GVHD occurs most commonly between 3 months and 2 years after allogeneic transplant, developing in 20–50% of recipients. The disease is more common in older patients, with the use of peripheral blood rather than marrow as the stem cell source, in recipients of mismatched or unrelated stem cells, and in those with a preceding episode of acute GVHD. The disease resembles an autoimmune disorder with malar rash, sicca syndrome, arthritis, obliterative bronchiolitis, and bile duct degeneration with cholestasis. Mild chronic GVHD can sometimes be managed using local therapies (topical glucocorticoids to skin and cyclosporine eye drops). More severe disease requires systemic therapy usually with prednisone, which leads to responses in 40–60% of patients. Three drugs have received U.S. Food and Drug Administration approval for the treatment of steroid-resistant chronic GVHD: ibrutinib, ruxolitinib, and belumosudil. All three are kinase inhibitors, a class of compounds that reduces growth signals and activation of key cellular proteins involved with cell activation, migration, and proliferation. Mortality rates from chronic GVHD average around 15% but range from 5 to 50% depending on severity. In most patients, chronic GVHD resolves, but it may require 1–3 years of immunosuppressive treatment before these agents can be withdrawn without the disease recurring. Because patients with chronic GVHD are susceptible to significant infection, they should receive prophylactic trimethoprim-sulfamethoxazole, and all suspected infections should be investigated and treated aggressively.

Although onset before or after 3 months after transplant is often used to discriminate between acute and chronic GVHD, occasional

TABLE 119-2 Clinical Staging and Grading of Acute Graft-Versus-Host Disease

CLINICAL STAGE	SKIN	LIVER—BILIRUBIN, λmol/L (mg/dL)	GUT
1	Rash <25% body surface	34–51 (2–3)	Diarrhea 500–1000 mL/d
2	Rash 25–50% body surface	51–103 (3–6)	Diarrhea 1000–1500 mL/d
3	Generalized erythroderma	103–257 (6–15)	Diarrhea >1500 mL/d
4	Desquamation and bullae	>257 (>15)	Ileus
OVERALL CLINICAL GRADE	**SKIN STAGE**	**LIVER STAGE**	**GUT STAGE**
I	1–2	0	0
II	1–3	1	1
III	1–3	2–3	2–3
IV	2–4	2–4	2–4

patients will develop signs and symptoms of acute GVHD after 3 months (late-onset acute GVHD), whereas others will exhibit signs and symptoms of both acute and chronic GVHD (overlap syndrome). No data suggest that these patients should be treated differently than those with classic acute or chronic GVHD.

From 3 to 5% of patients will develop an autoimmune disorder following allogeneic hematopoietic cell transplantation, most commonly autoimmune hemolytic anemia or idiopathic thrombocytopenic purpura. Unrelated donor source and chronic GVHD are risk factors, but autoimmune disorders have been reported in patients with no obvious GVHD. Treatment is with prednisone, cyclosporine, or rituximab.

Infection Posttransplant patients, particularly recipients of allogeneic transplantation, require unique approaches to the problem of infection. Early after transplantation, patients are profoundly neutropenic, and because the risk of bacterial infection is so great, most centers place patients on broad-spectrum antibiotics once the granulocyte count falls to <500/μL. Prophylaxis against fungal infections reduces rates of infection and improves overall survival. Fluconazole is often used for patients with standard risk, while prophylaxis with mold active agents (voriconazole, posaconazole, or isavuconazonium) should be considered for patients at higher risk, such as those with a prior fungal infection. Patients seropositive for herpes simplex should receive acyclovir or valacyclovir prophylaxis. One approach to infection prophylaxis is shown in **Table 119-3**. Despite these prophylactic measures, most patients will develop fever and signs of infection after transplant. The management of patients who become febrile despite bacterial and fungal prophylaxis is a difficult challenge and is guided by individual aspects of the patient and by the institution's experience.

The general problem of infection in the immunocompromised host is discussed in **Chap. 148**.

Once patients engraft, the incidence of bacterial infection diminishes; however, patients, particularly allogeneic transplant recipients, remain at significant risk of infection. During the period from engraftment until about 3 months after transplant, the most common causes of infection are gram-positive bacteria, fungi (particularly *Aspergillus*), and viruses including CMV. CMV disease, which in the past was frequently seen and often fatal, can be prevented in seronegative patients transplanted from seronegative donors using either seronegative blood products or products from which the white blood cells have been removed. In seropositive patients or patients transplanted from seropositive donors, either prophylaxis or preemptive therapy is used. Letermovir administered over the first 3 months after transplant is effective as prophylaxis. An alternative approach is to monitor blood of patients after transplant using polymerase chain reaction assays for viral DNA and to treat reactivation preemptively with ganciclovir before clinical disease develops. Foscarnet is effective for some patients who develop CMV antigenemia or infection despite the use of ganciclovir or who cannot tolerate the drug, but it can be associated with severe electrolyte wasting.

TABLE 119-3 Approach to Infection Prophylaxis in Allogeneic Transplant Recipients

ORGANISM	AGENT	APPROACH
Bacterial	Levofloxacin	750 mg PO or IV daily
Fungal	Fluconazole	400 mg PO qd to day 75 posttransplant
Pneumocystis jirovecii	Trimethoprim-sulfamethoxazole	1 double-strength tablet PO bid 2 days/week until day 180 or off immunosuppression
Viral		
Herpes simplex	Acyclovir	800 mg PO bid to day 30
Varicella-zoster	Acyclovir	800 mg PO bid to day 365
Cytomegalovirus	Ganciclovir	5 mg/kg IV bid for 7 days, then 5 (mg/kg)/d 5 days/week to day 100

Pneumocystis jirovecii pneumonia, once seen in 5–10% of patients, can be prevented by treating patients with oral trimethoprim-sulfamethoxazole for 1 week before transplant and resuming the treatment once patients engraft.

Respiratory viruses that cause community-acquired infections, including respiratory syncytial virus (RSV), parainfluenza virus, influenza virus, and metapneumovirus, can be life threatening or fatal in the posttransplant patient. Protection of patients from infected visitors and staff by avoiding such contacts is critical. Neuraminidase inhibitors are effective for influenza infections. Oral or inhaled ribavirin is sometimes used for RSV.

The risk of infection diminishes considerably beyond 3 months after transplant unless chronic GVHD requiring continuous immunosuppression develops. Most transplant centers recommend continuing trimethoprim-sulfamethoxazole prophylaxis while patients are receiving any immunosuppressive drugs and also recommend careful monitoring for late CMV reactivation. In addition, many centers recommend prophylaxis against varicella-zoster, using acyclovir for 1 year after transplant. Antibody titers to vaccine-preventable diseases (e.g., tetanus, polio, mumps, rubella, and encapsulated organisms) decline after allogeneic or autologous transplantation if the recipient is not revaccinated. Vaccination begins at 3 months after transplantation for SAR-CoV-2 and 6 months for influenza (or 3–4 months when seasonal prevalence is high). Other nonlive routine childhood vaccinations should be repeated, usually starting at 12 months after transplantation. Live vaccines (measles, mumps, and rubella [MMR] or MMR plus varicella [MMR-V]) are generally not administered before 2 years after hematopoietic cell transplantation.

TREATMENT

Nonmalignant Diseases

Evidence-based indications for hematopoietic cell transplantation have been published by several organizations and are guided not only by disease-related factors but also by patient comorbidities, socioeconomic issues, caregiver and donor availability, and patient preference.

IMMUNODEFICIENCY DISORDERS

By replacing abnormal stem cells with cells from a normal donor, hematopoietic cell transplantation can cure patients of a variety of immunodeficiency disorders including severe combined immunodeficiency, Wiskott-Aldrich syndrome, and Chédiak-Higashi syndrome. The widest experience is with severe combined immunodeficiency disease, where cure rates of >90% can be expected with allogeneic transplantation from a suitable related or unrelated donor when carried out shortly after birth **(Table 119-4)**. Treatment of severe refractory autoimmune diseases with hematopoietic stem cell transplantation is also beginning to be explored (see below).

APLASTIC ANEMIA

Transplantation from matched siblings after a preparative regimen of high-dose cyclophosphamide and antithymocyte globulin cures >95% of patients age <40 years with severe aplastic anemia. Historically, results in older patients and in recipients of mismatched family member or unrelated marrow were less favorable, and therefore, a trial of immunosuppressive therapy was recommended for such patients before considering transplantation. However, results with transplantation have improved leading many to recommend transplantation as initial therapy. Transplantation is effective in all forms of aplastic anemia including, for example, the syndromes associated with paroxysmal nocturnal hemoglobinuria and Fanconi's anemia. Patients with Fanconi's anemia are abnormally sensitive to the toxic effects of alkylating agents, and so less intensive preparative regimens are used in their treatment **(Chap. 107)**.

HEMOGLOBINOPATHIES

Marrow transplantation from an HLA-identical sibling following a preparative regimen of busulfan and cyclophosphamide can cure

Abbreviations: ID, insufficient data; NA, not applicable.

80–90% of patients with thalassemia major. The best outcomes can be expected if patients are transplanted before they develop hepatomegaly or portal fibrosis and if they have been given adequate iron chelation therapy. Among such patients, the probabilities of 5-year survival and disease-free survival are 95 and 90%, respectively. Although prolonged survival can be achieved with aggressive chelation therapy, transplantation is the only curative treatment for thalassemia. Transplantation is potentially curative for patients with sickle cell anemia. Two-year survival and disease-free survival rates of 95 and 85%, respectively, have been reported following matched sibling or cord blood transplantation. Decisions about patient selection and the timing of transplantation remain difficult, but transplantation is a reasonable option for children and young adults who have suffered complications of sickle cell anemia including stroke, recurrent vasoocclusive pain, sickle cell lung disease, or sickle nephropathy **(Chap. 103)**. As new gene therapies become available, the indications for allogeneic hematopoietic cell transplantation for thalassemia and sickle cell disease may change.

OTHER NONMALIGNANT DISEASES

Theoretically, hematopoietic cell transplantation should be able to cure any disease that results from an inborn error of the lymphohematopoietic system. Transplantation has been used successfully to treat congenital disorders of white blood cells such as Kostmann's syndrome, chronic granulomatous disease, and leukocyte adhesion deficiency. Congenital anemias such as Blackfan-Diamond anemia can also be cured with transplantation. Since the penetrance of some congenital marrow failure states is variable, potential family member donors should be carefully screened before use to assure they are not affected. Infantile malignant osteopetrosis is due to an inability of the osteoclast to resorb bone, and because osteoclasts derive from the marrow, transplantation can cure this rare inherited disorder.

Hematopoietic cell transplantation has been used as treatment for several storage diseases caused by enzymatic deficiencies, such as Gaucher's disease, Hurler's syndrome, Hunter's syndrome, and infantile metachromatic leukodystrophy. Transplantation for these diseases has not been uniformly successful, but treatment early in the course of these diseases, before irreversible damage to extramedullary organs has occurred, increases the chance for success.

Transplantation is being applied as a treatment for severe acquired autoimmune disorders. These approaches are based on studies demonstrating that transplantation can reverse autoimmune disorders in animal models and on the observation that occasional patients with coexisting autoimmune disorders and hematologic malignancies have been cured of both with transplantation. A prospective randomized trial found that patients with severe scleroderma have improved event-free and overall survival if treated with hematopoietic cell transplantation. Randomized studies are exploring a similar approach for patients with multiple sclerosis.

ACUTE LEUKEMIA

Allogeneic hematopoietic cell transplantation cures ~30% of patients who do not achieve a complete response after induction chemotherapy for acute myeloid leukemia (AML) and is the only form of therapy that can cure such patients. Thus, all patients with AML who are possible transplant candidates should have their HLA type determined soon after diagnosis to enable hematopoietic cell transplantation for those who fail to enter remission. Cure rates of 45–50% are seen when patients are transplanted in second remission or in first relapse. The best results with allogeneic transplantation are achieved when applied during first remission, with long-term disease-free survival rates averaging 55–60%. Meta-analyses of studies comparing matched related donor transplantation to chemotherapy for adult AML patients age <60 years show a survival advantage with transplantation. This advantage is greatest for those with adverse and intermediate-risk disease but is not seen in patients with favorable-risk AML. Some centers rely on measurements of minimal residual disease (MRD) as determined by either multidimensional flow cytometry or molecular methods to further define transplant candidacy, proceeding with transplantation in otherwise favorable risk patients if MRD positive and withholding transplantation in MRD-negative intermediate-risk patients. While hematopoietic cell transplantation can be performed in patients up to age 80, prospective trials comparing hematopoietic cell transplantation with chemotherapy are lacking for older patients. Autologous transplantation has no defined role in the treatment of AML.

Similar to patients with AML, adults with acute lymphocytic leukemia who do not achieve a complete response to induction chemotherapy can be cured in ~30% of cases with immediate transplantation. Cure rates improve to 40–50% in second remission, and therefore, transplantation can be recommended for adults who have persistent disease after induction chemotherapy or who subsequently relapse. Transplant outcomes in second remission are improved if carried out when MRD assessments are negative, and so use of agents such as blinatumomab to achieve an MRD-negative state before transplantation is recommended. Transplantation in first remission results in cure rates of about 65%. Transplantation appears to offer a survival advantage over chemotherapy for patients with high-risk disease as defined by molecular profiling. Debate continues about whether adults with standard-risk disease should be transplanted in first remission or whether transplantation should be reserved until relapse. Autologous transplantation is associated with a higher relapse rate but a somewhat lower risk of nonrelapse mortality when compared to allogeneic transplantation. Autologous transplantation has no obvious role in treatment for acute lymphocytic leukemia in first remission, and for second-remission patients, most experts recommend use of allogeneic stem cells if an appropriate donor is available.

CHRONIC LEUKEMIA

Allogeneic hematopoietic cell transplantation is indicated for patients with chronic myeloid leukemia (CML) who are in chronic phase but have failed therapy with two or more tyrosine kinase inhibitors. In such patients, cure rates of 70% can be expected.

Hematopoietic cell transplantation is also recommended for patients with CML who present or progress to accelerated phase or blast crisis, although lower cure rates are seen in such patients **(Chap. 110)**.

Although allogeneic transplantation can cure patients with chronic lymphocytic leukemia (CLL), it has not been extensively studied because of the chronic nature of the disease, the age profile of patients, and more recently, the availability of multiple effective therapies. In those cases where it was studied, complete remissions were achieved in the majority of patients, with disease-free survival rates of ~65% at 3 years, despite the advanced stage of the disease at the time of transplant.

MYELODYSPLASIA AND MYELOPROLIFERATIVE DISORDERS

Between 40 and 65% of patients with myelodysplasia can be cured with allogeneic transplantation. Results are better among younger patients and those with less advanced disease. However, patients with early-stage myelodysplasia can live for extended periods without intervention, and so transplantation is generally reserved for patients with an International Prognostic Scoring System (IPSS) score of Int-2 or higher, or for selected patients with an IPSS score of Int-1 who have other poor prognostic features **(Chap. 107)**. Allogeneic hematopoietic cell transplantation can cure patients with primary myelofibrosis or myelofibrosis secondary to polycythemia vera or essential thrombocythemia, with 5-year progression-free survival rates in excess of 65% being reported. It may require many months for the fibrosis to resolve.

LYMPHOMA

Patients with disseminated intermediate- or high-grade non-Hodgkin's lymphoma who have not been cured by first-line chemotherapy and are transplanted in first relapse or second remission can still be cured in 50–60% of cases. This represents a clear advantage over results obtained with conventional-dose salvage chemotherapy. It is unsettled whether patients with high-risk disease benefit from transplantation in first remission. Most experts favor the use of autologous rather than allogeneic transplantation for patients with intermediate- or high-grade non-Hodgkin's lymphoma, because fewer complications occur with this approach and survival appears equivalent. The use of chimeric antigen receptor T cells targeting CD19 has been reported to yield results similar to those achieved with autologous stem cell transplantation. As yet, no consensus has been reached about how to sequence these two therapies. Although autologous transplantation results in high response rates in patients with recurrent disseminated indolent non-Hodgkin's lymphoma, the availability of newer agents for this category of patient leaves the role of transplantation unsettled. Reduced-intensity conditioning regimens followed by allogeneic transplantation result in high rates of complete and enduring complete responses in patients with recurrent indolent lymphomas.

The role of transplantation in Hodgkin's lymphoma is similar to that in intermediate- and high-grade non-Hodgkin's lymphoma. With transplantation, 3-year disease-free survival is 40–50% in patients who never achieved a first remission with standard chemotherapy and up to 80% for those transplanted in second remission. Transplantation has no defined role in first remission in Hodgkin's lymphoma.

MYELOMA

Patients with myeloma whose disease progresses after first-line therapy can sometimes benefit from allogeneic or autologous transplantation. Prospective randomized studies demonstrate that the inclusion of autologous transplantation as part of initial therapy results in improved disease-free survival and overall survival. Further benefit is seen with the use of lenalidomide maintenance therapy following transplantation. The use of autologous transplantation followed by nonmyeloablative allogeneic transplantation has yielded mixed results.

SOLID TUMORS

Patients with testicular cancer in whom first-line platinum-containing chemotherapy has failed can still be cured in ~50% of cases if treated with high-dose chemotherapy with autologous stem cell support, an outcome better than that seen with low-dose salvage chemotherapy. The use of high-dose chemotherapy with autologous stem cell support is being studied for several other solid tumors, including neuroblastoma and pediatric sarcomas. As in most other settings, the best results were obtained in patients with limited amounts of disease and in whom the remaining tumor remains sensitive to conventional-dose chemotherapy. Few randomized trials of transplantation in these diseases have been completed.

POSTTRANSPLANT RELAPSE

Patients who relapse following autologous transplantation sometimes respond to further chemotherapy and may be candidates for possible allogeneic transplantation, particularly if the remission following the initial autologous transplant was long. Several options are available for patients who relapse following allogeneic transplantation. Treatment with infusions of unirradiated donor lymphocytes results in complete responses in as many as 75% of patients with chronic myeloid leukemia, 40% with myelodysplasia, 25% with AML, and 15% with myeloma. Major complications of donor lymphocyte infusions include transient myelosuppression and the development of GVHD. These complications depend on the number of donor lymphocytes given and the schedule of infusions, with less GVHD seen with lower dose, fractionated schedules.

120 Disorders of Platelets and Vessel Wall

Barbara A. Konkle

Hemostasis is a dynamic process in which the platelet and the blood vessel wall play key roles. Platelets are activated upon adhesion to von Willebrand factor (VWF) and collagen in the exposed subendothelium after injury. Platelet activation is also mediated through shear forces imposed by blood flow itself, particularly in areas where the vessel wall is diseased, and is also affected by the inflammatory state of the endothelium. The activated platelet surface provides the major physiologic site for coagulation factor activation, which results in further platelet activation and fibrin formation. Genetic and acquired influences on the platelet and vessel wall, as well as on the coagulation and fibrinolytic systems, determine whether normal hemostasis or bleeding or clotting symptoms will result.

THE PLATELET

Platelets are released from the megakaryocyte, likely under the influence of flow in the capillary sinuses. The normal blood platelet count is 150,000–450,000/μL. The major regulator of platelet production is the hormone thrombopoietin (TPO), which is synthesized in the liver and other organs. Synthesis is increased with inflammation and specifically by interleukin 6. TPO binds to its receptor on platelets and megakaryocytes, by which it is removed from the circulation. Thus, a reduction in platelet and megakaryocyte mass increases the level of TPO, which then stimulates platelet production. Platelets circulate with an average life span of 7–10 days. Approximately one-third of the platelets reside in the spleen, and this number increases in proportion to splenic size, although the platelet count rarely decreases to <40,000/μL as the spleen enlarges. Platelets are physiologically very active, but are anucleate, and thus have limited capacity to synthesize new proteins.

Normal vascular endothelium contributes to preventing thrombosis by inhibiting platelet function (Chap. 69). When vascular endothelium is injured, these inhibitory effects are overcome, and platelets adhere to the exposed intimal surface primarily through VWF, a large multimeric protein present in both plasma and in the extracellular matrix of the subendothelial vessel wall. Platelet adhesion results in the generation of intracellular signals that lead to activation of the platelet glycoprotein (Gp) IIb/IIIa ($\alpha_{IIb}\beta_3$) receptor and resultant platelet aggregation.

Activated platelets undergo release of their granule contents, which include nucleotides, adhesive proteins, growth factors, and procoagulants that serve to promote platelet aggregation and blood clot formation and influence the environment of the forming clot. During platelet aggregation, additional platelets are recruited to the site of injury, leading to the formation of an occlusive platelet thrombus. The platelet plug is stabilized by the fibrin mesh that develops simultaneously as the product of the coagulation cascade.

THE VESSEL WALL

Endothelial cells line the surface of the entire circulatory tree, totaling $1–6 \times 10^{13}$ cells, enough to cover a surface area equivalent to about six tennis courts. The endothelium is physiologically active, controlling vascular permeability, flow of biologically active molecules and nutrients, blood cell interactions with the vessel wall, the inflammatory response, and angiogenesis.

The endothelium normally presents an antithrombotic surface (Chap. 69) but rapidly becomes prothrombotic when stimulated, which promotes coagulation, inhibits fibrinolysis, and activates platelets. In many cases, endothelium-derived vasodilators are also platelet inhibitors (e.g., nitric oxide), and conversely, endothelium-derived vasoconstrictors (e.g., endothelin) can also be platelet activators. The net effect of vasodilation and inhibition of platelet function is to promote blood fluidity, whereas the net effect of vasoconstriction and platelet activation is to promote thrombosis. Thus, blood fluidity and hemostasis are regulated by the balance of antithrombotic/prothrombotic and vasodilatory/vasoconstrictor properties of endothelial cells.

DISORDERS OF PLATELETS

THROMBOCYTOPENIA

Thrombocytopenia results from one or more of three processes: (1) decreased bone marrow production; (2) sequestration, usually in an enlarged spleen; and/or (3) increased platelet destruction. Disorders of production may be either inherited or acquired. In evaluating a patient with thrombocytopenia, a key step is to review the peripheral blood smear and to first rule out "pseudothrombocytopenia," particularly in a patient without an apparent cause for the thrombocytopenia. Pseudothrombocytopenia (Fig. 120-1*B*) is an in vitro artifact resulting from platelet agglutination via antibodies (usually IgG, but also IgM and IgA) when the calcium content is decreased by blood collection in ethylenediamine tetraacetic (EDTA) (the anticoagulant present in tubes [purple top] used to collect blood for complete blood counts [CBCs]). If a low platelet count is obtained in EDTA-anticoagulated blood, a blood smear should be evaluated and a platelet count determined in blood collected into sodium citrate (blue top tube) or heparin (green top tube), or a smear of freshly obtained unanticoagulated blood, such as from a finger stick, can be examined.

APPROACH TO THE PATIENT

Thrombocytopenia

The history and physical examination, results of the CBC, and review of the peripheral blood smear are all critical components in the initial evaluation of thrombocytopenic patients (Fig. 120-2). The overall health of the patient and whether they are receiving drug treatment will influence the differential diagnosis. A healthy young adult with thrombocytopenia will have a much more limited differential diagnosis than an ill hospitalized patient who is receiving multiple medications. Except in less common inherited disorders, decreased platelet production usually results from bone marrow disorders that also affect red blood cell (RBC) and/or white blood cell (WBC) production. Because myelodysplasia can present with isolated thrombocytopenia, the bone marrow should be examined in patients presenting with isolated thrombocytopenia who are older than 60 years of age or who do not respond to initial therapy. While inherited thrombocytopenia is uncommon, any prior platelet counts should be retrieved and a family history regarding thrombocytopenia obtained. A careful history of drug ingestion should be obtained, including nonprescription and herbal remedies, because drugs are the most common cause of thrombocytopenia.

The physical examination can document an enlarged spleen, evidence of chronic liver disease, and other underlying disorders. Mild to moderate splenomegaly may be difficult to appreciate in many individuals due to body habitus and/or obesity but can be easily assessed by abdominal ultrasound. A platelet count of approximately 5000–10,000 is required to maintain vascular integrity in the microcirculation. When the count is markedly decreased, petechiae first appear in areas of increased venous pressure, the ankles and feet in an ambulatory patient. Petechiae are pinpoint, nonblanching hemorrhages and are usually a sign of a decreased platelet number and not platelet dysfunction. Wet purpura, blood blisters that form on the oral mucosa, are thought to denote an increased risk of life-threatening hemorrhage in the thrombocytopenic patient. Excessive bruising is seen in disorders of both platelet number and function.

Infection-Induced Thrombocytopenia Many viral and bacterial infections result in thrombocytopenia and are the most common

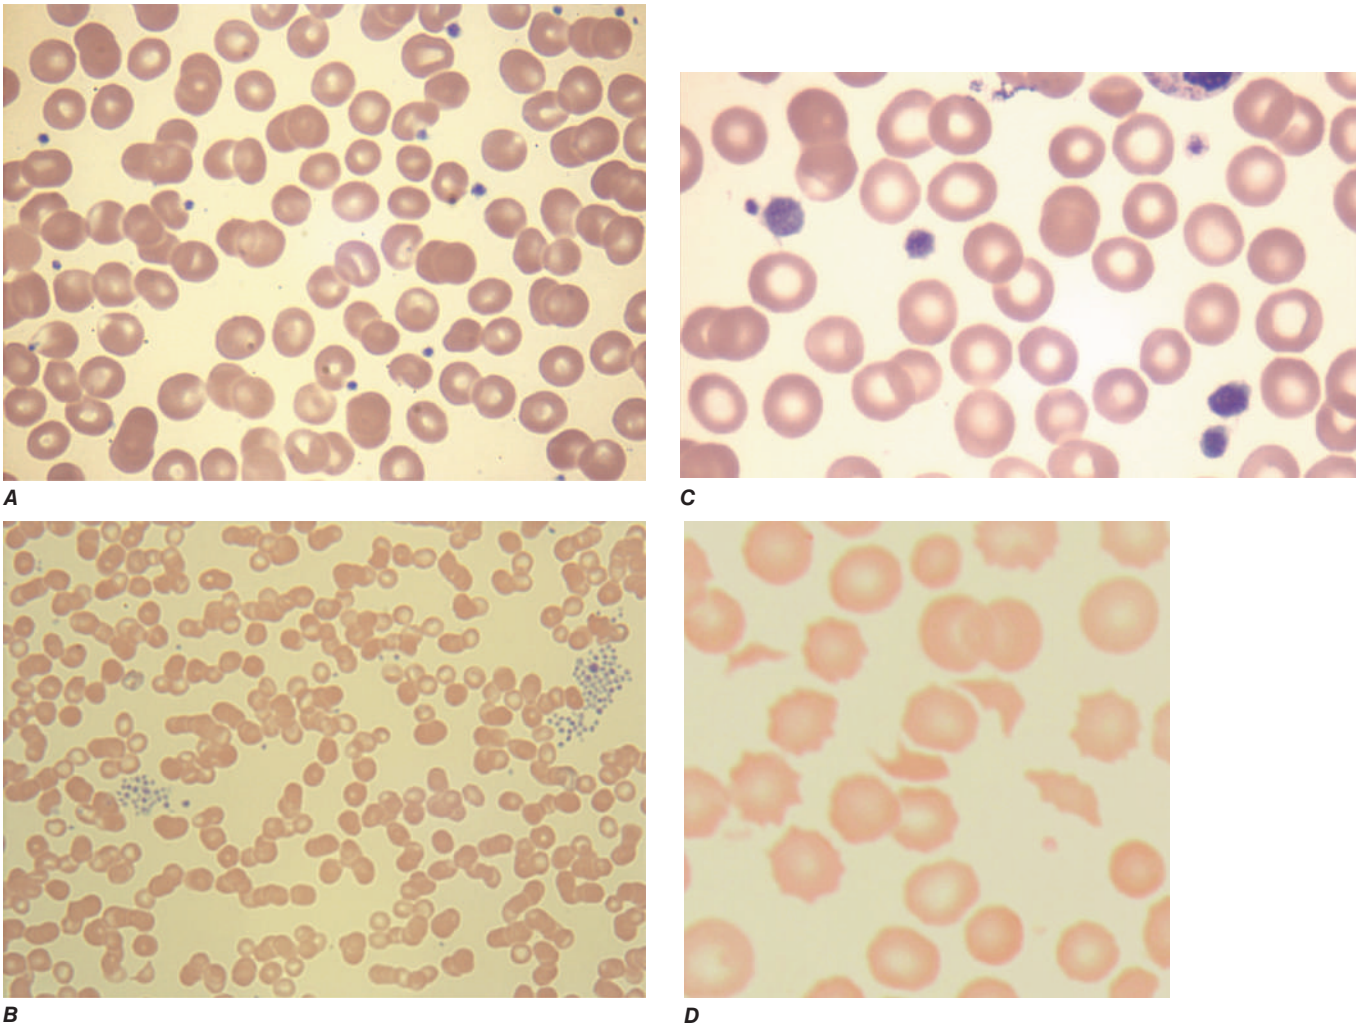

FIGURE 120-1 Photomicrographs of peripheral blood smears. ***A.*** Normal peripheral blood. ***B.*** Platelet clumping in pseudothrombocytopenia. ***C.*** Abnormal large platelet in autosomal dominant macrothrombocytopenia. ***D.*** Schistocytes and decreased platelets in microangiopathic hemolytic anemia.

noniatrogenic cause of thrombocytopenia. This may or may not be associated with laboratory evidence of disseminated intravascular coagulation (DIC), which is most commonly seen in patients with systemic infections with gram-negative bacteria and is seen in patients ill with COVID-19. Infections can affect both platelet production and platelet survival. In addition, immune mechanisms can be at work, as in infectious mononucleosis and early HIV infection. Late in HIV infection, pancytopenia and decreased and dysplastic platelet production are more common. Immune-mediated thrombocytopenia in children usually follows a viral infection and almost always resolves spontaneously. This association of infection with immune thrombocytopenic purpura is less clear in adults.

Drug-Induced Thrombocytopenia Many drugs have been associated with thrombocytopenia. A predictable decrease in platelet count occurs after treatment with many chemotherapeutic drugs due to bone marrow suppression (Chap. 78). Drugs that cause isolated thrombocytopenia and have been confirmed with positive laboratory testing are listed in Table 120-1, but all drugs should be suspect in a patient with thrombocytopenia without an apparent cause and should be stopped, or substituted, if possible. Although not as well studied, herbal and over-the-counter preparations may also result in thrombocytopenia and should be discontinued in patients who are thrombocytopenic.

Classic drug-dependent antibodies are antibodies that react with specific platelet surface antigens and result in thrombocytopenia only when the drug is present. Many drugs are capable of inducing these antibodies, but for some reason, they are more common with quinine and sulfonamides. Drug-dependent antibody binding can be demonstrated by laboratory assays, showing antibody binding in the presence

TABLE 120-1 Drugs Reported as Definitely or Probably Causing Isolated Thrombocytopenia[a]

Abciximab	Mirtazapine
Acetaminophen	Naproxen
Amiodarone	Oxaliplatin
Amlodipine	Penicillin
Ampicillin	Phenytoin
Carbamazepine	Piperacillin
Ceftriaxone	Quinidine
Cephamandole	Quinine
Ciprofloxacin	Ranitidine
Diazepam	Rosiglitazone
Eptifibatide	Roxifiban
Furosemide	Sulfisoxazole
Gold	Suramin
Haloperidol	Tirofiban
Heparin	Tranilast
Ibuprofen	Trimethoprim/sulfamethoxazole
Lorazepam	Vancomycin

[a]Based on scoring requiring a compatible clinical picture and positive laboratory testing. Note, this is not inclusive of newer medications.

of, but not without, the drug present in the assay. The thrombocytopenia typically occurs after a period of initial exposure (median length 21 days), or upon reexposure, and usually resolves in 7–10 days after drug withdrawal. The thrombocytopenia caused by the platelet Gp IIb/IIIa inhibitory drugs, such as abciximab, differs in that it may occur within 24 h of initial exposure. This appears to be due to the presence of naturally occurring antibodies that cross-react with the drug bound to the platelet.

Heparin-Induced Thrombocytopenia Drug-induced thrombocytopenia due to heparin differs from that seen with other drugs in two major ways. (1) The thrombocytopenia is not usually severe, with nadir counts rarely <20,000/μL. (2) Heparin-induced thrombocytopenia (HIT) is not associated with bleeding and, in fact, markedly increases the risk of thrombosis. The pathogenesis of HIT is complex. It results from antibody formation to a complex of the platelet-specific protein platelet factor 4 (PF4) and heparin or other glycosaminoglycans. The anti-heparin/PF4 antibody can activate platelets through the FcγRIIa receptor and also activate monocytes, endothelial cells, and coagulation proteins. Many patients exposed to heparin develop antibodies to heparin/PF4 but do not appear to have adverse consequences. A fraction of those who develop antibodies will develop HIT, and a portion of those (up to 50%) will develop thrombosis (HITT).

HIT can occur after exposure to low-molecular-weight heparin (LMWH) as well as unfractionated heparin (UFH), although it is more common with the latter. Most patients develop HIT after exposure to heparin for 5–14 days **(Fig. 120-3)**. It occurs before 5 days in those who were exposed to heparin in the prior few weeks or months (<~100 days) and have circulating anti-heparin/PF4 antibodies. Rarely, thrombocytopenia and thrombosis begin several days after all heparin has been stopped (termed *delayed-onset HIT*), and more rarely, spontaneous HIT, or autoimmune HIT syndrome, occurs where there is no history of heparin exposure. A syndrome similar to spontaneous HIT has been described rarely after COVID-19 vaccination with the adenovirus-based ChAdOx1-S/nCoV-19 vaccine and termed *vaccine-induced immune thrombocytopenia and thrombosis* (VITT). Even more rarely, a similar thrombotic syndrome can follow an adenovirus infection. then go to the 4Ts. The "4Ts" are recommended to be used in a diagnostic algorithm for HIT: *t*hrombocytopenia, *t*iming of platelet count drop, *t*hrombosis and other sequelae such as localized skin reactions, and o*t*her causes of thrombocytopenia not evident. Application of the 4T scoring system is very useful in excluding a diagnosis of HIT but will result in overdiagnosis of HIT in situations where thrombocytopenia and thrombosis due to other etiologies are common, such as in the intensive care unit.

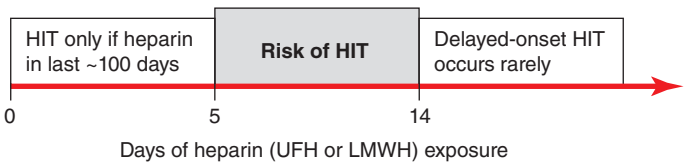

FIGURE 120-3 Time course of heparin-induced thrombocytopenia (HIT) development after heparin exposure. The timing of development after heparin exposure is a critical factor in determining the likelihood of HIT in a patient. HIT occurs early after heparin exposure in the presence of preexisting heparin/platelet factor 4 (PF4) antibodies, which disappear from circulation by ~100 days following a prior exposure. Rarely, HIT may occur later after heparin exposure (termed delayed-onset HIT). In this setting, heparin/PF4 antibody testing is usually markedly positive. HIT can occur after exposure to either unfractionated (UFH) or low-molecular-weight heparin (LMWH).

LABORATORY TESTING FOR HIT Because of the prevalence of anti-heparin antibodies without clinical disease, testing should be done in individuals who are at intermediate or high risk based on clinical pretest assessment. HIT (anti-heparin/PF4) antibodies can be detected using two types of assays. The most widely available are immunoassays usually with PF4/polyanion complex as the antigen. Because many patients develop antibodies but do not develop clinical HIT, the test has a low specificity for the diagnosis of HIT. This is especially true in patients who have undergone surgery requiring cardiopulmonary bypass, where approximately 50% of patients develop these antibodies postoperatively. The other assay is a platelet activation assay, most commonly the serotonin release assay, which measures the ability of the patient's serum to activate platelets in the presence of heparin in a concentration-dependent manner. This test has lower sensitivity but higher specificity than the enzyme-linked immunosorbent assay (ELISA). However, HIT remains a clinical diagnosis.

TREATMENT

Heparin-Induced Thrombocytopenia

Early recognition is key in treatment of HIT, with prompt discontinuation of heparin and use of alternative anticoagulants if bleeding risk does not outweigh thrombotic risk. Thrombosis is a common complication of HIT, even after heparin discontinuation, and can occur in both the venous and arterial systems. In patients diagnosed with HIT, imaging studies to evaluate the patient for thrombosis (at least lower extremity duplex Doppler imaging) are recommended. Patients requiring anticoagulation should be switched from heparin to an alternative anticoagulant. The direct thrombin inhibitor (DTI) argatroban is effective in HITT. The DTI bivalirudin, the antithrombin-binding pentasaccharide fondaparinux, and direct oral anticoagulants (DOACs) appear to have efficacy, although none of these are approved by the U.S. Food and Drug Administration (FDA) for this indication. Of the DOACs, the most experience reported is with rivaroxaban. In general, an intravenous DTI should be used in acutely ill patients with transition to fondaparinux or a DOAC when they are more stable, which then allows outpatient treatment. HIT antibodies cross-react with LMWH, and these drugs should not be used in the treatment of HIT.

Because of the high rate of thrombosis in patients with HIT, anticoagulation should be considered, even in the absence of thrombosis. In patients with thrombosis, anticoagulation is continued for 3–6 months, but in patients without thrombosis, the duration of anticoagulation is less well defined, but should be continued at least until platelet recovery. An increased risk of thrombosis is present for at least 1 month after diagnosis; however, most thromboses occur early, and whether thrombosis occurs later if the patient is initially anticoagulated is unknown. Introduction of warfarin alone in the setting of HIT or HITT may precipitate thrombosis, particularly venous gangrene, presumably due to clotting activation and severely reduced levels of proteins C and S. Warfarin therapy,

if started, should be overlapped with a DTI, fondaparinux, or a DOAC and started after resolution of the thrombocytopenia and lessening of the prothrombotic state.

The rare VITT syndrome is characterized by high D-dimer levels and thrombosis in unusual sites like the cerebral venous sinuses. Fatal in about 20%, treatment is usually intravenous gamma globulin (IVIgG) to block platelet activation through Fc receptors, the pathogenic effect of the anti–PF4-polyanion antibody, and a non-heparin anticoagulant.

Immune Thrombocytopenic Purpura Immune thrombocytopenic purpura (ITP; also termed *idiopathic thrombocytopenic purpura*) is an acquired disorder in which there is immune-mediated destruction of platelets and possibly inhibition of platelet release from the megakaryocyte. In children, it is usually an acute disease, most commonly following an infection, and with a self-limited course. In adults, it is a more chronic disease, although in some adults, spontaneous remission occurs, usually within months of diagnosis. ITP is termed *secondary* if it is associated with an underlying disorder; autoimmune disorders, particularly systemic lupus erythematosus (SLE), and infections, such as HIV and hepatitis C, are common causes. The association of ITP with *Helicobacter pylori* infection is unclear but appears to have a geographic distribution.

ITP is characterized by mucocutaneous bleeding and a low, often very low, platelet count, with an otherwise normal peripheral blood cells and smear. Patients usually present either with ecchymoses and petechiae or with thrombocytopenia incidentally found on a routine CBC. Mucocutaneous bleeding, such as oral mucosa, gastrointestinal, or heavy menstrual bleeding, may be present. Rarely, life-threatening, including central nervous system, bleeding can occur. Wet purpura (blood blisters in the mouth) and retinal hemorrhages may herald life-threatening bleeding.

LABORATORY TESTING IN ITP Laboratory testing for antibodies (serologic testing) is usually not helpful due to the low sensitivity and specificity of the current tests. Bone marrow examination can be reserved for those who have other signs or laboratory abnormalities not explained by ITP or in patients who do not respond to initial therapy. The peripheral blood smear may show large platelets, with otherwise normal morphology. Depending on the bleeding history, iron-deficiency anemia may be present.

Laboratory testing is performed to evaluate for secondary causes of ITP and should include testing for HIV infection and hepatitis C (and other infections if indicated). Serologic testing for SLE, serum protein electrophoresis, immunoglobulin levels to potentially detect hypogammaglobulinemia, selective testing for IgA deficiency or monoclonal gammopathies, and testing for *H. pylori* infection should be considered, depending on the clinical circumstance. If anemia is present, direct antiglobulin testing (Coombs' test) should be performed to rule out combined autoimmune hemolytic anemia with ITP (Evans' syndrome).

TREATMENT

Immune Thrombocytopenic Purpura

The treatment of ITP uses drugs that decrease reticuloendothelial uptake of the antibody-bound platelet, decrease antibody production, and/or increase platelet production. The diagnosis of ITP does not necessarily mean that treatment must be instituted. Patients with platelet counts >30,000/μL appear not to have increased mortality related to the thrombocytopenia.

Initial treatment in patients without significant bleeding symptoms, severe thrombocytopenia (<5000/μL), or signs of impending bleeding (e.g., retinal hemorrhage or large oral mucosal hemorrhages) can be instituted as an outpatient using single agents. Traditionally, this has been prednisone at 1 mg/kg or a 4-day course of dexamethasone, 40 mg/d, although Rh_0(D) immune globulin therapy, at 50–75 μg/kg, is also being used in this setting. Rh_0(D) immune globulin must be used only in Rh-positive patients because the mechanism of action is production of limited hemolysis, with antibody-coated cells "saturating" the Fc receptors, inhibiting Fc receptor function. Monitoring patients for 8 h after infusion is now advised by the FDA because of the rare complication of severe intravascular hemolysis. IVIgG, which is pooled, primarily IgG antibodies, also blocks the Fc receptor system, but appears to work primarily through different mechanism(s). IVIgG has more efficacy than anti-Rh_0(D) in postsplenectomized patients. IVIgG is dosed at 1–2 g/kg total, given over 1–5 days. Side effects are usually related to the volume of infusion and infrequently include aseptic meningitis and renal failure. All immunoglobulin preparations are derived from human plasma and undergo treatment for viral inactivation. Rituximab, an anti-CD20 (B-cell) antibody, has shown efficacy in the treatment of refractory ITP, although long-lasting remission only occurs in approximately 30% of patients. TPO receptor agonists (TPO-RA), administered subcutaneously (romiplostim) or orally (eltrombopag, avatrombopag), are effective in raising platelet counts in patients with chronic ITP.

For patients with severe ITP and/or symptoms of bleeding, hospital admission is required, and combined-modality therapy is given using high-dose glucocorticoids with IVIgG or anti-Rh_0(D) therapy and, as needed, additional immunosuppressive agents.

For chronic ITP, broad immune therapy and splenectomy are now generally used less frequently compared to TPO-RAs due to unfavorable side effects and a negative impact on quality of life. Newer drugs are under study. In individuals who achieve a complete response to a TPO-RA, many will maintain a sustained response off therapy.

In patients who are to undergo splenectomy, vaccination against encapsulated organisms (especially pneumococcus, but also meningococcus and *Haemophilus influenzae*, depending on patient age and potential exposure) is recommended. Accessory spleens are a very rare cause of relapse.

Inherited Thrombocytopenia Thrombocytopenia is rarely inherited, either as an isolated finding or as part of a syndrome, and may be inherited in an autosomal dominant, autosomal recessive, or X-linked pattern. Multiple genetic variants have now been identified in individuals with isolated thrombocytopenia and cytopenic syndromes, some of which carry an increased risk of hematologic malignancy. Many forms of autosomal dominant macrothrombocytopenia are now known to be associated with variants in the nonmuscle myosin heavy chain *MYH9* gene. These include the May-Hegglin anomaly, and Sebastian, Epstein's, and Fechtner syndromes, all of which have distinct distinguishing features. A common feature of these disorders is large platelets **(Fig. 120-1*C*)**. It is important that family history be explored in any individual with unexplained thrombocytopenia.

THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC-UREMIC SYNDROME

Thrombotic thrombocytopenic microangiopathies are a group of disorders characterized by microangiopathic hemolytic anemia (MAHA) defined by thrombocytopenia and fragmented RBCs **(Fig. 120-1*D*)** on peripheral blood smear, laboratory evidence of hemolysis (elevated lactate dehydrogenase [LDH] and unconjugated bilirubin and decreased haptoglobin), and microvascular thrombosis. They include thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS), as well as syndromes complicating bone marrow transplantation, certain medications and infections, pregnancy, and vasculitis. In DIC, although thrombocytopenia and microangiopathy are seen, a coagulopathy predominates, with consumption of clotting factors and fibrinogen resulting in an elevated prothrombin time (PT) and often activated partial thromboplastin time (aPTT). The PT and aPTT are characteristically normal in TTP or HUS.

Thrombotic Thrombocytopenic Purpura TTP was first described in 1924 by Eli Moschcowitz and characterized by a pentad of findings that include microangiopathic hemolytic anemia, thrombocytopenia, renal failure, neurologic findings, and fever. The full-blown

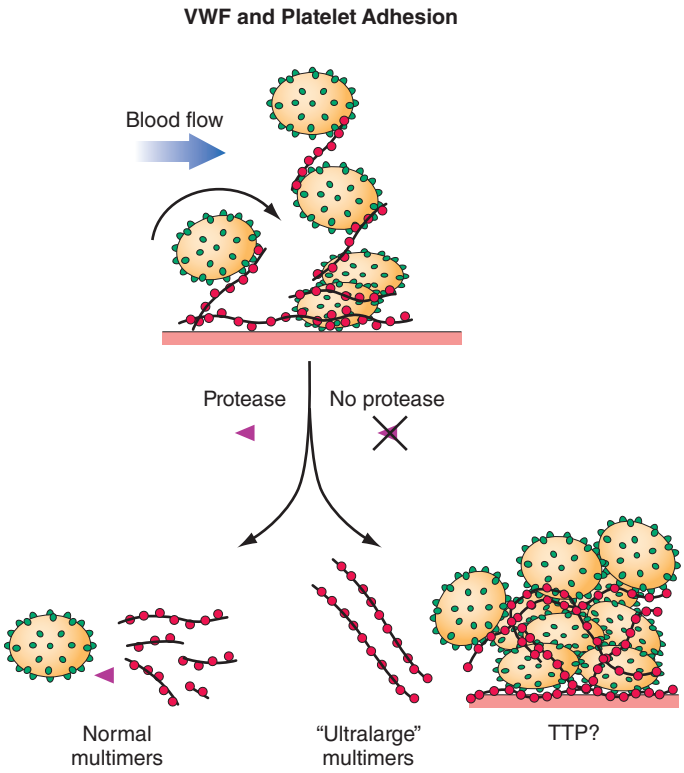

FIGURE 120-4 Pathogenesis of thrombotic thrombocytopenic purpura (TTP). Normally the ultra-high-molecular-weight multimers of von Willebrand factor (VWF) produced by the endothelial cells are processed into smaller multimers by a plasma metalloproteinase called ADAMTS13. In TTP, the activity of the protease is inhibited, and the ultra-high-molecular-weight multimers of VWF initiate platelet aggregation and thrombosis.

syndrome is less commonly seen now, probably due to earlier diagnosis. The introduction of treatment with plasma exchange markedly improved the prognosis in patients, with a decrease in mortality from 85–100% to 10–30%.

The pathogenesis of inherited (Upshaw-Schulman syndrome) and idiopathic TTP (ITTP) is related to a deficiency of, or antibodies to, the metalloprotease ADAMTS13, which cleaves VWF. VWF is normally secreted as ultra-large multimers, which are then cleaved by ADAMTS13. The persistence of ultra-large VWF molecules is thought to contribute to pathogenic platelet adhesion and aggregation (Fig. 120-4). This defect alone, however, is not sufficient to result in TTP because individuals with a congenital absence of ADAMTS13 develop TTP only episodically, including during first pregnancy. The level of ADAMTS13 activity, as well as antibodies to ADAMTS13, can be detected by laboratory assays, which play a critical role in the differential diagnosis of MAHA. ADAMTS13 activity levels of <10% are diagnostic of TTP.

Idiopathic TTP appears to be more common in women than in men. No geographic or racial distribution has been defined. TTP is more common in patients with HIV infection and in pregnant women. Medication-related MAHA may be secondary to antibody formation (ticlopidine and possibly clopidogrel) or direct endothelial toxicity (cyclosporine, gemcitabine, mitomycin C, tacrolimus), although this is not always so clear, and fear of withholding treatment, as well as lack of other treatment alternatives, may result in initial application of plasma exchange. However, withdrawal, or reduction in dose, of endothelial toxic agents usually decreases the microangiopathy.

TREATMENT

Thrombotic Thrombocytopenic Purpura

TTP is a devastating disease if not diagnosed and treated promptly. In patients presenting with new thrombocytopenia, with or without evidence of renal insufficiency and other elements of classic TTP, laboratory data (PT, aPTT, CBC with platelet count and peripheral smear, ADAMTS13 activity, LDH, bilirubin, haptoglobin, direct antiglobulin assay) should be obtained to rule out DIC and to evaluate for evidence of MAHA.

Therapeutic plasma exchange (TPE) remains the mainstay of treatment of TTP. TPE is continued until the platelet count is normal and signs of hemolysis are resolved for at least 2 days. Although never evaluated in clinical trials, the use of glucocorticoids seems a reasonable approach but should only be used as an adjunct to plasma exchange. The addition of rituximab to initial therapy decreases the risk of relapse. Caplacizumab, an anti-VWF nanobody, decreases mortality and burden of care when used in patients with ADAMTS13 <10% or with high clinical probability of disease. Guidelines from the International Society of Thrombosis and Hemostasis recommend starting caplacizumab and rituximab only in individuals with diagnostic ADAMTS13 levels (usually <10%) and, additionally for rituximab, in patients with evidence of an inhibitor, given potential side effects and costs.

Patients with persistently low ADAMTS13 have a greater risk of ongoing sequelae including stroke. There is a significant relapse rate; in patients treated with TPE, 25–45% of patients relapse within 30 days of initial "remission," and 12–40% of patients have late relapses. Relapses are more frequent in patients with severe ADAMTS13 deficiency at presentation. Treatment of patients with TTP relapses should be initiated before confirmatory laboratory assays are available.

Hemolytic-Uremic Syndrome HUS is a syndrome characterized by acute renal failure, microangiopathic hemolytic anemia, and thrombocytopenia. It is seen preceded by an episode of diarrhea, often hemorrhagic in nature, predominantly in children. *Escherichia coli* O157:H7 is the most frequent, although not only, etiologic serotype. HUS not associated with diarrhea is more heterogeneous in presentation and course. Atypical HUS (aHUS) is usually due to genetic defects in complement genes or antibodies directed against complementary regulatory proteins that result in chronic complement activation. Laboratory testing for DNA variants in complement regulatory genes is available, although assigning pathogenicity to variants remains challenging. Currently, a commercially available functional assay is not available that is diagnostic of the disease.

TREATMENT

Hemolytic-Uremic Syndrome

Treatment of HUS is primarily supportive. In HUS associated with diarrhea, many (~40%) children require at least some period of support with dialysis; however, the overall mortality is <5%. In HUS not associated with diarrhea, the mortality is higher, approximately 26%. Plasma infusion or plasma exchange has not been shown to alter the overall course in HUS or aHUS, except in patients with antibodies to factor H. ADAMTS13 levels are generally reported to be normal in HUS, although occasionally they have been reported to be decreased. In patients with aHUS, anticomplement therapy has efficacy in resolution of aHUS and improving or preserving renal function. Patients with aHUS may initially be treated with plasma exchange, until the ADAMTS13 level is returned and the diagnosis is more clear, since aHUS remains a diagnosis of exclusion. However, plasma exchange has not been shown to affect clinical outcomes in aHUS.

THROMBOCYTOSIS

Thrombocytosis is almost always due to (1) iron deficiency; (2) inflammation, cancer, or infection (reactive thrombocytosis); or (3) an underlying myeloproliferative process (essential thrombocythemia or polycythemia vera) (Chap. 108) or, rarely, the 5q– myelodysplastic process (Chap. 107). Patients presenting with an elevated platelet count should be evaluated for underlying inflammation and malignancy, and iron deficiency should be ruled out. Thrombocytosis in response to

acute or chronic inflammation has not been clearly associated with an increased thrombotic risk. In fact, patients with markedly elevated platelet counts (>1.5 million), usually seen in the setting of a myeloproliferative disorder, have an increased risk of bleeding. This appears to be due, at least in part, to acquired von Willebrand disease (VWD) due to platelet-VWF binding and removal from the circulation.

QUALITATIVE DISORDERS OF PLATELET FUNCTION

Inherited Disorders of Platelet Function Inherited platelet function disorders are thought to be relatively rare, although the prevalence of mild disorders of platelet function is unclear, in part because our testing for such disorders is suboptimal. Rare qualitative disorders include the autosomal recessive disorders Glanzmann's thrombasthenia (absence of the platelet Gp IIb/IIIa receptor) and Bernard-Soulier syndrome (absence of the platelet Gp Ib-IX-V receptor). Both are inherited in an autosomal recessive fashion and present with bleeding symptoms in childhood.

Platelet storage pool disorder (SPD) is the classic autosomal dominant qualitative platelet disorder. This results from abnormalities of platelet granule formation. It is also seen as a part of inherited disorders of granule formation, such as Hermansky-Pudlak syndrome. Bleeding symptoms in SPD are variable but often are mild. The most common inherited disorders of platelet function prevent normal secretion of granule content and are termed *secretion defects*. An increasing number of genetic variants are being found in patients with these disorders, although assigning pathogenicity remains challenging.

TREATMENT

Inherited Disorders of Platelet Dysfunction

Bleeding symptoms or prevention of bleeding in patients with severe platelet dysfunction frequently requires platelet transfusion. Care must be taken to limit the risk of alloimmunization by limiting exposure and using human leukocyte antigen–matched single donor platelets for transfusion when needed. Recombinant factor VIIa (rFVIIa) is FDA approved in Glanzmann's thrombasthenia and Bernard Soulier syndrome where use can avoid platelet alloimmunization and antireceptor antibody formation. Platelet disorders associated with milder bleeding symptoms frequently respond to desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]). DDAVP increases plasma VWF and factor VIII levels; it may also have a direct effect on platelet function. Particularly for mucosal bleeding symptoms, antifibrinolytic therapy (tranexamic acid or ε-aminocaproic acid) is used alone or in conjunction with DDAVP or platelet therapy.

Acquired Disorders of Platelet Function Acquired platelet dysfunction is common, usually due to medications, either intentionally as with antiplatelet therapy or unintentionally as with high-dose penicillins. Acquired platelet dysfunction occurs in uremia. This is likely multifactorial, but the resultant effect is defective adhesion and activation. The platelet defect is improved most by dialysis but may also be improved by increasing the hematocrit to 27–32%, giving DDAVP (0.3 μg/kg), or use of conjugated estrogens. Platelet dysfunction also occurs with cardiopulmonary bypass due to the effect of the artificial circuit on platelets, and bleeding symptoms respond to platelet transfusion. Platelet dysfunction seen with underlying hematologic disorders can result from nonspecific interference by circulating paraproteins or intrinsic platelet defects in myeloproliferative and myelodysplastic syndromes.

VON WILLEBRAND DISEASE

VWD is the most common inherited bleeding disorder, with prevalence of symptomatic disease of 1 in 1000 to 1 in 10,000 individuals. VWF serves two roles: (1) as the major adhesion molecule that tethers the platelet to the exposed subendothelium; and (2) as the binding protein for factor VIII (FVIII), resulting in significant prolongation of the FVIII half-life in circulation. The platelet-adhesive function of VWF is critically dependent on the presence of large VWF multimers, whereas FVIII binding is not. Most of the symptoms of VWD are "platelet-like" except in more severe VWD when the FVIII is low enough to produce symptoms similar to those found in FVIII deficiency (hemophilia A).

TABLE 120-2 Laboratory Diagnosis of von Willebrand Disease (VWD)

TYPE	aPTT	VWF ANTIGEN	VWF ACTIVITY	FVIII ACTIVITY	MULTIMER
1	NI or ↑	↓	↓	↓	Normal distribution, decreased in quantity
2A	NI or ↑	↓	↓↓	↓	Loss of high- and intermediate-MW multimers
2B[a]	NI or ↑	↓	↓↓	↓	Loss of high-MW multimers
2M	NI or ↑	↓	↓↓	↓	Normal distribution, decreased in quantity
2N	↑↑	NI or ↓[b]	NI or ↓[b]	↓↓	Normal distribution
3	↑↑	↓↓	↓↓	↓↓	Absent

[a]Usually also decreased platelet count. [b]For type 2N, in the homozygous state, factor VIII is very low; in the heterozygous state, it is only seen in conjunction with type 1 VWD.

Abbreviations: aPTT, activated partial thromboplastin time; F, factor; MW, molecular weight; NI, normal; VWF, von Willebrand factor.

VWD has been classified into three major types, with four subtypes of type 2 (Table 120-2). By far, the most common type of VWD is type 1 disease, with a parallel decrease in VWF protein, VWF function, and FVIII levels, accounting for at least 80% of cases. Type 1C is a subtype associated with increased VWF clearance. In type 1 VWD, patients have predominantly mucosal bleeding symptoms, although procedure-related and other bleeding is also seen. Bleeding symptoms are uncommon in infancy and usually manifest later in childhood with excessive bruising and epistaxis. Because these symptoms occur commonly in childhood, the clinician should particularly note bruising at sites unlikely to be traumatized and/or prolonged epistaxis requiring medical attention. Heavy menstrual bleeding is a common manifestation of VWD. Menstrual bleeding resulting in anemia should warrant an evaluation for VWD and, if negative, functional platelet disorders and other bleeding disorders. Type 1 VWD may first manifest with dental extractions, particularly wisdom tooth extraction, or tonsillectomy.

Not all patients with low VWF levels have bleeding symptoms. Whether patients bleed or not will depend on the overall hemostatic balance they have inherited, along with environmental influences and the type of hemostatic challenges they experience. Although the inheritance of VWD is autosomal, many factors modulate both VWF levels and bleeding symptoms. These have not all been defined, but include blood type, thyroid hormone status, race, stress, exercise, hormonal (both endogenous and exogenous) influences, and modulators of VWF clearance. Patients with type O blood have VWF protein levels of approximately one-half those of patients with AB blood type, and in fact, the normal range for patients with type O blood overlaps that which has been considered diagnostic for VWD. Patients with mildly decreased VWF levels should be diagnosed with VWD only in the setting of bleeding symptoms and/or a family history of VWD.

Patients with type 2 VWD have functional defects; thus, the VWF antigen measurement is significantly higher than the test of function. For types 2A, 2B, and 2M VWD, platelet-binding and/or collagen-binding VWF activity is decreased. In type 2A VWD, the impaired function is due either to increased susceptibility to cleavage by ADAMTS13, resulting in loss of intermediate- and high-molecular-weight multimers, or to decreased production of these multimers by the cell. Type 2B VWD results from gain-of-function DNA variants that result in increased binding of VWF to platelets in circulation with subsequent increased ADAMTS13 cleavage and clearance. The resulting VWF in the patients'

plasma lacks the highest molecular-weight multimers, and the platelet count is usually modestly reduced, but not uniformly. Type 2M occurs as a consequence of DNA variants that result in a dysfunctional protein not affecting multimer structure.

Type 2N VWD is due to variants in the *VWF* gene that affect binding of FVIII. As FVIII is stabilized by binding to VWF, the FVIII in patients with type 2N VWD has a very short half-life, and the FVIII level is markedly decreased. This is sometimes termed *autosomal hemophilia*. Type 3 VWD, or severe VWD, describes patients with virtually no VWF protein and usually FVIII levels <10%. Patients experience mucosal and joint bleeding, surgery-related bleeding, and other bleeding symptoms. Some patients with type 3 VWD, particularly those with large *VWF* gene deletions, are at risk of developing antibodies to infused VWF.

Acquired VWD or von Willebrand syndrome can be seen in patients with underlying lymphoproliferative disorders, including monoclonal gammopathies of underdetermined significance (MGUS), multiple myeloma, and Waldenström's macroglobulinemia. It is seen most commonly in the setting of MGUS and should be suspected in patients, particularly elderly patients, with a new onset of severe mucosal bleeding symptoms. Laboratory evidence of acquired VWD is found in patients with cardiac valvular disease. Heyde's syndrome (aortic stenosis with gastrointestinal bleeding) is attributed to the presence of angiodysplasia of the gastrointestinal tract in patients with aortic stenosis. The shear stress on blood passing through the stenotic aortic valve appears to unfold VWF, making it susceptible to proteolysis. Consequently, large multimer forms are lost, leading to an acquired type 2 VWD, but return when the stenotic valve is replaced.

TREATMENT

Von Willebrand Disease

The mainstay of treatment for type 1 VWD is DDAVP (desmopressin), which results in release of VWF and FVIII from endothelial stores. DDAVP can be given intravenously, by high-concentration intranasal spray (1.5 mg/mL), or when a concentrated form is available, by subcutaneous injection. The peak activity when given intravenously is approximately 30 min, whereas it is 2 h when given intranasally. The usual dose is 0.3 μg/kg intravenously or two squirts (one in each nostril) for patients >50 kg (one squirt for those <50 kg). It is recommended that patients with VWD be tested with DDAVP to assess their response before using it. In patients who respond well (increase in laboratory values greater than twofold with levels >50% for at least 4 h), it can be used for procedures with minor to moderate risk of bleeding. Depending on the procedure, additional doses may be needed; it is usually given every 12–24 h. Less frequent dosing may result in less tachyphylaxis, which occurs when synthesis cannot compensate for the released stores. The major side effect of DDAVP is hyponatremia due to decreased free water clearance. This occurs most commonly in the very young and the very old, but fluid restriction should be advised for all patients for the 24 h following each dose.

Some patients with type 2A VWD respond to DDAVP such that it can be used for minor procedures. For the other subtypes, for type 3 disease, and for major procedures requiring longer periods of normal hemostasis, VWF replacement can be given. Virally inactivated VWF-plasma-derived and recombinant factor concentrates are safer than cryoprecipitate as the replacement product.

Antifibrinolytic therapy using either tranexamic acid (TXA) or ε-aminocaproic acid is an important therapy, either alone or in an adjunctive capacity, particularly for the prevention or treatment of mucosal bleeding. These agents are particularly useful in treatment of heavy menstrual bleeding (TXA 1300 mg every 8 h) and postpartum hemorrhage, as prophylaxis for dental procedures, and with DDAVP or factor concentrate for dental extractions, tonsillectomies, and prostate procedures. Antifibrinolytic agents are contraindicated in the setting of upper urinary tract bleeding due to the risk of ureteral obstruction.

DISORDERS OF THE VESSEL WALL

The vessel wall is an integral part of hemostasis, and separation of a fluid phase is artificial, particularly in disorders such as TTP or HIT that clearly involve the endothelium as well. Inflammation localized to the vessel wall, such as vasculitis, and inherited connective tissue disorders are abnormalities inherent to the vessel wall.

Metabolic and Inflammatory Disorders Acute febrile illnesses may result in vascular damage. This can result from immune complexes containing viral antigens or the viruses themselves. Certain pathogens, such as the rickettsiae causing Rocky Mountain spotted fever, replicate in endothelial cells and damage them. SARS-CoV-2 also infects endothelial cells, resulting in activation and damage contributing to COVID-19 pathogenicity. Vascular purpura may occur in patients with polyclonal gammopathies but more commonly occurs in those with monoclonal gammopathies, including Waldenström's macroglobulinemia, multiple myeloma, and cryoglobulinemia. Patients with mixed cryoglobulinemia develop a more extensive maculopapular rash due to immune complex–mediated damage to the vessel wall.

Patients with scurvy (vitamin C deficiency) develop painful episodes of perifollicular skin bleeding as well as more systemic bleeding symptoms. Vitamin C is needed to synthesize hydroxyproline, an essential constituent of collagen. Patients with Cushing's syndrome or on chronic glucocorticoid therapy develop skin bleeding and easy bruising due to atrophy of supporting connective tissue. A similar phenomenon is seen with aging, where following minor trauma, blood spreads superficially under the epidermis. This has been termed *senile purpura*. It is most common on skin that has been previously damaged by sun exposure.

Immunoglobulin A vasculitis, formerly called Henoch-Schönlein purpura, is a distinct, self-limited type of vasculitis that occurs in children and young adults. Patients have an acute inflammatory reaction with IgA and complement components in capillaries, mesangial tissues, and small arterioles leading to increased vascular permeability and localized hemorrhage. The syndrome is often preceded by an upper respiratory infection, commonly with streptococcal pharyngitis, or is triggered by drug or food allergies. Patients develop a purpuric rash on the extensor surfaces of the arms and legs, usually accompanied by polyarthralgias or arthritis, abdominal pain, and hematuria from focal glomerulonephritis. All coagulation tests are normal, but renal impairment may occur. Glucocorticoids can provide symptomatic relief but do not alter the course of the illness.

Inherited Disorders of the Vessel Wall Patients with inherited disorders of the connective tissue matrix, such as Marfan's syndrome, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum, frequently report easy bruising. Inherited vascular abnormalities can result in increased bleeding. This is notably seen in hereditary hemorrhagic telangiectasia (HHT, or Osler-Weber-Rendu disease), a disorder where abnormal telangiectatic capillaries result in frequent bleeding episodes, primarily from the nose and gastrointestinal tract. Arteriovenous malformation (AVM) in the lung, brain, and liver may also occur in HHT. The telangiectasia can often be visualized on the oral and nasal mucosa. Signs and symptoms develop over time. Epistaxis begins, on average, at the age of 12 and occurs in >95% of affected individuals by middle age. Approximately 25% have gastrointestinal bleeding usually beginning after the age of 50. HHT is caused by pathogenic DNA variants in a number of genes involved in the TGFβ/BMP signaling cascade.

121 Coagulation Disorders

Jean M. Connors

Deficiencies of coagulation factors have been recognized for centuries. Patients with genetic deficiencies of plasma coagulation factors exhibit lifelong recurrent bleeding episodes into joints, muscles, and closed spaces, either spontaneously or following an injury. The most common inherited factor deficiencies are the hemophilias, X-linked diseases caused by deficiency of factor (F) VIII (hemophilia A) or FIX (hemophilia B). Rare congenital bleeding disorders due to deficiencies of other factors, including FII (prothrombin), FV, FVII, FX, FXI, FXIII, and fibrinogen, are commonly inherited in an autosomal recessive manner (Table 121-1). Disease phenotype often correlates with the level of factor activity. While patients can have a congenital deficiency of FXII accompanied by a significant prolongation in the activated partial thromboplastin time (aPTT), FXII deficiency is not accompanied by a bleeding phenotype, likely due to redundant paths to activation of the intrinsic pathway of the coagulation cascade, including direct activation of FXI by thrombin generated through the extrinsic pathway (Fig. 121-1). Advances in characterization of the molecular basis of clotting factor deficiencies have contributed to better understanding of the disease phenotypes allowing the development of more targeted therapeutic approaches, including the use of small molecules, recombinant proteins, or cell- and gene-based therapies.

The two most commonly used tests of hemostasis, the prothrombin time (PT) and the aPTT, were designed to perform the first screen for clotting factor deficiency (Fig. 121-1). An isolated prolonged PT suggests FVII deficiency, whereas a prolonged aPTT indicates an intrinsic pathway factor deficiency, most commonly hemophilia A or B (FVIII or FIX, respectively) or FXI deficiency (Fig. 121-1). The prolongation of both PT and aPTT suggests a deficiency of FV, FX, FII, or fibrinogen abnormalities. A mixing study, in which the addition of normal pooled plasma to the patient's plasma, will correct a prolonged aPTT or PT due to a factor deficiency, and is the next step in determining if there is a coagulation factor deficiency. If the clotting time does not correct, it suggests the presence of an inhibitor, an antibody to a specific factor; however, a mixing study will also detect the presence of anticoagulants. Many labs have testing methods for detecting inhibitors that neutralize anticoagulants. If the mixing study corrects with normal plasma, individual factor activity assays are performed to determine which factor is deficient.

Acquired deficiencies of plasma coagulation factors are more frequent than congenital disorders; the most common disorders include hemorrhagic diathesis of liver disease, disseminated intravascular coagulation (DIC), and vitamin K deficiency. In these disorders, blood coagulation is hampered by the deficiency of more than one clotting factor, and the bleeding episodes are the result of perturbation of both primary (e.g., platelet and vessel wall interactions) and secondary (coagulation) hemostasis.

The development of alloantibodies to coagulation plasma proteins, clinically termed *inhibitors*, is a relatively rare disease that often affects hemophilia A or B and FXI-deficient patients on repetitive exposure to the missing protein to control bleeding episodes. Inhibitory autoantibodies also occur among subjects without genetic deficiency of clotting factors and, although rare, can be seen in the postpartum setting, as a manifestation of underlying autoimmune or neoplastic disease, or idiopathically. Rare cases of acquired inhibitors to thrombin or FV have been reported in patients receiving topical bovine thrombin preparation as a local hemostatic agent in complex surgeries. A mixing study that does not correct with the addition of normal plasma indicates the presence of an inhibitor, requiring additional tests to identify the specificity of the inhibitor and measure its titer. Inhibitor detection in patients with hemophilia is of particular importance, with yearly screening performed at most hemophilia treatment centers.

The treatment of coagulation factor deficiencies in the setting of bleeding requires replacement of the deficient protein(s) using recombinant or purified plasma-derived products or fresh-frozen plasma

TABLE 121-1 Genetic and Laboratory Characteristics of Inherited Coagulation Disorders

CLOTTING FACTOR DEFICIENCY	INHERITANCE	PREVALENCE IN GENERAL POPULATION	LABORATORY ABNORMALITY[a]			MINIMUM HEMOSTATIC LEVELS	TREATMENT	PLASMA HALF-LIFE
			aPTT	PT	TT			
Fibrinogen	AR	1 in 1,000,000	+	+	+	100 mg/dL	Cryoprecipitate	2–4 d
Prothrombin	AR	1 in 2,000,000	+	+	–	20–30%	FFP/PCC	3–4 d
Factor V	AR	1 in 1,000,000	+/–	+/–	–	15–20%	FFP[c]	36 h
Factor VII	AR	1 in 500,000	–	+	–	15–20%	FFP/PCC	4–6 h
Factor VIII	X-linked	1 in 5000	+	–	–	30%	FVIII concentrates	8–12 h
Factor IX	X-linked	1 in 30,000	+	–	–	30%	FIX concentrates	18–24 h
Factor X	AR	1 in 1,000,000	+/–	+/–	–	15–20%	FFP/PCC	40–60 h
Factor XI	AR	1 in 1,000,000	+	–	–	15–20%	FFP	40–70 h
Factor XII	AR	ND	+	–	–	[b]	[b]	60 h
HK	AR	ND	+	–	–	[b]	[b]	150 h
Prekallikrein	AR	ND	+	–	–	[b]	[b]	35 h

[a]Values within normal range (–) or prolonged (+). [b]No risk for bleeding; treatment is not indicated. [c]Since platelets contain FV, platelet transfusion can be used as therapy.
Abbreviations: aPTT, activated partial thromboplastin time; AR, autosomal recessive; FFP, fresh-frozen plasma; HK, high-molecular-weight kininogen; ND, not determined; PCC, prothrombin complex concentrates; PT, prothrombin time; TT, thrombin time.

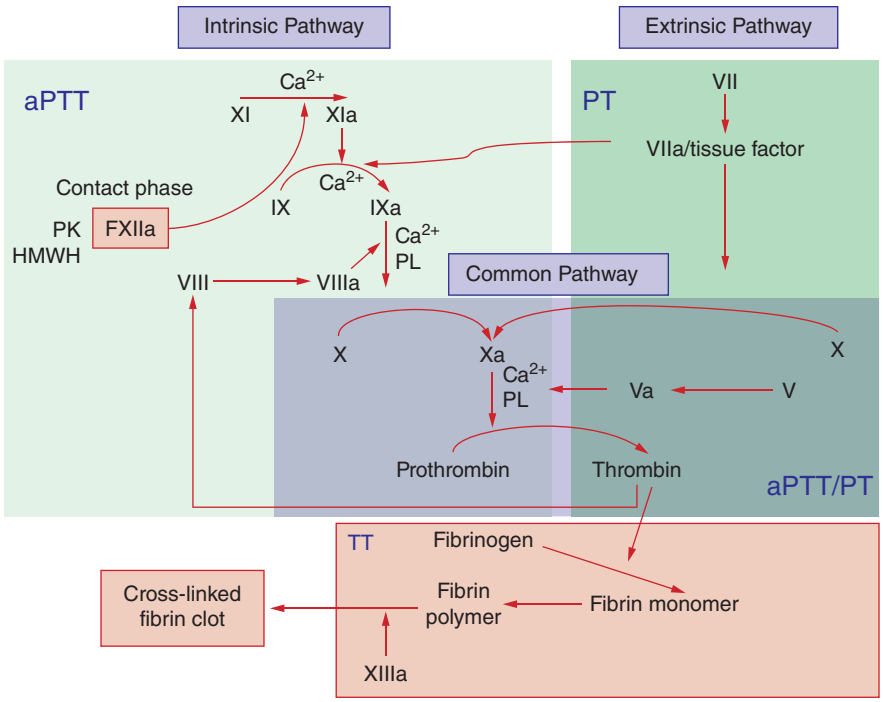

FIGURE 121-1 Coagulation cascade and laboratory assessment of clotting factor deficiency by activated partial thromboplastin time (aPTT), prothrombin time (PT), thrombin time (TT), and phospholipid (PL).

(FFP). Prothrombin complex concentrates (PCCs) are intermediate-purity plasma-derived factor concentrates initially used as sources of FVIII or FIX for hemophilia patients, but because they contain the vitamin K–dependent factors, they are also used for warfarin reversal. Three-factor PCC (3F-PCC) is less frequently used now for warfarin reversal because these preparations contain low levels of FVII, requiring FFP as a source of FVII. Four-factor PCC (4F-PCC), especially the one used in the United States, contains FII, FIX, FX, higher levels of FVII than 3F-PCC, and protein S and protein C.

HEMOPHILIA A AND B

PATHOGENESIS AND CLINICAL MANIFESTATIONS

Hemophilia is an X-linked recessive hemorrhagic disease due to mutations in the *F8* gene (hemophilia A or classic hemophilia) or *F9* gene (hemophilia B). The disease affects 1 in 10,000 males worldwide, in all ethnic groups; hemophilia A represents 80% of all cases. The large size of the *F8* gene makes it more susceptible to mutation events than the smaller *F9* gene. Male subjects are clinically affected; women, who carry a single mutated gene, are generally asymptomatic. However, increased bleeding tendencies with procedures are now more commonly appreciated based on F8 or F9 level. Family history of the disease is absent in ~30% of cases, and in these cases, 80% of the mothers are carriers of the de novo mutated allele. More than 500 different mutations have been identified in the *F8* or *F9* gene. One of the most common hemophilia A mutations results from an inversion of the intron 22 sequence, and it is present in 40% of cases of severe hemophilia A. Advances in molecular diagnosis now permit precise identification of mutations, allowing accurate diagnosis of women carriers of the hemophilia gene in affected families.

Clinically, hemophilia A and hemophilia B are indistinguishable. The disease phenotype correlates with the activity of FVIII or FIX and can be classified as severe (<1%), moderate (1–5%), or mild (6–30%). In the severe and moderate forms, the disease is characterized by bleeding into the joints (hemarthrosis), soft tissues, and muscles after minor trauma or even spontaneously. Patients with mild disease experience infrequent bleeding, usually secondary to trauma. Among those with baseline FVIII or FIX activity >25%, the disease is discovered only with bleeding after major trauma or during routine laboratory tests, usually an isolated prolongation of the aPTT that requires mixing study evaluation. FVIII has a short circulating half-life of 25–30 min that is extended to roughly 12 h when complexed with its carrier protein von Willebrand factor (VWF). In patients without a known history of hemophilia, a diagnosis of von Willebrand disease (VWD) needs to be excluded in patients with a prolonged aPTT and low FVIII activity. Early in life, bleeding may present after circumcision or rarely as intracranial hemorrhages. The disease is more evident when children begin to walk or crawl. In the severe form, the most common bleeding manifestations are recurrent hemarthroses, affecting primarily the knees, elbows, ankles, shoulders, and hips. Acute hemarthroses are painful, and clinical signs are local swelling and erythema. To avoid pain, the patient may adopt a fixed position, which leads eventually to muscle contractures. Very young children unable to communicate verbally show irritability and a lack of movement of the affected joint. Chronic hemarthroses are debilitating with synovial thickening and synovitis in response to the intraarticular blood. After a joint has been damaged, recurrent bleeding episodes result in the clinically recognized "target joint," which then establishes a vicious cycle of bleeding, resulting in progressive joint deformity that in critical cases requires surgery as the only therapeutic option. Hematomas into the muscle of distal parts of the limbs may lead to external compression of arteries, veins, or nerves that can result in compartment syndrome.

Bleeding into the oropharyngeal spaces, central nervous system (CNS), or retroperitoneum is life-threatening and requires immediate therapy. Retroperitoneal hemorrhages can accumulate large quantities of blood with formation of masses with calcification and inflammatory tissue reaction (pseudotumor syndrome) and also result in damage to the femoral nerve. Pseudotumors can also form in bones, especially long bones of the lower limbs. Hematuria is frequent among hemophilia patients, even in the absence of genitourinary pathology. It is often self-limited and may not require specific therapy.

TREATMENT

Hemophilia

Without treatment, severe hemophilia may limit life expectancy. Advances in the blood fractionation industry during World War II resulted in the realization that plasma could be used to treat hemophilia, but the volumes required to achieve even modest elevation

of circulating factor levels limit the utility of plasma infusion as an approach to disease management. The discovery in the 1960s that the cryoprecipitate fraction of plasma was enriched for FVIII, and the eventual purification of FVIII and FIX from plasma, led to the introduction of home infusion therapy with factor concentrates in the 1970s. The availability of factor concentrates resulted in a dramatic improvement in life expectancy and quality of life for people with severe hemophilia. However, the contamination of the blood supply with hepatitis viruses and HIV resulted in transmission of these bloodborne infections within the hemophilia population. The introduction of viral inactivation steps in the preparation of plasma-derived products in the mid-1980s greatly reduced the risk of HIV and hepatitis; the risks were further reduced by the production of recombinant FVIII and FIX proteins in the 1990s. It is uncommon for hemophilic patients born after 1985 to have contracted either hepatitis or HIV, and for these individuals, life expectancy is now ~65 years. In fact, since 1998, new infections with viral hepatitis or HIV have not been reported in hemophilia patients.

Factor replacement for hemophilia has been the mainstay of therapy for half a century; however, advances including uniquely functioning molecules and gene therapy have expanded treatment approaches. Factor replacement has been provided either in response to a bleeding episode or as prophylactic treatment. Primary prophylaxis is defined as maintaining the missing clotting factor at levels ~1% or higher on a regular basis to prevent bleeds, especially the onset of hemarthroses. Hemophilic boys receiving regular infusions of FVIII (3 days/week) or FIX (2 days/week) can reach puberty without detectable joint abnormalities. Therefore, prophylactic treatment has become more common. The Centers for Disease Control and Prevention reported that >51% of children with severe hemophilia who are aged <6 years receive prophylaxis, increasing considerably from 33% in 1995. Although prophylaxis with factor concentrates is the standard care for children and adults with severe hemophilia, teenagers and young adults do not always maintain treatment due to high cost and lifestyle factors including difficulties accessing peripheral veins for infusions that occur two to three times a week or potential infectious and thrombotic risks of long-term central vein catheters.

Treatment of hemophilia bleeds requires the following: (1) prompt initiation of factor replacement as symptoms often precede objective evidence of bleeding, especially for classic symptoms of bleeding into the joint in a reliable patient, headaches, or major trauma; and (2) avoidance of antiplatelet drugs.

FVIII and FIX are dosed in units. One unit is defined as the amount of FVIII (100 ng/mL) or FIX (5 μg/mL) in 1 mL of normal plasma. One unit of FVIII per kilogram of body weight increases the plasma FVIII level by 2%. One can calculate the dose needed to increase FVIII levels to 100% in a 70-kg severe hemophilia patient (<1%) using the simple formula below. Thus, 3500 units of FVIII will raise the circulating level to 100%.

$$\text{FVIII dose (IU)} = \text{Target FVIII levels} - \text{FVIII baseline levels} \times \text{body weight (kg)} \times 0.5 \text{ unit/kg}$$

The doses for FIX replacement are different from those for FVIII, because FIX recovery after infusion is usually only 50% of the predicted value. Therefore, the formula for FIX replacement is as follows:

$$\text{FIX dose (IU)} = \text{Target FIX levels} - \text{FIX baseline levels} \times \text{body weight (kg)} \times 1 \text{ unit/kg}$$

The FVIII half-life of 8–12 h requires injections twice a day to maintain therapeutic levels, whereas the FIX half-life is longer, ~24 h, so that once-a-day injection is sufficient. In specific situations such as after surgery, continuous infusion of factor may be desirable because of its safety in achieving sustained factor levels at a lower total cost.

Cryoprecipitate is enriched with FVIII protein bound to VWF (each bag contains ~80 IU of FVIII). This product should be used only in emergencies when factor concentrates are not available, although cryoprecipitate may be the only source of FVIII in developing countries.

Mild bleeds such as uncomplicated hemarthroses or superficial hematomas require achieving an initial factor level of 30–50%. Additional doses to maintain levels of 15–25% for 2 or 3 days are indicated for severe hemarthroses, especially when these episodes affect the "target joint." Large hematomas, or bleeds into deep muscles, require factor levels of 50% or even higher if the clinical symptoms do not improve, and factor replacement may be required for a period of 1 week or longer. The control of serious bleeds, including those that affect the oropharyngeal spaces, CNS, and the retroperitoneum, requires sustained protein levels of 50–100% for 7–10 days. Prophylactic replacement for surgery is aimed at achieving normal factor levels (100%) for a period of 7–10 days; replacement can then be tapered depending on the extent of the surgical wounds. Oral surgery is associated with extensive tissue damage that usually requires factor replacement for 1–3 days coupled with oral antifibrinolytic drugs.

NONTRANSFUSION THERAPY IN HEMOPHILIA

DDAVP (1-Amino-8-D-Arginine Vasopressin) DDAVP is a synthetic vasopressin analogue that causes a transient rise in FVIII and VWF, but not FIX, by release from stores in vascular endothelial cells. Patients with moderate or mild hemophilia A should be tested to determine if they respond to DDAVP before use. DDAVP at doses of 0.3 μg/kg body weight, over a 20-min period, is expected to raise FVIII levels by two- to threefold over baseline, peaking between 30 and 60 min after infusion. DDAVP does not improve FVIII levels in severe hemophilia A patients because no stores are available to release. Repeated dosing of DDAVP results in tachyphylaxis as storage pools are depleted. After three consecutive doses, if further therapy is indicated, exogenous FVIII is required.

Antifibrinolytic Drugs Bleeding in the gums, the gastrointestinal tract, and during oral surgery can be treated with oral antifibrinolytic drugs such as ε-aminocaproic acid (EACA) or tranexamic acid to prevent fibrin degradation by plasmin. The duration of the treatment depending on the clinical indication is 1 week or longer. Tranexamic acid is given at doses of 25 mg/kg three to four times a day. EACA treatment requires a loading dose of 200 mg/kg (maximum of 10 g) followed by 100 mg/kg per dose (maximum 30 g/d) every 6 h. These drugs are not indicated to control hematuria because of concern for forming an occlusive clot in the lumen of genitourinary tract structures.

COMPLICATIONS

Inhibitor Formation The formation of alloantibodies to FVIII or FIX is the major complication of hemophilia treatment. The prevalence of inhibitors to FVIII is estimated to be ~30% in severe hemophilia A patients and 10% among patients with nonsevere hemophilia A. Inhibitors to FIX are detected in only 3–5% of all hemophilia B patients. The high-risk group for inhibitor formation includes severe deficiency (>80% of all cases of inhibitors), familial history of inhibitor, African descent, mutations in the FVIII or FIX gene resulting in deletion of large coding regions, or gross gene rearrangements. Inhibitors usually appear early in life, at a median of 2 years of age, and after 10 cumulative days of exposure. However, intensive replacement therapy such as for major surgery, intracranial bleeding, or trauma increases the risk of inhibitor formation for patients of all ages and severity; all patients require close laboratory monitoring following these events.

The clinical diagnosis of an inhibitor is suspected when patients do not respond to factor replacement at therapeutic doses. Inhibitors increase both morbidity and mortality in hemophilia. Because early detection of an inhibitor is critical to a successful correction of the bleeding or to eradication of the antibody, most hemophilia centers perform annual screening with aPTT and mixing studies. The Bethesda assay uses a similar principle as a mixing study and

defines the specificity of the inhibitor and its titer. The results are expressed in Bethesda units (BU), in which 1 BU is the amount of antibody that neutralizes 50% of the FVIII or FIX present in normal plasma after 2 h of incubation at 37°C. Clinically, inhibitor patients are classified as low responders or high responders, with response defined as increase in antibody titer; knowledge of responder type guides therapy. Therapy for inhibitor patients has two goals: the control of acute bleeding episodes and the eradication of the inhibitor. For the control of bleeding episodes, low responders, those with titer <5 BU, respond well to high doses of human FVIII (50–100 U/kg), with minimal or no increase in the inhibitor titers. However, high-responder patients, those with initial inhibitor titer >5 BU or an anamnestic response with increase in the antibody titer to >5 BU, even if low titer initially, do not respond to FVIII. The control of bleeding episodes in high-responder patients can be achieved by using concentrates enriched for prothrombin, FVII, FIX, FX (PCCs but usually activated PCCs [aPCCs]), and recombinant activated FVII (FVIIa), known as "bypass agents" because they activate coagulation downstream of the inhibited/absent factor or through a different pathway (Fig. 121-1). For FIX inhibitor patients, high doses of FIX can be used (<5 BU); however, allergic or anaphylactic reactions are common in FIX inhibitor patients; thus, bypass products should be used to treat or prevent bleeding as well as for those cases of high titer inhibitors. For eradication of the inhibitory antibody, immunosuppression alone is not effective. The most effective strategy is immune tolerance induction (ITI) based on daily infusion of the missing protein until the inhibitor disappears, typically requiring periods >1 year, with success rates of ~60%. The management of patients with severe hemophilia and inhibitors resistant to ITI is challenging. The use of anti-CD20 monoclonal antibody (rituximab) combined with ITI was thought to be effective, but although it reduces the inhibitor titers in some cases, sustained eradication is uncommon.

Other Therapeutic Approaches for Hemophilia A and B Engineered clotting factors, using fusion to polyethylene glycol (FVIII, FIX), IgG1-Fc (FVIII, FIX), or albumin (FIX) or other strategies, extend the plasma half-life of the coagulation factor. A number of products have been approved for use. These extended half-life products (for FVIII and FIX) facilitate prophylaxis with fewer weekly injections to maintain circulating levels >1%, decreasing injections from 3 to 2 days a week in hemophilia A and to once a week for hemophilia B. Novel approaches to manipulating the coagulation cascade components, including targeting the natural anticoagulants and inhibitors of activation of coagulation, have shown promising clinical trial results but do not yet have regulatory approval.

Emicizumab is an asymmetric bispecific antibody with one immunoglobulin variable chain region that binds FIXa and another that binds FX bringing them in close contact and resulting in activation of FX by FIXa. FXa subsequently cleaves prothrombin to thrombin—without the need for FVIII **(Fig. 121-2)**. It is effective in patients with severe hemophilia A with or without inhibitors. Similar molecules are in development. After initial once-a-week subcutaneous injections (an improvement over intravenous administration of factors) for 4 weeks, patients can usually be maintained with once-a-month dosing to prevent spontaneous bleeds, an overwhelmingly dramatic improvement in quality of life when compared to even the twice-weekly infusion schedule of "long-acting" FVIII compounds. Breakthrough bleeds can occur, however, and need to be carefully managed, as a small number of patients with inhibitors treated with aPCC or recombinant FVIIa developed thrombotic events or fatal thrombotic microangiopathy. Routine aPTT and FVIII activity measurements are inaccurate when emicizumab is present; to detect endogenous or infused FVIII activity, a chromogenic FVIII activity assay using bovine factor substrates is required.

These X-linked disorders are ideally suited for gene therapy as small increases in plasma factor level will result in significant clinical improvement. FIX has been the most studied as the gene is smaller

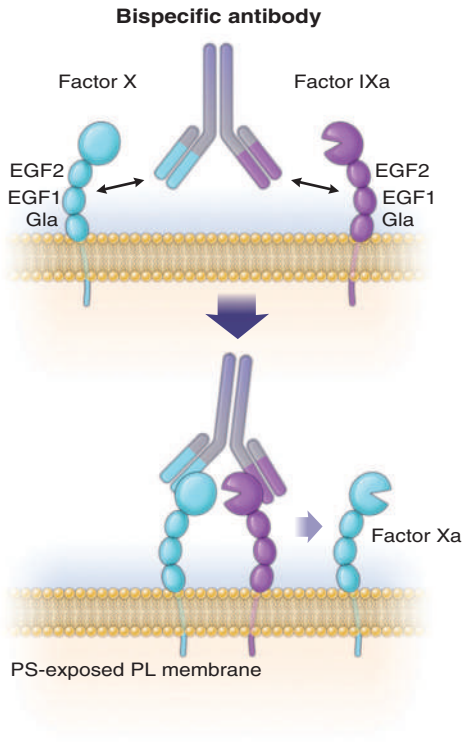

FIGURE 121-2 Mechanism of action of emicizumab. Emicizumab is a bifunctional antibody; the two binding sites recognize different protein sequences, unlike normal antibodies where both variable regions recognize the same antigen. One arm of emicizumab recognizes factor IXa and the other factor X. It functions to bring these two factors in proximity so that factor IXa can activate factor X to factor Xa, which then cleaves prothrombin to thrombin and activates the clotting cascade. *(From T Kitazawa, M Shima: Emicizumab, a humanized bispecific antibody to coagulation factors IXa and X with a factor VIIIa-cofactor activity. Int J Hematol 111:20, 2020.)*

and easier to package in the viral vectors used. In one approach, the sequence of a known spontaneous FIX gain-of-function mutation that has marked increase in specific activity, FIX Padua, is used so that small increments in plasma level of FIX are also accompanied by even greater increase in functional activity. The larger FVIII gene has also been successfully transferred through an adeno-associated viral vector to a few patients with hemophilia A. The early results appear promising. Complications include transaminitis and loss of gene expression for a variety of reasons. Gene therapy using adenoviral vector approaches have now been approved for patients with hemophilia A or B. Details on how to implement gene therapy, selection of appropriate patients, and follow-up monitoring are still being developed **(Chap. 483)**.

INFECTIOUS DISEASES

Hemophilia patients treated with clotting factor concentrates before the development of recombinant factors in the 1990s were almost universally infected with hepatitis C virus (HCV) and HIV, which became the second leading cause of death. Co-infection of HCV and HIV, present in almost 50% of hemophilia patients, is an aggravating factor for the evolution of liver disease as correction of both genetic and acquired (secondary to liver disease) factor deficiencies may be needed. Effective treatments for both HIV and HCV have altered the devastating prognosis. In some select cases with cirrhosis, liver transplant has been performed, which also is curative for hemophilia.

EMERGING CLINICAL PROBLEMS IN AGING HEMOPHILIA PATIENTS

Patients with hemophilia now live well into adulthood, with life expectancy of patients with severe hemophilia now only ~10 years shorter than the general male population and near normal in patients with mild or moderate hemophilia. The older hemophilia

population has distinct needs relating to more severe arthropathy, chronic pain, and high rates of HCV and/or HIV infections.

Although mortality from coronary artery disease is lower in hemophilia patients with hypocoagulability decreasing thrombus formation, atherogenesis is not prevented. Typical cardiovascular risk factors such as age, obesity, and smoking, along with physical inactivity, hypertension, and chronic renal disease, are seen in these patients as in the general population.

Management of an acute ischemic event and coronary revascularization should include collaboration among hematologists, cardiologists, and internists. Cancer due to HIV- and HCV-related malignancies is also a concern in this population, with hepatocellular carcinoma (HCC) the most common cause of death in HIV-negative patients. The recommendations for cancer screening for the general population should be the same for age-matched hemophilia patients, including routine screening for HCC. Hemophilia patients benefit from the same preventive and therapeutic approaches to minimize the risk of cardiovascular disease and malignancy as the general population.

MANAGEMENT OF CARRIERS OF HEMOPHILIA

Women carriers of hemophilia with factor levels ~50% of normal may not have an increased risk for bleeding. However, a wide range of factor activity (22–116%) due to random inactivation of the X chromosome (*lyonization*) can occur and lead to unexpected bleeding in women with low levels. The factor level of carriers should be measured to optimize perioperative management. During pregnancy, FVIII levels increase approximately two- to threefold in most carriers compared to nonpregnant women, whereas the FIX increase is less pronounced. After delivery, a rapid fall in the pregnancy-induced rise of maternal clotting factor levels occurs, resulting in increased risk for postpartum hemorrhage that can be prevented by infusion of factor concentrate to levels of 50–70% for 3 days for vaginal delivery and up to 5 days for cesarean delivery. In mild cases, the use of DDAVP and/or antifibrinolytic drugs is recommended.

FACTOR XI DEFICIENCY

FXI deficiency, also known as hemophilia C, is a rare autosomal bleeding disorder that occurs at a frequency of one in a million. However, it is highly prevalent among Ashkenazi and Iraqi Jewish populations, reaching a frequency of 6% heterozygotes and 0.1–0.3% homozygotes. More than 65 mutations in the FXI gene have been reported, whereas fewer mutations (two to three) are found among affected Jewish populations.

Normal FXI clotting activity levels range from 70–150 U/dL. Levels vary depending on the presence of heterozygous, homozygous, or double heterozygous mutations with levels <1 U/dL seen in the latter two. Patients with FXI levels <10% of normal have a high risk of bleeding, but the phenotype does not always correlate with FXI clotting activity. The family history is informative, with the bleeding risk based on bleeding in kindreds. Clinically, spontaneous bleeding is rare, but mucocutaneous bleeding such as bruises, gum bleeding, epistaxis, hematuria, and menorrhagia are common, especially following trauma. This hemorrhagic phenotype suggests that tissues rich in fibrinolytic activity are more susceptible to FXI deficiency. Postoperative bleeding is common but not always present, even among patients with very low FXI levels.

FXI replacement is indicated in patients with severe disease for major surgical procedures. A negative history of bleeding complications following invasive procedures does not exclude the possibility of an increased risk for hemorrhage.

TREATMENT

Factor XI Deficiency

Sources of FXI are limited to FFP in the United States, whereas a plasma-derived FXI concentrate is available in other countries. FFP at doses of 15–20 mL/kg to increase levels by 10–20% can be given every other day in the setting of bleeding or major surgery as FXI has a half-life of 40–70 h. Antifibrinolytic drugs can be used for minor bleeds and as adjunctive treatment with FXI replacement with the exception of genitourinary tract bleeding. The development of an FXI inhibitor can be seen in 10% of severely FXI-deficient patients. Although inhibitors are not associated with spontaneous bleeding, bleeding with surgery or trauma can be severe; treatment with PCC/aPCC or recombinant activated FVII is effective. Data for use of a single very low dose of recombinant activated FVII (10–15 μg/kg) and an antifibrinolytic agent before surgery in patients with severe FXI deficiency are good, avoiding the need for plasma products.

RARE BLEEDING DISORDERS

Inherited disorders resulting from deficiencies of clotting factors other than FVIII, FIX, and FXI (Table 121-1) occur infrequently. Bleeding manifestations vary from generally asymptomatic as with dysfibrinogenemia or FVII deficiency to life-threatening as with FX or FXIII deficiency. In contrast to hemophilia, hemarthroses are rare, but bleeding in the mucosal tract or after umbilical cord clamping is common. Individuals heterozygous for plasma coagulation deficiencies are often asymptomatic. The laboratory assessment for the specific deficient factor following screening with general coagulation tests (Table 121-1) identifies the diagnosis.

Replacement therapy using FFP or PCCs for deficiencies provides adequate hemostasis for bleeds or prophylactic treatment, although specific concentrates for FX and fibrinogen are available. Cryoprecipitate or FXIII concentrate is needed for FXIII deficiency. FVII deficiency, like FXI, has an increased prevalence in the Ashkenazi Jewish population and is best treated with recombinant FVIIa rather than FFP or PCCs depending on the severity of bleeding or type of surgery. It should be noted that deficiency of FXII is associated with significant prolongation of the aPTT but no bleeding phenotype.

FAMILIAL MULTIPLE COAGULATION DEFICIENCIES

Several bleeding disorders are characterized by the inherited deficiency of more than one plasma coagulation factor. To date, the genetic defects in two of these diseases have been characterized, and they provide new insights into the regulation of hemostasis by gene-encoding proteins outside blood coagulation.

Combined Deficiency of FV and FVIII Patients with combined FV and FVIII deficiency exhibit ~5% of residual clotting activity of each factor, yet have a mild bleeding tendency, often following trauma. A mutation in the lectin mannose binding 1 (*LMAN1*) gene, a mannose-binding protein localized in the Golgi apparatus that functions as a chaperone for both FV and FVIII, is responsible. In other families, mutations in the multiple coagulation factor deficiency 2 (*MCFD2*) gene have been defined; this gene product forms a Ca^{2+}-dependent complex with *LMAN1*, providing cofactor activity for intracellular mobilization of both FV and FVIII. Replacement therapy to control or prevent bleeding consists of FFP to maintain FV levels and DDAVP or FVIII concentrate to achieve FVIII levels of 20–40%. Alternatively, platelets, which contain FV, can also be used.

Multiple Deficiencies of Vitamin K–Dependent Coagulation Factors Two enzymes involved in vitamin K metabolism have been associated with combined deficiency of all vitamin K–dependent proteins, including the procoagulant proteins prothrombin (II), VII, IX, and X and the anticoagulant proteins C and S. Vitamin K, a fat-soluble vitamin, is a cofactor for carboxylation of the gamma carbon of the glutamic acid residues in the vitamin K–dependent factors, a critical step for calcium and phospholipid binding **(Fig. 121-3)**. The enzymes γ-glutamylcarboxylase and epoxide reductase are critical for the metabolism and regeneration of vitamin K. Mutations in the genes encoding the γ-carboxylase (GGCX) or vitamin K epoxide reductase complex 1 (VKORC1) result in defective enzymes and thus in vitamin K–dependent factors with reduced activity, varying from 1–30%

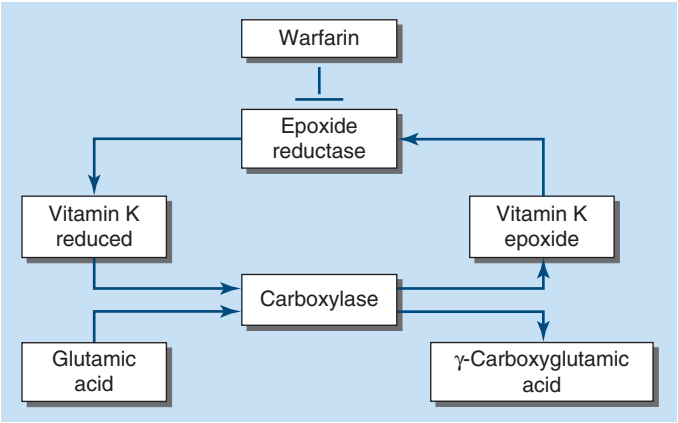

FIGURE 121-3 The vitamin K cycle. Vitamin K is a cofactor for the formation of γ-carboxyglutamic acid residues on coagulation proteins. Vitamin K–dependent γ-glutamylcarboxylase, the enzyme that catalyzes the vitamin K epoxide reductase, regenerates reduced vitamin K. Warfarin blocks the action of the reductase and competitively inhibits the effects of vitamin K.

of normal. Patients can have mild to severe bleeding episodes present from birth. Some patients respond to oral vitamin K_1 (5–20 mg/d) or parenteral vitamin K_1 at doses of 5–20 mg/week. For severe bleeding, replacement therapy with PCC may be necessary.

DISSEMINATED INTRAVASCULAR COAGULATION

In 2001, the International Society on Thrombosis and Haemostasis (ISTH) defined DIC as "an acquired syndrome characterized by the intravascular activation of coagulation with loss of localization arising from different causes that can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction." Many disparate processes are associated with DIC (Table 121-2).

The most common causes are bacterial sepsis, although viral and fungal sepsis can also cause DIC; trauma; obstetric causes such as abruptio placentae or amniotic fluid embolism; and malignant disorders, especially mucin-producing adenocarcinomas and acute promyelocytic leukemia. Activation of inflammatory pathways in response to infectious pathogens results in increased expression of tissue factor, activation of neutrophils and monocytes with release of cytokines and development of neutrophil extracellular traps, and release of polyphosphates that engage in cross-talk with the coagulation system to cause thrombin generation; this process is known as *thrombo-inflammation*. Damage to vascular endothelial cells results in the loss of their native antithrombotic properties; such damage especially occurs with sepsis and trauma. Systemic inflammatory response syndrome (SIRS) and cytokine storm are cytokine-mediated exuberant inflammatory responses often in the setting of infection that are associated with increased mortality and DIC. Purpura fulminans is a severe form of DIC resulting in thrombosis of extensive areas of the skin; it affects predominantly young children following viral or bacterial infection, particularly those with inherited or acquired hypercoagulability due to deficiencies of the components of the protein C pathway. Neonates homozygous for protein C deficiency can develop neonatal purpura fulminans with or without thrombosis of large vessels.

The central mechanism of DIC is the uncontrolled generation of thrombin by multiple mechanisms (Fig. 121-4). Simultaneous disruption of the physiologic anticoagulant mechanisms and abnormal fibrinolysis further accelerate the process. These abnormalities contribute to systemic fibrin deposition in small and midsize vessels. The duration and intensity of the fibrin deposition can compromise the blood supply of many organs, especially the lung, kidney, liver, and brain, with consequent organ failure; for example, pulmonary microvascular thrombosis is a component of adult respiratory distress syndrome (ARDS). The sustained activation of coagulation and formation of fibrin can result in consumption of clotting factors and platelets, which in turn leads to systemic bleeding that can be aggravated by secondary hyperfibrinolysis that occurs in late stages of DIC.

TABLE 121-2 Common Clinical Causes of Disseminated Intravascular Coagulation

SEPSIS	**IMMUNOLOGIC DISORDERS**
• Bacterial: Staphylococci, streptococci, pneumococci, meningococci, gram-negative bacilli • Viral • Mycotic • Parasitic • Rickettsial	• Acute hemolytic transfusion reaction • Organ or tissue transplant rejection • Immunotherapy • Graft-versus-host disease
TRAUMA AND TISSUE INJURY	**DRUGS**
• Brain injury (gunshot) • Extensive burns • Fat embolism • Rhabdomyolysis	• Fibrinolytic agents • Aprotinin • Warfarin (especially in neonates with protein C deficiency) • Prothrombin complex concentrates • Recreational drugs (amphetamines)
VASCULAR DISORDERS	**ENVENOMATION**
• Giant hemangiomas (Kasabach-Merritt syndrome) • Large vessel aneurysms (e.g., aorta)	• Snake • Insects
OBSTETRICAL COMPLICATIONS	**LIVER DISEASE**
• Abruptio placentae • Amniotic fluid embolism • Dead fetus syndrome • Septic abortion	• Fulminant hepatic failure • Cirrhosis • Fatty liver of pregnancy
CANCER	**MISCELLANEOUS**
• Adenocarcinoma (prostate, pancreas, etc.) • Hematologic malignancies (acute promyelocytic leukemia)	• Shock • Respiratory distress syndrome • Massive transfusion

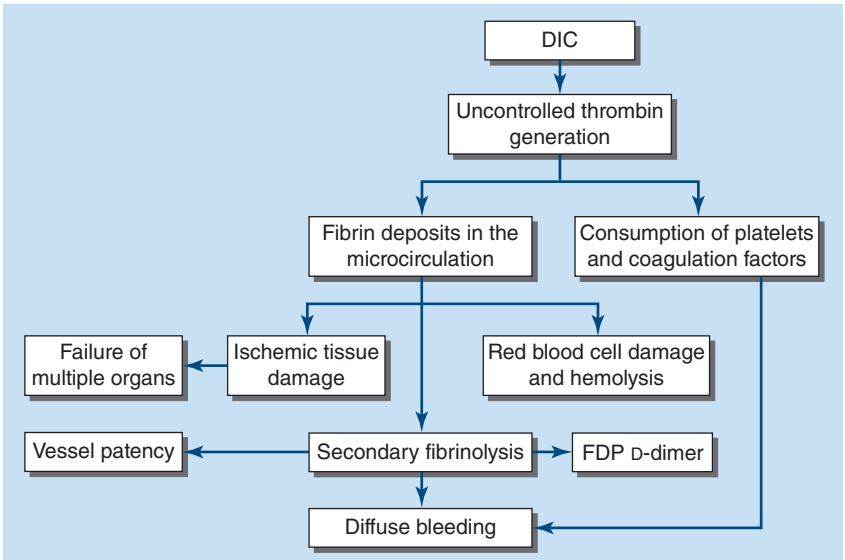

FIGURE 121-4 The pathophysiology of disseminated intravascular coagulation (DIC). Interactions between coagulation and fibrinolytic pathways result in bleeding and thrombosis in the microcirculation in patients with DIC. FDP, fibrin degradation product.

TABLE 121-3 International Society on Thrombosis and Haemostasis Criteria for Overt Disseminated Intravascular Congestion (DIC)

PARAMETER	VALUE	POINTS
Platelets	>100,000 × 10^9/L	0
	>50–<100 × 10^9/L	1
	<50 × 10^9/L	2
D-Dimer[a]	Normal	0
	Moderate increase	2
	Severe increase	3
Prothrombin time (PT) prolonged	<3 s	0
	3–<6 s	1
	>6 s	2
Fibrinogen	>1 g/L	0
	<1 g/L	1
Total Score		**<5 Low-grade DIC** **>5 Overt DIC**

[a]D-Dimer assays are not standardized and have different ranges of normal. Check your institution range of normal to assess degree of increase.

Note: A score of <5 suggests nonovert DIC/low-grade DIC and should be repeated every 1–2 days. A score of >5 suggests overt DIC; lab values should be repeated daily to assess critical changes. Not to be used in pregnant patients.

Clinical manifestations of DIC are related to the magnitude of the imbalance of hemostasis, to the underlying disease, or to both. The most common clinical findings include petechiae, ecchymoses, and bleeding ranging from oozing from venipuncture sites to severe hemorrhage from the gastrointestinal tract, lung, or into the CNS. In chronic DIC, the bleeding symptoms are discrete and restricted to skin or mucosal surfaces. The hypercoagulability of DIC manifests as the occlusion of vessels in the microcirculation resulting in organ failure. Thrombosis of large vessels and cerebral embolism can also occur. Hemodynamic complications and shock are common among patients with acute DIC, due to the underlying disease, with mortality ranging from 30 to >80%.

Making the diagnosis of DIC can be difficult. The ISTH has developed a validated scoring tool to aid in the diagnosis of overt DIC with a separate tool for pregnant women. It incorporates platelet count, D-dimer level, PT, and fibrinogen level, and assigns points for different levels of each with the aggregate score helping to make the diagnosis of DIC **(Table 121-3)**. The peripheral smear should be assessed for schistocytes. The laboratory diagnosis of DIC should prompt a search for the underlying disease if not already apparent. In critically ill patients, these tests should be repeated over a period of 6–8 h as patients can rapidly deteriorate.

Chronic DIC Low-grade, compensated DIC can occur in clinical situations including giant hemangioma, metastatic carcinoma, or late gestation fetal demise. Plasma levels of fibrin degradation product or D-dimers are elevated. aPTT, PT, and fibrinogen values are within the normal range or high. Mild thrombocytopenia or normal platelet counts are also common findings. Red cell fragmentation is often detected but at a lower degree than in acute DIC.

Differential Diagnosis Distinguishing between DIC and severe liver disease is challenging and requires serial measurements of the laboratory parameters of DIC. Patients with severe liver disease manifest laboratory features including thrombocytopenia due to platelet sequestration, portal hypertension, or hypersplenism; decreased synthesis of coagulation factors and natural anticoagulants; and elevated levels of D-dimer. However, in contrast to DIC, these laboratory parameters in liver disease do not change rapidly.

Although microangiopathic disorders such as immune thrombotic thrombocytopenic purpura present with acute onset accompanied by thrombocytopenia, red cell fragmentation, and multiorgan failure, the clinical presentation and laboratory findings including presence of an inhibitor to ADAMTS13 assist in diagnosis **(Chap. 120)**.

TREATMENT

Disseminated Intravascular Coagulation

The morbidity and mortality associated with DIC are primarily related to the underlying disease. Management of the underlying disease is required to control and eliminate DIC; however, support with platelets and coagulation factors may be needed until the inciting cause is under control. Many patients with overt DIC are critically ill, usually requiring management in the intensive care unit to treat shock physiology and other manifestations of the underlying illness.

MANAGEMENT OF HEMORRHAGIC SYMPTOMS

Patients with active bleeding or at high risk of bleeding during invasive procedures or after chemotherapy require transfusion support; however, transfusion solely to correct mildly to moderately abnormal coagulation parameters is not indicated. Platelet transfusion for platelet counts <10,000–20,000/μL and replacement of fibrinogen and coagulation factors with FFP, cryoprecipitate, or fibrinogen concentrate as a source of fibrinogen are indicated with amounts determined by the degree of abnormal PT, aPTT, and fibrinogen levels, as well as severity of bleeding or bleeding risk with invasive procedures. For these situations, fibrinogen level should be maintained at >150 mg/dL and PT prolonged no more than 3 s above the upper limit of normal. Vitamin K should be given. Patients should be frequently monitored, and transfusion support adjusted as the patient's condition changes and dictates.

REPLACEMENT OF COAGULATION OR FIBRINOLYSIS INHIBITORS

Anticoagulants such as heparin, concentrates of antithrombin and thrombomodulin, and antifibrinolytic drugs have all been tried in the treatment of DIC. Low doses of continuous-infusion heparin (5–10 U/kg per h) may be effective in patients with low-grade DIC associated with solid tumors, acute promyelocytic leukemia, or in a setting with recognized thrombosis. Heparin is also indicated for the treatment of purpura fulminans. In acute hemorrhagic DIC, the use of heparin is likely to aggravate bleeding. The use of heparin in patients with severe DIC, although demonstrating improved coagulation parameters, is not associated with a survival benefit; professional society recommendations for use vary widely. Although the use of concentrates of the serine protease inhibitors, antithrombin and thrombomodulin, for sepsis demonstrated little efficacy in all treated patients, post hoc analyses of those with sepsis and confirmed DIC suggest a survival advantage and require further study. Activated protein C treatment for septic shock was withdrawn from the market years ago as findings in clinical practice did not replicate the mortality advantage seen in the clinical trial; impact on DIC was not evaluated.

In patients who have DIC characterized by a primary hyperfibrinolytic state with concomitant severe bleeding, the administration of antifibrinolytics may be considered. However, concern for increasing the risk of thrombosis has led to consideration of concomitant use of heparin. Patients with acute promyelocytic leukemia or those with chronic DIC associated with giant hemangiomas are among the few patients who may benefit from this therapy.

VITAMIN K DEFICIENCY

Vitamin K–dependent proteins are a heterogeneous group, including clotting factor proteins and proteins found in bone, lung, kidney, and placenta. Vitamin K mediates posttranslational modification of glutamate residues to γ-carboxylglutamate, which is necessary for calcium binding and proper assembly on phospholipid membranes (Fig. 121-3). Inherited mutations with decreased functional activity of the enzymes GGCX or VKORC1 (see above) result in bleeding disorders. Vitamin K in the diet is often limiting for the carboxylation reaction; thus, recycling of the vitamin K by these enzymes is essential to maintain normal levels of vitamin K–dependent proteins. In adults, severe vitamin K deficiency due to low dietary intake is rare but is common in

association with the use of broad-spectrum antibiotics or with disease or surgical interventions that affect the ability of the intestinal tract to absorb vitamin K, through anatomic alterations or by changing the fat content of bile salts and pancreatic enzymes in the proximal small bowel. Chronic liver diseases such as primary biliary cirrhosis also deplete vitamin K stores. Neonatal vitamin K deficiency and the resulting hemorrhagic disease of the newborn have been almost entirely eliminated by routine administration of vitamin K to all neonates. Prolongation of PT values is the most common and earliest finding in vitamin K–deficient patients due to the short half-life of FVII and occurs before prolongation of the aPTT. Parenteral administration of 10 mg of vitamin K is sufficient to restore normal levels of clotting factor within 8–10 h. More rapid correction of the coagulopathy requires replacement with FFP or PCC, with the choice depending on patient intravascular volume status and need for rapidity of correction. The reversal of excessive anticoagulant therapy with vitamin K antagonists, such as warfarin, can be achieved by minimal doses of vitamin K (1 mg orally or by intravenous injection) for asymptomatic patients. This strategy can diminish the risk of bleeding while maintaining therapeutic anticoagulation for an underlying prothrombotic state. For emergent reversal of warfarin in the setting of life-threatening bleeding or need for emergency surgery, use of 4F-PPC is the standard of care.

In patients with underlying vascular disease, vascular trauma, atrial fibrillation, and other comorbidities, re-initiation of anticoagulation needs to be carefully considered to prevent subsequent thromboembolic complications.

COAGULATION DISORDERS ASSOCIATED WITH LIVER FAILURE

The liver is the site of synthesis and clearance of most procoagulant and natural anticoagulant proteins and of essential components of the fibrinolytic system. Acute liver failure is associated with a high risk of bleeding due to deficient synthesis of procoagulant factors and enhanced fibrinolysis; hepatologists refer to this as accelerated intravascular coagulation and fibrinolysis (AICF). Thrombocytopenia is common in patients with liver disease and may be due to decreased thrombopoietin that is synthesized in the liver, congestive splenomegaly (hypersplenism), or immune-mediated shortened platelet life span (primary biliary cirrhosis). In addition, several anatomic abnormalities secondary to underlying liver disease further increase the risk of bleeding (Table 121-4). Dysfibrinogenemia is a relatively common finding in patients with liver disease due to impaired fibrin polymerization. The development of DIC in patients with chronic liver disease is not uncommon and may enhance the risk for bleeding. Laboratory evaluation is mandatory for an optimal therapeutic strategy, either to control ongoing bleeding or before invasive procedures. Typically, these patients present with prolonged PT, aPTT, and thrombin time (TT) depending on the degree of liver damage, thrombocytopenia, and normal or slight increase in D-dimer. Fibrinogen levels are low only in fulminant hepatitis, decompensated cirrhosis, advanced liver disease, or in the presence of DIC. The presence of prolonged TT and normal fibrinogen and D-dimer levels suggests dysfibrinogenemia. FVIII levels are often normal or elevated in patients with liver failure, and decreased levels suggest superimposed DIC. FV is only synthesized in the hepatocyte and is not a vitamin K–dependent protein; therefore, reduced levels of FV may be an indicator of liver failure. Normal levels of FV and low levels of FVII suggest vitamin K deficiency. Vitamin K levels may be reduced in patients with liver failure due to compromised storage in hepatocellular disease, changes in bile acids, or cholestasis that can diminish the absorption of vitamin K. Replacement with intravenous vitamin K may improve hemostasis.

TABLE 121-4 Coagulation Disorders and Hemostasis in Liver Disease

Bleeding
Portal hypertension
Esophageal varices
Thrombocytopenia
Splenomegaly
Chronic or acute DIC
Decreased synthesis of clotting factors
Hepatocyte failure
Vitamin K deficiency
Systemic fibrinolysis
DIC
Dysfibrinogenemia
Thrombosis
Decreased synthesis of coagulation inhibitors: protein C, protein S, antithrombin
Hepatocyte failure
Vitamin K deficiency (protein C, protein S)
Failure to clear activated coagulation proteins (DIC)
Dysfibrinogenemia

Abbreviation: DIC, disseminated intravascular coagulation.

Patients with chronic stable liver disease are now recognized to have rebalanced hemostasis with simultaneous changes in both procoagulant and anticoagulant proteins. Although traditional clinical laboratory tests may suggest increased bleeding risk, these patients in fact do not have spontaneous bleeding and often do not need treatment for minor to moderate bleeding risk procedures. If the patient is bleeding, treatment with FFP was the standard approach to correcting hemostasis in patients with acute liver failure; however, the use of 4F-PCC is now favored due to lower volume, less increase in portal pressure, reduced risk of circulatory overload, and other complications associated with FFP transfusion. As in any clinical situation, treatment should not be given simply to correct laboratory abnormalities in a patient who is not bleeding or with no need for invasive procedures. Platelet concentrates are indicated when platelet counts are <10,000–20,000/μL to control bleeding or immediately before an invasive procedure if counts are <50,000/μL. Cryoprecipitate is indicated only when fibrinogen levels are <100–150 mg/mL unless the patient is bleeding, in which case a higher target is used. The use of antifibrinolytic drugs as adjuncts to control bleeding in patients with liver failure is not thought to result in an increased risk of thrombosis; however, their impact on acute thrombosis propagation is not well studied.

Liver Disease and Thromboembolism Bleeding in patients with stable liver disease is often mild or even asymptomatic. However, as the disease progresses, the hemostatic balance is precarious and easily disturbed; comorbid complications such as infections and renal failure can rapidly upset this balance (Fig. 121-5). Past assumptions based on abnormal coagulation tests have been that patients with liver disease have a decreased risk of thrombosis; however, multiple factors contribute to hypercoagulability, including decreased levels of the natural anticoagulant proteins S and C, as well as endothelial cell changes and hemodynamic changes that result in stasis such that portal vein thrombosis is common. Patients with liver disease can also develop deep-vein thrombosis and pulmonary embolism; those with cirrhosis appear to have a 1.5- to 2-fold increase in the rate of venous thromboembolism (VTE). Patients with compensated cirrhosis do not appear to have increased bleeding with the use of VTE prophylaxis or even therapeutic dose heparin to treat acute portal vein thrombosis when carefully managed. In the outpatient setting, warfarin is avoided, but low-molecular-weight heparin and direct oral anticoagulants have been safely used to treat thrombosis.

Acquired Inhibitors of Coagulation Factors An acquired inhibitor is an immune-mediated disease characterized by the presence of an autoantibody against a specific clotting factor. Almost half of patients with an acquired factor inhibitor will have an underlying autoimmune or immunoproliferative disorder, have a malignancy, or be peripartum. FVIII is the most common target of antibody formation and is often referred to as acquired hemophilia A, but inhibitors to prothrombin (FII), FV, FIX, FX, and FXI are also reported. Acquired inhibitor to FVIII occurs predominantly in older adults (median age of 60 years) but occasionally in pregnant or postpartum women with

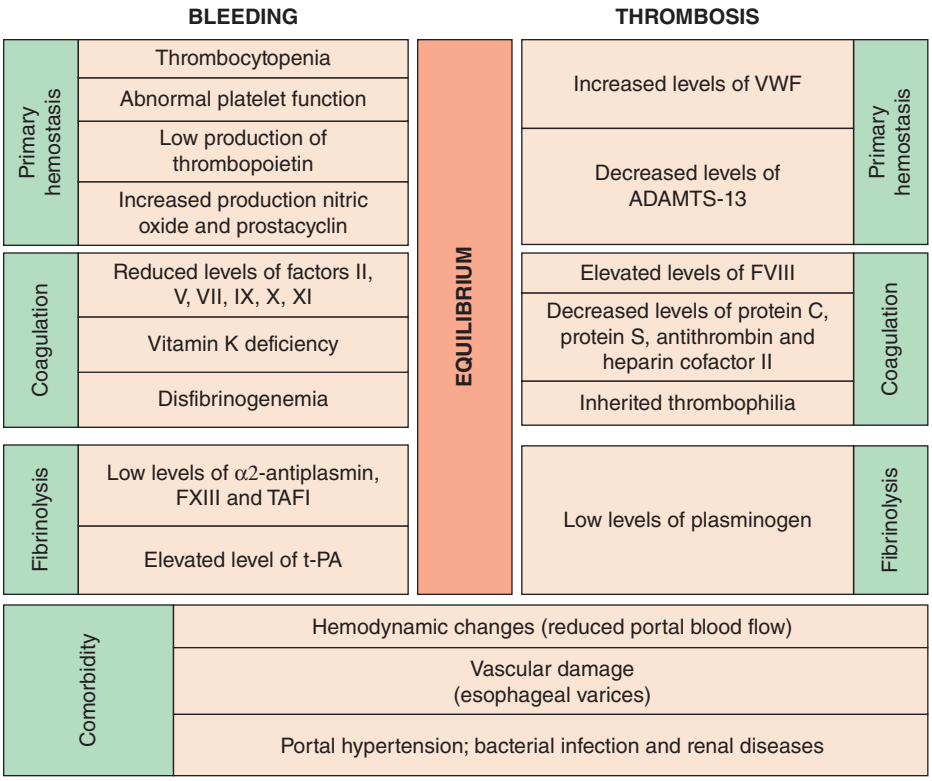

FIGURE 121-5 Balance of hemostasis in liver disease. TAFI, thrombin-activated fibrinolytic inhibitor; t-PA, tissue plasminogen activator; VWF, von Willebrand factor.

no previous history of bleeding. Bleeding episodes occur commonly in soft tissues, the gastrointestinal or urinary tracts, and skin. In contrast to congenital hemophilia, hemarthrosis is rare in these patients. Retroperitoneal hemorrhages and other life-threatening bleeding may appear suddenly. The overall mortality in untreated patients ranges from 8–22%, and most deaths occur within the first few weeks after presentation. The diagnosis is based on the prolonged aPTT with normal PT and TT and a mixing study that does not correct with normal pooled plasma. The Bethesda assay using factor-specific deficient plasma as performed for inhibitor detection in hemophilia will confirm the diagnosis. Treatment of acquired inhibitors of coagulation factors requires control of bleeding and eradication of the inhibitor. Many patients can have life-threatening bleeding. The use of activated "bypass products" such as aPCC or recombinant FVIIa is required. The use of recombinant porcine FVIII can be effective for acquired inhibitors of FVIII. The use of emicizumab to treat acquired FVIII inhibitors has been reported, and trials in this population are underway in Europe.

In contrast to inhibitors in patients with congenital factor deficiencies, acquired inhibitors are typically responsive to immune suppression, and treatment should be initiated early for most cases. High-dose intravenous γ-globulin and anti-CD20 monoclonal antibody are reported to be effective in patients with autoantibodies to FVIII; however, no firm evidence confirms that these alternatives are superior to the first line of immunosuppressive drugs (glucocorticoids and cyclophosphamide), effective in 70% of patients. Relapse of an inhibitor to FVIII is relatively common (up to 20%) within the first 6 months following withdrawal of immunosuppression; patients should be followed up regularly for relapse.

Topical plasma-derived bovine and human thrombin are commonly used during major cardiovascular, thoracic, neurologic, and pelvic surgeries as well as in trauma patients with extensive burns. Antibody formation to the xenoantigen or its contaminant (bovine clotting protein) has the potential to cross-react with human clotting factors, particularly FV and thrombin, and can result in bleeding that can be life-threatening. The development of antibodies to FV with the use of topical preparations of recombinant human thrombin has also been reported. The clinical diagnosis of these acquired coagulopathies is rare but is often complicated by the fact that the bleeding episodes may be detectable during or immediately following major surgery and could be assumed to be due to the procedure itself.

The risk of developing a cross-reacting antibody is increased by repeated exposure to topical thrombin preparations. Thus, a careful medical history of previous surgical interventions that may have occurred even decades earlier is critical to assessing risk.

The laboratory abnormalities include a combined prolongation of the aPTT and PT that often fails to improve by transfusion of FFP and vitamin K, and a mixing study that does not correct with normal pooled plasma. The specificity of the antibody is determined by the measurement of the residual activity of human FV or other suspected human clotting factor. No assays specific for bovine thrombin coagulopathy are commercially available.

No treatment guidelines have been established. Platelet transfusions have been used as a source of FV replacement for patients with FV inhibitors. FFP and vitamin K supplementation may function as co-adjuvants rather than as effective treatments for the coagulopathy itself. Experience with recombinant FVIIa as a bypass agent is limited, and outcomes have been generally poor. Specific treatments to eradicate the antibodies based on immunosuppression with glucocorticoids, intravenous immunoglobulin, or serial plasmapheresis have been sporadically reported. Patients should be advised to avoid any topical thrombin sealant in the future.

The presence of lupus anticoagulant can be associated with venous or arterial thrombotic disease. However, bleeding has also been reported rarely with lupus anticoagulants due to antibodies to prothrombin, resulting in hypoprothrombinemia. Both disorders show a prolonged aPTT that does not correct on mixing. To distinguish acquired inhibitors from lupus anticoagulant, note that the dilute Russell viper venom time (dRVVT) and the hexagonal-phase phospholipids test will be negative in patients with an acquired inhibitor and positive in patients with lupus anticoagulants. Moreover, lupus anticoagulant interferes with the clotting activity of many factors (FVIII, FIX, FXI, FXII), which can be assessed in the clinical laboratory; acquired inhibitors are specific to a single factor.

122 Arterial and Venous Thrombosis

Jane E. Freedman, Joseph Loscalzo

OVERVIEW OF THROMBOSIS

GENERAL OVERVIEW

Thrombosis is hemostasis "at the wrong place and at the wrong time" (MacFarlane). The obstruction of blood flow due to the formation of thrombus may result in tissue anoxia and damage, and it is a major cause of morbidity and mortality in a wide range of arterial and venous diseases and patient populations. As reported in 2020, 655,000 Americans die from heart disease each year or about 1 in 4 deaths. In 2020, coronary disease killed 382,820 people and stroke killed 160,747 in the United States with approximately 805,000 suffering from heart attacks and 795,000 having strokes.

It is estimated that as many as 600,000 people each year have a pulmonary embolism or deep-venous thrombotic event, and 60,000–80,000 Americans die of these conditions annually. In the nondiseased state, physiologic hemostasis reflects a delicate interplay between factors that promote and inhibit blood clotting, favoring the former. This response is crucial as it prevents uncontrolled hemorrhage and exsanguination following injury. In specific settings, the same processes that regulate normal hemostasis can cause pathologic thrombosis, leading to arterial or venous occlusion. Importantly, many commonly used therapeutic interventions may also alter the thrombotic–hemostatic balance adversely.

Hemostasis and thrombosis primarily involve the interplay among three factors: the vessel wall, coagulation and fibrinolytic proteins, and platelets. Many prevalent acute vascular diseases are due to thrombus formation within a vessel, including myocardial infarction, thrombotic cerebrovascular events, and venous thrombosis. Although the end result is vessel occlusion and tissue ischemia, the pathophysiologic processes governing these pathologies have similarities as well as distinct differences. While many of the pathways regulating thrombus formation are similar to those that regulate hemostasis, the processes triggering or perpetuating thrombosis may be distinct and can vary in different clinical and genetic settings. In venous thrombosis, primary hypercoagulable states reflecting defects in the proteins governing coagulation and/or fibrinolysis or secondary hypercoagulable states involving abnormalities of blood vessels and blood flow or stasis lead to thrombosis. By contrast, arterial thrombosis is highly dependent on the state of the vessel wall, the platelet, and factors related to blood flow.

ARTERIAL THROMBOSIS

OVERVIEW OF ARTERIAL THROMBOSIS

In arterial thrombosis, platelets and abnormalities of the vessel wall typically play a key role in vessel occlusion. Arterial thrombus forms via a series of sequential steps in which platelets adhere to the vessel wall, additional platelets are recruited, and thrombin is activated (Fig. 122-1). The regulation of platelet adhesion, activation, aggregation, and recruitment will be described in detail below. In addition, while the primary function of platelets is regulation of hemostasis, our understanding of their role in other processes, such as immunity, metastasis, wound healing, and inflammation, continues to evolve.

ARTERIAL THROMBOSIS AND VASCULAR DISEASE

Arterial thrombosis is a major cause of morbidity and mortality both in the United States and, increasingly, worldwide. Although the rates have declined in the United States, the overall burden remains high. Overall, in 2020, heart disease was estimated to cause about 1 of every 4 deaths in the United States. In addition to the 605,000 Americans who will have a new coronary event annually, an additional 200,000 myocardial infarctions occur in those with previous heart attacks. Although the rate of strokes has fallen, each year about 795,000 people experience a new or recurrent ischemic stroke. In 2018, about 1 in 6 deaths from cardiovascular disease were due to stroke in the United States.

THE PLATELET

Many processes in platelets have parallels with other cell types, such as the presence of specific receptors and signaling pathways; however, unlike most cells, platelets lack a nucleus and are unable to adapt to changing biologic settings by altered gene transcription. Platelets sustain limited protein synthetic capacity from megakaryocyte-derived and intracellularly transported messenger RNA (mRNA) and microRNA (miRNA). Most of the molecules needed to respond to various stimuli, however, are maintained in storage granules and membrane compartments.

Platelets are disc-shaped, very small, anucleate cells (1–5 μm in diameter) that circulate in the blood at concentrations of 200–400,000/μL, with an average life span of 7–10 days. Platelets are derived from megakaryocytes, polyploidal hematopoietic cells found in the bone marrow. The primary regulator of platelet formation is thrombopoietin (TPO). The precise mechanism by which megakaryocytes produce and release fully formed platelets is unclear, but the process likely involves formation of proplatelets, pseudopod-like structures generated by the

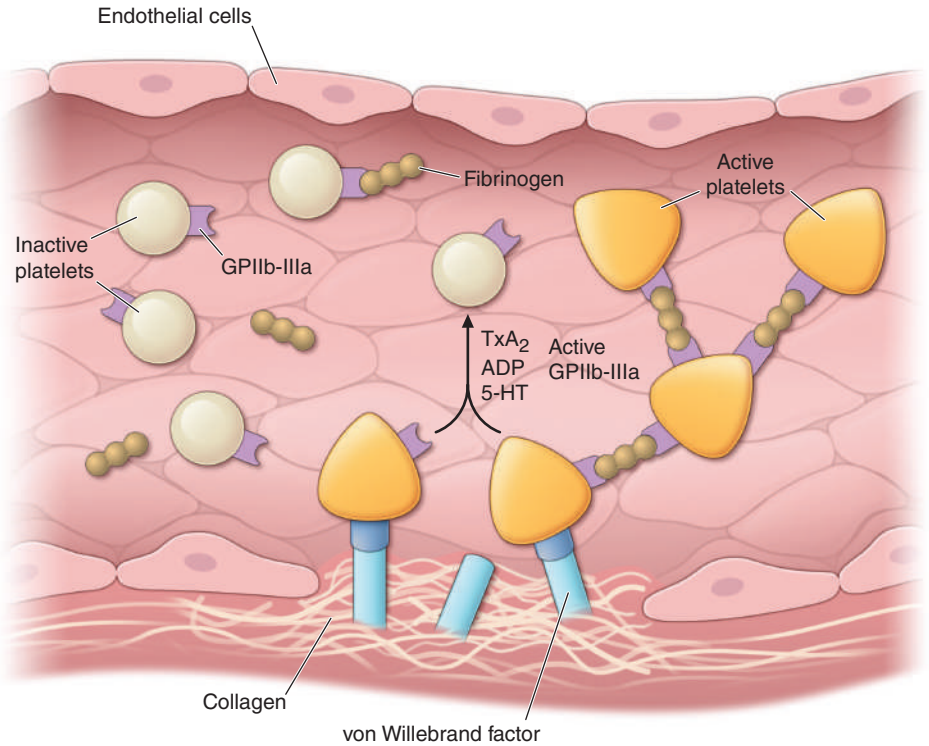

FIGURE 122-1 Platelet activation and thrombosis. Platelets circulate in an inactive form in the vasculature. Damage to the endothelium and/or external stimuli activate platelets that adhere to the exposed subendothelial von Willebrand factor and collagen. This adhesion leads to activation of the platelet, shape change, and the synthesis and release of thromboxane (TxA_2), serotonin (5-HT), and adenosine diphosphate (ADP). Platelet stimuli cause conformational change in the platelet integrin glycoprotein (GP) IIb/IIIa receptor, leading to the high-affinity binding of fibrinogen and the formation of a stable platelet thrombus.

evagination of the cytoplasm from which platelets bud. After release into the circulation, (young, large) platelets may continue to divide. Platelet granules are synthesized in megakaryocytes before thrombopoiesis and contain an array of prothrombotic, proinflammatory, and antimicrobial mediators. The two major types of platelet granules, alpha and dense, are distinguished by their size, abundance, and content. Alpha-granules contain soluble coagulation proteins, adhesion molecules, growth factors, integrins, cytokines, and inflammatory modulators. Platelet dense-granules are smaller than alpha-granules and less abundant. Whereas alpha-granules contain proteins that may be more important in the inflammatory response, dense-granules contain high concentrations of small molecules, including adenosine diphosphate (ADP) and serotonin, that influence platelet aggregation and other related vascular processes, such as vasomotor tone.

Platelet Adhesion (See Fig. 122-1) The formation of a thrombus is initiated by the adherence of platelets to the damaged vessel wall. Damage exposes subendothelial components responsible for triggering platelet reactivity, including collagen, von Willebrand factor, fibronectin, and other adhesive proteins, such as vitronectin and thrombospondin. The hemostatic response may vary, depending on the extent of damage, the specific proteins exposed, and flow conditions. Certain proteins are expressed on the platelet surface that subsequently regulate collagen-induced platelet adhesion, particularly under flow conditions, and include glycoprotein (GP) IV, GPVI, and the integrin $\alpha_2\beta_1$. The platelet GPIb-IX-V complex adhesive receptor is central both to platelet adhesion and to the initiation of platelet activation. Damage to the blood vessel wall exposes subendothelial von Willebrand factor and collagen to the circulating blood. The GPIb-IX-V complex binds to the exposed von Willebrand factor, causing platelets to adhere (Fig. 122-1). In addition, the engagement of the GPIb-IX-V complex with ligand induces signaling pathways that lead to platelet activation. von Willebrand factor–bound GPIb-IX-V promotes a calcium-dependent conformational change in the GPIIb/IIIa receptor, transforming it from an inactive low-affinity state to an active high-affinity receptor for fibrinogen.

Platelet Activation The activation of platelets is controlled by a variety of surface receptors that regulate various functions in the activation process. Platelet receptors control many distinct processes and are stimulated by a wide variety of agonists and adhesive proteins that result in variable degrees of activation. In general terms, the stimulation of platelet receptors triggers two specific processes: (1) activation of internal signaling pathways that lead to further platelet activation and granule release, and (2) the capacity of the platelet to bind to other adhesive proteins/platelets. Both of these processes contribute to the formation of a thrombus. Stimulation of nonthrombotic receptors results in platelet adhesion or interaction with other vascular cells, including endothelial cells, neutrophils, and mononuclear cells.

Many families and subfamilies of receptors are found on platelets that regulate a variety of platelet functions. These include the seven transmembrane receptor family, which is the main agonist-stimulated receptor family. Several seven transmembrane receptors are found on platelets, including the ADP receptors, prostaglandin receptors, lipid receptors, and chemokine receptors. Receptors for thrombin comprise the major seven transmembrane receptors found on platelets. Among this last group, the first identified was the protease activation receptor 1 (PAR1). The PAR class of receptors has a distinct mechanism of activation that involves specific cleavage of the N-terminus by thrombin, which, in turn, acts as a ligand for the receptor. Other PAR receptors are present on platelets, including PAR2 (not activated by thrombin) and PAR4. Adenosine receptors are responsible for transduction of ADP-induced signaling events, which are initiated by the binding of ADP to purinergic receptors on the platelet surface. There are several distinct ADP receptors, classified as $P2X_1$, $P2Y_1$, and $P2Y_{12}$. The activation of both the $P2Y_{12}$ and $P2Y_1$ receptors is essential for ADP-induced platelet aggregation. The thienopyridine derivatives, clopidogrel and prasugrel, are clinically used inhibitors of ADP-induced platelet aggregation.

Platelet Aggregation Activation of platelets results in a rapid series of signal transduction events, including tyrosine kinase, serine/threonine kinase, and lipid kinase activation. In unstimulated platelets, the major platelet integrin GPIIb/IIIa is maintained in an inactive conformation and functions as a low-affinity adhesion receptor for fibrinogen. This integrin is unique as it is only expressed on platelets. After stimulation, the interaction between fibrinogen and GPIIb/IIIa forms intercellular connections between platelets, leading to the formation of a platelet aggregate (Fig. 122-1). A calcium-sensitive conformational change in the extracellular domain of GPIIb/IIIa enables the high-affinity binding of soluble plasma fibrinogen as a result of a complex network of inside-out signaling events. The GPIIb/IIIa receptor serves as a bidirectional conduit with GPIIb/IIIa-mediated signaling (outside-in signaling) occurring immediately after the binding of fibrinogen. This binding interaction leads to additional intracellular signaling that further stabilizes the platelet aggregate and transforms platelet aggregation from a reversible to an irreversible process (inside-out signaling).

THE ROLE OF PLATELETS AND THROMBOSIS IN INFLAMMATION

Inflammation plays an important role during the acute thrombotic phase of acute coronary and other vascular occlusive syndromes. In the setting of acute upper respiratory infections, people are at higher risk of myocardial infarction and thrombotic stroke. Patients with acute coronary syndromes have not only increased interactions between platelets (homotypic aggregates) but also increased interactions between platelets and leukocytes (heterotypic aggregates) detectable in circulating blood. These latter aggregates form when platelets are activated, often directly by pathogens, and adhere to circulating leukocytes as part of their contribution to the immune process. Platelets bind via P-selectin (CD62P) expressed on the surface of activated platelets to the leukocyte receptor, P-selectin glycoprotein ligand 1 (PSGL-1). This association leads to increased expression of CD11b/CD18 (Mac-1) on leukocytes, which amplifies immunity but may also support further interactions with platelets partially via bivalent fibrinogen linking this integrin with its platelet surface counterpart, GPIIb/IIIa. Platelet surface P-selectin also induces the expression of tissue factor on monocytes, which promotes fibrin formation.

In addition to platelet–monocyte aggregates, the immunomodulator, soluble CD40 ligand (CD40L or CD154), also reflects a link between thrombosis and inflammation. The CD40 ligand is a trimeric transmembrane protein of the tumor necrosis factor family and, with its receptor CD40, is an important contributor to the inflammatory process, leading both to thrombosis and atherosclerosis. While many immunologic and vascular cells have been found to express CD40 and/or CD40 ligand, in platelets, CD40 ligand is rapidly translocated to the surface after stimulation and is upregulated in the newly formed thrombus. The surface-expressed CD40 ligand is cleaved from the platelet to generate a soluble fragment (soluble CD40 ligand).

Links have also been established among platelets, infection, immunity, and inflammation. Bacterial and viral infections are associated with a transient increase in the risk of acute thrombotic events, such as acute myocardial infarction and stroke. In addition, platelets contribute significantly to the pathophysiology and high mortality rates of sepsis. The expression, functionality, and signaling pathways of Toll-like receptors (TLRs) have been established in platelets. Stimulation of platelet TLR2, TLR3, and TLR4 directly and indirectly activates the platelet's thrombotic and inflammatory responses, and live bacteria induce a proinflammatory response in platelets in a TLR2-dependent manner, suggesting a mechanism by which specific bacteria and bacterial components can directly activate platelet-dependent thrombosis. Additionally, viruses, such as SARS-CoV-2, HIV, hepatitis C virus, and Dengue, are also known to elevate thrombosis; recently, platelets have been shown to regulate immune responses to viruses via receptors TLR7 and TLR8.

Risk Factors for Arterial Thrombosis In addition to immune burden, various factors increase the risk of developing arterial thrombosis. Classically, the cardiovascular-dependent risk factors implicated in thrombosis have been hypertension, high levels of low-density lipoprotein cholesterol, and smoking. However, diabetes, pregnancy, age, and chemotherapeutic agents may also contribute to arterial thrombosis.

Stillbirth and loss of multiple pregnancies may increase the risk of ischemic stroke and myocardial infarction, as does hormonal replacement therapy. Systemic lupus erythematosus and rheumatoid arthritis are now well-recognized risks for thrombosis, and the former, in particular, may contribute in the pediatric population. The antiphospholipid syndrome is also another widely recognized autoimmune prothrombotic risk for arterial (and venous) thrombosis.

GENETICS OF ARTERIAL THROMBOSIS

Some studies have associated arterial thrombosis with genetic variants (Table 122-1*A*); however, the associations have been weak and not consistently confirmed in larger series. Platelet count and mean platelet volume have been studied by genome-wide association studies (GWAS), and this approach identified signals located to noncoding regions. Of 15 quantitative trait loci associated with mean platelet volume and platelet count, one located at 12q24 is also a risk locus for coronary artery disease.

In the area of genetic variability and platelet function, studies have primarily dealt with pharmacogenetics, the field of pharmacology dealing with the interindividual variability in drug response based on genetic determinants (Table 122-2). This focus has been driven by the wide variability among individuals in terms of response to antithrombotic drugs and the lack of a common explanation for this variance. The best described is the issue of "aspirin resistance," although heterogeneity for other antithrombotics (e.g., clopidogrel) has also been extensively examined. Primarily, platelet-dependent genetic determinants have been defined at the level of (1) drug effect, (2) drug compliance, and (3) drug metabolism. Many candidate platelet genes have been studied for their interaction with antiplatelet and antithrombotic agents.

Many patients have an inadequate response to the inhibitory effects of aspirin. Heritable factors contribute to the variability; however, ex vivo tests of residual platelet responsiveness after aspirin administration have not provided firm evidence for a pharmacogenetic interaction between aspirin and *COX1* or other relevant platelet receptors. As such, currently there is no clinical indication for genotyping to optimize aspirin's antiplatelet efficiency. For the platelet P2Y12 receptor inhibitor clopidogrel, additional data suggest that genetics may affect the drug's responsiveness and utility. The responsible genetic variant appears not to be the expected P2Y12 receptor but an enzyme responsible for drug metabolism. Clopidogrel is a prodrug, and liver metabolism by specific cytochrome P450 enzymes is required for activation. The genes encoding the CYP-dependent oxidative steps are polymorphic, and carriers of specific alleles of the CYP2C19 and CYP3A4 loci have increased platelet aggregability. Increased platelet activity has also been specifically associated with the CYP2C19*2 allele, which causes loss of platelet function in select patients. Because these are common genetic variants, this observation has been shown to be clinically relevant in large studies. In summary, although the loss-of-function polymorphisms in CYP2C19 is the strongest individual variable affecting pharmacokinetics and antiplatelet response to clopidogrel, it only accounts for 5–12% of the variability in ADP-induced platelet aggregation by clopidogrel. In addition, genetic variables do not appear to contribute significantly to the clinical outcomes of patients treated with the P2Y12 receptor antagonists prasugrel or ticagrelor.

VENOUS THROMBOSIS

OVERVIEW OF VENOUS THROMBOSIS

Coagulation is the process by which thrombin is activated and soluble plasma fibrinogen is converted into insoluble fibrin. These steps account for both normal hemostasis and the pathophysiologic processes influencing the development of venous thrombosis. The primary forms of venous thrombosis are deep-vein thrombosis (DVT) in the extremities and the subsequent embolization to the lungs (pulmonary embolism), referred to together as venous thromboembolic disease (VTE). Although the majority of venous thromboembolic events occur as pulmonary embolism or DVT of the lower extremities, up to 10% of events may occur in other vascular locations. Venous thrombosis has both heritable causes (Table 122-1*B*) and acquired causes (Table 122-3).

DEEP-VENOUS THROMBOSIS AND PULMONARY EMBOLISM

It is estimated that DVT or pulmonary embolism (PE) occurs in ~1–2 individuals per 1000 each year, resulting in 300,000–600,000 new cases of venous thromboembolism each year in the United States. Approximately, 60,000–80,000 deaths are attributed to DVT or PE annually. Of new cases, up to 30% of patients die within 30 days and one-fifth suffer

sudden death due to PE; 30% go on to develop recurrent VTE within 10 years. Data from the Atherosclerosis Risk in Communities (ARIC) study reported a 9% 28-day fatality rate from DVT and a 15% fatality rate from PE. PE in the setting of cancer has a 25% fatality rate. The mean incidence of first DVT in the general population is 5 per 10,000 person-years; the incidence is similar in males and females when adjusting for factors related to reproduction and birth control and increases dramatically with age from 2–3 per 10,000 person-years at 30–49 years of age to 20 per 10,000 person-years at 70–79 years of age.

OVERVIEW OF THE COAGULATION CASCADE AND ITS ROLE IN VENOUS THROMBOSIS

Coagulation is defined as the formation of fibrin by a series of linked enzymatic reactions in which each reaction product converts the subsequent inactive zymogen into an active serine protease (Fig. 122-2). This coordinated sequence is called the coagulation cascade and is a key mechanism for regulating hemostasis. Central to the function of the coagulation cascade is the principle of amplification: owing to a series of linked enzymatic reactions, a small stimulus can lead to much greater quantities of fibrin, the end product that prevents hemorrhage at the site of vascular injury. In addition to the known risk factors relevant to hypercoagulopathy, stasis, and vascular dysfunction, newer areas of research have identified contributions from procoagulant microparticles, inflammatory cells, microvesicles, and fibrin structure.

The coagulation cascade is primarily initiated by vascular injury exposing tissue factor to blood components (Fig. 122-2). Tissue factor may also be found in bloodborne cell-derived microparticles and, under pathophysiologic conditions, in leukocytes or platelets. Plasma factor VII (FVII) is the ligand for and is activated (FVIIa) by binding to tissue factor exposed at the site of vessel damage. The binding of FVII/VIIa to tissue factor activates the downstream conversion of factor X (FX) to active FX (FXa). In an alternative reaction, the FVII/FVIIa–tissue factor complex initially converts FIX to FIXa, which then activates FX in conjunction with its cofactor factor VIII (FVIIIa). Thrombin can also activate factor XI (FXI) to active FXI (FXIa), which, in turn, can also activate FIX. FXa with its cofactor FVa converts prothrombin to thrombin, which then converts soluble plasma fibrinogen to insoluble fibrin, leading to clot or thrombus formation. Thrombin also activates FXIII to FXIIIa, a transglutaminase that covalently cross-links and stabilizes the fibrin clot. Formation of thrombi is affected by mechanisms governing fibrin structure and stability, including specific fibrinogen variants and how they alter fibrin formation, strength, and structure.

Several antithrombotic factors also regulate coagulation; these include antithrombin, tissue factor pathway inhibitor (TFPI), heparin cofactor II, and protein C/protein S. Under normal conditions, these factors limit the production of thrombin to prevent the perpetuation of coagulation and thrombus formation. Typically, after the clot has caused occlusion at the damage site and begins to expand toward adjacent uninjured vessel segments, the anticoagulant reactions governed by the normal endothelium become pivotal in limiting the extent of this hemostatically protective clot.

RISK FACTORS FOR VENOUS THROMBOSIS

An array of different factors contributes to the risk of VTE; it is notable that women and men of all ages, races, and ethnicities are at risk for VTE. The risk factors for venous thrombosis are primarily related to hypercoagulability, which can be genetic (Table 122-1) or acquired, or due to immobilization and venous stasis. Independent predictors for recurrence include increasing age, obesity, malignant neoplasm, and acute extremity paresis. It is estimated that 5–8% of the U.S. population has a genetic risk factor known to predispose to venous thrombosis. Often, multiple risk factors are present in a single individual. Significant risk is incurred by major orthopedic, abdominal, or neurologic surgeries. Cancer patients have an approximately fourfold increased risk of VTE as compared with the general population, and cancer patients with VTE have reduced survival. Hospitalized patients have a greatly increased risk of venous thrombosis with risk factors (increased age, male, ethnicity) and comorbid conditions, including infection, renal disease, and weight loss. Community- or hospital-acquired infection is also associated with increased risk of VTE. Supportive of this risk, nearly 20% of hospitalized COVID-19 patients were noted to have coagulation abnormalities as well as increased PE, DVT, and peripheral thrombotic risk. Moderate risk is promoted by prolonged bedrest; certain types of cancer; pregnancy; hormone replacement therapy or oral contraceptive use; and other sedentary conditions, such as long-distance plane travel. It has been reported that the risk of developing a VTE event doubles after air travel lasting 4 h, although the absolute

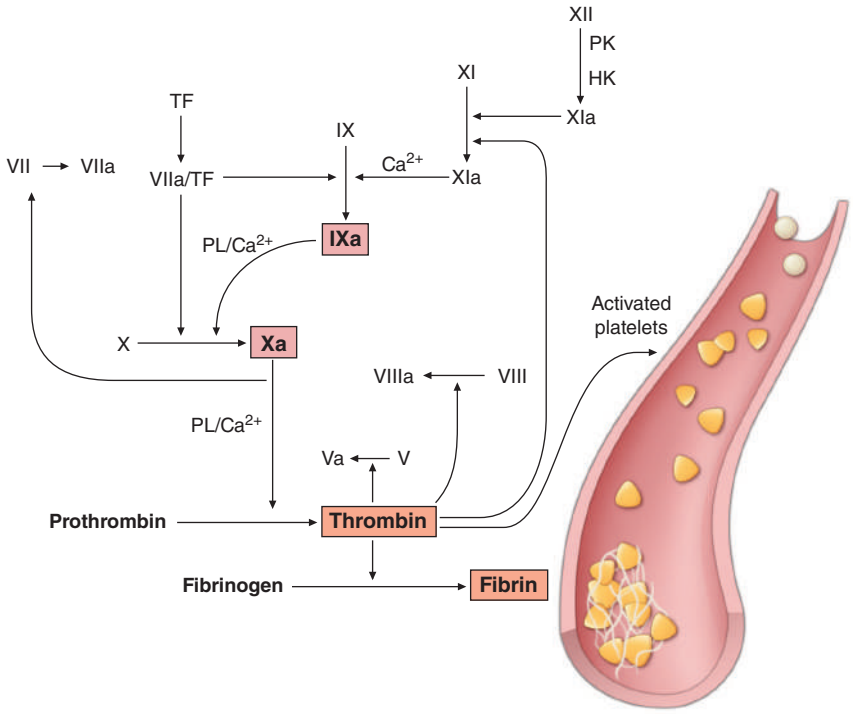

FIGURE 122-2 Summary of the coagulation pathways. Specific coagulation factors ("a" indicates activated form) are responsible for the conversion of soluble plasma fibrinogen into insoluble fibrin. This process occurs via a series of linked reactions in which the enzymatically active product subsequently converts the downstream inactive protein into an active serine protease. In addition, the activation of thrombin leads to stimulation of platelets. HK, high-molecular-weight kininogen; PK, prekallikrein; TF, tissue factor.

risk remains low (1 in 6000). The relative risk of VTE among pregnant or postpartum women is 4.3, and the overall incidence (absolute risk) is 199.7 per 100,000 woman-years.

GENETICS OF VENOUS THROMBOSIS

(See Table 122-2) Less common causes of venous thrombosis are those due to genetic variants. These abnormalities include loss-of-function mutations of endogenous anticoagulants as well as gain-of-function mutations of procoagulant proteins. Heterozygous antithrombin deficiency and homozygosity of the factor V Leiden mutation significantly increase the risk of venous thrombosis. While homozygous protein C or protein S deficiencies are rare and may lead to fatal purpura fulminans, heterozygous deficiencies are associated with a moderate risk of thrombosis. Activated protein C impairs coagulation by proteolytic degradation of FVa. Patients resistant to the activity of activated protein C may have a point mutation in the FV gene, a mutant denoted factor V Leiden. Mildly increased risk has been attributed to elevated levels of procoagulant factors, as well as low levels of tissue factor pathway inhibitor. Polymorphisms of methylene tetrahydrofolate reductase as well as hyperhomocysteinemia have been shown to be independent risk factors for venous thrombosis, as well as arterial vascular disease; however, many of the initial descriptions of genetic variants and their associations with thromboembolism are being questioned in larger, more contemporary studies.

FIBRINOLYSIS AND THROMBOSIS

Specific abnormalities in the fibrinolytic system have been associated with enhanced thrombosis. Factors such as elevated levels of tissue plasminogen activator (tPA) and plasminogen activator inhibitor type 1 (PAI-1) have been associated with decreased fibrinolytic activity and an increased risk of arterial thrombotic disease. Specific genetic variants have been associated with decreased fibrinolytic activity, including the 4G/5G insertion/deletion polymorphism in the (plasminogen activator type 1) *PAI-1* gene. Additionally, the 311-bp Alu insertion/deletion in tPA's intron 8 has been associated with enhanced thrombosis; however, genetic abnormalities have not been associated consistently with altered function or tPA levels, raising questions about the relevant pathophysiologic mechanism. Thrombin-activatable fibrinolysis inhibitor (TAFI) is a carboxypeptidase that regulates fibrinolysis; elevated plasma TAFI levels have been associated with an increased risk of both DVT and cardiovascular disease.

The metabolic syndrome also is accompanied by altered fibrinolytic activity. This syndrome, which comprises abdominal fat (central obesity), altered glucose and insulin metabolism, dyslipidemia, and hypertension, has been associated with atherothrombosis. The mechanism for enhanced thrombosis appears to be due both to altered platelet function and to a procoagulant and hypofibrinolytic state. One of the most frequently documented prothrombotic abnormalities reported in this syndrome is an increase in plasma levels of PAI-1.

In addition to contributing to platelet function, inflammation plays a role in both coagulation-dependent thrombus formation and thrombus resolution. Both polymorphonuclear neutrophils and monocytes/macrophages contribute to multiple overlapping thrombotic functions, including fibrinolysis, chemokine and cytokine production, and phagocytosis.

THE DISTINCTION BETWEEN ARTERIAL AND VENOUS THROMBOSIS

Although there is overlap, venous thrombosis and arterial thrombosis are initiated differently, and clot formation progresses by somewhat distinct pathways. In the setting of stasis or states of hypercoagulability, venous thrombosis is activated with the initiation of the coagulation cascade primarily due to exposure of tissue factor; this leads to the formation of thrombin and the subsequent conversion of fibrinogen to fibrin. In the artery, thrombin formation also occurs, but thrombosis is primarily promoted by the adhesion of platelets to an injured vessel and stimulated by exposed extracellular matrix (Figs. 122-1 and 122-2). There is wide variation in individual responses to vascular injury, an important determinant of which is the predisposition an individual has to arterial or venous thrombosis. This concept has been supported indirectly in prothrombotic animal models in which there is poor correlation between the propensity to develop venous versus arterial thrombosis.

Despite considerable progress in elucidating the role of hypercoagulable states in VTE, the contribution of hypercoagulability to arterial vascular disease is much less well understood. Although specific thrombophilic conditions, such as factor V Leiden and the prothrombin G20210A mutation, are risk factors for DVT, PE, and other VTE events, their contribution to arterial thrombosis is less well defined. In fact, to the contrary, many of these thrombophilic factors have not been found to be clinically important risk factors for arterial thrombotic events, such as acute coronary syndromes.

Clinically, although the pathophysiology is distinct, arterial and venous thrombosis do share common risk factors, including age, obesity, cigarette smoking, diabetes mellitus, arterial hypertension, hyperlipidemia, and metabolic syndrome. Select genetic variants, including those of the glutathione peroxidase-3 (*GPx3*) gene, have also been associated with arterial and venous thrombo-occlusive disease. Importantly, arterial and venous thrombosis may both be triggered by pathophysiologic stimuli responsible for activating inflammatory and oxidative pathways.

The diagnosis and treatment of ischemic heart disease are discussed in Chap. 284. Stroke diagnosis and management are discussed in Chap. 318. The diagnosis and management of DVT and PE are discussed in Chap. 290.

123 Antiplatelet, Anticoagulant, and Fibrinolytic Drugs

Jeffrey I. Weitz

Thromboembolic disorders are major causes of morbidity and mortality. Thrombosis can occur in arteries or veins. Arterial thrombosis is the most common cause of acute myocardial infarction (MI), ischemic stroke, and limb gangrene. VTE encompasses DVT, which can lead to postthrombotic syndrome, and PE, which can be fatal or can result in chronic thromboembolic pulmonary hypertension.

Most arterial thrombi are superimposed on disrupted atherosclerotic plaque because plaque rupture exposes thrombogenic material in the core to the blood. This material then triggers platelet aggregation and fibrin formation, which results in the generation of a platelet-rich thrombus that can temporarily or permanently occlude blood flow. In contrast, venous thrombi rarely form at sites of obvious vascular

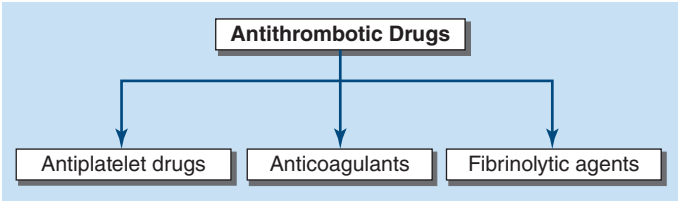

FIGURE 123-1 Classification of antithrombotic drugs.

disruption. Although they can develop after surgical trauma to veins or secondary to indwelling venous catheters, venous thrombi usually originate in the valve cusps of the deep veins of the calf or in the muscular sinuses. Sluggish blood flow reduces the oxygen supply to the avascular valve cusps. Endothelial cells lining these valve cusps become activated and express adhesion molecules on their surface. Tissue factor–bearing leukocytes and microvesicles adhere to these activated cells and induce coagulation. DNA extruded from neutrophils forms neutrophil extracellular traps (NETs) that provide a scaffold that binds platelets, promotes their activation and aggregation, and activates factor XII. Local thrombus formation is exacerbated by reduced clearance of activated clotting factors because of impaired blood flow. If the thrombi extend from the calf veins into the popliteal and more proximal veins of the leg, thrombus fragments can dislodge, travel to the lungs, and produce PE.

Arterial and venous thrombi are composed of platelets, fibrin, and trapped red blood cells, but the proportions differ. Arterial thrombi are rich in platelets because of the high shear in the injured arteries. In contrast, venous thrombi, which form under low shear conditions, contain relatively few platelets and are predominantly composed of fibrin and trapped red cells. Because of the predominance of platelets, arterial thrombi appear white, whereas venous thrombi are red in color, reflecting the trapped red cells.

Antithrombotic drugs are used for the prevention and treatment of thrombosis. Targeting the components of thrombi, these agents include (1) antiplatelet drugs, (2) anticoagulants, and (3) fibrinolytic agents **(Fig. 123-1)**. With the predominance of platelets in arterial thrombi, strategies to attenuate arterial thrombosis focus mainly on antiplatelet agents, although, in the acute setting, they may include anticoagulants and fibrinolytic agents. The addition of low-dose rivaroxaban, an oral factor Xa inhibitor, to dual-antiplatelet therapy reduces recurrent ischemic events and stent thrombosis in patients with acute coronary syndrome, whereas its addition to aspirin reduces the risk of major adverse coronary and limb events in patients with stable coronary or peripheral artery disease. These findings highlight the utility of combining low-dose anticoagulants with antiplatelet agents for secondary prevention in patients at high risk for recurrent atherothrombotic events.

Anticoagulants are the mainstay of prevention and treatment of VTE because fibrin is the predominant component of venous thrombi. Antiplatelet drugs are less effective than anticoagulants in this setting because of the limited platelet content of venous thrombi. Fibrinolytic therapy is used in selected patients with VTE. For example, patients with massive PE can benefit from systemic or catheter-directed fibrinolytic therapy. Pharmaco-mechanical therapy is also used to restore blood flow in patients with extensive DVT involving the iliac and/or femoral veins.

ANTIPLATELET DRUGS

ROLE OF PLATELETS IN ARTERIAL THROMBOSIS

In healthy vasculature, circulating platelets are maintained in an inactive state by nitric oxide (NO) and prostacyclin released by endothelial cells lining the blood vessels. In addition, endothelial cells also express CD39 on their surface, a membrane-associated ecto-adenosine diphosphatase (ADPase) that degrades ADP released from activated platelets. When the vessel wall is damaged, the release of these substances is impaired and the subendothelial matrix is exposed. Platelets adhere to exposed collagen via $\alpha_2\beta_1$ and glycoprotein (Gp) V1 and to von Willebrand factor (VWF) via Gp Ibα—receptors that are constitutively expressed on the platelet surface. Adherent platelets undergo a change in shape, secrete ADP from their dense granules, and synthesize and release thromboxane A2. Released ADP and thromboxane A_2, which are platelet agonists, activate ambient platelets and recruit them to the site of vascular injury **(Fig. 123-2)**.

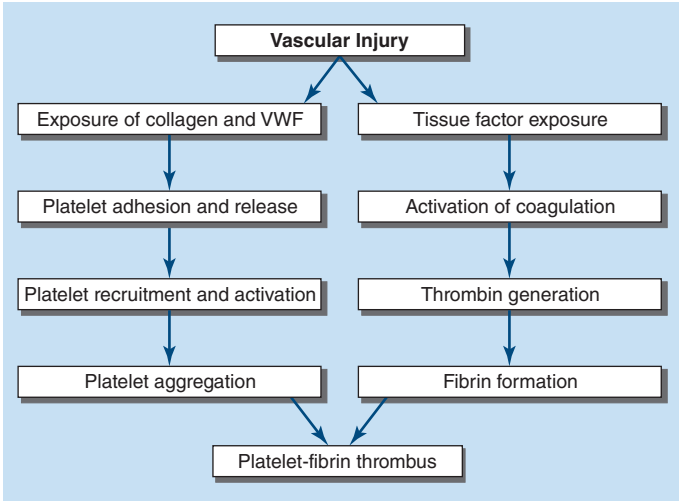

FIGURE 123-2 Coordinated role of platelets and the coagulation system in thrombogenesis. Vascular injury simultaneously triggers platelet activation and aggregation and activation of the coagulation system. Platelet activation is initiated by exposure of subendothelial collagen and von Willebrand factor (VWF), onto which platelets adhere. Adherent platelets become activated and release ADP and thromboxane A_2, platelet agonists that activate ambient platelets and recruit them to the site of injury. When platelets are activated, glycoprotein IIb/IIIa on their surface undergoes a conformational change that enables it to ligate fibrinogen and/or VWF and mediate platelet aggregation. Coagulation is triggered by tissue factor exposed at the site of injury. Tissue factor triggers thrombin generation. As a potent platelet agonist, thrombin amplifies platelet recruitment to the site of injury. Thrombin also converts fibrinogen to fibrin, and the fibrin strands then weave the platelet aggregates together to form a platelet/fibrin thrombus.

Disruption of the vessel wall also exposes tissue factor–expressing cells to the blood. Tissue factor binds to factor VII and induces its activation, and the tissue factor–factor VIIa complex then initiates coagulation. Activated platelets potentiate coagulation by providing a negatively charged surface that binds clotting factors and supports the assembly of activation complexes that enhance thrombin generation. In addition to converting fibrinogen to fibrin, thrombin serves as a potent platelet agonist and recruits more platelets to the site of vascular injury. Thrombin also amplifies its generation by feedback activation of factors V, VIII, and XI and solidifies the fibrin network by activating factor XIII, which then cross-links the fibrin strands and renders them more resistant to degradation.

When platelets are activated, Gp IIb/IIIa, the most abundant receptor on the platelet surface, undergoes a conformational change that enables it to bind fibrinogen and, under high shear conditions, VWF. Divalent fibrinogen or multivalent VWF molecules bridge adjacent platelets together to form platelet aggregates. Fibrin strands, generated through the action of thrombin, then weave these aggregates together to form a platelet-rich fibrin clot.

Antiplatelet drugs target various steps in this process. The commonly used antiplatelet drugs include aspirin, ADP receptor inhibitors, which include thienopyridines (clopidogrel and prasugrel) as well as ticagrelor and cangrelor, dipyridamole, Gp IIb/IIIa antagonists, and vorapaxar.

ASPIRIN

The most widely used antiplatelet agent worldwide is aspirin. As a cheap and effective antiplatelet drug, aspirin serves as the foundation of most antiplatelet strategies.

Mechanism of Action Aspirin produces its antithrombotic effect by irreversibly acetylating and inhibiting platelet cyclooxygenase

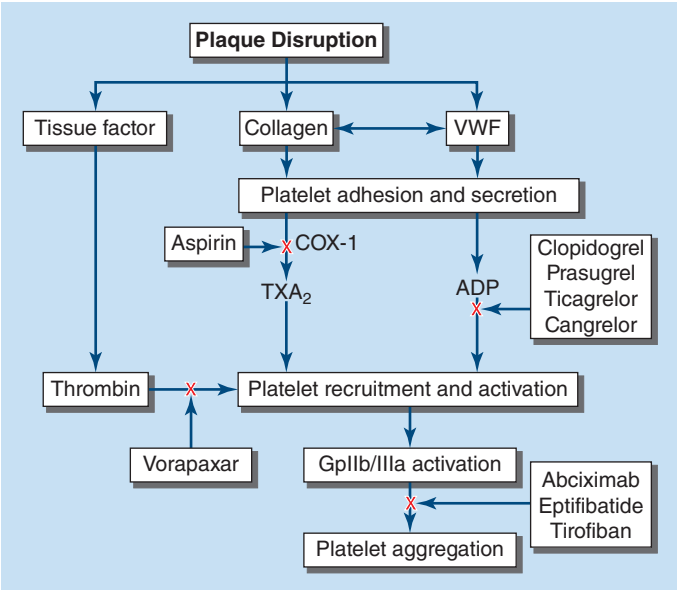

FIGURE 123-3 Site of action of antiplatelet drugs. Aspirin inhibits thromboxane A_2 (TXA_2) synthesis by irreversibly acetylating cyclooxygenase-1 (COX-1). Reduced TXA_2 release attenuates platelet activation and recruitment to the site of vascular injury. Clopidogrel and prasugrel irreversibly block $P2Y_{12}$, a key ADP receptor on the platelet surface; cangrelor and ticagrelor are reversible inhibitors of $P2Y_{12}$. Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen and von Willebrand factor (VWF) binding to activated glycoprotein (Gp) IIb/IIIa. Vorapaxar inhibits thrombin-mediated platelet activation by targeting protease-activated receptor-1 (PAR-1), the major thrombin receptor on human platelets.

(COX)-1 **(Fig. 123-3)**, a critical enzyme in the biosynthesis of thromboxane A_2. At high doses (~1 g/d), aspirin also inhibits COX-2, an inducible COX isoform found in endothelial cells and inflammatory cells. In endothelial cells, COX-2 initiates the synthesis of prostacyclin, a potent vasodilator and inhibitor of platelet aggregation.

Indications Aspirin is widely used for secondary prevention of cardiovascular events in patients with established coronary artery, cerebral artery, or peripheral artery disease. Compared with placebo in this setting, aspirin produces a 25% reduction in the risk of cardiovascular death, MI, or stroke. Aspirin is no longer used routinely for primary prevention because recent studies suggest that the risk of gastrointestinal and intracerebral hemorrhage outweigh the benefits. Consequently, aspirin is only recommended for primary cardiac prevention if the baseline cardiovascular risk is at least 1% per year over 10 years and patients are at low risk for bleeding.

Dosages Aspirin is usually administered at doses of 75–325 mg once daily. Higher doses of aspirin are not more effective than lower aspirin doses, and some analyses suggest reduced efficacy with higher doses. Because the side effects of aspirin are dose-related, daily aspirin doses of 75–100 mg are recommended for most indications. When rapid platelet inhibition is required, an initial aspirin dose of at least 160 mg should be given.

Side Effects The most common side effects are gastrointestinal and range from dyspepsia to erosive gastritis or peptic ulcers with bleeding and perforation. These side effects are dose related. Use of enteric-coated or buffered aspirin in place of plain aspirin does not eliminate gastrointestinal side effects. The overall risk of major bleeding with aspirin is 1–3% per year. The risk of bleeding is increased two- to threefold when aspirin is given in conjunction with other antiplatelet drugs, such as clopidogrel or ticagrelor, or with anticoagulants, such as warfarin. When dual or triple therapy is prescribed, low-dose aspirin should be given (75–100 mg daily). Eradication of *Helicobacter pylori* infection and administration of proton pump inhibitors may reduce the risk of aspirin-induced upper gastrointestinal bleeding in patients with peptic ulcer disease.

Aspirin should not be administered to patients with a history of aspirin allergy characterized by bronchospasm. This problem occurs in ~0.3% of the general population but is more common in those with chronic urticaria or asthma, particularly in individuals with nasal polyps or chronic rhinitis. Hepatic and renal toxicity are observed with aspirin overdose.

Aspirin Resistance Clinical aspirin resistance is defined as the failure of aspirin to protect patients from ischemic vascular events. This is not a helpful definition because it is made after the event occurs. Furthermore, it is not realistic to expect aspirin, which only blocks thromboxane A_2–induced platelet activation, to prevent all vascular events.

Aspirin resistance has also been described biochemically as a failure of the drug to produce its expected inhibitory effects on tests of platelet function, such as thromboxane A_2 synthesis or arachidonic acid–induced platelet aggregation. Potential causes of aspirin resistance include poor compliance, reduced absorption, drug-drug interaction with ibuprofen, and overexpression of COX-2. Unfortunately, the tests for aspirin resistance have not been well standardized, and there is little evidence that they identify patients at increased risk of recurrent vascular events, or that resistance can be reversed by giving higher doses of aspirin or by adding other antiplatelet drugs. Until such information is available, testing for aspirin resistance remains a research tool.

ADP RECEPTOR ANTAGONISTS

The ADP receptor antagonists include the thienopyridines (clopidogrel and prasugrel) as well as ticagrelor and cangrelor. All these drugs target $P2Y_{12}$, the key ADP receptor on platelets.

Thienopyridines • **MECHANISM OF ACTION** The thienopyridines are structurally related drugs that selectively inhibit ADP-induced platelet aggregation by irreversibly blocking $P2Y_{12}$ (Fig. 123-3). Clopidogrel and prasugrel are prodrugs that require metabolic activation by the hepatic cytochrome P450 (CYP) enzyme system. Prasugrel is about 10-fold more potent than clopidogrel and has a more rapid onset of action because of better absorption and more streamlined metabolic activation.

INDICATIONS When compared with aspirin in patients with recent ischemic stroke, recent MI, or a history of peripheral arterial disease, clopidogrel reduced the risk of cardiovascular death, MI, and stroke by 8.7%. Therefore, clopidogrel is more effective than aspirin but is also more expensive. Clopidogrel and aspirin are often combined to capitalize on their capacity to block complementary pathways of platelet activation. For example, the combination of aspirin plus clopidogrel is recommended for at least 4 weeks after implantation of a bare metal stent in a coronary artery and at least a year in those with a drug-eluting stent. Concerns about late in-stent thrombosis with drug-eluting stents have led some experts to recommend long-term use of clopidogrel plus aspirin for the latter indication. The course of dual-antiplatelet therapy is often shortened in patients at high risk of bleeding with the dropping of aspirin and continuation of the $P2Y_{12}$ inhibitor.

The combination of clopidogrel and aspirin is effective in patients with non-ST-segment elevation MI. Thus, in 12,562 such patients, the risk of cardiovascular death, MI, or stroke was 9.3% in those randomized to the combination of clopidogrel and aspirin and 11.4% in those given aspirin alone. This 20% relative risk reduction with combination therapy was highly statistically significant. However, combining clopidogrel with aspirin increases the risk of major bleeding to about 2% per year. This bleeding risk persists even if the daily dose of aspirin is ≤100 mg. Therefore, the combination of clopidogrel and aspirin should only be used when there is a clear benefit. For example, this combination was not proven to be superior to clopidogrel alone in patients with acute ischemic stroke or to aspirin alone for primary prevention in those at risk for cardiovascular events.

Prasugrel was compared with clopidogrel in 13,608 patients with acute coronary syndrome who were scheduled to undergo percutaneous coronary intervention. The incidence of the primary efficacy endpoint, a composite of cardiovascular death, MI, or stroke, was significantly lower with prasugrel than with clopidogrel (9.9% and 12.1%, respectively),

mainly reflecting a reduction in nonfatal MI. The incidence of stent thrombosis also was significantly lower with prasugrel than with clopidogrel (1.1% and 2.4%, respectively). However, these advantages were at the expense of significantly higher rates of fatal bleeding (0.4% and 0.1%, respectively) and life-threatening bleeding (1.4% and 0.9%, respectively) with prasugrel. Because patients older than 75 years of age and those with a history of prior stroke or transient ischemic attack are at high risk of bleeding, prasugrel should generally be avoided in older patients, and the drug is contraindicated in those with a history of cerebrovascular disease. Caution is required if prasugrel is used in patients weighing <60 kg or in those with renal impairment.

When prasugrel was compared with clopidogrel in 7243 patients with unstable angina or MI without ST-segment elevation, prasugrel failed to reduce the rate of the primary efficacy endpoint, which was a composite of cardiovascular death, MI, and stroke. Because of the negative results of this study, prasugrel is reserved for patients undergoing percutaneous coronary intervention. In this setting, prasugrel is usually given in conjunction with aspirin. To reduce the risk of bleeding, the daily aspirin dose should be ≤100 mg.

For patients with noncardioembolic stroke or high-risk transient ischemic attack, the combination of clopidogrel or ticagrelor plus aspirin for 21–30 days followed by aspirin alone thereafter reduces the risk of stroke, MI, and vascular death by up to 30% compared with aspirin alone. Therefore, dual antiplatelet therapy is often administered for the first 3–4 weeks in such patients.

DOSING Clopidogrel is given once daily at a dose of 75 mg. Loading doses of clopidogrel are given when rapid ADP receptor blockade is desired. For example, patients undergoing coronary stenting are often given a loading dose of 300–600 mg, which produces inhibition of ADP-induced platelet aggregation in about 4–6 h. After a loading dose of 60 mg, prasugrel is given once daily at a dose of 10 mg. Patients older than age 75 years or weighing <60 kg should receive a lower daily prasugrel dose of 5 mg.

SIDE EFFECTS The most common side effect of clopidogrel and prasugrel is bleeding. Because of its greater potency, bleeding is more common with prasugrel than with clopidogrel. To reduce the risk of bleeding, clopidogrel and prasugrel should be stopped 5–7 days before major surgery. In patients taking clopidogrel or prasugrel who present with serious bleeding, platelet transfusion may be helpful.

Hematologic side effects, including neutropenia, thrombocytopenia, and thrombotic thrombocytopenic purpura, are rare.

THIENOPYRIDINE RESISTANCE The capacity of clopidogrel to inhibit ADP-induced platelet aggregation varies among subjects. This variability reflects, at least in part, genetic polymorphisms in the CYP isoenzymes involved in the metabolic activation of clopidogrel. The most important of these is CYP2C19. Clopidogrel-treated patients who are homozygous for the loss-of-function *CYP2C192* allele exhibit reduced platelet inhibition compared with those with the wild-type *CYP2C19* allele and experience a higher rate of cardiovascular events. This is important because estimates suggest that up to 25% of whites, 30% of African Americans, and 50% of Asians carry the loss-of-function allele, which would render them resistant to clopidogrel. Even patients with the reduced-function *CYP2C19* alleles may derive less benefit from clopidogrel than those with the full-function *CYP2C19* allele. Concomitant administration of clopidogrel with proton pump inhibitors, which are inhibitors of *CYP2C19*, produces a small reduction in the inhibitory effects of clopidogrel on ADP-induced platelet aggregation. The extent to which this interaction increases the risk of cardiovascular events remains controversial.

In contrast to their effect on the metabolic activation of clopidogrel, *CYP2C19* polymorphisms appear to be less important determinants of the activation of prasugrel. Thus, no association was detected between the loss-of-function allele and decreased platelet inhibition or increased rate of cardiovascular events with prasugrel. The observation that genetic polymorphisms affecting clopidogrel absorption or metabolism influence clinical outcomes raised the possibility that pharmacogenetic profiling might be useful for identifying clopidogrel-resistant patients and that point-of-care assessment of the extent of clopidogrel-induced platelet inhibition may help detect patients at higher risk for subsequent cardiovascular events. Clinical trials designed to evaluate these possibilities have thus far been negative. Although administration of higher doses of clopidogrel can overcome a reduced response to clopidogrel, the clinical benefit of this approach is uncertain. Instead, prasugrel or ticagrelor may be better choices for these patients.

Ticagrelor As an orally active inhibitor of $P2Y_{12}$, ticagrelor differs from the thienopyridines in that ticagrelor does not require metabolic activation and it produces reversible inhibition of the ADP receptor.

MECHANISM OF ACTION Like the thienopyridines, ticagrelor inhibits $P2Y_{12}$. Because it does not require metabolic activation, ticagrelor has a more rapid onset and offset of action than clopidogrel, and it produces greater and more predictable inhibition of ADP-induced platelet aggregation than clopidogrel.

INDICATIONS Ticagrelor is indicated for the secondary prevention of atherothrombotic events in patients with an acute coronary syndrome treated medically or with percutaneous coronary intervention (PCI) with or without stent implantation or with coronary artery bypass graft (CABG) surgery. Ticagrelor is also indicated for up to 3 years for secondary prevention in patients with a prior history of MI at least 1 year ago who are at high risk for atherothrombotic events. For patients with acute coronary syndrome undergoing PCI, guidelines give preference to ticagrelor over clopidogrel, particularly in higher risk patients.

DOSING Ticagrelor is initiated with an oral loading dose of 180 mg followed by 90 mg twice daily. The dose does not require adjustment in patients with renal impairment, but the drug should be used with caution in patients with hepatic disease and in those receiving potent inhibitors or inducers of *CYP3A4* because ticagrelor is metabolized in the liver via *CYP3A4*. Ticagrelor is usually administered in conjunction with aspirin; the daily aspirin dose should not exceed 100 mg.

SIDE EFFECTS In addition to bleeding, the most common side effects of ticagrelor are dyspnea, which can occur in up to 15% of patients, and asymptomatic ventricular pauses. The dyspnea, which tends to occur soon after initiating ticagrelor, is usually self-limiting and mild in intensity. The mechanism responsible for this side effect is unknown.

To reduce the risk of bleeding, ticagrelor should be stopped at least 5 days before major surgery. Platelet transfusion is unlikely to be of benefit in patients with ticagrelor-related bleeding or those requiring urgent surgery because the drug will bind to $P2Y_{12}$ on the transfused platelets. Bentracimab, an antibody fragment that binds ticagrelor and its metabolite with high affinity and rapidly reverses their platelet inhibitory effects, is under development for ticagrelor reversal before urgent surgery or intervention or for patients with serious bleeding.

Cangrelor Cangrelor is a rapidly acting reversible inhibitor of $P2Y_{12}$ that is administered intravenously. It has an immediate onset of action, a half-life of 3–5 min, and an offset of action within an hour. Cangrelor is licensed for use in patients undergoing PCI and produces rapid ADP receptor blockade in those who have not received pretreatment with clopidogrel, prasugrel, or ticagrelor.

Cangrelor is administered as a 30 μg/kg IV bolus before PCI followed by an infusion of 4 μg/kg per minute for at least 2 h or for the duration of the procedure, whichever is longer. When transitioning to oral $P2Y_{12}$ inhibitor therapy, ticagrelor can be given at a loading dose of 180 mg at any time during the cangrelor infusion or immediately after discontinuation. In contrast, loading doses of prasugrel or clopidogrel (60 and 600 mg, respectively) should only be given after cangrelor is stopped because cangrelor blocks the interaction of their active metabolites with $P2Y_{12}$.

DIPYRIDAMOLE

Dipyridamole is a relatively weak antiplatelet agent on its own, but an extended-release formulation of dipyridamole combined with low-dose aspirin, a preparation known as Aggrenox, is sometimes used for secondary prevention in patients with transient ischemic attacks or ischemic stroke.

MECHANISM OF ACTION By inhibiting phosphodiesterase, dipyridamole blocks the breakdown of cyclic adenosine monophosphate (AMP). Increased levels of cyclic AMP reduce intracellular calcium and inhibit platelet activation. Dipyridamole also blocks the uptake of adenosine by platelets and other cells. This produces a further increase in local cyclic AMP levels because the platelet adenosine A_2 receptor is coupled to adenylate cyclase **(Fig. 123-4)**.

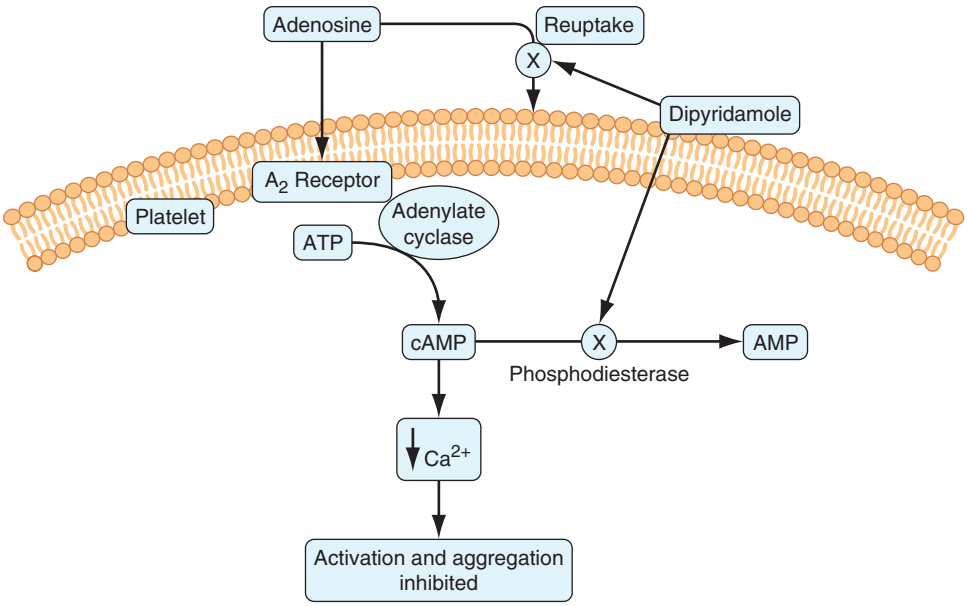

FIGURE 123-4 Mechanism of action of dipyridamole. Dipyridamole increases levels of cyclic AMP (cAMP) in platelets by (1) blocking the reuptake of adenosine and (2) inhibiting phosphodiesterase-mediated cyclic AMP degradation. By promoting calcium uptake, cyclic AMP reduces intracellular levels of calcium. This, in turn, inhibits platelet activation and aggregation.

INDICATIONS Dipyridamole plus aspirin was compared with aspirin or dipyridamole alone, or with placebo, in patients with an ischemic stroke or transient ischemic attack. The combination reduced the risk of stroke by 22.1% compared with aspirin and by 24.4% compared with dipyridamole. A second trial compared dipyridamole plus aspirin with aspirin alone for secondary prevention in patients with ischemic stroke. Vascular death, stroke, or MI occurred in 13% of patients given combination therapy and in 16% of those treated with aspirin alone. Another trial randomized 20,332 patients with noncardioembolic ischemic stroke to either Aggrenox or clopidogrel. The primary efficacy endpoint of recurrent stroke occurred in 9.0% of those given Aggrenox and in 8.8% of patients treated with clopidogrel. Although this difference was not statistically significant, the study failed to meet the prespecified margin to claim noninferiority of Aggrenox relative to clopidogrel. These results have dampened enthusiasm for the use of Aggrenox.

Because of its vasodilatory effects and the paucity of data supporting the use of dipyridamole in patients with symptomatic coronary artery disease, Aggrenox should not be used for stroke prevention in such patients. Clopidogrel is a better choice in this setting.

DOSING Aggrenox is given twice daily. Each capsule contains 200 mg of extended-release dipyridamole and 25 mg of aspirin.

SIDE EFFECTS Because dipyridamole has vasodilatory effects, it must be used with caution in patients with coronary artery disease. Gastrointestinal complaints, headache, facial flushing, dizziness, and hypotension can also occur. These symptoms often subside with continued use of the drug.

GP IIB/IIIA RECEPTOR ANTAGONISTS

As a class, parenteral Gp IIb/IIIa receptor antagonists have a niche in patients with acute coronary syndrome. The three agents in this class are abciximab, eptifibatide, and tirofiban. However, abciximab is no longer available.

Mechanism of Action A member of the integrin family of adhesion receptors, Gp IIb/IIIa is found on the surface of platelets and megakaryocytes. With about 80,000 copies per platelet, Gp IIb/IIIa is the most abundant receptor. Consisting of a noncovalently linked heterodimer, Gp IIb/IIIa is inactive on resting platelets. When platelets are activated, inside-outside signal transduction pathways trigger a conformational activation of the receptor. Once activated, Gp IIb/IIIa binds adhesive molecules, such as fibrinogen and, under high shear conditions, VWF. Binding is mediated by the Arg-Gly-Asp (RGD) sequence found on the α chains of fibrinogen and on VWF, and by the Lys-Gly-Asp (KGD) sequence located within a unique dodecapeptide domain on the γ chains of fibrinogen. Once bound, fibrinogen and/or VWF bridge adjacent platelets together to induce platelet aggregation. Although abciximab, eptifibatide, and tirofiban all target the Gp IIb/IIIa receptor, they are structurally and pharmacologically distinct **(Table 123-1)**. Abciximab is a Fab fragment of a humanized murine monoclonal antibody directed against the activated form of Gp IIb/IIIa. Abciximab binds to the activated receptor with high affinity and blocks the binding of adhesive molecules. In contrast, eptifibatide and tirofiban are synthetic small molecules. Eptifibatide is a cyclic heptapeptide that binds Gp IIb/IIIa because it incorporates the KGD motif, whereas tirofiban is a nonpeptidic tyrosine derivative that acts as an RGD mimetic. Abciximab has a long half-life and can be detected on the surface of platelets for up to 2 weeks; eptifibatide and tirofiban have short half-lives.

Indications Abciximab and eptifibatide are used in patients undergoing PCIs, particularly those who have not been pretreated with an ADP receptor antagonist. Tirofiban and eptifibatide are used in high-risk patients with non-ST-segment elevation MI.

Dosing All the Gp IIb/IIIa antagonists are given as an IV bolus followed by an infusion. The recommended dose of abciximab is a bolus of 0.25 mg/kg followed by an infusion of 0.125 μg/kg per minute to a maximum of 10 μg/kg for 12 h. In patients undergoing PCI, eptifibatide is given as two 180 μg/kg boluses given 10 min apart, followed by an infusion of 2.0 μg/kg per minute for 18–24 h. For patients with acute coronary syndrome, the second eptifibatide bolus is withheld. Tirofiban is started at a rate of 0.4 μg/kg per minute for 30 min; the drug is then continued at a rate of 0.1 μg/kg per minute for up to 18 h. Because eptifibatide and tirofiban are cleared by the kidneys, the doses must be reduced in patients with renal insufficiency. Thus, the eptifibatide infusion is reduced to 1 μg/kg per minute in patients with a creatinine clearance below 50 mL/min, whereas the dose of tirofiban is cut in half for patients with a creatinine clearance below 30 mL/min.

TABLE 123-1 Features of Gp IIb/IIIa Antagonists

FEATURE	ABCIXIMAB	EPTIFIBATIDE	TIROFIBAN
Description	Fab fragment of humanized mouse monoclonal antibody	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD mimetic
Specific for Gp IIb/IIIa	No	Yes	Yes
Plasma half-life	Short (min)	Long (2.5 h)	Long (2.0 h)
Platelet-bound half-life	Long (days)	Short (s)	Short (s)
Renal clearance	No	Yes	Yes

Abbreviation: Gp, glycoprotein.

Side Effects In addition to bleeding, thrombocytopenia is the most serious complication. Thrombocytopenia is immune-mediated and is caused by antibodies directed against neoantigens on Gp IIb/IIIa that are exposed upon antagonist binding. With abciximab, thrombocytopenia occurs in up to 5% of patients. Thrombocytopenia is severe in ~1% of these individuals. Thrombocytopenia is less common with the other two agents, occurring in ~1% of patients.

VORAPAXAR

An orally active PAR-1 antagonist, vorapaxar blocks thrombin-induced platelet activation. Vorapaxar has a half-life of about 200 h.

Indications When compared with a placebo in 12,944 patients with acute coronary syndrome without ST-segment elevation, vorapaxar failed to significantly reduce the primary efficacy endpoint, a composite of cardiovascular death, MI, stroke, recurrent ischemia requiring rehospitalization, and urgent coronary revascularization. Moreover, vorapaxar was associated with increased rates of bleeding, including intracranial bleeding.

In a second trial, vorapaxar was compared with placebo for secondary prevention in 26,449 patients with prior MI, ischemic stroke, or peripheral arterial disease. Overall, vorapaxar reduced the risk of cardiovascular death, MI, or stroke by 13%, but doubled the risk of intracranial bleeding. In the prespecified subgroup of 17,779 patients with prior MI, however, vorapaxar reduced the risk for cardiovascular death, MI, or stroke by 20% compared with placebo (from 9.7% to 8.1%, respectively). The rate of intracranial hemorrhage was higher with vorapaxar than with placebo (0.6% and 0.4%, respectively; $p = .076$) as was the rate of moderate or severe bleeding (3.4% and 2.1%, respectively; $p < .0001$). Based on these data, vorapaxar is licensed for patients younger than 75 years of age with MI or peripheral artery disease who have no history of stroke, transient ischemic attack, or intracranial bleeding and weigh >60 kg.

Dosing Vorapaxar is given at a dose of 2.08 mg once daily.

Side Effects The major side effect is bleeding. Platelet transfusion may be of benefit for vorapaxar reversal.

ANTICOAGULANTS

There are both parenteral and oral anticoagulants. The parenteral anticoagulants include heparin, low-molecular-weight heparin (LMWH), fondaparinux (a synthetic pentasaccharide), lepirudin, desirudin, bivalirudin, and argatroban. Currently available oral anticoagulants include warfarin; dabigatran etexilate, an oral thrombin inhibitor; and rivaroxaban, apixaban, and edoxaban, which are oral factor Xa inhibitors.

PARENTERAL ANTICOAGULANTS

Heparin A sulfated polysaccharide, heparin is isolated from mammalian tissues rich in mast cells. Most commercial heparin is derived from porcine intestinal mucosa and is a polymer of alternating D-glucuronic acid and *N*-acetyl-D-glucosamine residues.

MECHANISM OF ACTION Heparin acts as an anticoagulant by activating antithrombin (previously known as antithrombin III) and accelerating the rate at which antithrombin inhibits clotting enzymes, particularly thrombin and factor Xa. Antithrombin, the obligatory plasma cofactor for heparin, is a member of the serine protease inhibitor (serpin) superfamily. Synthesized in the liver and circulating in plasma at a concentration of 2.6 ± 0.4 μM, antithrombin acts as a suicide substrate for its target enzymes.

To activate antithrombin, heparin binds to the serpin via a unique pentasaccharide sequence that is found on one-third of the chains of commercial heparin (Fig. 123-5). Heparin chains without this pentasaccharide sequence have little or no anticoagulant activity. Once bound to antithrombin, heparin induces a conformational change in the reactive center loop of antithrombin that renders it more readily accessible to its target proteases. This conformational change enhances the rate at which antithrombin inhibits factor Xa by at least two orders of magnitude but has little effect on the rate of thrombin inhibition. To catalyze thrombin inhibition, heparin serves as a template that binds antithrombin and thrombin simultaneously. Formation of this ternary complex brings the enzyme in close apposition to the inhibitor, thereby promoting the formation of a stable covalent thrombin-antithrombin complex.

Only pentasaccharide-containing heparin chains composed of at least 18 saccharide units (which correspond to a molecular weight of 5400) are of sufficient length to bridge thrombin and antithrombin

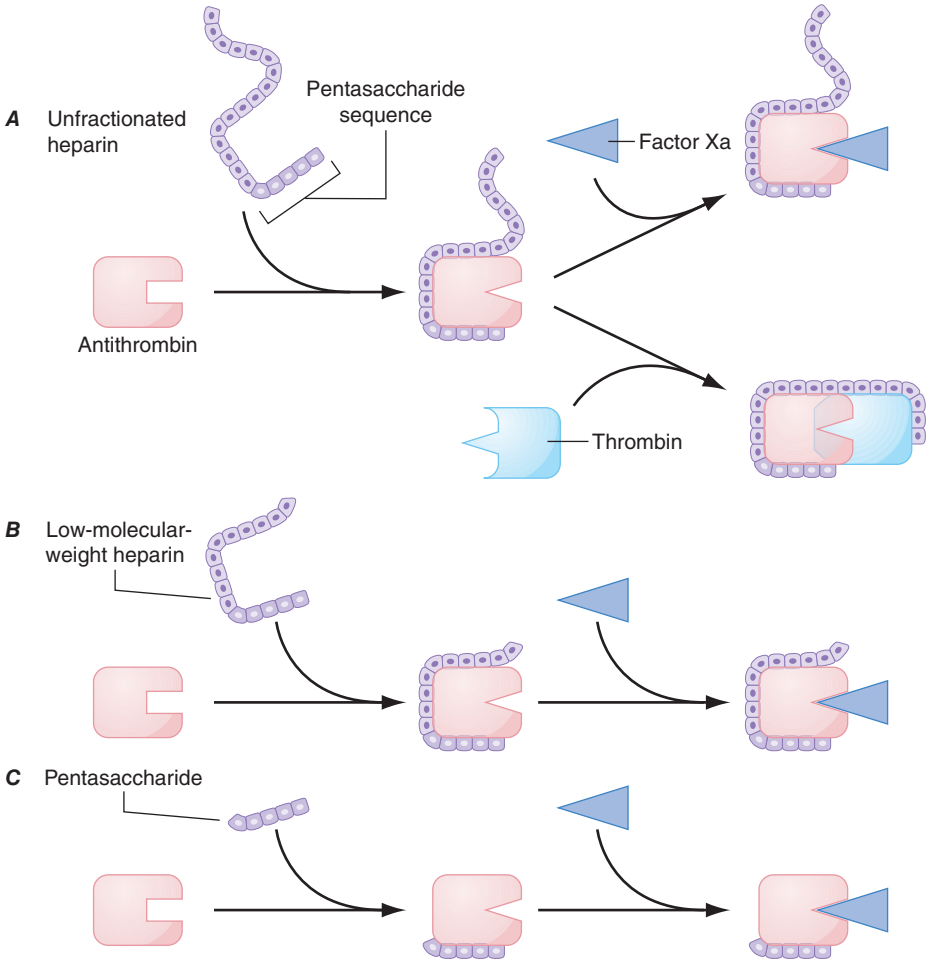

FIGURE 123-5 Mechanism of action of heparin, low-molecular-weight heparin (LMWH), and fondaparinux, a synthetic pentasaccharide. ***A.*** Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units, which corresponds to a molecular weight of 5400, are of sufficient length to perform this bridging function. With a mean molecular weight of 15,000, all the heparin chains are long enough to do this. ***B.*** LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin because, with a mean molecular weight of 4500–5000, at least half of the LMWH chains are too short to bridge antithrombin to thrombin. ***C.*** Fondaparinux, a synthetic pentasaccharide, only accelerates factor Xa inhibition by antithrombin because it is too short to bridge antithrombin to thrombin.

together. With a mean molecular weight of 15,000, and a range of 5000–30,000, almost all the chains of unfractionated heparin are long enough to do so. Consequently, by definition, heparin has equal capacity to promote the inhibition of thrombin and factor Xa by antithrombin and is assigned an anti–factor Xa to anti–factor IIa (thrombin) ratio of 1:1.

Heparin causes the release of tissue factor pathway inhibitor (TFPI) from the endothelium. A factor Xa–dependent inhibitor of tissue factor–bound factor VIIa, TFPI may contribute to the antithrombotic activity of heparin. Longer heparin chains induce the release of more TFPI than shorter ones.

PHARMACOLOGY Heparin must be given parenterally. It is usually administered SC or by continuous IV infusion. When used for therapeutic purposes, the IV route is most often employed. If heparin is given SC for treatment of thrombosis, the dose of heparin must be high enough to overcome the limited bioavailability associated with this method of delivery.

In the circulation, heparin binds to the endothelium and to plasma proteins other than antithrombin. Heparin binding to endothelial cells explains its dose-dependent clearance. At low doses, the half-life of heparin is short because it binds rapidly to the endothelium. With higher doses of heparin, the half-life is longer because heparin is cleared more slowly once the endothelium is saturated. Clearance is mainly extrarenal; heparin binds to macrophages, which internalize and depolymerize the long heparin chains and secrete shorter chains back into the circulation. Because of its dose-dependent clearance mechanism, the plasma half-life of heparin ranges from 30 to 60 min with bolus IV doses of 25 and 100 units/kg, respectively.

Once heparin enters the circulation, it binds to plasma proteins other than antithrombin, a phenomenon that reduces its anticoagulant activity. Some of the heparin-binding proteins found in plasma are acute-phase reactants whose levels are elevated in ill patients. Others, such as high-molecular-weight multimers of VWF, are released from activated platelets or endothelial cells. Activated platelets also release platelet factor 4 (PF4), a highly cationic protein that binds heparin with high affinity. The large amounts of PF4 found in the vicinity of platelet-rich arterial thrombi can neutralize the anticoagulant activity of heparin. This phenomenon may attenuate heparin's capacity to suppress thrombus growth.

Because the levels of heparin-binding proteins in plasma vary from person to person, the anticoagulant response to fixed or weight-adjusted doses of heparin is unpredictable. Consequently, coagulation monitoring is essential to ensure that a therapeutic response is obtained. This is particularly important when heparin is administered for treatment of established thrombosis because a subtherapeutic anticoagulant response may render patients at risk for recurrent thrombosis, whereas excessive anticoagulation increases the risk of bleeding.

MONITORING THE ANTICOAGULANT EFFECT Heparin therapy can be monitored using the activated partial thromboplastin time (aPTT) or anti–factor Xa level. Although the aPTT is the test most often used for this purpose, there are problems with this assay. aPTT reagents vary in their sensitivity to heparin, and the type of coagulometer used for testing can influence the results. Consequently, laboratories must establish a therapeutic aPTT range with each reagent-coagulometer combination by measuring the aPTT and anti–factor Xa level in plasma samples collected from heparin-treated patients. For most of the aPTT reagents and coagulometers in current use, therapeutic heparin levels are achieved with a two- to threefold prolongation of the aPTT. Anti–factor Xa levels also can be used to monitor heparin therapy. With this test, therapeutic heparin levels range from 0.3 to 0.7 units/mL.

Up to 25% of heparin-treated patients with VTE require >35,000 units/d to achieve a therapeutic aPTT. These patients are considered heparin resistant. It is useful to measure anti–factor Xa levels in heparin-resistant patients because many will have a therapeutic anti–factor Xa level despite a subtherapeutic aPTT. This dissociation in test results occurs because elevated plasma levels of fibrinogen and factor VIII, both of which are acute-phase proteins, shorten the aPTT but have no effect on anti–factor Xa levels. Heparin therapy in patients who exhibit this phenomenon is best monitored using anti–factor Xa levels instead of the aPTT. Patients with congenital or acquired antithrombin deficiency and those with elevated levels of heparin-binding proteins may also need high doses of heparin to achieve a therapeutic aPTT or anti–factor Xa level. If there is good correlation between the aPTT and the anti–factor Xa level, either test can be used to monitor heparin therapy.

DOSING For prophylaxis, heparin is usually given in fixed doses of 5000 units SC two or three times daily. With these low doses, coagulation monitoring is unnecessary. In contrast, monitoring is essential when the drug is given in therapeutic doses. Fixed-dose or weight-based heparin nomograms are used to standardize heparin dosing and to shorten the time required to achieve a therapeutic anticoagulant response. At least two heparin nomograms have been validated in patients with VTE and reduce the time required to achieve a therapeutic aPTT. Weight-adjusted heparin nomograms have also been evaluated in patients with acute coronary syndromes. After an IV heparin bolus of 5000 units or 70 units/kg, a heparin infusion rate of 12–15 units/kg per hour is usually administered. In contrast, weight-adjusted heparin nomograms for patients with VTE use an initial bolus of 5000 units or 80 units/kg, followed by an infusion of 18 units/kg per hour. Thus, patients with VTE appear to require higher doses of heparin to achieve a therapeutic aPTT than do patients with acute coronary syndromes. This may reflect differences in the thrombus burden. Heparin binds to fibrin, and the amount of fibrin in patients with extensive DVT is greater than that in those with coronary thrombosis.

LIMITATIONS Heparin has pharmacokinetic and biophysical limitations (Table 123-2). The pharmacokinetic limitations reflect heparin's propensity to bind in a pentasaccharide-independent fashion to cells and plasma proteins. Heparin binding to endothelial cells explains its dose-dependent clearance, whereas binding to plasma proteins results in a variable anticoagulant response and can lead to heparin resistance.

The biophysical limitations of heparin reflect the inability of the heparin-antithrombin complex to inhibit factor Xa when it is incorporated into the prothrombinase complex, the complex that converts prothrombin to thrombin, and to inhibit thrombin bound to fibrin. Consequently, factor Xa bound to activated platelets within platelet-rich thrombi has the potential to generate thrombin, even in the face of heparin. Once this thrombin binds to fibrin, it too is protected from inhibition by the heparin-antithrombin complex. Clot-associated thrombin can then trigger thrombus growth by locally activating platelets and amplifying its own generation through feedback activation of factors V, VIII, and XI. Further compounding the problem is the potential for heparin neutralization by the high concentrations of PF4 released from activated platelets within the platelet-rich thrombus.

SIDE EFFECTS The most common side effect of heparin is bleeding. Other complications include thrombocytopenia, osteoporosis, and elevated levels of transaminases.

Bleeding The risk of bleeding rises as the dose of heparin is increased. Concomitant administration of drugs that affect hemostasis, such as antiplatelet or fibrinolytic agents, increases the risk of bleeding, as does

TABLE 123-2 Pharmacokinetic and Biophysical Limitations of Heparin

LIMITATIONS	MECHANISM
Poor bioavailability at low doses	Binds to endothelial cells and macrophages
Dose-dependent clearance	Binds to macrophages
Variable anticoagulant response	Binds to plasma proteins whose levels vary from patient to patient
Reduced activity in the vicinity of platelet-rich thrombi	Neutralized by platelet factor 4 released from activated platelets
Limited activity against factor Xa incorporated in the prothrombinase complex and thrombin bound to fibrin	Reduced capacity of heparin-antithrombin complex to inhibit factor Xa bound to activated platelets and thrombin bound to fibrin

TABLE 123-3 Features of Heparin-Induced Thrombocytopenia

FEATURES	DETAILS
Thrombocytopenia	Platelet count of ≤100,000/μL or a decrease in platelet count of ≥50%
Timing	Platelet count falls 5–14 days after starting heparin
Type of heparin	More common with unfractionated heparin than low-molecular-weight heparin
Type of patient	More common in surgical patients and patients with cancer than general medical patients; more common in women than in men
Thrombosis	Venous thrombosis more common than arterial thrombosis

recent surgery or trauma. Heparin-treated patients with serious bleeding can be given protamine sulfate to neutralize the heparin. Protamine sulfate, a mixture of basic polypeptides isolated from salmon sperm, binds heparin with high affinity, and the resultant protamine-heparin complexes are then cleared. Typically, 1 mg of protamine sulfate neutralizes 100 units of heparin. Protamine sulfate is given IV at a maximum amount of 50 mg per dose. Anaphylactoid reactions to protamine sulfate can occur, and drug administration by slow IV infusion is recommended to reduce the risk.

Thrombocytopenia Heparin can cause thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is an antibody-mediated process that is triggered by antibodies directed against neoantigens on PF4 that are exposed when heparin binds to this protein. These antibodies, which are usually of the IgG isotype, bind simultaneously to the heparin-PF4 complex and to platelet Fc receptors. Such binding activates the platelets and generates platelet microparticles. Circulating microparticles are procoagulant because they express anionic phospholipids on their surface and can bind clotting factors and promote thrombin generation. The clinical features of HIT are illustrated in Table 123-3. Typically, HIT occurs 5–14 days after initiation of heparin therapy, but it can manifest earlier if the patient has received heparin within the past 3 months. A platelet count <100,000/μL or a 50% decrease in the platelet count from the pretreatment value should raise the suspicion of HIT. HIT is more common in surgical patients than in medical patients and, like many autoimmune disorders, occurs more frequently in females than in males.

HIT can be associated with thrombosis, either arterial or venous. Venous thrombosis, which manifests as DVT and/or PE, is more common than arterial thrombosis. Arterial thrombosis can manifest as ischemic stroke or acute MI. Rarely, platelet-rich thrombi in the distal aorta or iliac arteries can cause critical limb ischemia.

The diagnosis of HIT is established using enzyme-linked assays to detect antibodies against heparin-PF4 complexes or with platelet activation assays. Enzyme-linked assays are sensitive but can be positive in the absence of any clinical evidence of HIT. The most specific diagnostic test for HIT is the serotonin release assay. This test is performed by quantifying serotonin release when washed platelets loaded with labeled serotonin are exposed to patient serum in the absence or presence of varying concentrations of heparin. If the patient serum contains the HIT antibody, heparin addition induces platelet activation and serotonin release. Management of HIT is outlined in Table 123-4. Heparin should be stopped in patients with suspected or documented HIT, and an alternative anticoagulant should be administered to prevent or treat thrombosis. The agents most often used for this indication are parenteral direct thrombin inhibitors, such as argatroban or bivalirudin, or factor Xa inhibitors, such as fondaparinux or rivaroxaban. A HIT-like syndrome known as vaccine-induced thrombotic thrombocytopenia was reported as a rare complication after vaccination with adenovirus COVID-19 vaccines. Characterized by thrombosis and thrombocytopenia that occurred 4–28 days after vaccination, patients presented with cerebral or splanchnic vein thrombosis as well as DVT or PE. The diagnosis is established by the detection of antibodies against PF4 and a positive serotonin release assay with added PF4. Treatment can include intravenous immunoglobulin, steroids, and plasma exchange to offset the effects of the antibodies against PF4, as well as anticoagulants such as argatroban, fondaparinux, or rivaroxaban to treat the thrombosis.

Patients with HIT, particularly those with associated thrombosis, often have evidence of increased thrombin generation that can lead to consumption of protein C. If these patients are given warfarin without a concomitant anticoagulant that inhibits thrombin or thrombin generation, the further decrease in protein C levels induced by the warfarin can trigger skin necrosis. To avoid this problem, patients with HIT should be treated with a direct thrombin inhibitor or with fondaparinux until the platelet count returns to normal levels. At this point, low-dose warfarin therapy can be introduced, and the parenteral anticoagulant can be discontinued when the international normalized ratio (INR) has been therapeutic for at least 2 days. Alternatively, a direct oral anticoagulant, such as apixaban or rivaroxaban, can be given.

Osteoporosis Treatment with therapeutic doses of heparin for >1 month can cause a reduction in bone density. This complication has been reported in up to 30% of patients given long-term heparin therapy, and symptomatic vertebral fractures occur in 2–3% of these individuals.

Heparin affects the activity of osteoblasts and osteoclasts and causes bone loss both by decreasing bone formation and by enhancing bone resorption.

Elevated Levels of Transaminases Therapeutic doses of heparin are frequently associated with modest elevations in the serum levels of hepatic transaminases without a concomitant increase in the level of bilirubin. The levels of transaminases rapidly return to normal when heparin is stopped. The mechanism responsible for this phenomenon is unknown.

Low-Molecular-Weight Heparin Consisting of smaller fragments of heparin, LMWH is prepared from unfractionated heparin by controlled enzymatic or chemical depolymerization. The mean molecular weight of LMWH is about 5000, one-third the mean molecular weight of unfractionated heparin. LMWH has advantages over heparin (Table 123-5) and has replaced heparin for most indications.

MECHANISM OF ACTION Like heparin, LMWH exerts its anticoagulant activity by activating antithrombin. With a mean molecular weight of 5000, which corresponds to about 17 saccharide units, at least half of the pentasaccharide-containing chains of LMWH are too short to bridge thrombin to antithrombin (Fig. 123-5). However, these chains retain the capacity to accelerate factor Xa inhibition by antithrombin

TABLE 123-4 Management of Heparin-Induced Thrombocytopenia

Stop all heparins.
Give an alternative anticoagulant, such as argatroban, bivalirudin, fondaparinux, or rivaroxaban.
Do not give platelet transfusions.
Do not give warfarin until the platelet count returns to its baseline level. If warfarin was administered, give vitamin K to restore the INR to normal.
Evaluate for thrombosis, particularly deep vein thrombosis.

Abbreviation: INR, international normalized ratio.

TABLE 123-5 Advantages of LMWH Over Heparin

ADVANTAGE	CONSEQUENCE
Better bioavailability and longer half-life after subcutaneous injection	Can be given subcutaneously once or twice daily for both prophylaxis and treatment
Dose-independent clearance	Simplified dosing
Predictable anticoagulant response	Coagulation monitoring is unnecessary in most patients
Lower risk of heparin-induced thrombocytopenia	Safer than heparin for short- or long-term administration
Lower risk of osteoporosis	Safer than heparin for extended administration

Abbreviation: LMWH, low-molecular-weight heparin.

because this activity is largely the result of the conformational changes in antithrombin evoked by pentasaccharide binding. Consequently, LMWH catalyzes factor Xa inhibition by antithrombin more than thrombin inhibition. Depending on their unique molecular weight distributions, LMWH preparations have anti–factor Xa to anti–factor IIa ratios ranging from 2:1 to 4:1.

PHARMACOLOGY Although usually given SC, LMWH also can be administered IV if a rapid anticoagulant response is needed. LMWH has pharmacokinetic advantages over heparin. These advantages reflect the fact that shorter heparin chains bind less avidly to endothelial cells, macrophages, and heparin-binding plasma proteins. Reduced binding to endothelial cells and macrophages eliminates the rapid, dose-dependent, and saturable mechanism of clearance that is a characteristic of unfractionated heparin. Instead, the clearance of LMWH is dose-independent and its plasma half-life is longer. Based on measurement of anti–factor Xa levels, LMWH has a plasma half-life of ~4–6 h. LMWH is cleared almost exclusively by the kidneys, and the drug can accumulate in patients with renal insufficiency.

LMWH exhibits about 90% bioavailability after SC injection. Because LMWH binds less avidly to heparin-binding proteins in plasma than heparin, LMWH produces a more predictable dose response, and resistance to LMWH is rare. With a longer half-life and more predictable anticoagulant response, LMWH can be given SC once or twice daily without coagulation monitoring, even when the drug is given in treatment doses. These properties render LMWH more convenient to administer than unfractionated heparin. Capitalizing on this feature, studies in patients with VTE have shown that home treatment with LMWH is as effective and safe as in-hospital treatment with continuous IV infusions of heparin. Outpatient treatment with LMWH streamlines care, reduces health care costs, and increases patient satisfaction.

MONITORING In most patients, LMWH does not require coagulation monitoring. If monitoring is necessary, anti–factor Xa levels must be measured because LMWH preparations have little effect on the aPTT. Therapeutic anti–factor Xa levels for once-daily and twice-daily dosing of LMWH range from 0.5 to 1.2 units/mL and 1.0 to 2.0 units/mL, respectively, when measured 3–4 h after drug administration. When LMWH is given in prophylactic doses, peak anti–factor Xa levels of 0.2–0.5 units/mL are desirable.

Indications for LMWH monitoring include renal impairment and obesity. LMWH monitoring in patients with a creatinine clearance ≤30 mL/min is advisable to ensure that there is no drug accumulation. Although weight-adjusted LMWH dosing appears to produce therapeutic anti–factor Xa levels in patients who are overweight, this approach has not been extensively evaluated in those with morbid obesity. It may also be advisable to monitor the anticoagulant activity of LMWH during pregnancy because dose requirements can change, particularly in the third trimester. Monitoring should also be considered in high-risk settings, such as in pregnant women with mechanical heart valves who are given LMWH to prevent valve thrombosis, and when LMWH is used in treatment doses in infants or children.

DOSING The doses of LMWH recommended for prophylaxis or treatment vary depending on the LMWH preparation. For prophylaxis, once-daily SC doses of 4000–5000 units are often used, whereas doses of 2500–3000 units are given when the drug is administered twice daily. For treatment of VTE, a dose of 150–200 units/kg is given if the drug is administered once daily. If a twice-daily regimen is used, a dose of 100 units/kg is given. In patients with unstable angina, LMWH is given SC on a twice-daily basis at a dose of 100–120 units/kg.

SIDE EFFECTS The major complication of LMWH is bleeding. Meta-analyses suggest that the risk of major bleeding is lower with LMWH than with unfractionated heparin. HIT and osteoporosis are less common with LMWH than with unfractionated heparin.

Bleeding Like the situation with heparin, bleeding with LMWH is more common in patients receiving concomitant therapy with antiplatelet or fibrinolytic drugs. Recent surgery, trauma, or underlying hemostatic defects also increase the risk of bleeding with LMWH.

Although protamine sulfate can be used as an antidote for LMWH, protamine sulfate incompletely neutralizes the anticoagulant activity of LMWH because it only binds the longer chains of LMWH. Because longer chains are responsible for catalysis of thrombin inhibition by antithrombin, protamine sulfate completely reverses the anti–factor IIa activity of LMWH. In contrast, protamine sulfate only partially reverses the anti–factor Xa activity of LMWH because the shorter pentasaccharide-containing chains of LMWH do not bind to protamine sulfate. Consequently, patients at high risk for bleeding may be more safely treated with continuous IV unfractionated heparin than with SC LMWH. Andexanet alfa, a recombinant factor Xa variant licensed for reversal of oral factor Xa inhibitors, reverses that anti–factor Xa activity of LMWH but not its anti–factor IIa activity. The utility of andexanet for LMWH reversal is uncertain, and it is not licensed for this indication.

Thrombocytopenia The risk of HIT is about fivefold lower with LMWH than with heparin. LMWH binds less avidly to platelets and causes less PF4 release. Furthermore, with lower affinity for PF4 than heparin, LMWH is less likely to induce the conformational changes in PF4 that trigger the formation of HIT antibodies.

LMWH should not be used to treat HIT patients because most HIT antibodies exhibit cross-reactivity with LMWH. This in vitro cross-reactivity is more than a laboratory phenomenon because there are case reports of thrombosis when HIT patients were switched from heparin to LMWH.

Osteoporosis Because the risk of osteoporosis is lower with LMWH than with heparin, LMWH is a better choice than heparin for extended treatment.

Fondaparinux A synthetic analogue of the antithrombin-binding pentasaccharide sequence, fondaparinux differs from LMWH in several ways (Table 123-6). Fondaparinux is licensed for thromboprophylaxis in general medical or surgical patients and in high-risk orthopedic patients and as an alternative to heparin or LMWH for initial treatment of patients with established VTE. Although fondaparinux is used in Europe as an alternative to heparin or LMWH in patients with acute coronary syndrome, the drug is not licensed for this indication in the United States.

MECHANISM OF ACTION Fondaparinux has a molecular weight of 1728. Fondaparinux binds only to antithrombin (Fig. 123-5) and is too short to bridge thrombin to antithrombin. Consequently, fondaparinux catalyzes factor Xa inhibition by antithrombin and does not enhance the rate of thrombin inhibition.

PHARMACOLOGY Fondaparinux exhibits complete bioavailability after SC injection. With no binding to endothelial cells or plasma proteins, the clearance of fondaparinux is dose independent, and its plasma half-life is 17 h. The drug is given SC once daily. Because fondaparinux is cleared unchanged via the kidneys, it is contraindicated in patients with a creatinine clearance <30 mL/min and should be used with caution in those with a creatinine clearance <50 mL/min.

DOSING Fondaparinux produces a predictable anticoagulant response after administration in fixed doses because it does not bind to plasma proteins. The drug is given at a dose of 2.5 mg once daily for prevention of VTE. For initial treatment of established VTE, fondaparinux is

TABLE 123-6 Comparison of LMWH and Fondaparinux

FEATURES	LMWH	FONDAPARINUX
Number of saccharide units	15–17	5
Catalysis of factor Xa inhibition	Yes	Yes
Catalysis of thrombin inhibition	Yes	No
Bioavailability after subcutaneous administration (%)	90	100
Plasma half-life (h)	4	17
Renal excretion	Yes	Yes
Induces release of tissue factor pathway inhibitor	Yes	No
Neutralized by protamine sulfate	Partially	No

given at a dose of 7.5 mg once daily. The dose can be reduced to 5 mg once daily for those weighing <50 kg and increased to 10 mg for those >100 kg. When given in these doses, fondaparinux is as effective as heparin or LMWH for initial treatment of patients with DVT or PE and is associated with similar rates of bleeding.

Fondaparinux is used at a dose of 2.5 mg once daily in patients with acute coronary syndrome. When this prophylactic dose of fondaparinux was compared with treatment doses of enoxaparin in patients with non-ST-segment elevation MI, there was no difference in the rate of cardiovascular death, MI, or stroke at 9 days. However, the rate of major bleeding was 50% lower with fondaparinux than with enoxaparin, a difference that likely reflects the fact that the dose of fondaparinux was lower than that of enoxaparin. In acute coronary syndrome patients who require PCI, there is a risk of catheter thrombosis with fondaparinux unless adjunctive heparin is given at the time of the procedure.

SIDE EFFECTS Fondaparinux does not cause HIT because it does not bind to PF4. In contrast to LMWH, there is no cross-reactivity of fondaparinux with HIT antibodies. Consequently, fondaparinux appears to be effective for treatment of HIT patients, although large clinical trials supporting its use are lacking.

The major side effect of fondaparinux is bleeding. Fondaparinux has no antidote. Protamine sulfate has no effect on the anticoagulant activity of fondaparinux because it fails to bind to the drug. Andexanet alfa has been reported to reverse fondaparinux in vitro, but studies in patients are lacking. Recombinant activated factor VII reverses the anticoagulant effects of fondaparinux in volunteers, but it is unknown whether this agent controls fondaparinux-induced bleeding.

Parenteral Direct Thrombin Inhibitors Direct thrombin inhibitors bind directly to thrombin and block its interaction with its substrates. Approved parenteral direct thrombin inhibitors include recombinant hirudins (lepirudin and desirudin), argatroban, and bivalirudin (Table 123-7). Lepirudin and desirudin are no longer available.

ARGATROBAN A univalent inhibitor that targets the active site of thrombin, argatroban is metabolized in the liver. Consequently, this drug must be used with caution in patients with hepatic insufficiency. Argatroban is administered by continuous IV infusion and has a plasma half-life of ~45 min. The aPTT is used to monitor its anticoagulant effect, and the dose is adjusted to achieve an aPTT 1.5–3 times the baseline value, but not to exceed 100 s. Argatroban also prolongs the INR, a feature that can complicate the transitioning of patients from argatroban to warfarin. This problem can be circumvented by using the levels of factor X to monitor warfarin instead of the INR. Alternatively, argatroban can be stopped for 2–3 h before INR determination.

Argatroban is licensed for treatment of patients with HIT or a history of HIT, including those requiring PCI. In such patients, argatroban is most useful for those with severe kidney disease because unlike fondaparinux and bivalirudin, it is not cleared through the kidneys.

BIVALIRUDIN A synthetic 20-amino-acid analogue of hirudin, bivalirudin is a divalent thrombin inhibitor. Thus, the N-terminus of bivalirudin interacts with the active site of thrombin, whereas its C-terminus binds to exosite 1. Bivalirudin has a plasma half-life of 25 min, the shortest half-life of all the parenteral direct thrombin inhibitors. Bivalirudin is degraded by peptidases and is partially excreted via the kidneys. When given in high doses in the cardiac catheterization laboratory, the anticoagulant activity of bivalirudin is monitored using the activated clotting time. With lower doses, its activity can be assessed using the aPTT.

Bivalirudin is licensed as an alternative to heparin in patients undergoing PCI. Bivalirudin also has been used successfully in HIT patients who require PCI or cardiac bypass surgery.

TABLE 123-7 Comparison of the Properties of Desirudin, Bivalirudin, and Argatroban

	DESIRUDIN	BIVALIRUDIN	ARGATROBAN
Molecular mass	7000	1980	527
Site(s) of interaction with thrombin	Active site and exosite 1	Active site and exosite 1	Active site
Renal clearance	Yes	No	No
Hepatic metabolism	No	No	Yes
Plasma half-life (min)	60 (IV) 120–180 (SC)	25	45

ORAL ANTICOAGULANTS

For many years, vitamin K antagonists such as warfarin were the only available oral anticoagulants. This situation changed with the introduction of the direct oral anticoagulants, which include dabigatran, rivaroxaban, apixaban, and edoxaban.

Warfarin A water-soluble vitamin K antagonist initially developed as a rodenticide; warfarin is the coumarin derivative most often prescribed in North America. Like other vitamin K antagonists, warfarin interferes with the synthesis of the vitamin K–dependent clotting proteins, which include prothrombin (factor II) and factors VII, IX, and X. The synthesis of the vitamin K–dependent anticoagulant proteins, proteins C and S, is also reduced by vitamin K antagonists.

MECHANISM OF ACTION All of the vitamin K–dependent clotting factors possess glutamic acid residues at their N termini. A posttranslational modification adds a carboxyl group to the γ-carbon of these residues to generate γ-carboxyglutamic acid. This modification is essential for expression of the activity of these clotting factors because it permits their calcium-dependent binding to negatively charged phospholipid surfaces. The γ-carboxylation process is catalyzed by a vitamin K–dependent carboxylase. Thus, vitamin K from the diet is reduced to vitamin K hydroquinone by vitamin K reductase (Fig. 123-6). Vitamin K hydroquinone serves as a cofactor for the carboxylase enzyme, which in the presence of carbon dioxide replaces the hydrogen on the γ-carbon of glutamic acid residues with a carboxyl group. During this process, vitamin K hydroquinone is oxidized to vitamin K epoxide, which is then reduced to vitamin K by vitamin K epoxide reductase.

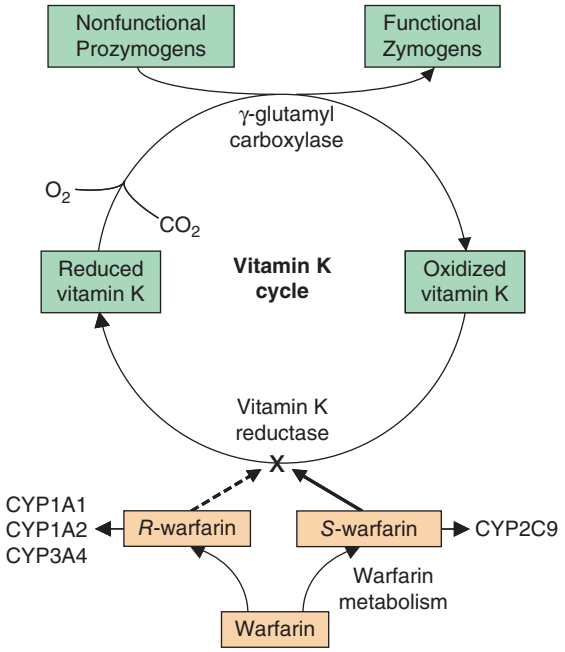

FIGURE 123-6 Mechanism of action of warfarin. A racemic mixture of *S*- and *R*-enantiomers, *S*-warfarin is most active. By blocking vitamin K epoxide reductase, warfarin inhibits the conversion of oxidized vitamin K into its reduced form. This inhibits vitamin K–dependent γ-carboxylation of factors II, VII, IX, and X because reduced vitamin K serves as a cofactor for a γ-glutamyl carboxylase that catalyzes the γ-carboxylation process, thereby converting pro-zymogens to zymogens capable of binding calcium and interacting with anionic phospholipid surfaces. *S*-warfarin is metabolized by *CYP2C9*. Common genetic polymorphisms in this enzyme can influence warfarin metabolism. Polymorphisms in the C1 subunit of vitamin K reductase (*VKORC1*) also can affect the susceptibility of the enzyme to warfarin-induced inhibition, thereby influencing warfarin dosage requirements.

Warfarin inhibits vitamin K epoxide reductase (VKOR), thereby blocking the γ-carboxylation process. This results in the synthesis of vitamin K–dependent clotting proteins that are only partially γ-carboxylated. Warfarin acts as an anticoagulant because these partially γ-carboxylated proteins have little or no biological activity. The onset of action of warfarin is delayed until the newly synthesized clotting factors with reduced activity gradually replace their fully active counterparts.

The antithrombotic effect of warfarin depends on a reduction in the functional levels of factor X and prothrombin, clotting factors that have half-lives of 24 and 72 h, respectively. Because the antithrombotic effect of warfarin is delayed, patients with established thrombosis or at high risk for thrombosis require concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux, for at least 5 days.

PHARMACOLOGY Warfarin is a racemic mixture of R and S isomers. Warfarin is rapidly and almost completely absorbed from the gastrointestinal tract. Levels of warfarin in the blood peak about 90 min after drug administration. Racemic warfarin has a plasma half-life of 36–42 h, and >97% of circulating warfarin is bound to albumin. Only the small fraction of unbound warfarin is biologically active.

Warfarin accumulates in the liver where the two isomers are metabolized via distinct pathways. *CYP2C9* mediates oxidative metabolism of the more active S isomer (Fig. 123-6). Two relatively common variants, *CYP2C9*2* and *CYP2C9*3*, encode an enzyme with reduced activity. Patients with these variants require lower maintenance doses of warfarin. Approximately 25% of Caucasians have at least one variant allele of *CYP2C9*2* or *CYP2C9*3*, whereas those variant alleles are less common in African Americans and Asians **(Table 123-8)**. Heterozygosity for *CYP2C9*2* or *CYP2C9*3* decreases the warfarin dose requirement by 20–30% relative to that required in subjects with the wild-type *CYP2C9*1/*1* alleles, whereas homozygosity for the *CYP2C9*2* or *CYP2C9*3* alleles reduces the warfarin dose requirement by 50–70%.

Consistent with their decreased warfarin dose requirement, subjects with at least one *CYP2C9* variant allele are at increased risk for bleeding. Compared with individuals with no variant alleles, the risk of warfarin-associated bleeding is almost twofold higher in *CYP2C9*2* or *CYP2C9*3* carriers.

Polymorphisms in *VKORC1* also can influence the anticoagulant response to warfarin. Several genetic variations of *VKORC1* are in strong linkage disequilibrium and have been designated as non-A haplotypes. *VKORC1* variants are more prevalent than variants of *CYP2C9*. Asians have the highest prevalence of *VKORC1* variants, followed by Caucasians and African Americans (Table 123-8). Polymorphisms in *VKORC1* likely explain 30% of the variability in warfarin dose requirements. Compared with *VKORC1* non-A/non-A homozygotes, the warfarin dose requirement decreases by 25 and 50% in A haplotype heterozygotes and homozygotes, respectively. These findings prompted the U.S. Food and Drug Administration (FDA) to amend the prescribing information for warfarin to indicate that lower initiation doses should be considered for patients with *CYP2C9* and *VKORC1* genetic variants. In addition to genotype data, other pertinent patient information has been incorporated into warfarin dosing algorithms. Although such algorithms help predict suitable warfarin doses, it remains unclear whether better dose identification improves patient outcome in terms of reducing hemorrhagic complications or recurrent thrombotic events.

TABLE 123-8 Frequencies of *CYP2C9* Genotypes and *VKORC1* Haplotypes in Different Populations and their Effect on Warfarin Dose Requirements

GENOTYPE/ HAPLOTYPE	FREQUENCY, %			PERCENTAGE DOSE REDUCTION COMPARED WITH WILD-TYPE

Non-A/A	45	12	30	26
A/A	18	6	63	50

In addition to genetic factors, the anticoagulant effect of warfarin is influenced by diet, drugs, and various disease states. Fluctuations in dietary vitamin K intake affect the activity of warfarin. A wide variety of drugs can alter absorption, clearance, or metabolism of warfarin. Because of the variability in the anticoagulant response to warfarin, coagulation monitoring is essential to ensure that a therapeutic response is obtained.

MONITORING Warfarin therapy is most often monitored using the prothrombin time, a test that is sensitive to reductions in the levels of prothrombin, factor VII, and factor X. The test is performed by adding thromboplastin, a reagent that contains tissue factor, phospholipid, and calcium, to citrated plasma and determining the time to clot formation. Thromboplastins vary in their sensitivity to reductions in the levels of the vitamin K–dependent clotting factors. Thus, less sensitive thromboplastins will trigger the administration of higher doses of warfarin to achieve a target prothrombin time. This is problematic because higher doses of warfarin increase the risk of bleeding.

The INR was developed to circumvent many of the problems associated with the prothrombin time. To calculate the INR, the patient's prothrombin time is divided by the mean normal prothrombin time, and this ratio is then multiplied by the international sensitivity index (ISI), which is an index of the sensitivity of the thromboplastin used for prothrombin time determination to reductions in the levels of the vitamin K–dependent clotting factors. Sensitive thromboplastins have an ISI near 1.0. Most current thromboplastins have ISI values that range from 0.9 to 1.4.

Although the INR has helped to standardize anticoagulant practice, problems persist. The precision of INR determination varies depending on reagent-coagulometer combinations. This leads to variability in the INR results. Also complicating INR determination is unreliable reporting of the ISI by thromboplastin manufacturers. Furthermore, every laboratory must establish the mean normal prothrombin time with each new batch of thromboplastin reagent. To accomplish this, the prothrombin time must be measured in fresh plasma samples from at least 20 healthy volunteers using the same coagulometer that is used for patient samples.

For most indications, warfarin is administered in doses that produce a target INR of 2.0–3.0. An exception is patients with mechanical heart valves, particularly those in the mitral position or older ball and cage valves in the aortic position, and valves in any position associated with atrial fibrillation, where a target INR of 2.5–3.5 is recommended. Studies in atrial fibrillation demonstrate an increased risk of cardioembolic stroke when the INR falls below 1.7 and an increase in bleeding with INR values >4.5. These findings highlight the fact that vitamin K antagonists have a narrow therapeutic window. In support of this concept, a study in patients receiving long-term warfarin therapy for unprovoked VTE demonstrated a higher rate of recurrent VTE with a target INR of 1.5–1.9 compared with a target INR of 2.0–3.0.

DOSING Warfarin is usually started at a dose of 5–10 mg. Lower doses are used for patients with *CYP2C9* or *VKORC1* polymorphisms, which affect the pharmacodynamics or pharmacokinetics of warfarin and render patients more sensitive to the drug. The dose is then titrated to achieve the desired target INR. Because of its delayed onset of action, patients with established thrombosis or those at high risk for thrombosis are given concomitant initial treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux. Early prolongation of the INR reflects reduction in the functional levels

of factor VII. Consequently, concomitant treatment with the parenteral anticoagulant should be continued until the INR has been therapeutic for at least 2 consecutive days. A minimum 5-day course of parenteral anticoagulation is recommended to ensure that the levels of factor Xa and prothrombin have been reduced into the therapeutic range with warfarin.

Because warfarin has a narrow therapeutic window, frequent coagulation monitoring is essential to ensure that a therapeutic anticoagulant response is maintained. Even patients with stable warfarin dose requirements should have their INR determined every 3–4 weeks although there are studies suggesting that less frequent monitoring is feasible. More frequent monitoring is necessary when new medications are introduced because so many drugs enhance or reduce the anticoagulant effects of warfarin and when the dosing regimen has been changed.

SIDE EFFECTS Like all anticoagulants, the major side effect of warfarin is bleeding. A rare complication is skin necrosis. Warfarin crosses the placenta and can cause fetal abnormalities. Consequently, warfarin should not be used during pregnancy.

Bleeding At least half of the bleeding complications with warfarin occur when the INR exceeds the therapeutic range. Bleeding complications may be mild, such as epistaxis or hematuria, or more severe, such as retroperitoneal or gastrointestinal bleeding. Life-threatening intracranial bleeding can also occur.

To minimize the risk of bleeding, the INR should be maintained in the therapeutic range. In asymptomatic patients whose INR is between 3.5 and 10, warfarin should be withheld until the INR returns to the therapeutic range. If the INR is over 10, oral vitamin K can be administered at a dose of 2.5–5 mg, although there is no evidence that doing so reduces the bleeding risk. Higher doses of oral vitamin K (5–10 mg) produce more rapid reversal of the INR but may render patients temporarily resistant to warfarin when the drug is restarted.

Patients with an increased INR associated with serious bleeding should be given 5–10 mg of vitamin K by slow IV infusion. Additional vitamin K should be given until the INR is in the normal range. Treatment with vitamin K should be supplemented with four-factor prothrombin complex concentrate, which contains all four vitamin K–dependent clotting proteins. Prothrombin complex concentrate normalizes the INR more rapidly than transfusion of fresh-frozen plasma.

Warfarin-treated patients who experience bleeding when their INR is in the therapeutic range require investigation into the cause of the bleeding. Those with gastrointestinal or genitourinary bleeding often have underlying disorders.

Skin Necrosis A rare complication of warfarin, skin necrosis usually is seen 2–5 days after initiation of therapy. Well-demarcated erythematous lesions form on the thighs, buttocks, breasts, or toes. Typically, the center of the lesion becomes progressively necrotic. Examination of skin biopsies taken from the border of these lesions reveals thrombi in the microvasculature.

Warfarin-induced skin necrosis is seen in patients with congenital or acquired deficiencies of protein C or protein S. Initiation of warfarin therapy in these patients produces a precipitous fall in plasma levels of proteins C or S, thereby eliminating this important anticoagulant pathway before warfarin exerts an antithrombotic effect through lowering of the functional levels of factor X and prothrombin. The resultant procoagulant state triggers thrombosis. Why the thrombosis is localized to the microvasculature of fatty tissues is unclear.

Treatment involves discontinuation of warfarin and reversal with vitamin K, if needed. An alternative anticoagulant, such as heparin or LMWH, should be given in patients with thrombosis. Protein C concentrate can be given to protein C–deficient patients to accelerate healing of the skin lesions; fresh-frozen plasma may be of value if protein C concentrate is unavailable and for those with protein S deficiency. Occasionally, skin grafting is necessary when there is extensive skin loss.

Because of the potential for skin necrosis, patients with known protein C or protein S deficiency require overlapping treatment with a parenteral anticoagulant when initiating warfarin therapy. Warfarin should be started in low doses in these patients, and the parenteral anticoagulant should be continued until the INR is therapeutic for at least 2–3 consecutive days. Alternatively, treatment with rivaroxaban or apixaban could be given, although there is limited information about their efficacy and safety in patients with severe protein C or S deficiency.

Pregnancy Warfarin crosses the placenta and can cause fetal abnormalities or bleeding. The fetal abnormalities include a characteristic embryopathy, which consists of nasal hypoplasia and stippled epiphyses. The risk of embryopathy is highest if warfarin is given in the first trimester of pregnancy. Central nervous system abnormalities can also occur with exposure to warfarin at any time during pregnancy. Finally, maternal administration of warfarin produces an anticoagulant effect in the fetus that can cause bleeding. This is of particular concern at delivery when trauma to the head during passage through the birth canal can lead to intracranial bleeding. Because of these potential problems, warfarin is contraindicated in pregnancy, particularly in the first and third trimesters. Instead, heparin, LMWH, or fondaparinux can be given during pregnancy for prevention or treatment of thrombosis.

Warfarin does not pass into the breast milk. Consequently, warfarin can safely be given to nursing mothers.

Special Problems Patients with antiphospholipid syndrome and those who need urgent or elective surgery present special challenges. Although observational studies suggested that patients with thrombosis complicating antiphospholipid syndrome required higher intensity warfarin regimens to prevent recurrent thromboembolic events, two randomized trials showed that targeting an INR of 2.0–3.0 is as effective as higher intensity treatment and produces less bleeding. Monitoring warfarin therapy can be problematic in patients with the lupus anticoagulant because it prolongs the baseline INR; factor X levels can be used instead of the INR in such patients.

There is no need to stop warfarin before procedures associated with a low risk of bleeding; these include dental cleaning, simple dental extraction, cataract surgery, or skin biopsy. For procedures associated with a moderate or high risk of bleeding, warfarin should be stopped 5 days before the procedure to allow the INR to return to normal levels. Patients at high risk for thrombosis, such as those with mechanical heart valves, can be bridged with once- or twice-daily SC injections of LMWH when the INR falls to <2.0. The last dose of LMWH should be given 12–24 h before the procedure, depending on whether LMWH is administered twice or once daily. After the procedure, treatment with warfarin can be restarted.

Direct Oral Anticoagulants The direct oral anticoagulants (DOACs) include dabigatran, which inhibits thrombin, and rivaroxaban, apixaban, and edoxaban, which inhibit factor Xa. These drugs have a rapid onset and offset of action and have half-lives that permit once- or twice-daily administration. Designed to produce a predictable level of anticoagulation, the DOACs are more convenient to administer than warfarin because they are given in fixed doses without routine coagulation monitoring.

MECHANISM OF ACTION The DOACs are small molecules that bind reversibly to the active site of their target enzyme. **Table 123-9** summarizes the distinct pharmacologic properties of these agents.

INDICATIONS All four DOACs are licensed for stroke prevention in patients with atrial fibrillation except those with mechanical heart valves or severe rheumatic mitral valve disease, and for treatment of VTE. Dabigatran, rivaroxaban, and apixaban are licensed for thromboprophylaxis after elective hip or knee arthroplasty; edoxaban is only licensed for this indication in Japan. Finally, low-dose rivaroxaban is licensed for use with aspirin for secondary prevention in patients with coronary or peripheral artery disease.

DOSING For prevention of stroke in patients with atrial fibrillation, rivaroxaban is given at a dosage of 20 mg once daily, with a reduction to 15 mg once daily in patients with a creatinine clearance of 15–49 mL/min; dabigatran is given at a dosage of 150 mg twice daily, with a reduction to 75 mg twice daily in those with a creatinine clearance of 15–30 mL/min; apixaban is given at a dosage of 5 mg twice daily, with a reduction to 2.5 mg twice daily for patients with at least two of the

TABLE 123-9 Comparison of the Pharmacologic Properties of the Direct Oral Anticoagulants

CHARACTERISTIC	RIVAROXABAN	APIXABAN	EDOXABAN	DABIGATRAN
Target	Factor Xa	Factor Xa	Factor Xa	Thrombin
Prodrug	No	No	No	Yes
Bioavailability	80%	60%	50%	6%
Dosing	qd (bid)	bid	qd	bid (qd)
Half-life	7–11 h	12 h	9–11 h	12–17 h
Renal excretion	33% (66%)	25%	35%	80%
Interactions	3A4/P-gp	3A4/P-gp	P-gp	P-gp

Abbreviations: bid, twice a day; P-gp, P-glycoprotein; qd, once a day.

"ABC" criteria (i.e., age >80 years, body weight <60 kg, and creatinine >1.5 g/dL); and edoxaban is given at a dosage of 60 mg once daily for patients with a creatinine clearance of 50–95 mL/min and with a reduction to 30 mg once daily for patients with any one of the following criteria: creatinine clearance of 15–50 mL/min, body weight of 60 kg or less, or use of potent P-glycoprotein inhibitors, such as verapamil or quinidine. At doses of 15 or 20 mg once daily, rivaroxaban must be administered with food to enhance absorption. Apixaban and edoxaban can be given with or without food. Administration of dabigatran with food may reduce dyspepsia.

For treatment of VTE, dabigatran and edoxaban are started after patients have received at least a 5-day course of treatment with a parenteral anticoagulant such as LMWH. Dabigatran is given at a dose of 150 mg twice daily provided the creatinine clearance is >30 mL/min. The dosage regimen for edoxaban is identical to that used in patients with atrial fibrillation. Rivaroxaban and apixaban can be given in all-oral regimens; rivaroxaban is started at a dose of 15 mg twice daily for 21 days and is then reduced to 20 mg once daily thereafter, whereas apixaban is started at a dose of 10 mg twice daily for 7 days and is then reduced to 5 mg twice daily thereafter. For secondary VTE prevention after 6 months of full-dose treatment, the dosage of apixaban can be lowered to 2.5 mg twice daily while the dose of rivaroxaban can be lowered to 10 mg once daily, doses that have safety profiles like those of placebo and aspirin, respectively.

Thromboprophylaxis after elective hip or knee replacement surgery is started after surgery and is often continued for 30 days in patients undergoing hip replacement and for 10–14 days in patients undergoing knee replacement. Dabigatran is given at a dose of 220 mg once daily, whereas rivaroxaban and apixaban are given at doses of 10 mg once daily and 2.5 mg twice daily, respectively. In lower risk patients undergoing hip or knee replacement surgery, a 5-day course of rivaroxaban followed by a 30-day course of aspirin at a dose of 81 mg daily appears to be as effective and safe as extended thromboprophylaxis with rivaroxaban.

For secondary prevention of adverse cardiac or limb events in patients with coronary or peripheral artery disease, rivaroxaban is given at a dose of 2.5 mg twice daily on top of aspirin (81 or 100 mg once daily).

MONITORING Although designed to be administered without routine monitoring, there are situations where determination of the anticoagulant activity of the DOACs can be helpful. These include assessment of adherence, detection of accumulation or overdose, identification of bleeding mechanisms, and determination of activity before surgery, intervention, or reversal. For qualitative assessment of anticoagulant activity, the prothrombin time can be used for factor Xa inhibitors and the aPTT for dabigatran. Rivaroxaban and edoxaban prolong the prothrombin time more than apixaban. In fact, because apixaban has such a limited effect on the prothrombin time, anti–factor Xa assays are needed to assess its activity. The effect of the drugs on tests of coagulation varies depending on the time that the blood is drawn relative to the timing of the last dose of the drug and the reagents used to perform the tests. Chromogenic anti–factor Xa assays and the diluted thrombin clotting time or ecarin clot time with appropriate calibrators provide quantitative assays to measure the plasma levels of the factor Xa inhibitors and dabigatran, respectively.

SIDE EFFECTS Like all anticoagulants, bleeding is the most common side effect of the DOACs. The DOACS are associated with less intracranial bleeding than warfarin, but the higher dose regimens of dabigatran, rivaroxaban, and edoxaban are associated with more gastrointestinal bleeding.

Dyspepsia occurs in up to 10% of patients treated with dabigatran; this problem improves with time and can be minimized by administering the drug with food. Dyspepsia is rare with rivaroxaban, apixaban, and edoxaban.

PERIPROCEDURAL MANAGEMENT Like warfarin, the DOACs must be stopped before procedures associated with a moderate or high risk of bleeding. The drugs should be held for 1–2 days, or longer if renal function is impaired. Assessment of residual anticoagulant activity before procedures associated with a high bleeding risk is prudent.

MANAGEMENT OF BLEEDING With minor bleeding, withholding one or two doses of drug is usually sufficient. With more serious bleeding, the approach is like that with warfarin, except that vitamin K administration is of no benefit; the anticoagulant and any long-acting antiplatelet drugs should be withheld, the patient should be resuscitated with fluids and blood products as necessary, and the bleeding site should be identified and managed. Coagulation testing or measurement of the DOAC level will determine the extent of anticoagulation, and renal function should be assessed so that the half-life of the drug can be calculated. Timing of the last dose of anticoagulant is important; in cases of overdose, oral activated charcoal may help prevent absorption of drug administered in the past 4 h. If >24 h have elapsed since the last intake, the DOAC is unlikely to be responsible for the bleeding unless there is marked impairment of renal function.

Anticoagulant reversal should be considered if bleeding continues despite supportive measures or if the bleeding is life-threatening or occurs in a critical organ (e.g., intracranial) or in a closed space (e.g., the pericardium or retroperitoneum). Idarucizumab is licensed for dabigatran reversal in such patients or in those requiring urgent surgery or intervention. A humanized antibody fragment, idarucizumab, binds dabigatran with high affinity to form an essentially irreversible complex that is cleared by the kidneys. Idarucizumab is given intravenously as a 5-g bolus and is supplied in a box containing two 50-mL vials, each containing 2.5 g of idarucizumab. Idarucizumab rapidly reverses the anticoagulant effects of dabigatran and normalizes the aPTT, diluted thrombin time, or ecarin clot time.

Andexanet alfa is available for reversal of rivaroxaban and apixaban. A recombinant variant of factor Xa without catalytic activity, andexanet serves as a decoy to sequester oral factor Xa inhibitors until they are cleared from the circulation. Low- or high-dose IV andexanet regimens are used. The low-dose regimen starts with a bolus of 400 mg followed by an infusion of 4 mg/min for up to 120 min, whereas the high-dose regimen starts with a bolus of 800 mg followed by an infusion of 8 mg/min for up to 120 min. The low-dose regimen is used for reversal of doses of rivaroxaban or apixaban of 10 mg or 5 mg or less, respectively, or for any dose of rivaroxaban or apixaban if the last dose was taken >8 h before presentation. The high-dose regimen is used to reverse rivaroxaban or apixaban doses over 10 and 5 mg, respectively, if the last dose was taken <8 h since presentation, or if the timing of the last dose of rivaroxaban or apixaban is unknown.

Andexanet alfa is expensive and is not available in all hospitals. Because of its cost, andexanet alfa is often reserved for reversal in patients with life-threatening bleeds such intracranial hemorrhage or bleeds into a closed space such as retroperitoneal or pericardial bleeds. If andexanet is unavailable, the results of prospective cohort studies suggest that four-factor prothrombin complex concentrate (25–50 units/kg) also is effective at restoring hemostasis. If there is continued bleeding, activated prothrombin complex concentrate (50 units/kg) or recombinant factor VIIa (90 μg/kg) can be considered.

Neither andexanet alfa nor four-factor prothrombin complex concentrate has been evaluated for reversal in patients requiring urgent surgery or intervention. Furthermore, andexanet alfa not only reverses oral factor Xa inhibitors but also reverses heparin and LMWH. This could be problematic in patients who require cardiac surgery or vascular surgery, procedures where heparin is used routinely. To circumvent this problem, most surgical procedures and interventions can be undertaken without reversal, and four-factor prothrombin complex concentrate can be given if necessary. For patients requiring surgery to stop bleeding such as those with a ruptured aortic aneurysm or with bleeding secondary to polytrauma, upfront four-factor prothrombin concentrate administration can be considered.

PREGNANCY As small molecules, the DOACs pass through the placenta. Consequently, these agents are contraindicated in pregnancy, and when used by women of childbearing potential, appropriate contraception is important. DOACs should be avoided in nursing mothers because small amounts have been found in breast milk.

FIBRINOLYTIC DRUGS

ROLE OF FIBRINOLYTIC THERAPY

Fibrinolytic drugs are used to degrade thrombi and are administered systemically or can be delivered via catheters directly into the substance of the thrombus. Systemic delivery is used for treatment of acute MI, acute ischemic stroke, and most cases of massive PE. The goal of therapy is to produce rapid thrombus dissolution, thereby restoring blood flow. In the coronary circulation, restoration of blood flow reduces morbidity and mortality rates by limiting myocardial damage, whereas in the cerebral circulation, rapid thrombus dissolution decreases the neuronal death and brain infarction that produce irreversible brain injury. For patients with massive PE, the goal of thrombolytic therapy is to restore pulmonary artery perfusion.

Peripheral arterial thrombi and thrombi in the proximal deep veins of the leg are most often treated using catheter-directed thrombolytic therapy. Catheters with multiple side holes can be used to enhance drug delivery. In some cases, intravascular devices that fragment and extract the thrombus are used to hasten treatment. These devices can be used alone or in conjunction with fibrinolytic drugs.

MECHANISM OF ACTION

Currently approved fibrinolytic agents include streptokinase; acylated plasminogen streptokinase activator complex (anistreplase); urokinase; recombinant tissue-type plasminogen activator (rtPA), which is also known as alteplase or activase; and two recombinant derivatives of rtPA, tenecteplase and reteplase. Of these, streptokinase, anistreplase, and urokinase are no longer available in the United States. All these agents act by converting plasminogen, the zymogen, to plasmin, the active enzyme (Fig. 123-7). Plasmin then degrades the fibrin matrix of thrombi and produces soluble fibrin degradation products.

Endogenous fibrinolysis is regulated at two levels. Plasminogen activator inhibitors, particularly the type 1 form (PAI-1), prevent excessive plasminogen activation by regulating the activity of tPA and urokinase-type plasminogen activator (uPA). Once plasmin is generated, it is regulated by plasmin inhibitors, the most important of which is α_2-antiplasmin. The plasma concentration of plasminogen is twofold higher than that of α_2-antiplasmin. Consequently, with pharmacologic doses of plasminogen activators, the concentration of plasmin that is generated can exceed that of α_2-antiplasmin. In addition to degrading fibrin, unregulated plasmin can also degrade fibrinogen and other clotting factors. This process, which is known as the systemic lytic state, reduces the hemostatic potential of the blood and increases the risk of bleeding.

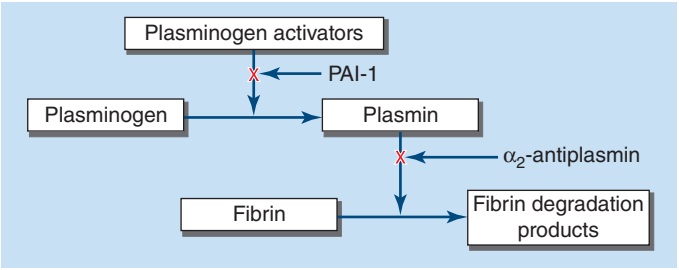

FIGURE 123-7 The fibrinolytic system and its regulation. Plasminogen activators convert plasminogen to plasmin. Plasmin then degrades fibrin into soluble fibrin degradation products. The system is regulated at two levels. Type 1 plasminogen activator inhibitor (PAI-1) inhibits the plasminogen activators, whereas α_2-antiplasmin serves as the major inhibitor of plasmin.

The endogenous fibrinolytic system is geared to localize plasmin generation to the fibrin surface. Both plasminogen and tPA bind to fibrin to form a ternary complex that promotes efficient plasminogen activation. In contrast to free plasmin, plasmin generated on the fibrin surface is relatively protected from inactivation by α_2-antiplasmin, a feature that promotes fibrin dissolution. Furthermore, C-terminal lysine residues, exposed as plasmin degrades fibrin, provide binding sites for additional plasminogen and tPA molecules. This creates positive feedback that enhances plasmin generation. When used pharmacologically, the various plasminogen activators capitalize on these mechanisms to a lesser or greater extent.

Plasminogen activators that preferentially activate fibrin-bound plasminogen are considered fibrin-specific. In contrast, nonspecific plasminogen activators do not discriminate between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in the generation of unopposed plasmin that can trigger the systemic lytic state. Alteplase and its derivatives are fibrin-specific plasminogen activators, whereas streptokinase, anistreplase, and urokinase are nonspecific agents.

STREPTOKINASE

Unlike other plasminogen activators, streptokinase is not an enzyme and does not directly convert plasminogen to plasmin. Instead, streptokinase forms a 1:1 stoichiometric complex with plasminogen. Formation of this complex induces a conformational change in plasminogen that exposes its active site (Fig. 123-8). The streptokinase-plasminogen complex then converts additional plasminogen to plasmin.

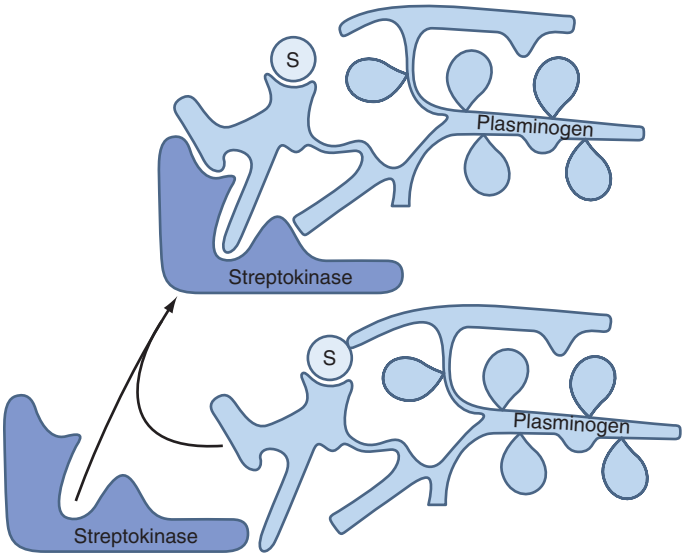

FIGURE 123-8 Mechanism of action of streptokinase. Streptokinase binds to plasminogen and induces a conformational change in plasminogen that exposes its active site. The streptokinase/plasmin(ogen) complex then serves as the activator of additional plasminogen.

Streptokinase has no affinity for fibrin, and the streptokinase-plasminogen complex activates both free and fibrin-bound plasminogen. Activation of circulating plasminogen generates enough plasmin to overwhelm α_2-antiplasmin. Unopposed plasmin not only degrades fibrin in the occlusive thrombus but also induces a systemic lytic state.

When given systemically to patients with acute MI, streptokinase reduces mortality. For this indication, the drug is usually given as an IV infusion of 1.5 million units over 30–60 min. Patients who receive streptokinase can develop antibodies against the drug, as can patients with prior streptococcal infection. These antibodies can reduce the effectiveness of streptokinase.

Allergic reactions occur in ~5% of patients treated with streptokinase. These may manifest as a rash, fever, chills, and rigors. Although anaphylactic reactions can occur, these are rare. Transient hypotension is common with streptokinase and has been attributed to plasmin-mediated release of bradykinin from kininogen. The hypotension usually responds to leg elevation and administration of IV fluids and low doses of vasopressors, such as dopamine or norepinephrine.

ANISTREPLASE

To generate this drug, streptokinase is combined with equimolar amounts of Lys-plasminogen, a plasmin-cleaved form of plasminogen with a Lys residue at its N terminal. The active site of Lys-plasminogen that is exposed upon combination with streptokinase is then masked with an anisoyl group. After IV infusion, the anisoyl group is slowly removed by deacylation, giving the complex a half-life of ~100 min. This allows drug administration via a single bolus infusion.

Although it is more convenient to administer, anistreplase offers few mechanistic advantages over streptokinase. Like streptokinase, anistreplase does not distinguish between fibrin-bound and circulating plasminogen. Consequently, it too produces a systemic lytic state. Likewise, allergic reactions and hypotension are just as frequent with anistreplase as they are with streptokinase.

When anistreplase was compared with alteplase in patients with acute MI, reperfusion was obtained more rapidly with alteplase than with anistreplase. Improved reperfusion was associated with a trend toward better clinical outcomes and reduced mortality rate with alteplase. These results and the high cost of anistreplase dampened the enthusiasm for its use.

UROKINASE

Urokinase is a two-chain serine protease derived from cultured fetal kidney cells with a molecular weight of 34,000. Urokinase converts plasminogen to plasmin directly by cleaving the Arg560-Val561 bond. Unlike streptokinase, urokinase is not immunogenic, and allergic reactions are rare. Urokinase produces a systemic lytic state because it does not discriminate between fibrin-bound and circulating plasminogen.

Despite many years of use, urokinase has never been systemically evaluated for coronary thrombolysis. Instead, urokinase is often employed for catheter-directed lysis of thrombi in the deep veins or the peripheral arteries. Because of production problems, urokinase is no longer available.

ALTEPLASE

A recombinant form of single-chain tPA, alteplase has a molecular weight of 68,000. Alteplase is rapidly converted into its two-chain form by plasmin. Although single- and two-chain forms of tPA have equivalent activity in the presence of fibrin, in its absence, single-chain tPA has 10-fold lower activity.

Alteplase consists of five discrete domains **(Fig. 123-9)**; the N-terminal A chain of two-chain alteplase contains four of these domains. Residues 4 through 50 make up the finger domain, a region that resembles the finger domain of fibronectin; residues 50 through 87 are homologous with epidermal growth factor, whereas residues 92 through 173 and 180 through 261, which have homology to the kringle domains of plasminogen, are designated as the first and second kringle, respectively. The fifth alteplase domain is the protease domain; it is located on the C-terminal B chain of two-chain alteplase.

The interaction of alteplase with fibrin is mediated by the finger domain and, to a lesser extent, by the second kringle domain. The affinity of alteplase for fibrin is considerably higher than that for fibrinogen. Consequently, the catalytic efficiency of plasminogen activation by alteplase is two to three orders of magnitude higher in the presence of fibrin than in the presence of fibrinogen. This phenomenon helps to localize plasmin generation to the fibrin surface.

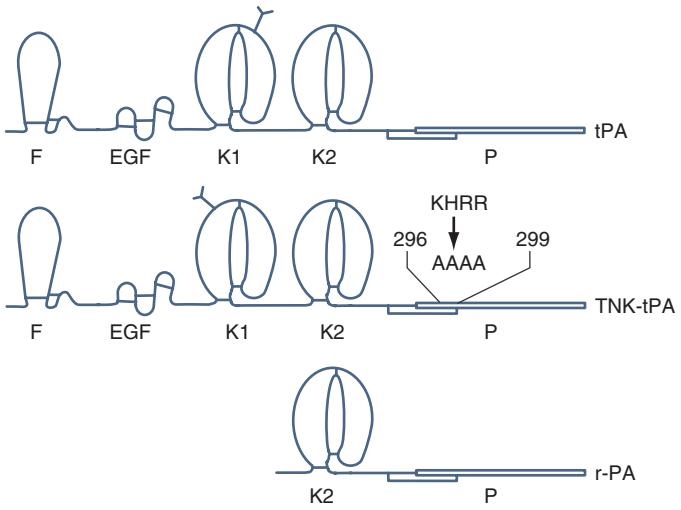

FIGURE 123-9 Domain structures of alteplase (tPA), tenecteplase (TNK-tPA), and reteplase (r-PA). The finger (F), epidermal growth factor (EGF), first and second kringles (K1 and K2, respectively), and protease (P) domains are illustrated. The glycosylation site (Y) on K1 has been repositioned in tenecteplase to endow it with a longer half-life. In addition, a tetra-alanine substitution in the protease domain renders tenecteplase resistant to type 1 plasminogen activator inhibitor (PAI-1) inhibition. Reteplase is a truncated variant that lacks the F, EGF, and K1 domains.

Although alteplase preferentially activates plasminogen in the presence of fibrin, alteplase is not as fibrin selective as was first predicted. Its fibrin specificity is limited because, like fibrin, (DD)E, the major soluble degradation product of cross-linked fibrin, binds alteplase and plasminogen with high affinity. Consequently, (DD)E is as potent as fibrin as a stimulator of plasminogen activation by alteplase. Whereas plasmin generated on the fibrin surface results in thrombolysis, plasmin generated on the surface of circulating (DD)E degrades fibrinogen. Fibrinogen degradation results in the accumulation of fragment X, a high-molecular-weight clottable fibrinogen degradation product. Incorporation of fragment X into hemostatic plugs formed at sites of vascular injury renders them susceptible to lysis. This phenomenon may contribute to alteplase-induced bleeding.

A trial comparing alteplase with streptokinase for treatment of patients with acute MI demonstrated significantly lower mortality with alteplase than with streptokinase, although the absolute difference was small. The greatest benefit was seen in patients age <75 years with anterior MI who presented <6 h after symptom onset.

For treatment of acute MI or acute ischemic stroke, alteplase is given as an IV infusion over 60–90 min. The total dose of alteplase usually ranges from 90 to 100 mg. Allergic reactions and hypotension are rare, and alteplase is not immunogenic.

TENECTEPLASE

Tenecteplase is a genetically engineered variant of tPA and was designed to have a longer half-life than tPA and to be resistant to inactivation by PAI-1. To prolong its half-life, a new glycosylation site was added to the first kringle domain (Fig. 123-9). Because addition of this extra carbohydrate side chain reduced fibrin affinity, the existing glycosylation site on the first kringle domain was removed. To render the molecule resistant to inhibition by PAI-1, a tetra-alanine substitution was introduced at residues 296–299 in the protease domain, the region responsible for the interaction of tPA with PAI-1.

Tenecteplase is more fibrin-specific than tPA. Although both agents bind to fibrin with similar affinity, the affinity of tenecteplase for (DD)E is significantly lower than that of tPA. Consequently, (DD)E does not stimulate systemic plasminogen activation by tenecteplase to the same extent as tPA. As a result, tenecteplase produces less fibrinogen degradation than tPA.

For coronary thrombolysis, tenecteplase is given as a single IV bolus. In a large phase III trial that enrolled >16,000 patients, the 30-day mortality rate with single-bolus tenecteplase was like that with accelerated-dose tPA. Although rates of intracranial hemorrhage were similar with both treatments, patients given tenecteplase had fewer noncerebral bleeds and a reduced need for blood transfusions than those treated with tPA. The improved safety profile of Tenecteplase likely reflects its enhanced fibrin specificity.

RETEPLASE

Reteplase is a single-chain, recombinant tPA derivative that lacks the finger, epidermal growth factor, and first kringle domains (Fig. 123-9). This truncated derivative has a molecular weight of 39,000. The affinity of reteplase for fibrin is lower than that of tPA likely because reteplase lacks the finger domain. Because it is produced in *Escherichia coli*, reteplase is not glycosylated. This endows it with a plasma half-life longer than that of tPA. Consequently, reteplase is given as two IV boluses, which are separated by 30 min. Clinical trials have demonstrated that reteplase is at least as effective as streptokinase for treatment of acute MI, but the agent is not superior to tPA.

CONCLUSIONS AND FUTURE DIRECTIONS

Thrombosis involves a complex interplay among the vessel wall, platelets, the coagulation system, and the fibrinolytic pathways. Activation of coagulation also triggers inflammatory pathways that may exacerbate thrombosis. A better understanding of the biochemistry of blood coagulation and advances in structure-based drug design have identified new targets and resulted in the development of novel antithrombotic drugs. Well-designed clinical trials have provided detailed information on which drugs to use and when to use them. Despite these advances, however, thromboembolic disorders remain a major cause of morbidity and mortality. Therefore, the search for better and safer targets continues.

Section 1 Basic Considerations in Infectious Diseases

124 Approach to the Patient with an Infectious Disease

Neeraj K. Surana, Dennis L. Kasper

HISTORIC PERSPECTIVE

The origins of the field of infectious diseases are humble. The notion that communicable diseases were due to a *miasma* ("bad air") can be traced back to at least the mid-sixteenth century. Not until the work of Louis Pasteur and Robert Koch in the late nineteenth century was there credible evidence supporting the germ theory of disease—i.e., that microorganisms are the direct cause of infections. In contrast to this relatively slow start, the twentieth century saw remarkable advances in the field of infectious diseases, and the etiologic agents of numerous infectious diseases were soon identified. Furthermore, the discovery of antibiotics and the advent of vaccines against some of the most deadly and debilitating infections greatly altered the landscape of human health. Indeed, the twentieth century saw the elimination of smallpox, one of the great scourges in the history of humanity. These remarkable successes prompted Sir Frank MacFarlane Burnet, a noted immunologist and Nobel laureate, to write in a 1962 publication entitled *Natural History of Infectious Diseases*: "In many ways one can think of the middle of the twentieth century as the end of one of the most important social revolutions in history, the virtual elimination of infectious disease." Professor Burnet was not alone in this view. Robert Petersdorf, a renowned infectious disease expert and former editor of this textbook, wrote in 1978 that "even with my great personal loyalties to infectious diseases, I cannot conceive a need for 309 more [graduating trainees in infectious diseases] unless they spend their time culturing each other." Given the enormous growth of interest in the microbiome in the past 20 years, Dr. Petersdorf's statement might have been ironically clairvoyant, although he could have had no idea what was in store for humanity, with an onslaught of new, emerging, and reemerging infectious diseases.

Clearly, even with all the advances of the twentieth century, infectious diseases continue to represent a formidable challenge for patients and physicians alike. Furthermore, during the latter half of the century, several chronic diseases were demonstrated to be directly or indirectly caused by infectious microbes; perhaps the most notable examples are the associations of *Helicobacter pylori* with peptic ulcer disease and gastric carcinoma, human papillomavirus with cervical cancer, and hepatitis B and C viruses with liver cancer. In fact, ~16% of all malignancies are now known to be associated with an infectious cause. In addition, numerous emerging and reemerging infectious diseases continue to have a dire impact on global health: HIV/AIDS, SARS-CoV-2, Ebola, and mpox are but a few examples. The fear of weaponizing pathogens for bioterrorism is ever present and poses a potentially enormous threat to public health. Moreover, escalating antimicrobial resistance in clinically relevant microbes (e.g., carbapenem-resistant Enterobacteriaceae and *Acinetobacter* spp., *Candida auris*, drug-resistant *Mycobacterium tuberculosis*, and vancomycin-resistant enterococci) signifies that the administration of antimicrobial agents—once thought to be a panacea—requires appropriate stewardship. For all these reasons, infectious diseases continue to exert grim effects on individual patients as well as on international public health. Even with all the successes of the past century, physicians must be as thoughtful about infectious diseases now as they were at the beginning of the twentieth century.

GLOBAL CONSIDERATIONS

Infectious diseases remain the second leading cause of death worldwide. Although the rate of infectious disease–related deaths has decreased dramatically over the past 25 years, there were still 9.6 million such deaths in 2019 **(Fig. 124-1*A*)**. These deaths disproportionately affect children <1 year of age, adults older than 70 years, and persons living in low- and middle-income countries **(Fig. 124-1*B* and 124-1*C*; Chap. 487)**; in 2019, ~17% of all deaths worldwide were related to infectious diseases, with a rate as high as ~69% in sub-Saharan Africa.

Given that infectious diseases are still a major cause of global mortality, understanding the local epidemiology of disease is critically important in evaluating patients. Diseases such as HIV/AIDS have decimated southern Africa, with HIV-infected adults representing 16–20% of the total population in countries like South Africa, Botswana, and Lesotho, and more than 25% in Eswatini. Moreover, drug-resistant tuberculosis is rampant throughout the former Soviet-bloc countries, India, China, and South Africa. The ready availability of this type of information allows physicians to develop appropriate differential diagnoses and treatment plans for individual patients. Programs such as the Global Burden of Disease seek to quantify human losses (e.g., deaths, disability-adjusted life-years) due to diseases by age, sex, and country over time; these data not only help inform local, national, and international health policy but can also help guide local medical decision-making.

Even though some diseases (e.g., pandemic influenza, mpox) are seemingly geographically restricted, the increasing ease of rapid worldwide travel has raised concern about their swift spread around the globe. Indeed, human migration has historically been the source of epidemics: *Yersinia pestis* spread along trade routes in the fourteenth century, Native American populations were devastated by diseases such as smallpox and *Salmonella* that were imported by European explorers in the fifteenth and sixteenth centuries, military maneuvers helped facilitate the spread of the 1918 influenza pandemic, and religious pilgrimages (e.g., the Hajj) provide the means for worldwide dissemination of diseases. The continued effects of global travel on the spread of infectious diseases are perhaps best highlighted by the SARS-CoV-2 pandemic **(Chap. 204)**. Although this virus was first identified in Wuhan, China, it quickly spread across the globe and brought an abrupt end to virtually all travel and commerce throughout the world, plunging economies into a deep recession, resulting at one point in more than half the world's population living under stay-at-home orders, and causing the death of ~7 million people worldwide. Not only can travelers carry person-to-person transmitted infections (e.g., SARS-CoV-2, HIV) anywhere in the world, but they can also introduce vector-borne infections to new geographic areas (e.g., chikungunya and Zika viruses) and contribute to the worldwide spread of multidrug-resistant organisms. The world's increasing interconnectedness has profound implications not only for the global economy but also for medicine and the spread of infectious diseases.

UNDERSTANDING THE MICROBIOTA

Normal, healthy humans are colonized with ~40 trillion bacteria as well as countless viruses, fungi, and archaea; taken together, these microorganisms outnumber human cells by ~10 times in the human body **(Chap. 484)**. The major reservoir of these microbes is the gastrointestinal tract, but substantial numbers of microbes live in the female genital tract, the oral cavity, and the nasopharynx. There is increasing interest in the skin and lungs as sites where microbial colonization might be highly relevant to the biology and disease susceptibility of the host. These commensal organisms provide the host with myriad benefits, from aiding in metabolism to shaping the immune system. With regard to infectious diseases, the vast majority of infections are caused by organisms that are part of the normal microbiota (e.g., *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Pseudomonas aeruginosa*), with relatively few infections due to organisms that are strictly pathogens (e.g., *Neisseria gonorrhoeae*, rabies virus). Perhaps it is not surprising that a general understanding

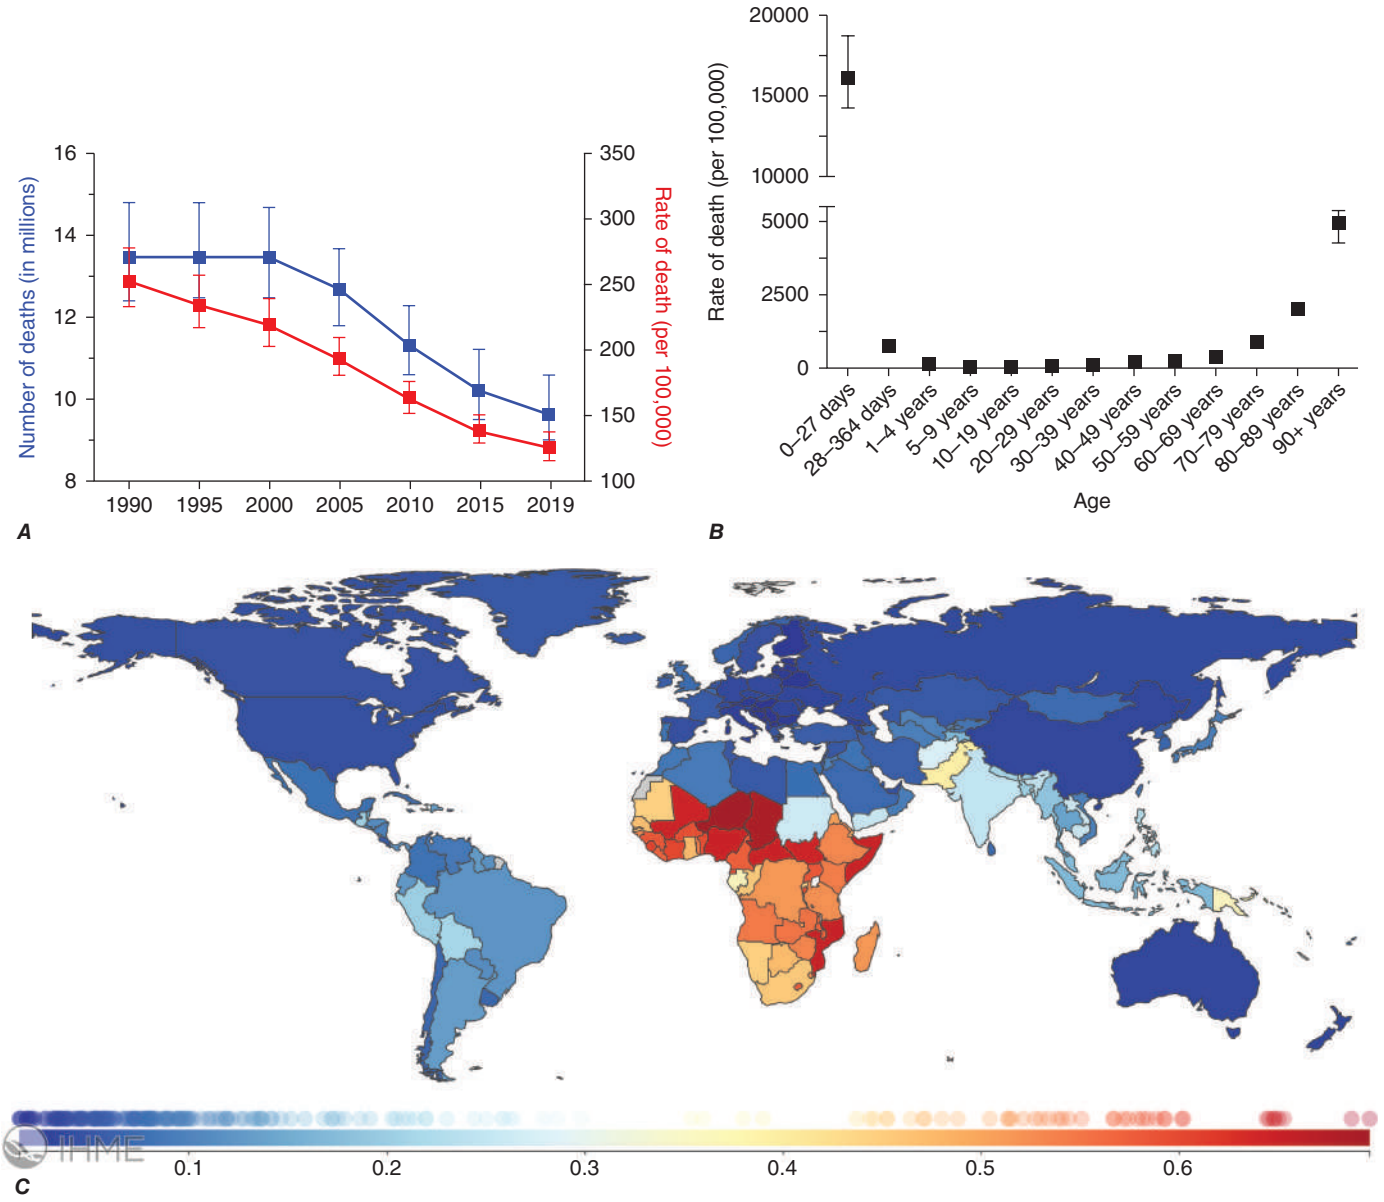

FIGURE 124-1 Magnitude of infectious disease–related deaths globally. ***A.*** The absolute number (*blue line; left axis*) and rate (*red line; right axis*) of infectious disease–related deaths throughout the world since 1990. ***B.*** Age-specific rates of infectious disease–related deaths in 2019. In both ***A*** and ***B***, the charts depict the mean estimate and 95% uncertainty intervals. ***C.*** A map depicting country-specific data for the percent of total deaths that were attributable to communicable, maternal, neonatal, and nutritional disorders in 2019. *(Source: Institute for Health Metrics and Evaluation. Used with permission. All rights reserved.)*

of the microbiota is essential in the evaluation of infectious diseases. Individuals' microbiotas have a major impact on their susceptibility to infectious diseases and even their responses to vaccines. Site-specific knowledge of the indigenous microbiota may facilitate appropriate interpretation of culture results, aid in selection of empirical antimicrobial therapy based on the likely causative agents, and provide additional impetus for rational antibiotic use to minimize the untoward effects of these drugs on the "beneficial" microbes that inhabit the body.

WHEN TO CONSIDER AN INFECTIOUS ETIOLOGY

The title of this chapter may appear to presuppose that the physician knows when a patient has an infectious disease. In reality, this chapter can serve only as a guide to the evaluation of a patient in whom an infectious disease is a possibility. Once a specific diagnosis is made, the reader should consult the subsequent chapters that deal with specific microorganisms in detail. The challenge for the physician is to recognize which patients may have an infectious disease as opposed to some other underlying disorder. This task is greatly complicated by the fact that infections have an infinite range of presentations, from acute life-threatening conditions (e.g., meningococcemia) to chronic diseases of varying severity (e.g., *H. pylori*–associated peptic ulcer disease) to no symptoms at all (e.g., latent *M. tuberculosis* infection). While it is impossible to generalize about a presentation that encompasses all infections, common findings in the history, physical examination, and basic laboratory testing often suggest that the patient either has an infectious disease or should be more closely evaluated for one. This chapter focuses on these common findings and how they may direct the ongoing evaluation of the patient.

APPROACH TO THE PATIENT

Infectious Disease

See also Chap. 127.

HISTORY

As in all of medicine, a complete and thorough history is paramount in the evaluation of a patient with a possible infectious disease. The history is critical for developing a focused differential diagnosis and for guiding the physical exam and initial diagnostic testing. Although a detailing of all the elements of a history is beyond the scope of this chapter, specific components relevant to infectious diseases require

particular attention. In general, these aspects focus on two areas: (1) an exposure history that may identify microorganisms with which the patient may have come into contact and (2) host-specific factors that may predispose to the development of an infection.

Exposure History • **History of infections or exposure to drug-resistant microbes** Information about a patient's previous infections, with the associated microbial susceptibility profiles, is very helpful in determining possible etiologic agents. Specifically, knowing whether a patient has a history of infection with drug-resistant organisms (e.g., methicillin-resistant *S. aureus,* vancomycin-resistant *Enterococcus* species, enteric organisms that produce an extended-spectrum β-lactamase or carbapenemase) or may have been exposed to drug-resistant microbes (e.g., during a recent stay in a hospital, nursing home, or long-term acute-care facility) may alter the choice of empirical antibiotics. For example, a patient presenting with sepsis who is known to have a history of invasive infection with a multidrug-resistant isolate of *P. aeruginosa* should be treated empirically with an antimicrobial regimen that will cover this strain.

Social history Although the social history taken by physicians is often limited to inquiries about a patient's alcohol and tobacco use, a complete social history can offer a number of clues to the underlying diagnosis. Knowing whether the patient has any high-risk behaviors (e.g., unsafe sexual behaviors, intravenous [IV] drug use), potential hobby-associated exposures (e.g., avid gardening, with possible *Sporothrix schenckii* exposure), or occupational exposures (e.g., increased risk for *M. tuberculosis* exposure in funeral service workers) can facilitate diagnosis. The importance of the social history is exemplified by a case in 2009 in which a laboratory researcher died of a *Y. pestis* infection acquired during his work; although this patient had visited both an outpatient clinic and an emergency department, his records at both sites failed to include his occupation—information that potentially could have led quickly to appropriate treatment and infection control measures.

Dietary habits Because certain pathogens are associated with specific dietary habits, inquiring about a patient's diet can provide insight into possible exposures. For example, Shiga toxin–producing strains of *Escherichia coli*, and *Toxoplasma gondii* are associated with the consumption of raw or undercooked meat; *Salmonella typhimurium*, *Listeria monocytogenes*, and *Mycobacterium bovis* with unpasteurized milk; *Leptospira* species, parasites, and enteric bacteria with unpurified water; and *Vibrio* species, norovirus, helminths, and protozoa with raw seafood.

Animal exposures Because animals are often important vectors of infectious diseases, patients should be asked about exposures to any animals, including contact with their own pets, visits to petting zoos, or random encounters (e.g., home rodent infestation). For example, dogs can carry ticks that serve as agents for the transmission of several infectious diseases, including Lyme disease, Rocky Mountain spotted fever, and ehrlichiosis. Cats are associated with *Bartonella henselae* infection, reptiles with *Salmonella* infection, rodents with leptospirosis, and rabbits with tularemia **(Chap. 146)**.

Travel history Attention should be paid to both international and domestic travel. Fever in a patient who has recently returned from abroad significantly broadens the differential diagnosis **(Chap. 130)** and, as exemplified by the COVID-19 pandemic, can help identify the beginnings of international outbreaks. Even a remote history of international travel may reflect patients' exposure to infections with pathogens such as *M. tuberculosis* or *Strongyloides stercoralis*. Similarly, domestic travel may have exposed patients to pathogens that are not normally found in their local environment and therefore may not routinely be considered in the differential diagnosis. For example, a patient who has recently visited California or Martha's Vineyard may have been exposed to *Coccidioides immitis* or *Francisella tularensis*, respectively. Beyond simply identifying locations that a patient may have visited, the physician needs to delve deeper to learn what kinds of activities and behaviors the patient engaged in during travel (e.g., the types of food and sources of water consumed, freshwater swimming, animal exposures) and whether the patient had the necessary immunizations and/or took the necessary prophylactic medications prior to travel; these additional exposures, which the patient may not think to report without specific prompting, are as important as exposures during a patient's routine daily living.

Host-Specific Factors Because many opportunistic infections (e.g., with *Pneumocystis jirovecii*, *Aspergillus* species, or JC virus) affect primarily immunocompromised patients, it is of vital importance to determine the immune status of the patient. Defects in the immune system may be due to an underlying disease (e.g., malignancy, HIV infection, malnutrition), a medication (e.g., chemotherapy, glucocorticoids, monoclonal antibodies to components of the immune system), a treatment modality (e.g., total body irradiation, splenectomy), or a primary immunodeficiency. The type of infection for which the patient is at increased risk varies with the specific type of immune defect. In concert with determining whether a patient is immunocompromised for any reason, the physician should review the immunization record to ensure that the patient is adequately protected against vaccine-preventable diseases **(Chap. 129)**.

PHYSICAL EXAMINATION

Like the history, a thorough physical examination is crucial in evaluating patients with an infectious disease. Some elements of the physical exam (e.g., skin, lymphatics) that are often performed in a cursory manner as a result of the ever-increasing pace of medical practice may help identify the underlying diagnosis. Moreover, serial exams are critical since new findings may appear as the illness progresses. A description of all the elements of a physical exam is beyond the scope of this chapter, but the following components have particular relevance to infectious diseases.

Vital Signs Given that elevations in temperature are often a hallmark of infection, paying close attention to the temperature may be of value in diagnosing an infectious disease **(Chap. 20)**. The idea that 37°C (98.6°F) is the normal human body temperature dates to the nineteenth century and was initially based on axillary measurements. Rectal temperatures more accurately reflect the core body temperature and are 0.4°C (0.7°F) and 0.8°C (1.4°F) higher than oral and axillary temperatures, respectively. This idea of a "normal" body temperature does not consider the fact that temperatures tend to be higher later in the day, in women, and in younger people. Moreover, the average body temperature seems to have dropped ~0.03°C every decade since the early 1800s to a new normal of ~36.7°C. Although the definition of fever varies greatly throughout the medical literature, the most common definition, which is based on studies defining fever of unknown origin **(Chap. 22)**, uses a core temperature ≥38.3°C (≥101°F). Although fever is very commonly associated with infection, it is also documented in many other diseases **(Chap. 20)**. For every 1°C (1.8°F) increase in core temperature, the heart rate typically rises by ~10 beats/min. **Table 124-1** lists infections that are associated with relative bradycardia (*Faget's sign*), where patients have a lower heart rate than might be expected for a given body temperature. Although this pulse–temperature dissociation is not highly sensitive or specific for establishing a diagnosis, it is potentially useful in low-resource settings given its ready availability and simplicity.

Lymphatics There are ~600 lymph nodes throughout the body, and infections are an important cause of lymphadenopathy. A physical examination should include evaluation of lymph nodes in multiple regions (e.g., popliteal, inguinal, epitrochlear, axillary, multiple cervical regions), with notation of the location, size (normal, <1 cm), presence or absence of tenderness, and consistency (soft, firm, or rubbery) and of whether the nodes are matted (i.e., connected and moving together). Nodes that are small and firm can also be described as "shotty," referring to the size and consistency of buckshot pellets. Of note, palpable epitrochlear nodes are always

TABLE 124-1 Causes of Relative Bradycardia

Infectious Causes	
Intracellular organisms	
Gram-negative bacteria	*Salmonella typhi* *Francisella tularensis* *Brucella* spp. *Coxiella burnetii* (Q fever) *Leptospira interrogans* *Legionella pneumophila* *Mycoplasma pneumoniae*
Tick-borne organisms	*Rickettsia* spp. *Orientia tsutsugamushi* (scrub typhus) *Babesia* spp.
Other	*Corynebacterium diphtheriae* *Plasmodium* spp. (malaria)
Viruses/viral infections	Yellow fever virus Dengue virus Viral hemorrhagic fevers[a] Viral myocarditis
Noninfectious Causes	
	Drug fever Beta blocker use Central nervous system lesions Malignant lymphoma Factitious fever

[a]Primarily early in the course of infection with Marburg or Ebola virus.

pathologic. Of patients presenting with lymphadenopathy, 75% have localized findings, and the remaining 25% have generalized lymphadenopathy (i.e., that involving more than one anatomic region). Localized lymphadenopathy in the head and neck region is found in 55% of patients, inguinal lymphadenopathy in 14%, and axillary lymphadenopathy in 5%. Determining whether the patient has generalized versus localized lymphadenopathy can help narrow the differential diagnosis, as various infections present differently.

Skin The fact that many infections have cutaneous manifestations gives the skin examination particular importance in the evaluation of patients **(Chaps. 21, 61, 134, and A1)**. It is important to perform a complete skin exam, with attention to both front and back. Specific rashes are often extremely helpful in narrowing the differential diagnosis of an infection **(Chaps. 21 and A1)**. In numerous anecdotal instances, patients in the intensive care unit have had "fever of unknown origin" that was actually due to unrecognized pressure ulcers. Moreover, close examination of the distal extremities for splinter hemorrhages, Janeway lesions, or Osler's nodes may yield evidence of endocarditis or other causes of septic emboli.

Foreign Bodies As previously mentioned, many infections are caused by members of the indigenous microbiota. These infections typically occur when these microbes escape their normal habitat and enter a new one. Thus, maintenance of epithelial barriers is one of the most important mechanisms in protection against infection. However, hospitalization of patients is often associated with breaches of these barriers—e.g., due to placement of IV lines, surgical drains, or tubes (e.g., endotracheal tubes and Foley catheters) that allow microorganisms to localize in sites to which they normally would not have access **(Chap. 147)**. Accordingly, knowing what lines, tubes, and drains are in place is helpful in ascertaining what body sites might be infected.

DIAGNOSTIC TESTING

Laboratory and radiologic testing has advanced greatly over the past few decades and has become an important component in the evaluation of patients. The dramatic increase in the number of serologic diagnostics, antigen tests, and molecular diagnostics available to the physician has, in fact, revolutionized medical care. However, all of these tests should be viewed as adjuncts to the history and physical examination—not a replacement for them. The selection of initial tests should be based directly on the patient's history and physical exam findings. Moreover, diagnostic testing should generally be limited to those conditions that are reasonably likely and treatable, important in terms of public health considerations, and/or capable of providing a definitive diagnosis that will consequently limit other testing.

White Blood Cell (WBC) Count Elevations in the WBC count are often associated with infection, although many viral infections are associated with leukopenia. It is important to assess the WBC differential, given that different classes of microbes are associated with various leukocyte types. For example, bacteria are associated with an increase in polymorphonuclear neutrophils, often with elevated levels of earlier developmental forms such as bands; viruses are associated with an increase in lymphocytes; and certain parasites are associated with an increase in eosinophils. **Table 124-2** lists the major infectious causes of eosinophilia.

Inflammatory Markers The erythrocyte sedimentation rate (ESR) and the C-reactive protein (CRP) level are indirect and direct measures of the acute-phase response, respectively, that can be used to assess a patient's general level of inflammation. Moreover, these markers can be followed serially over time to monitor disease progress/resolution. It is noteworthy that the ESR changes relatively slowly, and its measurement more often than weekly usually is not useful; in contrast, CRP concentrations change rapidly, and daily measurements can be useful in the appropriate context. Although these markers are sensitive indicators of inflammation, neither is very specific. An extremely elevated ESR (>100 mm/h) has a 90% predictive value for a serious underlying disease **(Table 124-3)**. Work is ongoing to identify other potentially useful inflammatory markers (e.g., procalcitonin, serum amyloid A protein); their clinical utility requires further validation.

Analysis of Cerebrospinal Fluid (CSF) Assessment of CSF is critical for patients with suspected meningitis or encephalitis. An opening pressure should always be recorded, and fluid should routinely be sent for cell counts, Gram's stain and culture, and determination of glucose and protein levels. A CSF Gram's stain typically requires $>10^5$ bacteria/mL for reliable positivity; its specificity approaches 100%. **Table 124-4** lists the typical CSF profiles for various infections. In general, CSF with lymphocytic pleocytosis and a low glucose concentration suggests either infection (e.g., with *Listeria*, *M. tuberculosis*, or a fungus) or a noninfectious disorder (e.g., neoplastic meningitis, sarcoidosis). Bacterial antigen tests of CSF (e.g., latex agglutination tests for *Haemophilus influenzae* type b, group B *Streptococcus*, *S. pneumoniae*, and *Neisseria meningitidis*) are not recommended for screening, given that these tests are no more sensitive than Gram's stain; however, these assays can be helpful in presumptively identifying organisms seen on Gram's stain. In contrast, other antigen tests (e.g., for *Cryptococcus*) and some CSF serologic testing (e.g., for *Treponema pallidum*, *Coccidioides*) are highly sensitive and are useful for select patients. In addition, polymerase chain reaction (PCR) analysis of CSF is increasingly being used for the diagnosis of bacterial (e.g., *N. meningitidis*, *S. pneumoniae*, mycobacteria) and viral (e.g., herpes simplex virus, enterovirus) infections; while these molecular tests permit rapid diagnosis with a high degree of sensitivity and specificity, they often do not allow determination of antimicrobial resistance profiles.

Cultures The mainstays of infectious disease diagnosis include the culture of infected tissue (e.g., surgical specimens) or fluid (e.g., blood, urine, sputum, pus from a wound). Samples can be sent for culture of bacteria (aerobic or anaerobic), fungi, or viruses. Ideally, specimens are collected before the administration of antimicrobial therapy; in instances where this order of events is not clinically

TABLE 124-2 Major Infectious Causes of Eosinophilia[a]

ORGAN INVOLVED	ORGANISM	EXPOSURE	GEOGRAPHIC DISTRIBUTION	DEGREE OF EOSINOPHILIA[b]
Central nervous system	*Angiostrongylus*	Raw seafood	Asia	Mild
	Gnathostoma	Raw poultry and seafood	Asia	Moderate to extreme
Eye	*Loa loa*	Insect bite	Africa	Moderate (expatriates), mild (patients living in endemic areas)
	Onchocerca	Insect bite	Africa	Mild (expatriates), moderate (patients living in endemic areas)
Lung	*Chlamydia trachomatis*	Sexual transmission	Worldwide	Mild
	Strongyloides	Soil	Tropical	Moderate (acute), mild (chronic)
	Toxocara canis/Toxocara cati[c]	Dogs, soil	Worldwide	Moderate to extreme

	Bartonella henselae	Cats	Worldwide	Mild
Other	Recovery from bacterial or viral infections	—	—	Mild
	HIV	Contaminated bodily fluid	Worldwide	Mild
	Cryptococcus neoformans	Soil	Worldwide	Moderate to extreme (disseminated)

[a]There are numerous noninfectious causes of eosinophilia, such as atopic disease, DRESS (drug reaction with eosinophilia and systemic symptoms) syndrome, and pernicious anemia, which can cause mild eosinophilia; drug hypersensitivity and serum sickness, which can cause mild to moderate eosinophilia; collagen vascular disease, which can cause moderate eosinophilia; and malignancy, Churg-Strauss syndrome, and hyper-IgE syndromes, which can cause moderate to extreme eosinophilia. [b]Mild: 500–1500 cells/μL; moderate: 1500–5000 cells/μL; extreme: >5000 cells/μL. [c]Can also affect the liver and the eyes. [d]Can also affect the lungs. [e]Can also affect the eyes and the central nervous system. [f]Levels are typically higher with pulmonary infections.

feasible, microscopic examination of the specimen (e.g., Gram-stained or potassium hydroxide [KOH]–treated preparations) is particularly important. Culture of the organism(s) allows identification of the etiologic agent(s), determination of the antimicrobial susceptibility profile, and—when there is concern about an outbreak—isolate typing. While cultures are extremely useful in the evaluation of patients, determining whether culture results are clinically meaningful or represent contamination (e.g., a non-*aureus*, non-*lugdunensis* staphylococcal species growing in a blood culture) can sometimes be challenging and requires an understanding of the patient's immune status, exposure history, and microbiota. In some cases, serial cultures to demonstrate clearance of the organism may be helpful.

Pathogen-Specific Testing Numerous pathogen-specific tests (e.g., serology, antigen testing, PCR testing) are commercially available, and many hospitals now offer some of these tests in-house to facilitate rapid turnaround that ultimately enhances patient care. The reader is directed to relevant chapters on the pathogens of interest for specific details. Some of these tests (e.g., universal PCRs, shotgun metagenomic sequencing) identify organisms that currently are not easily cultivable and have unclear relationships to disease, thereby complicating diagnosis. As these tests become more commonplace, the relevance of some of these previously unrecognized bacteria to human health will likely become more apparent.

Radiology Imaging provides an important adjunct to the physical examination, allowing evaluation for lymphadenopathy in regions that are not externally accessible (e.g., mediastinum, intraabdominal sites), assessment of internal organs for evidence of infection, and facilitation of image-guided percutaneous sampling of deep spaces. The choice of imaging modality (e.g., CT, MRI, ultrasound,

TABLE 124-3 Causes of an Extremely Elevated Erythrocyte Sedimentation Rate (>100 mm/h)

ETIOLOGIC CATEGORY (% OF CASES)	SPECIFIC CAUSES

nuclear medicine, use of contrast) is best made in consultation with a radiologist to ensure that the results will address the physician's specific concerns.

TREATMENT

Physicians often must balance the need for empirical antibiotic treatment with the patient's clinical condition. When clinically feasible, it is best to obtain relevant samples (e.g., blood, CSF, tissue, purulent exudate) for culture prior to the administration of antibiotics, as antibiotic treatment often makes subsequent diagnosis more difficult. Although a general maxim for antibiotic treatment is to use a regimen with as narrow a spectrum as possible **(Chap. 149)**, empirical regimens are necessarily somewhat broad, given that a specific diagnosis has not yet been made. **Table 124-5** lists empirical antibiotic treatment regimens for commonly encountered infectious presentations. These regimens should be narrowed as appropriate once a specific diagnosis is made. In addition to antibiotics, there is sometimes a role for adjunctive therapies, such as intravenous immunoglobulin G (IVIG) pooled from healthy adults or hyperimmune globulin prepared from the blood of individuals with high titers of specific antibodies to select pathogens (e.g., cytomegalovirus, hepatitis B virus, rabies virus, vaccinia virus, *Clostridium tetani*, varicella-zoster virus, *Clostridium botulinum* toxin). Although the data suggesting efficacy are limited, IVIG is sometimes used for patients with suspected staphylococcal or streptococcal toxic shock syndrome.

INFECTION CONTROL

When evaluating a patient with a suspected infectious disease, the physician must consider what infection control methods are necessary to prevent transmission of any possible infection to other people. In 2007, the U.S. Centers for Disease Control and Prevention published guidelines for isolation precautions that are available for download at *www.cdc.gov/infectioncontrol/guidelines/isolation/*. Persons exposed to certain pathogens (e.g., *N. meningitidis*, HIV, *Bacillus anthracis*) should receive postexposure prophylaxis to prevent disease acquisition. (See relevant chapters for details on specific pathogens.)

WHEN TO OBTAIN AN INFECTIOUS DISEASE CONSULT

At times, primary physicians need assistance with patient management from a diagnostic and/or therapeutic perspective. Multiple studies have demonstrated that an infectious disease consult is associated with improved outcomes, shorter length of hospital stay, and decreased costs for patients with various diseases. For example, in a prospective cohort study of patients with *S. aureus* bacteremia, infectious disease consultation was independently associated with a 56% reduction in 28-day mortality. While artificial intelligence–based chatbots are beginning to be utilized in healthcare settings, they are not yet sophisticated enough to supplant an actual infectious disease consultation. In addition, infectious disease specialists provide other services (e.g., infection control, antimicrobial stewardship, management of outpatient antibiotic therapy, occupational exposure programs) that have been shown to benefit patients. Whenever such assistance would be advantageous to a patient with a possible infection, the primary physician should opt for an infectious disease consult. Specific situations that might prompt a consult include (1) difficult-to-diagnose patients with presumed infections, (2) patients who are not responding to treatment as expected, (3) patients with a complicated medical history (e.g., organ transplant recipients, patients immunosuppressed due to autoimmune or inflammatory conditions), and (4) patients with "exotic" diseases (i.e., diseases that are not typically seen within the region).

TABLE 124-4 Typical Cerebrospinal Fluid Profiles for Meningitis and Encephalitis[a]

	NORMAL	BACTERIAL MENINGITIS	VIRAL MENINGITIS	FUNGAL MENINGITIS[b]	PARASITIC MENINGITIS	TUBERCULOUS MENINGITIS	ENCEPHALITIS

CLINICAL SYNDROME	COMMON ETIOLOGIES	ANTIBIOTIC(S)	COMMENTS	SEE CHAPTER(S)
Skin and soft tissue infection	*S. aureus, Streptococcus pyogenes*	Dicloxacillin, 250–500 mg PO qid ***or*** Cephalexin, 250–500 mg PO qid ***or*** Clindamycin, 300–450 mg PO tid ***or*** Nafcillin/oxacillin, 1–2 g q4h	If MRSA is a consideration, clindamycin, vancomycin (15 mg/kg q12h[b]), linezolid (600 mg IV/PO q12h), or TMP-SMX (1–2 double-strength tablets PO bid[g]) can be used.	**134** and pathogen-specific chapters

[a]This table refers to immunocompetent adults with normal renal and hepatic function. All doses listed are for parenteral administration unless indicated otherwise. Local antimicrobial susceptibility profiles may influence the choice of antibiotic. Therapy should be tailored once a specific etiologic agent and its susceptibilities are identified. [b]Trough levels for vancomycin should be 15–20 µg/mL. [c]Trough levels for amikacin should be <4 µg/mL. [d]In patients with late onset (i.e., after ≥5 days of hospitalization) or risk factors for multidrug-resistant organisms. [e]Trough levels for gentamicin and tobramycin should be <1 µg/mL. [f]If *P. aeruginosa* is a concern, the dosage may be increased to 3.375 g IV q4h or 4.5 g IV q6h. [g]Data on the efficacy of TMP-SMX in skin and soft tissue infections are limited. [h]Comorbidities include chronic heart, lung, liver, or renal disease; diabetes mellitus; alcoholism; malignancy; or asplenia.

Abbreviations: CNS, central nervous system; ICU, intensive care unit; MRSA, methicillin-resistant *S. aureus*; TMP-SMX, trimethoprim-sulfamethoxazole.

PERSPECTIVE

The study of infectious diseases is really a study of host–microbial interactions and represents evolution by both the host and the microbe—an endless struggle in which microbes have generally been more creative and adaptive. Given that nearly one-sixth of deaths worldwide are still related to infectious diseases, it is clear that the war against infectious diseases has not been won. For example, a cure for HIV infection is still lacking, there have been only marginal improvements in the methods for detection and treatment of tuberculosis after more than a half century of research, new infectious disease outbreaks (e.g., viral hemorrhagic fevers, SARS-CoV-2, mpox) continue to emerge, and the threat of microbial bioterrorism remains high. The subsequent chapters in Part 5 detail—on both a syndrome and a microbe-by-microbe basis—the current state of medical knowledge about infectious diseases. At their core, all these chapters carry a similar message: Despite numerous advances in the diagnosis, treatment, and prevention of infectious diseases, much work and research are required before anyone can confidently claim we have achieved "the virtual elimination of infectious disease." In reality, this goal will never be attained, given the rapid adaptability of microbes.

125 Molecular Mechanisms of Microbial Pathogenesis

Jordan B. Jastrab, Marcia B. Goldberg

Infectious diseases involve intricate interactions among the infecting microbe, human tissue and immune system, and the host microbiome. The co-evolution of humans and microbes has led to the emergence of microbial factors that promote infection and corresponding human cellular responses to microbes. Among the microbial factors that promote disease are those that alter human cells, inhibit host immune responses, and respond to the microbiota. The process of infection can be divided into several stages: microbial entry into the human body (*colonization*), microbial attachment in its favored niche and avoidance of host defenses (*infection*), deployment of microbial factors and host inflammatory responses that damage human tissue (*disease*), and microbial release into the environment, where the microbe can infect others (*transmission*). It is notable that for most pathogens, the host inflammatory response contributes substantially to symptoms and tissue damage. Moreover, the microbiota (the collection of microbes that reside in and on the human body) modulates, directly or indirectly, every stage of infection **(Chap. 484)**. This chapter describes the best-understood molecular and cellular mechanisms that contribute to human disease caused by bacterial pathogens.

ENTRY INTO THE HUMAN HOST

Infectious diseases occur when a live pathogen enters or a toxic pathogen product is ingested by the host. Entry of a live microbe into a host can occur by crossing a tissue barrier, through entry into or penetration of the skin or a mucous membrane of the respiratory, gastrointestinal, or genitourinary tract. If live bacteria spread to the connective tissue surrounding a barrier, an infectious collection may form (e.g., skin or intraabdominal abscess, empyema). Microbial penetration of barrier surfaces may also result in bloodstream infection, which can in turn lead to infection of other organ systems.

Infection of the skin and underlying soft tissue (*cellulitis*) typically occurs when bacteria reach the dermis via a physical disruption of the epidermal barrier. This disruption can result from trauma, fungal infection, pressure ulcers, or venous stasis ulcers. Bacteria that are already associated with the skin are most likely to traverse this barrier defect; therefore, *Staphylococcus aureus* and group A streptococci are the most common causes of cellulitis. In patients with diabetic foot ulcers, infections with *Pseudomonas aeruginosa* and anaerobic bacteria are also common.

Entry into the respiratory tract occurs via respiratory droplet nuclei (airborne particles 1–5 µm in diameter) or via fomites introduced on a contaminated hand. Infectious droplet nuclei are generated when an individual with a communicable respiratory infection (e.g., tuberculosis, influenza, COVID-19 infection) sneezes, coughs, or talks, or when environmental fluid contaminated with a noncommunicable infectious agent is aerosolized (e.g., Legionnaires' disease, aspergillosis). A cough may generate 3000 particles, whereas a sneeze may generate up to 40,000 particles; large particles may evaporate down to 0.5 µm, and hygroscopic particles can increase in size as they pass through the moist respiratory tree.

Entry into the gastrointestinal tract occurs via ingestion of contaminated food or water or via person-to-person contact. Pathogens for which the minimum infectious inoculum is large (e.g., 10^8 organisms for epidemic spread of *Vibrio cholerae*, 10^5 organisms for *Salmonella enterica* serovar Typhimurium) are generally acquired via

contaminated food or water, whereas pathogens for which the minimum infectious inoculum is small (e.g., 10^1 to 10^2 organisms for *Shigella* spp.) are typically acquired by person-to-person spread.

Entry into the genitourinary tract occurs via colonization of the urethral meatus or vaginal introitus with fecal organisms followed by ascension of the organisms into the bladder or kidneys or via instrumentation. Pyelonephritis can also result from hematogenous seeding of the kidney.

ESTABLISHMENT OF INFECTION

NICHE

Live Pathogens Many bacterial pathogens display tissue tropism; sites of infection are often pathogen-specific and restricted, such that adjacent tissues may be uninvolved. For example, group A streptococci cause pharyngitis and soft tissue infection, but rarely pneumonia. Cholera is an infection of the small intestine, whereas *Shigella* spp. cause disease only in the rectosigmoid colon. To establish infection, the pathogen must access and then survive within its niche **(Table 125-1)**. In the respiratory tree, the site at which pathogens settle is determined by mode of spread: droplet nuclei reach the bronchial tree or alveoli, whereas fomites reach the pharynx or nasal passages. Pathogens move through the gastrointestinal tract via normal intestinal motility.

Tissue association and invasion are dictated by bacterial interaction with host factors, such as glycan-decorated receptors and the extracellular matrix. The environmental conditions of the niche trigger expression of virulence factors required for establishing infection; for example, bile salts in the gut stimulate the expression of *V. cholerae* adhesins and the germination of *Clostridioides difficile* spores. Bacteria commonly manipulate their niche environment in ways that facilitate infection. For example, the gastroduodenal pathogen *Helicobacter pylori* converts urea into ammonia, thereby increasing the pH of the acidic stomach environment, which creates a more hospitable environment.

Preformed Toxins A small number of diseases are caused by ingestion of preformed bacterial toxins. The most common among these are *S. aureus* enterotoxins and the *Bacillus cereus* emetic enterotoxin. *S. aureus* enteroxins are strongly emetic and can be present in prepared foods such as dairy, meat, eggs, salads, and produce. *B. cereus* produces the peptide toxin cereulide, which acts as a potassium ionophore and induces emesis; this toxin is most often found in rice or other starchy food that has been improperly refrigerated. Although these pathogens may be killed when food is cooked, their toxins are heat stable. Less common but important is botulinum toxin, produced by *Clostridium botulinum* and the cause of botulism. Botulinum toxin blocks neurotransmitter release in motor neurons, inhibiting the central nervous system and resulting in a flaccid paralysis that may be complicated by fatal respiratory failure. Although botulinum toxin is heat-labile, *C. botulinum* spores are heat-stable.

TABLE 125-1 Bacterial Pathogens, Diseases, and Niches

MOST COMMON TROPISM	BACTERIUM	DISEASE
Skin, respiratory tract, small intestine	*Bacillus anthracis*	Anthrax
Respiratory tract	*Bordetella pertussis*	Pertussis
Systemic	*Borrelia burgdorferi*	Lyme disease
Systemic	*Brucella abortus*	Brucellosis
Systemic	*Burkholderia pseudomallei*	Melioidosis
Eyes, venereal	*Chlamydia trachomatis*	Various chlamydioses, including trachoma
Colon	*Clostridioides difficile*	Colitis
Pharynx	*Corynebacterium diphtheriae*	Diphtheria
Systemic	*Coxiella burnetii*	Q fever
Colon	Enterohemorrhagic *Escherichia coli*	
Stomach	*Helicobacter pylori*	Gastritis, gastric ulcers
Respiratory tract	*Legionella pneumophila*	Legionnaires' disease
Systemic, central nervous system	*Listeria monocytogenes*	Listeriosis
Respiratory tract	*Mycobacterium tuberculosis*	Tuberculosis
Urogenital tract	*Neisseria gonorrhoeae*	Gonorrhea
Respiratory tract	*Pseudomonas aeruginosa*	
Systemic	*Salmonella enterica* serovar Typhi	Typhoid fever
Gastrointestinal tract	*Salmonella enterica* serovar Typhimurium	
Colon, rectum	*Shigella* spp.	Dysentery, shigellosis
Multiple sites	*Staphylococcus aureus*	
Soft tissue	Group A *Streptococcus*	
Small intestine	*Vibrio cholerae*	Cholera
Systemic	*Yersinia pestis*	Plague

ATTACHMENT

Attachment of bacteria to host tissue surfaces is a prerequisite for the pathogen's establishment of an infection and is mediated by specific receptor–ligand interactions. The tissue specificity of the host cell surface receptor repertoire is a critical factor in delimiting a pathogen's niche(s). These physical associations additionally facilitate the pathogen's avoidance of host clearance mechanisms (see "Avoidance of Innate Immune Responses," below) and may contribute to formation of biofilms by the pathogen (see "Biofilms," below). Because adhesion to cellular receptors often triggers cellular signal transduction and innate immune signaling, therapeutic blockade of this interaction may in some circumstances exacerbate infection.

Adhesins Bacterial pathogens have evolved a wide range of strategies by which to attach to the diverse host cell structures they encounter. For many bacterial pathogens, ligands or adhesins for specific host receptors are known. Adhesins comprise a wide variety of surface structures, including single proteins, carbohydrates, glycoproteins, lipids, lipoproteins, and multiprotein filamentous complexes that extend several micrometers from the bacterial surface, each anchored in the outer-surface cell envelope. Most bacteria produce multiple adhesins with varying specificity, enabling the pathogen to interact with multiple receptors, including those on several distinct cell and tissue types encountered during the process of infection. These interactions are often partially redundant, are serologically variable, and contribute additively or synergistically with other binding interactions.

Common classes of adhesins are pili (also known as fimbriae), flagella, and autotransporter proteins **(Table 125-2)**. Pili are hairlike extensions consisting of a polymer of the major pilin subunit capped with minor pilins that provide the adherence function of the structure. Pili are classified by type and are produced by many gram-negative bacteria and a smaller number of gram-positive bacteria. To date, efforts to prevent infection with pilus-based vaccines have been unsuccessful.

Types of pili include type I, type P, and type IV. Type I pili frequently function at mucosal surfaces. For example, they mediate the close association of uropathogenic *Escherichia coli* (UPEC) with bladder epithelial cells and the ability of this pathogen to persist, causing relapsing urinary tract infections. UPEC also produces type P pili and afimbrial adhesins. These adhesins bind sugar moieties on host surface glycoproteins, with varied specificity depending on the adhesin. The minor pilin lectins at the tip of the pili generally bind D-mannose glycans, albeit with strain specificity. For example, the type I pilus adhesin FimH of intestinal *E. coli* strains often preferentially binds oligomannose, whereas the FimH of UPEC strains commonly binds monomannose. Thus, the same pilus structures in different bacterial strains can dictate adherence to distinct tissues. Type IV pili (Tfp) are widespread among gram-negative bacteria, and similar structures exist among gram-positive bacteria. These are evolutionarily related to the type II secretion system (T2SS) and, in addition to mediating adherence, allow the uptake of

TABLE 125-2 Classes of Bacterial Adhesion Proteins and Their Host Receptors

ADHESIN	EXAMPLE	RECEPTOR
Type I pili	Fim protein, uropathogenic *Escherichia coli*	Terminal mannose of uroplakin *N*-glycan in urinary epithelial cells
Type P pili	Pap protein, uropathogenic *E. coli*	Galactose disaccharides
Type IV pili	Tfp protein, *Neisseria gonorrhoeae*	CD64, CR3, I domain–containing integrins
MSCRAMM	SdrC protein, *Staphylococcus aureus*	β-Neurexin
Opa	Opa protein, *Neisseria meningitidis*	CEACAMs[a]
Flagellum	FliC protein, *Pseudomonas aeruginosa*	Asialo-GM1 ganglioside
Autotransporter	Invasin, *Yersinia pseudotuberculosis*	β1-Integrins
Autotransporter	Ag85, *Mycobacterium tuberculosis*	Fibronectin

[a]Carcinoembryonic antigen–related cell adhesion molecules.

DNA into bacteria and the motility of bacteria on surfaces. The Tfp of *Neisseria* spp. and *V. cholerae* mediate aggregation of individual bacteria into microcolonies, which promotes colonization.

Flagella are polymeric helical filaments that propel bacteria through liquid environments by rotating about their long axis. Because flagella confer the ability to swim toward a target surface, often following a chemotactic gradient where chemical sensing influences the direction of motility, they are vital virulence factors of many pathogenic bacteria. Flagella can be localized to one end of the bacterial cell (*polar*) or distributed around the bacterial surface (*peritrichous*). Flagella are evolutionarily related to type III secretion systems (T3SSs) (see "Replicative Niche" and "Survival in the Vacuole," below) and have been shown in some instances to be responsible for the secretion of bacterial toxins. Flagella may also act as adhesins, binding to mucins of mucosal surfaces in the case of the gastrointestinal pathogens enteropathogenic *E. coli* (EPEC) and enterohemorrhagic *E. coli* (EHEC).

Autotransporter proteins comprise a subdivision of type V secretion systems (T5SSs), which are prevalent among gram-negative bacteria (Fig. 125-1). Extended adhesive projections anchored in the bacterial outer membrane, autotransporter proteins are pivotal virulence determinants for several human pathogens, including the filamentous hemagglutinin of *Bordetella pertussis* (the etiologic agent of whooping cough) and the IcsA adhesin and intracellular motility determinant of *Shigella* spp. (responsible for dysenteric diseases). The autotransporter proteins intimin and invasin are required for the intimate association of adhering and effacing pathogens, such as EPEC, and invasion by *Yersinia* spp., respectively. Besides these main classes of adhesins, other bacterial surface proteins involved in adhesion include the Opa family of membrane proteins of *Neisseria* spp. and the gram-positive cell wall–anchored microbial surface component recognizing adhesive matrix molecules (MSCRAMMs) of *S. aureus* and various enterococci.

Receptors Carbohydrates (glycans) on the surface of and secreted by human cells play major roles in the adherence of bacterial pathogens. The surfaces of human cells are coated with glycoproteins and glycolipids, whereas the extracellular matrix (ECM) scaffold of tissues is mainly composed of secreted proteoglycans. Most mucosal surfaces are covered with a layer of mucus, which consists primarily of mucins, a family of proteins that are heavily glycosylated. Among the human enzymes involved in glycan decoration of secreted proteins is *FUT2*, for which ~20% of the human population harbors two nonfunctional alleles; the importance of human glycans in infection is highlighted by the observation that individuals who lack functional *FUT2* display increased susceptibility to certain bacterial infections, decreased susceptibility to certain viral infections, and altered susceptibility to chronic noninfectious inflammatory diseases. These data are confounded by a relative increase in secretion of sialylated glycans in individuals lacking functional *FUT2*. Glycans participate in many adhesive interactions and serve as receptors for certain bacterial toxins. Certain bacteria enzymatically alter host glycans in a manner that enables improved access to the epithelial surface, as in the case of *V. cholerae* and the oral pathogen *Tannerella forsythia*.

The GM1 ganglioside, a glycolipid, is the receptor for cholera toxin (CTX), *Pseudomonas aeruginosa* flagella, and the *Clostridium perfringens* α toxin, and contributes to tropism of the gastric pathogen *H. pylori* through interactions with the bacterial membrane proteins BabA and SabA. Heparan sulfate proteoglycans and other glycosaminoglycan-conjugated proteins are commonly associated with the basolateral membranes of epithelial layers and act as ligands for the

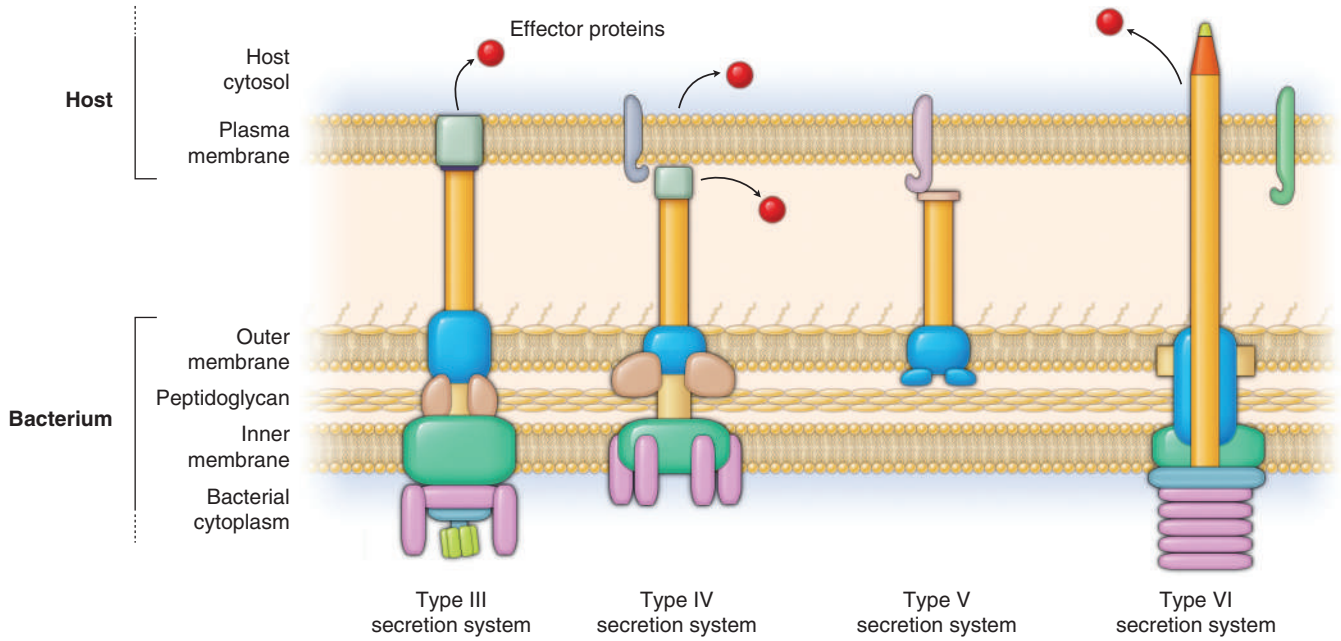

FIGURE 125-1 Major bacterial secretion systems involved in pathogenesis. Schematic of the types III, IV, V, and VI secretion systems (T3SS, T4SS, T5SS, and T6SS, respectively) of gram-negative bacteria. The T3SS, T4SS, and T6SS deliver bacterial effector proteins into host cells, whereas the T5SS participates in adhesion to the surface of cells. The architecture of the extracellular portion of the T4SS and how it translocates effector proteins remain poorly defined. Colored shapes with hooks in the host plasma membrane represent host membrane proteins that, it is thought, may participate in these processes.

chlamydial OmcB protein and the *E. coli* cytotoxic necrotizing factor toxin; these interactions promote initial bacterial adherence in proximity to the plasma membrane and lead to engagement of additional surface molecules.

In mammals, the ECM and integrin proteins are ubiquitous. The ECM consists of laminin, vimentin, and type IV collagen, which interact via fibronectin with integrin receptors in the plasma membrane. Because of direct interaction with plasma membrane–embedded integrins, ECM alterations can result in signal transduction that directly influences immune cell behavior. Many bacterial pathogens engage integrins and the functionally related carcinoembryonic antigen–related cell adhesion molecules (CEACAMs) as host cell receptors and as triggers for their internalization into human cells (see "Mechanisms of Microbial Entry into Cells," below). The receptor for adherent-invasive *E. coli*, a pathogenic type of *E. coli*, is CEACAM6, whose levels are increased on epithelial cells in inflammatory bowel disease; adherent-invasive *E. coli* adhere at increased levels in Crohn disease, and sites of excessive bacterial adherence display increased inflammation.

Among the many other host cell surface proteins that serve as receptors for bacterial adherence is the cystic fibrosis transmembrane conductance regulator (CFTR), a chloride channel involved in the maintenance of adequate hydration of mucosal surfaces. Mutation of the *CFTR* gene gives rise to the hereditary disease cystic fibrosis. These patients are hypersusceptible to respiratory infection because the cilia are unable to clear viscous mucus from the bronchial epithelial surface. The remarkably high frequency of cystic fibrosis (>2.5%) in Caucasian populations has been attributed to relative resistance to *Salmonella enterica* serovar Typhi infection, since *S.* Typhi adheres to CFTR via type IV pili. Epithelial cells utilize CFTR during internalization-mediated clearance of the extracellular pathogen *P. aeruginosa*, potentially contributing to the decreased ability of cystic fibrosis patients to clear infections by this pathogen.

REPLICATIVE NICHE

Once bacterial pathogens find their niche and associate with target host cells, they must replicate to persist. Some pathogens remain predominantly associated with the surface of epithelial cells (e.g., *Bordetella*, *Pseudomonas*, *Vibrio*, and *Clostridium* spp.); others predominantly enter into cells, where they may survive within the cytosol (e.g., *Shigella*, *Francisella*, and *Listeria* spp.) or within a membrane-bound compartment (vacuole) comprised of host-derived lipids (e.g., *Salmonella*, *Legionella pneumophila*). Phagocytic cells actively engulf pathogens for destruction (*phagocytosis*); to remain associated with the cell surface, extracellular bacteria must avoid or inhibit phagocytosis. Many pathogens deliver cytoskeleton-disrupting proteins that perturb the phagocytic process. Others create structures, such as *P. aeruginosa* biofilms and streptococcal cell chains, that impede phagocytosis. A subpopulation of any infecting pathogen will nevertheless be phagocytosed by macrophages, neutrophils, and/or dendritic cells (phagocytes). Many pathogens have evolved mechanisms to survive within phagocytes; for example, during colonization of the nasopharynx, *Streptococcus pneumoniae* survives within vacuoles in dendritic cells and macrophages. Nonphagocytic cells, such as epithelial cells, may also internalize bacteria in processes triggered by either the host cell (as a clearance mechanism) or the pathogen (for tissue invasion).

Extracellular Pathogens Extracellular pathogens replicate at the surface of host cells. Many secrete enzymes that liberate nutrients and other factors that fashion a hospitable niche. For example, *V. cholerae* secretes the mucinase vibriolysin that degrades the mucus barrier overlying intestinal epithelial cells, providing bacterial access to the cell surface. When phagocytosed, *V. cholerae* inhibits further phagocytosis of extracellular bacteria. *Yersinia* spp., which associates with the surface of leukocytes, delivers into these cells bacterial proteins that inhibit phagocytosis.

EPEC and EHEC efface the microvilli of the brush border of intestinal epithelial cells and adhere to the surface of these cells. These bacteria induce formation of actin-rich pedestals at the plasma membrane that inhibit bacterial internalization. Tight junctions mediate intimate associations between neighboring epithelial cells, thereby maintaining tissue barrier function; the dissolution of tight junctions by pathogens facilitates bacterial penetration into the tissue.

BIOFILMS Some extracellular pathogens, including *S. aureus* and *P. aeruginosa*, establish chronic infections by producing extracellular polymeric matrices called *biofilms*, which encase the bacteria. Biofilms commonly develop where tissue integrity has been compromised, such as in burn wounds and on prosthetic material. The biofilm matrix is composed of extracellular polysaccharides and DNA, to which the bacteria adhere. Biofilms protect bacteria from phagocytosis while impairing the diffusion of antibodies and antibiotics, enabling the bacteria to avoid elimination and persist.

Mechanisms of Microbial Entry into Cells Bacterial pathogens that are predominantly intracellular during infection can induce internalization into host cells. Even pathogens that replicate within normally phagocytic cells such as macrophages (e.g., *Salmonella* spp., *L. monocytogenes*) possess mechanisms for inducing internalization into these cells.

TRIGGER MECHANISM Bacterial systems that deliver proteins into human cells are critical to many aspects of pathogenesis (Fig. 125-1). An important example is the type III secretion system (T3SS), which delivers proteins from the bacterial cytoplasm directly into the cytosol of eukaryotic cells. Evolutionarily conserved T3SSs are found in many gram-negative bacterial pathogens. Delivery of bacterial proteins (*effector* proteins) into the host cell can have dramatic effects on host cell function; for many pathogens, these effects include induction of bacterial uptake into the host cell and alteration of cellular processes in ways that promote infection.

The T3SS forms an apparatus on the bacterial surface that resembles a needle and syringe, with a channel down its long axis (Fig. 125-1). The base of the organelle spans the two bacterial membranes. Anchored to the organelle base and protruding from the bacterial surface is a long needle-like structure. Upon contact of the needle tip with the eukaryotic plasma membrane, two proteins secreted through the channel form a pore in the cell's plasma membrane. The tip of the needle docks onto the extracellular face of the pore, forming a continuous conduit between the bacterial cytoplasm, where proteins are synthesized, and the host cell cytosol. Bacterial effector proteins are then delivered into the cell through this conduit.

For those pathogens that use a T3SS to induce entry into human cells (*Salmonella*, *Shigella*, and *Chlamydia* spp.), several of the first effector proteins to be translocated activate actin polymerization immediately beneath the point where the bacterium is docked on the plasma membrane. Polymerized actin pushes outwardly against the plasma membrane, generating large membrane ruffles that engulf the bacterium into a membrane-bound vacuole **(Fig. 125-2)**. *Shigella* spp. escape the vacuole and reside in the host cell cytosol, whereas *Salmonella* and *Chlamydia* spp. predominantly reside within the vacuole.

ZIPPER MECHANISM Several invasive pathogens enter host cells using a zipper-like mechanism that does not require a T3SS. In these instances, bacterial surface molecules engage with and stimulate the clustering of host cell receptors, which form close associations with the bacterium in a processive fashion until the plasma membrane is tightly opposed to and surrounding the bacterium (Fig. 125-2). For example, *Y. pseudotuberculosis* binds β1-integrins; this binding stimulates phosphoinositide 3-kinase (PI3K) and protein kinase B (Akt) signaling pathways, leading to zipper-mediated entry. *L. monocytogenes* engages E-cadherin and the Met receptor, activating β-catenin signaling and zipper-mediated entry. Subpopulations of bacteria classically considered extracellular, such as *P. aeruginosa* and *S. aureus*, may also promote bacterial uptake in a similar fashion.

ENTRY OF CYTOSOLIC BACTERIA INTO NEIGHBORING CELLS Bacteria are initially taken up into a vacuole (nonphagocytic cells) or a phagosome (phagocytic cells). Yet for some pathogens, residence in the vacuole or phagosome is transient; the lifestyles of these pathogens include residence in the cytosol, actin-based motility, and cell-to-cell spread. *L. monocytogenes*, *Shigella* spp., spotted fever group *Rickettsia* spp. (the

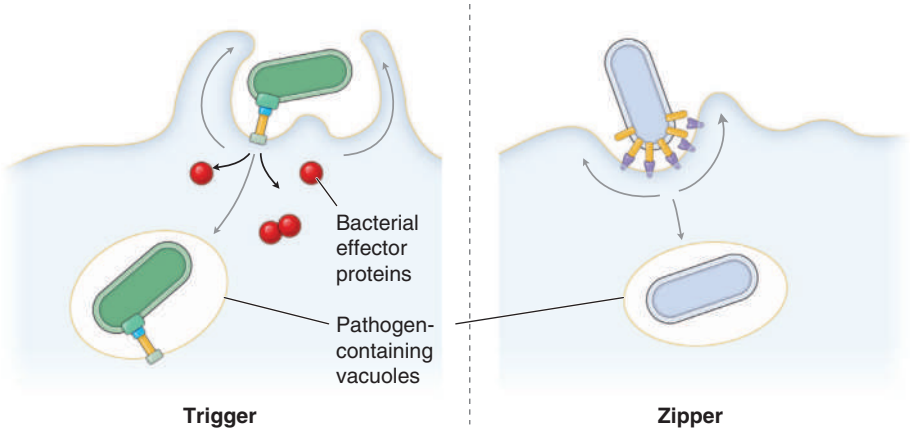

FIGURE 125-2 Common mechanisms of bacterial invasion. The mechanisms for internalization of bacteria into nonphagocytic cells are typically classified as *trigger* or *zipper* mechanisms. As examples of the trigger mechanism, *Shigella* and *Salmonella* spp. use their T3SSs to deliver into host cells effector proteins that manipulate the cytoskeleton in ways leading to the formation of cytoskeleton-supported membrane ruffles. These membrane ruffles extend and surround the pathogen, with consequent endocytosis of the bacterium. As examples of the zipper mechanism, bacterial membrane proteins of *Yersinia* and *Listeria* spp. induce clustering of host receptors. Clustering and subsequent intracellular signaling result in the uptake of the bacterium in a tightly opposed vacuole.

etiologic agents of Rocky Mountain spotted fever, rickettsialpox, and other spotted fever diseases), and *Burkholderia pseudomallei* (the etiologic agent of melioidosis) rapidly lyse the vacuole. *L. monocytogenes* produces a pore-forming toxin, listeriolysin O, and phospholipases that mediate escape into the cytosol, whereas the mechanism of vacuolar escape of *Shigella* spp. is still uncertain except for a requirement of its T3SS.

Once they have escaped into the cytosol, *L. monocytogenes*, *Shigella* spp., *B. pseudomallei*, and spotted fever group *Rickettsia* spp. spread into adjacent cells via actin-based motility. These organisms recruit actin-polymerizing host factors that drive actin polymerization at one end of the bacterium, propelling the microbe through the cell cytosol. Actin-based motility pushes bacteria into host cell membranes to form protrusions that are taken up by the neighboring cell, resolving into a double-membrane vacuole containing the bacterium. This vacuole is lysed once more, releasing bacteria into the cytosol to begin another round of replication. Subversion of the host cytoskeleton aids bacterial cytosolic survival and promotes dissemination through epithelial tissues. *Burkholderia* spp. instead trigger the infected host cell to fuse its membranes with adjacent cells in a T6SS-dependent manner, forming a multinucleated giant cell with contiguous cytoplasm.

SURVIVAL IN THE VACUOLE

After uptake into cells, the majority of invasive bacterial pathogens remain in a vacuole. Uptake vacuoles normally enter the endosomal pathway, acquiring host proteins that promote vesicle maturation, acidification, and degradation of contents. Many bacterial pathogens contained in these endosomes subvert this intracellular trafficking in ways that block endosomal maturation and lysosomal degradation of the pathogen. A distinct subset of bacteria actively damage vacuolar membrane integrity, thereby escaping into the cytosol, where they replicate. For bacteria that remain in the vacuole, various bacterial effector proteins are delivered by secretion systems either into the vacuolar space or across the vacuolar membrane into the cytosol (Fig. 125-1), where these proteins manipulate host processes to the benefit of the pathogen.

TYPE III SECRETION SYSTEMS

T3SSs (Fig. 125-1) are versatile virulence systems, helping bacteria such as *P. aeruginosa* remain extracellular, but promoting both the uptake and the intracellular survival of the intracellular pathogens *S. enterica* serovar Typhimurium, *Chlamydia* spp., and *Shigella* spp. *S. enterica* serovar Typhimurium uses distinct T3SSs for the invasion and subsequent maintenance of the *Salmonella*-containing vacuole (SCV), whereas *Chlamydia* and *Shigella* each encode only one such system. The effector proteins delivered are the major determinants of the lifestyles of these pathogens; *Shigella* quickly escapes the vacuole in a T3SS-dependent manner, whereas *Chlamydia* remains in the vacuolar compartment (the *inclusion*) and uses effector proteins to hijack cellular trafficking and perturb innate immune responses. The SCV and the *Chlamydia* inclusion exhibit distinct traits: the SCV is associated with thin membranous tubules that aid nutrient acquisition, whereas the inclusion is localized at the microtubule-organizing center, which is thought to facilitate recruitment of vesicles.

TYPE IV SECRETION SYSTEMS

For other pathogens, type IV secretion systems (T4SSs; Fig. 125-1)—conceptually similar, evolutionarily distinct effector protein delivery systems—are key to the ability to survive in cellular phagocytic vacuoles. These T4SSs are similar to the T3SSs described above in that they form a multiprotein apparatus that contains a continuous channel between the bacterial cytoplasm and the eukaryotic cell cytosol. However, T4SSs are functionally more diverse than T3SSs, in that (1) they are present among both gram-negative and gram-positive bacteria as well as some archaea, (2) a large subset of T4SSs transport DNA in a process called conjugation, and (3) some T4SSs deliver proteins, typically toxins, into bacterial cells rather than eukaryotic cells. Not surprisingly, T4SSs also display great structural diversity.

For the human pathogens *L. pneumophila* and *Coxiella burnetii*, bacterial effector proteins delivered across the vacuolar membrane into the cell cytosol by a T4SS alter maturation of the vacuole in a manner that makes it hospitable for bacterial survival; the resulting vacuole is known as a *Legionella*-containing or *Coxiella*-containing vacuole (LCV or CCV, respectively). The delivered effector proteins block fusion of lysosomes with the vacuole, thereby preventing bacterial degradation by lysosomal enzymes; manipulate host vesicular trafficking pathways; and remodel intracellular membranes to alter the lipid and protein content of the vacuolar membrane. For example, the *L. pneumophila* phospholipase VipD, a T4SS substrate, reduces the levels of phosphatidylinositol 3-phosphate on the LCV, thereby preventing recruitment of the host protein Rab5 GTPase, which is involved in endosomal maturation. The mature LCV membrane contains many features that resemble cellular endoplasmic reticulum. In the case of *C. burnetii*, the vacuole displays more lysosome-like characteristics, including a relatively low pH, which induces the activation of T4SS effector delivery. The delivered bacterial effectors stimulate efficient vesicle recruitment from endosomal and autophagosomal (see "Autophagy," below) networks, massively increasing the membrane of the CCV until it occupies much of the cytosol. For both *L. pneumophila* and *C. burnetii*, the mature bacterium-containing vacuoles are hospitable to bacterial replication and long-term survival.

OTHER SECRETION SYSTEMS

Francisella tularensis, the etiologic agent of the zoonotic infection tularemia, is a gram-negative facultative intracellular bacterium that displays a tropism for macrophages. *F. tularensis* resides in a phagosome, the maturation of which it delays by remodeling the lipid content of the vacuolar membrane through the action of its type VI secretion system (T6SS; Fig. 125-1). *F. tularensis* then avoids destruction by lysosomal enzymes by escaping into the cytosol, where it replicates. Another pathogen that escapes into the cytosol of macrophages is the respiratory pathogen *Mycobacterium tuberculosis*. Here, the ESX-1 type VII secretion system (T7SS) is required for lysis of the phagosomal membrane. For both of these pathogens, few effectors of their cognizant secretion system have been characterized, and the process of phagosomal membrane lysis remains poorly understood.

NUTRIENT ACQUISITION

Regardless of the site of bacterial infection, microbes must acquire nutrients to replicate. Both extracellular and vacuolar pathogens must circumvent the nutrient-poor conditions of these sites. Also impacting extracellular bacteria is the microbiota, which contributes to nutritional immunity through competition for resources **(Chap. 484)**. Bacterial pathogens possess an arsenal of nutrient acquisition mechanisms to overcome these challenges. For example, upon oxidative stress, to maximize nutrient uptake, several pathogens secrete metal ion-binding proteins through T4SSs (Fig. 125-1) and upregulate expression of cell surface receptors. Many bacteria manipulate host restriction of nutrients, with intracellular bacteria commonly delivering factors that inhibit host mRNA translation to increase the available pool of amino acids. Pathogens within vacuoles have evolved methods of redirecting host nutrient transport to these vacuoles (see "Cellular Trafficking," below).

CELLULAR TRAFFICKING

Because the vacuolar environment is poor in nutrients, bacteria that survive in vacuoles have evolved intricate strategies for the manipulation of host processes to meet their metabolic needs. Vacuolar pathogens modulate endosomal trafficking to prevent degradation by lysosomal compartments. Whereas cytoskeletal rearrangements are regulated by small GTPases of the Rho family, the transport of vesicles through the cell cytosol is controlled by Rab and Arf GTPases. The coevolution of vacuole-residing bacteria with their eukaryotic hosts has promoted the acquisition of eukaryotic-like domains in many secreted bacterial effector proteins. Many of these effector proteins mimic host cellular trafficking proteins such as guanine nucleotide exchange factors (GEFs), which regulate GTPase activation, and soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors (SNAREs), which control vesicle fusion with vacuolar and other membranes. These bacterial effectors cause the accumulation of host protein and lipid markers on vacuolar membranes, thereby causing the vacuoles to resemble other host compartments. Consequently, host vesicles are redirected from the endoplasmic reticulum, Golgi apparatus, and secretory pathways to the pathogen-containing vacuole, thus delivering nutrients to the pathogen. *Chlamydia* spp., which are obligate intracellular bacteria, acquire host-derived lipids in the bacterial membranes. Dissection of the modes of action of bacterial effectors has revealed novel biochemical modifications of host trafficking regulators. For example, the *L. pneumophila* T4SS secretes two effector proteins that inactivate the cellular GTPase Rab1: AnkX inactivates Rab1 by transferring to it the phospholipid phosphatidylcholine, and SidM modifies Rab1 by adding an adenosine monophosphate molecule to it. This bacterium delivers >300 effector proteins through its T4SS; some of these proteins (*meta-effectors*) modulate the activity of other effectors rather than host factors. The coordinated activity of the numerous effector proteins provides precise spatiotemporal control of host processes.

AVOIDANCE OF INNATE IMMUNE RESPONSES

For the host to respond to and clear an infection, it must first be capable of sensing it. The route of infection and properties of the pathogen contribute to determining the nature of the immune response. The human immune system is generally considered to consist of two arms: the innate immune system, initiated by germline-encoded sensors, and the adaptive immune system, where lymphocytes are clonally selected in response to specific antigens. Initial interactions of pathogens are with specific host cell types, influenced by bacterial tropism; the resulting release of danger signals and cytokines from the innate immune response shapes the later adaptive immune response.

Epithelia (e.g., in the intestinal and respiratory tracts) are commonly the first tissues that a pathogen encounters. The mucosal surfaces of these epithelia are covered in a gel-like mucus layer that contains secretory immunoglobulins, antimicrobial peptides, and commensal bacteria, which offer the first line of defense that infecting pathogens must overcome **(Chap. 484)**. In the gastrointestinal tract, this barrier can be overcome through hijacking of microfold cells (M cells) in the follicle-associated epithelia. M cells sample antigens, including intact pathogenic bacteria, from the gut lumen and deliver them to the underlying gut-associated lymphoid tissue in a process known as *transcytosis*. Within the gut-associated lymphoid tissue, dendritic cells, macrophages, and neutrophils engulf transcytosed material for destruction. Lysosomal degradation of pathogenic bacteria in macrophages and dendritic cells can then lead to antigen presentation, where the hydrolytic products are processed for display by the major histocompatibility complexes (MHCs). These antigen-presenting cells migrate through the lymphatic system to lymph nodes, where the adaptive immune response is stimulated through activation of B-cell and T-cell clones.

COMPLEMENT

Once bacteria have crossed epithelial barriers into the lamina propria, they encounter components of humoral immunity. The complement system is a complex of plasma and tissue-resident proteins that can undergo activation from their pre-protein or zymogen forms to either label pathogens for phagocytosis (*opsonization*) or lyse them directly **(Fig. 125-3)**. Complement activation commences with detection of the pathogen through the binding of circulating antibodies, which are recognized by the C1 complex (*classical pathway*), or of lectins (*lectin pathway*) to surface carbohydrates. These pathways converge at the deposition of the C3 convertase complex on the bacterium. The *alternative pathway* is the third route of complement activation, whereby an alternative C3 convertase complex is formed either spontaneously or by the action of plasma factors, promoting amplification of the cascade. Activation of further complement components results in chemokine production, bacterial opsonization, or assembly of the membrane attack complex pore on the bacterial surface, which lyses the pathogen. Bacterial virulence factors have been described that inhibit each step of the complement pathway, highlighting the importance of this antimicrobial system to host immunity. The various strategies of bacterial interference include prevention of initial recognition by assembly of a polysaccharide capsule, modification of bacterial lipopolysaccharide (LPS), degradation of complement components, and masking of surfaces with host proteins. Streptococci employ numerous mechanisms for complement evasion. The streptococcal proteases ScpA and SpeB degrade many complement proteins, whereas the bacterial surface-exposed M proteins bind the complement inhibitor C4BP, thereby preventing C3b deposition. The thick peptidoglycan layer of gram-positive bacteria provides modest resistance to membrane attack complex–mediated lysis. Furthermore, streptococci produce a hyaluronic capsule that shields the bacterial surface from complement recognition. In comparison, *Borrelia burgdorferi*, the etiologic agent of Lyme disease, encodes a CD59-like protein that inhibits the completion of membrane attack complex assembly. Whereas many pathogens inhibit opsonization, thereby avoiding phagocytosis, other bacteria, including *Francisella* and *Yersinia* spp., promote this process, leading to uptake into the phagosomal compartment, wherein they replicate and prevent lysosomal fusion.

LYSOSOMES

Lysosomes are vesicular organelles of the endosomal system that contain hydrolytic and antimicrobial enzymes within an acidic environment. These enzymes are crucial for recycling of cellular material but also participate in direct killing of microbes and initiation of antibacterial immunity. Lysozyme is a lysosomal enzyme that hydrolyzes the polymeric glycan chains in peptidoglycan, resulting in bacterial lysis. Liberated peptidoglycan fragments may then stimulate innate immune receptors to drive antibacterial immunity. Lysozyme is highly effective against most gram-positive bacteria; however, the peptidoglycan layer of gram-negative bacteria lies between the bacterial outer and inner membranes, making it inaccessible to lysozyme. Gram-positive bacteria can decrease their susceptibility to lysozyme with peptidoglycan modifications that block access of lysozyme to the glycan chain, such as acetylation of sugars in the glycan strand. Metabolites present within the lysosome may also contribute to immunity; for example, the mitochondria-derived metabolite itaconate accumulates within lysosomes during infection of macrophages with *S. enterica* serovar Tymphimurium, where it limits bacterial growth.

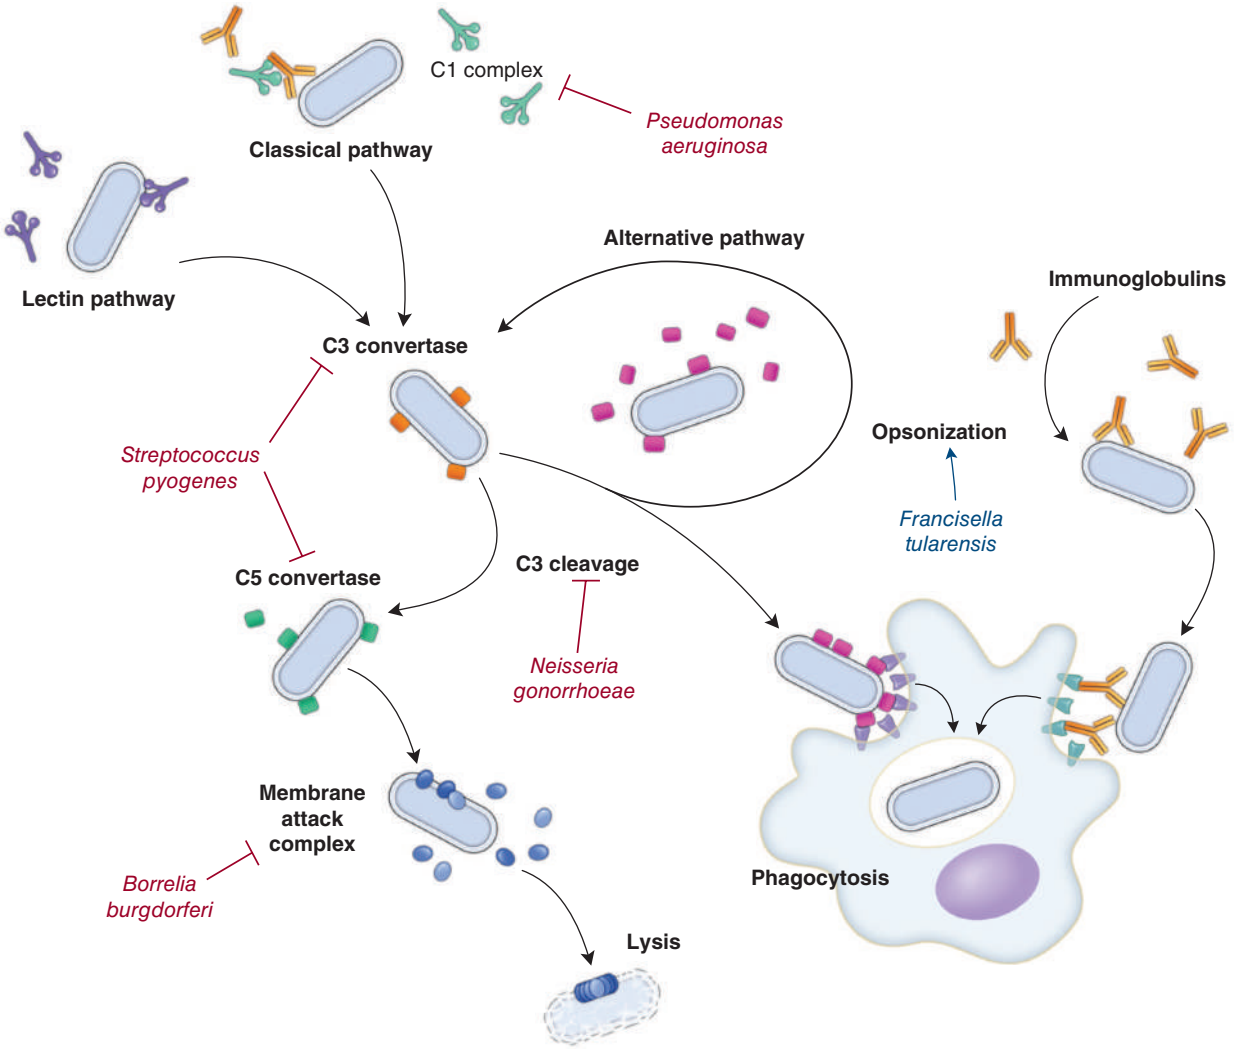

FIGURE 125-3 Overview of the complement system in bacterial infection. The *classical* and *lectin* pathways of complement activation are initiated by the binding of the C1 complex to antibodies bound to bacteria or to lectins binding carbohydrate moieties on the bacterial surface, respectively. A cascade of proteolytic cleavage generates the C3 convertase complex on the bacterial surface, which, upon activation, leads to C5 convertase formation. In the *alternative* pathway, spontaneous C3 cleavage forms alternative C3 products that lead to bacterial opsonization and to amplification of C3 convertase activation. The three complement pathways converge at the point of C3 convertase activation. In a manner similar to that seen for bacteria opsonized with circulating immunoglobulin, opsonized bacteria bind to surface receptors of phagocytes, triggering their engulfment for destruction and stimulation of the adaptive immune system. The C5 convertase, generated by conventional C3 convertase activation, recruits further complement proteins to form the membrane attack complex that directly lyses bacteria. Many bacterial pathogens inhibit specific points in the complement cascade, a selection of which are shown with blunt-ended arrows; in contrast, others, such as *Francisella* spp., promote their own opsonization and subsequent phagocytosis, enabling them to reach their intracellular replicative niche.

ANTIMICROBIAL PEPTIDES

Antimicrobial peptides, such as the positively charged defensins and cathelicidins, are concentrated in degradative compartments. These molecules bind the anionic surface of bacteria and perturb the integrity of LPS of the gram-negative outer membrane and wall teichoic acids in the gram-positive cell wall. Many bacterial pathogens modify their surfaces to reduce the net negative charge, thereby decreasing the binding of positively charged antimicrobial peptides. *S. aureus* and the respiratory pathogen *Burkholderia cenocepacia* secrete proteases that cleave antimicrobial peptides, facilitating survival at mucosal surfaces and within phagosomes.

OXIDATIVE BURST

Pathogens are exposed to reactive oxygen species and reactive nitrogen species produced by cells responding to infection. A well-characterized example is the neutrophil oxidative burst, in which the membrane complex nicotinamide adenine dinucleotide phosphate oxidase (NADPH oxidase) produces superoxide radicals through the transfer of electrons to molecular oxygen. NADPH oxidase activation at the site of infection generates reactive oxygen species in the phagosome of neutrophils and/or in the extracellular space. Bacterial detoxification enzymes, including superoxide dismutases, peroxiredoxins, and catalases, enable bacteria to survive this oxidative burst. Many bacteria can also block the activity of NADPH oxidase; several pathogens prevent assembly of the NADPH oxidase complex by T3SS effector protein–mediated posttranslational modification of small GTPases. The importance of NADPH oxidase in immune defense is highlighted clinically by the marked susceptibility to certain bacterial and fungal infections in patients with chronic granulomatous disease, which results from nonfunctional alleles for essential subunits of this complex.

NEUTROPHIL EXTRACELLULAR TRAPS

The oxidative burst also stimulates the release of the proinflammatory tumor necrosis factor α, azurophilic granules, and neutrophil extracellular traps (NETs). NETs are an extruded mesh of decondensed chromatin that are thought to ensnare pathogens, thereby restricting their spread and destroying them. Streptococci encode deoxyribonucleases (DNases) and *S. aureus* nuclease degrades NETs. *S. aureus* then converts the nucleotide products of this degradation into deoxyadenosine, which functions as a potent macrophage toxin. This process showcases how bacterial pathogens may utilize antimicrobial responses to their own benefit.

PATTERN RECOGNITION RECEPTORS, GUARD PROTEINS, AND THEIR EVASION

The first line of detection of pathogens by the innate immune system is via recognition of molecular patterns that are indicative of the presence of pathogens, termed pathogen-associated molecular patterns (PAMPs). Host proteins referred to as pattern-recognition receptors (PRRs) recognize PAMPs, enabling cells to establish that an infection is occurring. Membrane-associated PRRs surveil the extracellular or endosomal milieu, whereas cytosolic PRRs monitor for threats within the cytosol. Cytosolic ligands tend to stimulate stronger proinflammatory responses than extracellular ligands, and detection of bacteria-derived PAMPs tends to elicit a more powerful inflammatory response than detection of virus-derived PAMPs. Thus, both the subcellular localization and ligand specificity of PRRs play important roles in dictating the character and amplitude of an immune response. Another class of innate immune proteins, termed *guards*, can also initiate innate immune signaling in a process referred to as effector-triggered immunity. In contrast to the direct binding of PRRs to PAMPs, guards become activated upon sensing activities or cellular changes associated with infection.

TOLL-LIKE RECEPTOR DETECTION OF EXTRACELLULAR AND PHAGOSOMAL LIGANDS

The most extensively studied PRRs for bacterial PAMPs are Toll-like receptors (TLRs), which are membrane-associated. On phagocytic cells, TLRs may employ scavenger receptors as co-stimulatory surface receptors. Different TLRs recognize distinct conserved molecules that include LPS, peptidoglycan, flagellin, and nucleic acids **(Table 125-3)**. Upon binding their cognate ligands, TLRs trigger assembly of supramolecular organizing centers, large protein complexes that are signaling platforms for signal transduction. Ultimately, TLR signaling results in nuclear translocation of transcription factors, including nuclear factor-κB (NF-κB), AP-1, and interferon-regulatory factors (IRFs), which induce expression of cytokines, chemokines, and other immunity-related genes **(Fig. 125-4)**.

ALTERATION OF PAMPS TO PREVENT IMMUNE RECOGNITION Pathogens have evolved a plethora of strategies to avoid immunity; one common strategy is to mask PAMPs. For example, TLR4 binds efficiently to LPS that contains hexa-acylated lipid A. *Y. pestis*, the etiologic agent of plague, produces hexa-acylated LPS in the flea vector, but upon transmission into a human host switches to production of tetra-acylated LPS, which does not activate TLR4. Tetra-acylated LPS is also synthesized by *F. tularensis*, *H. pylori,* and the periodontal pathogen *Porphyromonas gingivalis*.

Bacteria can also mask immune recognition of flagella. The flagellum of *H. pylori* facilitates bacterial access to the gastric epithelium and is essential for virulence. Flagellin, the monomeric protein subunit of the flagellum, is a ligand for TLR5, but *H. pylori* bypasses immune recognition by producing a flagellin epitope that does not bind TLR5. CpG motifs in mammalian DNA are usually methylated, but CpG motifs in bacterial DNA are not; thus, methylation state provides a method of discriminating self from nonself. TLR9 recognizes CpG-containing unmethylated DNA in intracellular membrane compartments of the endosomal system. Group A streptococci secrete the Sda1 DNase that degrades CpG DNA, thereby reducing the immunogenicity of lysed bacteria.

TABLE 125-3 Pattern Recognition Receptors of the Innate Immune System and Their Ligands

PATTERN RECOGNITION RECEPTOR	LIGAND OR MODE OF ACTIVATION
TLR2 (with TLR1 or TLR6)	Lipoproteins
TLR4	LPS
TLR5	Flagellin
TLR9	CpG DNA
NLRP1	Enzymatic cleavage
NLRP3	Ionic flux, mitochondrial damage
NLRP6	Lipoteichoic acid, RNA
NAIPs/NLRC4	Flagellin/T3SS
STING	Cyclic dinucleotides
NOD1 and NOD2	Peptidoglycan

INHIBITION OF NF-κB AND MAPK SIGNALING NF-κB signaling plays a central role in controlling both antibacterial and steady-state immunity. A plethora of bacterial effector proteins target components of the NF-κB pathway in ways that maintain repression of NF-κB-dependent proinflammatory genes, thereby counteracting activation of innate immune responses triggered by their conserved PAMPs.

Many bacteria produce virulence factors with eukaryotic-like domains that enable pathogens to hijack host signal transduction, including the NF-κB pathway. *Ubiquitination*, a posttranslational modification in which a chain of the small protein ubiquitin is covalently linked to a target protein, is a common bacterial mechanism of host signaling inhibition. Ubiquitin is added to a target protein by an E3 ubiquitin ligase, which transfers ubiquitin from an E2 ubiquitin-conjugating enzyme to the target protein. Depending on the precise structure of the ubiquitin chain, the modified protein is subsequently degraded by the proteasome, targeted to particular vesicular compartments, or recruits adaptor proteins that initiate signal transduction.

The translocation of NF-κB into the nucleus requires the successive phosphorylation, ubiquitination, and degradation of IκBα by the IκB kinase (IKK) complex, which in resting cells inhibits NF-κB; the dissociation of the IKK complex from NF-κB enables the latter to translocate into the nucleus, where it functions as a transcription factor **(Fig. 125-4*C*)**. The T3SS of *Shigella* spp. delivers into cells several E3 ubiquitin ligases that target components of the NF-κB pathway for degradation. The intracellular pathogens *C. trachomatis* and *B. pseudomallei* secrete bacterial deubiquitinases through T3SS and T2SS, respectively, which cleave the ubiquitin moiety from IκBα, thereby preventing its degradation, maintaining inhibited NF-κB in the cytosol, and repressing proinflammatory gene expression.

Other enzymatic activities of bacterial effectors can also inhibit NF-κB activation by ubiquitin-dependent or -independent processes. *Shigella* spp. and *L. pneumophila* deliver effectors via their T3SS and T4SS, respectively, that inactivate E2 enzymes to prevent modification and degradation of the IKK complex. EPEC and *Shigella* spp. release cysteine methyltransferases that inhibit IKK modification, whereas *S. enterica* serovar Typhimurium targets NF-κB directly for degradation via T3SS effectors with metalloprotease activity.

Another cellular pathway of pro-inflammatory signaling stimulated by PRRs is the mitogen-activated protein kinase (MAPK) phosphorylation cascade, which activates transcription factor AP-1. The *B. anthracis* metalloprotease exotoxin lethal factor ablates this kinase cascade by cleaving the N-terminal region of MAPKs. Homologous T3SS effectors of *Yersinia* spp., *S. enterica* serovar Typhimurium, and *V. parahaemolyticus* acetylate MAPKs, preventing their phosphorylation. Finally, *Shigella* spp. and *S. enterica* serovar Typhimurium produce phosphothreonine lyases that cleave phosphorylated threonine residues from MAPKs, preventing their activities.

The broad range of effector protein mechanisms that bacteria employ to subvert TLR and MAPK signaling underscores the critical roles of these pathways in preventing pathogens from establishing infection (Fig. 125-4).

PRR SENSING OF CYTOSOLIC INFECTION Whereas the extracellular environment is surveilled for signs of infection by TLRs, the cytosol is monitored by other PRRs. Among the signaling pathways activated upon recognition of intracellular bacterial pathogens are the cytosolic PRRs NOD1 and NOD2, which activate NF-κB signaling upon binding modified peptidoglycan fragments. These PRRs are critical for defense against numerous bacterial pathogens, yet polymorphisms in the *NOD1* and *NOD2* genes confer susceptibility to inflammatory bowel disease. Another important cytosolic (and occasionally nuclear) innate immune surveillance system is the cyclic guanosine monophosphate–adenosine monophosphate (cGAMP) synthase-stimulator of interferon genes

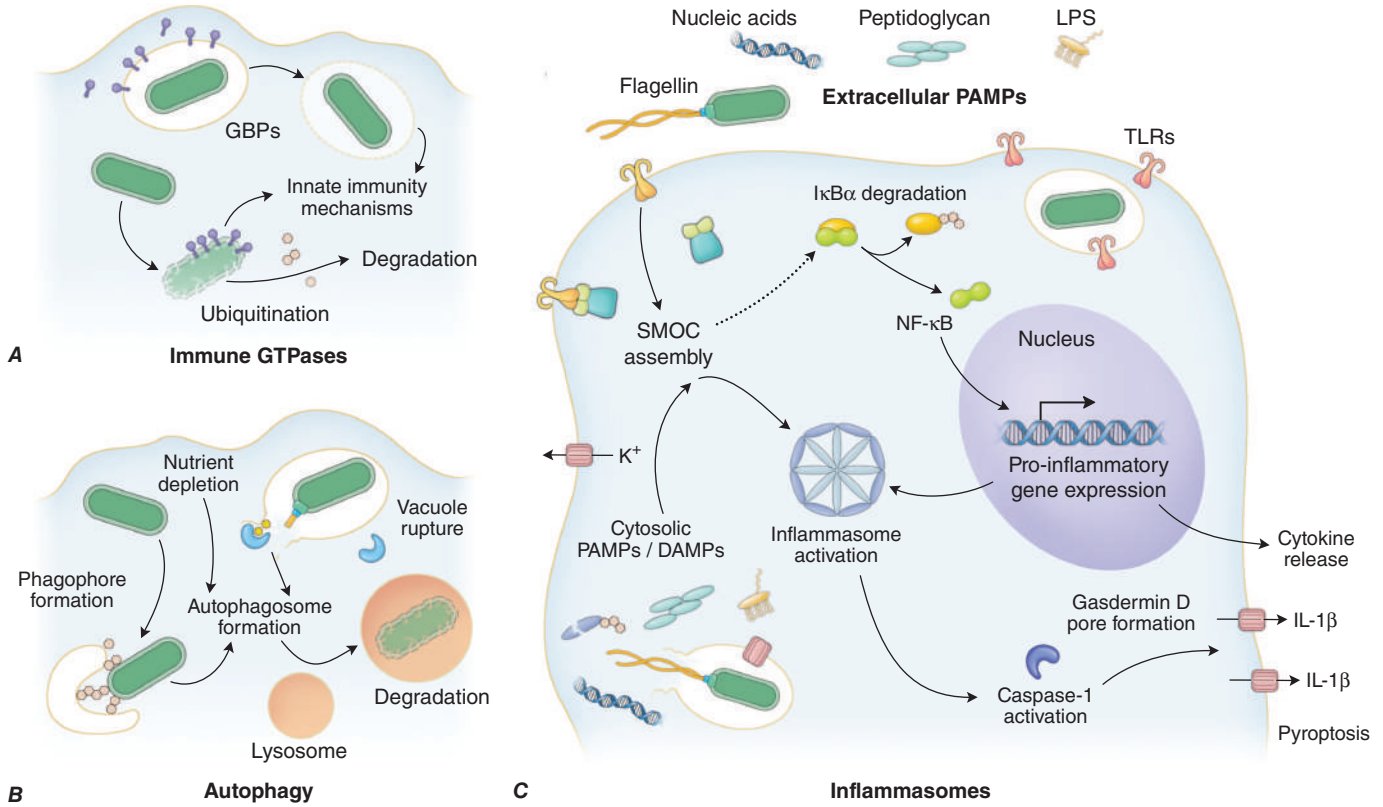

FIGURE 125-4 Overview of innate immune recognition and response to bacterial pathogens. ***A.*** Immune GTPases. Proteins of the GBP family associate with the bacterial surface, LPS shed from the bacterial surface, or pathogen-containing vacuoles, disrupting the integrity of the pathogen and leading to bacterial lysis. Alternatively, labeling of intracellular pathogens with immune GTPases may stimulate ubiquitination of the bacterium and its destruction by cell-autonomous immune mechanisms such as autophagy. ***B.*** Autophagy. Recognition of bacterial invasion leads to host-mediated sequestration of the pathogen in an autophagosome and destruction of the pathogen upon fusion of the autophagosome with lysosomes. Bacteria may be directly labeled by ubiquitination, damaged vacuoles are recognized by the binding of galectins to exposed glycans, and/or the cellular autophagy may be induced in response to sensing starvation. ***C.*** Pattern recognition receptors and innate immune signaling. Conserved PAMPs, DAMPs, and danger signals are recognized by all cells, triggering innate immune signaling pathways and proinflammatory gene expression. TLRs surveil the cell surface and endosomal interior for PAMPs that include LPS, nucleic acids, and flagellin. Cytosolic PRRs and guards, including NLRs and ALRs, recognize similar ligands as well as distinct stimuli, including dysregulation of ion homeostasis. TLR activation promotes supramolecular organizing center assembly and NF-κB signaling. Under resting conditions, NF-κB is sequestered in the cytosol by IκBα, but TLR activation leads to IκBα phosphorylation, ubiquitination, and degradation, with the consequent release of NF-κB. Resultant translocation of NF-κB into the nucleus leads to pro-inflammatory gene expression and the production and release of cytokines. Stimulation of cytosolic PRRs and guards may lead to assembly of supramolecular organizing centers known as inflammasomes, resulting in activation of inflammatory caspases. A well-characterized example is the activation of caspase-1 by canonical and noncanonical inflammasomes, subsequent activation of the pore-forming protein GSDMD, maturation and release of proinflammatory cytokines IL-1β and IL-18, and pyroptotic death of the cell.

(cGAS-STING) pathway. In response to recognition of cytosolic DNA, cGAS synthesizes the second messenger cGAMP. Upon binding cGAMP, STING activates interferon regulatory factor 3 (IRF3) and NF-κB, which subsequently promote transcription of interferon-regulated proinflammatory genes. The products of these genes include cytokines that alert bystander cells and recruit immune cells from the circulation, creating a heightened immune state in the local area.

INFLAMMASOMES Some cytosolic PRRs, including members of the NOD- and AIM2-like receptor (NLR and ALR, respectively) families, can seed formation of supramolecular organizing centers known as *inflammasomes*. Upon binding to a PAMP, these PRRs oligomerize and recruit the zymogen procaspase-1; some PRRs recruit procaspase-1 directly, whereas others bind the adaptor protein ASC, which then recruits procaspase-1. Upon its recruitment, procaspase-1 undergoes autocatalytic cleavage, thereby converting into active caspase-1 and completing formation of an active inflammasome. PRRs capable of triggering inflammasome assembly include NAIP-NLRC4, AIM2, and NLRP6. Select guard proteins can also trigger inflammasome assembly, including NLRP3, Pyrin, and NLRP1. In addition, caspase-4 and -5 (and their murine homolog caspase-11) serve as PRRs that drive assembly of the "non-canonical" NLRP3 inflammasome (see below). The importance of inflammasome signaling is underscored by a plethora of polymorphisms within inflammasome-associated genes that predispose to autoinflammatory disorders or susceptibility to infection.

Upon their activation within an inflammasome, caspases drive immunity by cleaving inflammasome effector proteins. The best-described inflammasome effectors are gasdermin D (GSDMD) and IL-1 family cytokines, including interleukin-1β (IL-1β) and IL-18. Cleavage of GSDMD liberates its N-terminal domain, which forms pores in the plasma membrane; cleavage of the zymogen forms of IL-1 family cytokines converts them into mature, active cytokines, which are released through GSDMD pores and bind the IL-1 receptor, in turn driving robust inflammation (Fig. 125-4). The formation of GSDMD pores in the plasma membrane is often associated with cell death, termed *pyroptosis* (inflammatory cell death).

Inflammasome-seeding PRRs are activated by binding to PAMPs. NAIPs sense the needle protein of the T3SS or the related flagellin protein and subsequently recruit NLRC4 to seed inflammasome formation. Many pathogens have evolved mechanisms to overcome activation of the NAIP-NLRC4 inflammasome. In *L. pneumophila*, *L. monocytogenes*, *P. aeruginosa*, and *S. enterica* serovar Typhimurium, flagellin expression is repressed during infection; similarly, in *S. enterica* serovar Typhimurium, expression of an immunogenic T3SS is repressed and that of a less immunogenic T3SS is upregulated. *S. enterica* serovar Typhimurium also produces a T3SS effector that blunts *NLRC4* expression. AIM2 is activated upon binding cytosolic double-stranded DNA, which is released during lysis of cytosolic bacteria. Bacterial cell wall and membrane modifications that reduce bacteriolysis dampen AIM2 activation during cytosolic infection. Overall,

the inhibition of inflammasomes by bacterial pathogens enables pathogens to avoid elimination by the innate immune system.

The NLRP3 inflammasome appears to be activated upon sensing cell stress and homeostatic dysregulation, including via ion flux, mitochondrial damage, and release of oxidized mitochondrial DNA. Because these processes are triggered by membrane damage, NLRP3 can be activated by many bacterial pore-forming toxins; bacteria may avoid stimulating NLRP3 by downregulating the production of toxins. The pyrin inflammasome becomes activated upon the inactivation of Rho GTPases, thereby serving as a sensor of cytoskeletal perturbations. *C. difficile, C. botulinum*, and *B. cenocepacia* all produce effectors that inactivate RhoA via distinct covalent modifications, which induces cell death by alteration of the actin cytoskeleton yet ultimately drives pyrin activation. Meanwhile, NLRP1 acts as bait for cleavage by microbial proteases or E3 ubiquitin ligases; partial degradation of NLRP1 stimulates its activity and subsequent pyroptosis.

Caspases-4 and -5 trigger formation of the noncanonical NLRP3 inflammasome in response to LPS. In human cells, LPS is bound by the PRR NLRP11, which facilitates activation of caspase-4; alternatively, caspases-4 and -5 can themselves serve as PRRs for LPS. Upon activation, these caspases cleave GSDMD but not IL-1β; the formation of GSDMD membrane pores indirectly drives activation of the NLRP3 inflammasome, which subsequently cleaves IL-1β. *S. flexneri* produces an effector that inactivates caspase-4 via ADP-riboxanation, which blocks host cell mechanisms of cytosolic bacteriolysis, thereby preventing release of LPS into the cytosol. Although caspases-4 and -5 play important roles in host defense, they also contribute to pathologic inflammation during gram-negative sepsis, as the murine homolog caspase-11 drives mortality in murine models of sepsis.

Immune GTPases During many infections, the initial pathogen interaction triggers expression of host immunity-related genes that prime host cells for a more robust response. For example, detection of bacteria can drive interferon signaling, which induces production of the guanylate binding protein (GBP) family of immune GTPases. GBPs are recruited to pathogen-containing vacuoles or bacterial membranes and promote the release of PAMPs, making them available as ligands for PRRs. Some GBPs extract LPS from the surface of cytosolic gram-negative bacterial pathogens, facilitating noncanonical inflammasome activation. GBPs contribute to lysis of *F. novicida* (a subspecies of *F. tularensis*) and *Neisseria meningitidis*, causing release of bacterial DNA into the cytosol. Recruitment of GBPs to *Shigella* spp. prevents bacterial actin-based motility and promotes bacterial ubiquitination, which targets the bacteria for proteasomal degradation; simultaneously, *Shigella* spp. secrete an effector that ubiquitinates GBPs, targeting them for degradation.

Inhibition of Nonpyroptotic Cell Death Several types of regulated (*programmed*) cell death besides pyroptosis can occur, of which inflammatory necroptosis and noninflammatory apoptosis are best characterized. In *necroptosis*, activation of any of a variety of innate immune signaling pathways (interferon-γ, TLRs) leads to kinase-dependent assembly of a plasma membrane pore complex that induces cell lysis and release of DAMPs into the extracellular space, events that induce an intense inflammatory response. Necroptosis can drive both pathologic inflammation and antibacterial immunity.

In *apoptosis*, cells condense and form membranous blebs without releasing cytosolic contents and thus without inducing inflammation in adjacent tissues. Apoptotic blebs and dead cells are disposed of by macrophages in a process known as *efferocytosis*. In addition to its role during infection, apoptosis plays a key role in development and is required for normal cell turnover in many epithelial tissues, including the intestine. Apoptosis can be initiated by intrinsic or extrinsic cellular stimuli, resulting in activation of apoptosis-specific caspases that demolish cellular contents. The intrinsic pathway occurs upon dissolution of the mitochondrial membrane potential, which commonly occurs during infection due to cellular stress or the action of bacterial toxins. The extrinsic pathway can be stimulated by interactions of cell-surface death receptors with proinflammatory ligands like TNF-α.

The gastrointestinal pathogens *S. enterica* serovar Typhimurium, *Yersinia enterocolitica*, and pathogenic *E. coli* inhibit signal transduction from cell-surface death receptors by modifying or cleaving the components of death receptor–associated supramolecular organizing centers (Fig. 125-4), thereby blocking cell death. Inhibition of extrinsic apoptotic signaling can stimulate alternative inflammatory cell death pathways, including necroptosis, highlighting the functional redundancy of cell death pathways in some contexts.

Vacuolar *Chlamydia* spp. activate survival pathways through phosphoinositide 3-kinase (PI3K) and Wnt/β-catenin signaling, while simultaneously inhibiting apoptosis. T4SS effectors of vacuolar *L. pneumophila* and *C. burnetii* inhibit apoptosis by sequestering pro-apoptotic host factors. Cyclomodulins, a group of bacterial effector proteins that arrest the cell cycle, are delivered into cells by EPEC and EHEC. The cyclomodulin Cif deamidates ubiquitin and related proteins, inactivating host E3 ligases involved in cell cycle progression and thereby reducing epithelial turnover; this disruption can be sensed by host cells and triggers other cell death pathways. The diversity of mechanisms that bacteria have accumulated to modulate host cell death pathways highlights the importance of these pathways during infection.

Autophagy Host cells deploy mechanisms of cell-autonomous immunity to neutralize microbial threats. One such mechanism is autophagy, which recycles organelles and protein complexes by generating double-membrane compartments (*autophagosomes*) around the cargo and delivering their contents to the lysosome; the cargo is subsequently degraded to amino acids and other molecules. Autophagy can isolate and dispose of cytosolic pathogens; host polysaccharide-binding molecules termed galectins can bind microbes and induce ubiquitination of the bacterial surface, which drives recruitment of LC3, a host protein that triggers engulfment into autophagosomes.

Intracellular bacterial pathogens must inhibit autophagy to survive. Common mechanisms used by bacteria to interfere with autophagy include masking bacterial ubiquitination sites, inhibiting autophagosome maturation, and altering host pathways that regulate autophagy. *L. monocytogenes* recruits the host factor Arp2/3 to mask the bacterial surface, *F. tularensis* produces an LPS O-antigen that prevents surface access of E3 ligases, and *S. flexneri* produces an effector protein that blocks ubiquitination of the bacterial surface protein IcsA. To inhibit autophagosomal flux, *L. pneumophila* secretes an effector protein that cleaves LC3, *S. enterica* serovar Typhimurium secretes effector proteins that block activation of a kinase required for autophagosome generation, and *M. tuberculosis* and *C. trachomatis* prevent autophagosome-lysosome fusion. An important metabolic trigger of autophagy is intracellular depletion of amino acids, which occurs upon replication of metabolically active intracellular pathogens and triggers inactivation of a master regulator of cell metabolism, mammalian target of rapamycin (mTOR). mTOR inactivation derepresses autophagy; invasive pathogens including *M. tuberculosis*, *S. enterica* serovar Typhimurium, and *Shigella* spp. can reactivate mTOR signaling during infection, thereby blunting autophagy.

Epigenetic Control of Innate Immune Responses Dysregulated immune responses (e.g., sepsis, severe COVID-19 infection) can cause morbidity or death, whereas weak immune responses may lead to pathogen-induced morbidity and mortality. A cellular mechanism that promotes appropriate amplitude of the immune response is innate immune training, in which cells are epigenetically primed for immunity via alterations in chromatin structure. Posttranslational modification of histones influences chromatin structure and access of transcription factors to regulatory elements in the DNA. Mounting evidence indicates that the microbiota modifies the methylation state of promoters of genes involved in immunity, facilitating appropriately tuned responses to infection. Pathogens also regulate host responses at the epigenetic level. *B. anthracis* and *L. pneumophila* deliver into cells histone methyltransferases that control inflammation and ribosome activity. *L. monocytogenes* listeriolysin O, the *P. aeruginosa* T3SS pore, and other pore-forming toxins exert epigenetic modulation through

alterations in ion homeostasis, thereby manipulating the gene expression profiles of infected host cells.

INHIBITION OF ADAPTIVE IMMUNE RESPONSES

Early interactions of pathogens with host cells trigger the innate immune response, releasing cytokines that recruit additional antigen-presenting immune cells to the site of infection. To establish chronic infection, bacterial pathogens need not only to suppress the innate immune system but also to avoid elimination by the adaptive immune response. The adaptive immune system comprises clonally expanded lineages of B and T lymphocytes that have been activated by antigen-presenting cells, the best characterized of which are dendritic cells and macrophages. B cells are required for humoral immunity; genetic diseases that affect B-cell function often manifest as the inability to produce adequate antibody titers to clear extracellular bacterial infections. T cells generally mediate cell-mediated immunity, helping the host clear infected cells. The activation of T cells occurs by the presentation of processed antigen on MHC molecules of antigen-presenting cells. The activation of T cells is controlled by the specificity of MHC molecules and of their receptors. The large variety of receptors possessed by T cells enables collective recognition of a wide variety of antigens. Mutations that ablate the development of the adaptive immune system result in severe combined immunodeficiency, rendering the individual extremely vulnerable to infection.

M. tuberculosis is notorious for its ability to establish latent infections, avoiding elimination by the immune system for decades. Once phagocytosed, the pathogen induces secretion of immunosuppressive cytokines, including IL-6, IL-10, and transforming growth factor β. The result is inhibition of interferon-γ-dependent gene expression, with downregulation of MHC class II and other immune-stimulatory molecules, which inhibits induction of helper $CD4^+$ T lymphocytes. Similarly, *B. pertussis* induces dendritic cells to produce IL-10, which skews T-cell maturation into regulatory T cells, dampening the immune response. The *S. enterica* serovar Typhimurium T3SS effector protein SteD depletes MHC class II molecules from the surface of dendritic cells by the activation of the E3 ubiquitin ligase MARCH8. MARCH8 ubiquitinates MHC class II, interfering with its trafficking to the cell surface and thereby decreasing interaction with and subsequent activation of T lymphocytes.

In addition to preventing antigen-presenting cells from stimulating lymphocytes, pathogens may also directly alter B-cell and T-cell activity. The *Yersinia* T3SS effector YopH, a protein tyrosine phosphatase, dephosphorylates B-cell and T-cell receptors and thus prevents both signal transduction upon stimulation by antigen-presenting cells and lymphocyte activation. Staphylococcal toxic shock syndrome is induced by the production of superantigens by *S. aureus*. These extremely inflammatory exotoxins are potent activators of T cells, stimulating exuberant and at times fatal cytokine production. Rather than binding the specificity-determining variable regions of MHC molecules and the T-cell receptor, superantigens bind invariable regions and are therefore able to nonspecifically activate vast numbers of T cells, with a consequent cytokine storm.

BACTERIAL CYTOTOXINS

Many bacteria produce *cytotoxins*—toxins that trigger host cell death. The best-characterized group of bacterial cytotoxins are the AB toxins, which are composed of an enzymatically active (A) subunit and a binding (B) subunit, which interacts with the cellular receptor. This family of toxins includes Shiga toxins of *Shigella* spp. and some strains of pathogenic *E. coli*, diphtheria toxin of *Corynebacterium diphtheriae*, pertussis toxin of *B. pertussis*, and CTX of *V. cholerae*. In general, upon binding to cell surface receptors, the toxin is endocytosed, whereupon the A-subunit translocates across the endosome membrane into the cytosol where its toxic enzymatic activity is stimulated. CTX and pertussis toxin ADP-ribosylate G-protein regulators of adenylate cyclases, thereby increasing cellular cyclic AMP (cAMP) concentrations. Within the cell, increased cAMP perturbs ion homeostasis and apoptosis; on a tissue level, increased intracellular cAMP induces chloride secretion via CFTR and inhibits sodium chloride absorption, driving massive fluid secretion into the lumen of the small intestine and the diarrheal symptoms of cholera. *C. perfringens* and *P. aeruginosa* produce non-AB family toxins that ADP-ribosylate elongation factor-2, thereby inhibiting host translation. *S. enterica* serovar Typhimurium and *C. difficile* produce toxins that target actin, inhibiting normal cellular cytoskeletal rearrangements. As dictated by the host targets modified, the effects of bacterial toxins on the host cell generally fall into the few broad categories of cytoskeletal manipulation, inhibition of innate immune signaling, and hijacking of cellular trafficking.

Pore-forming toxins are secreted virulence factors produced by many extracellular pathogens, including *S. pneumoniae*, *C. perfringens*, *B. anthracis*, and *L. monocytogenes*, among many others. *S. aureus* produces several types of pore-forming toxins, including leukocidins, hemolysins, and phenol-soluble modulins. Leukocidins and α- and γ-hemolysins oligomerize within host plasma membranes, leading to host cell lysis. The cell-type specificities of leukocidins and hemolysins are driven by toxin binding to specific cell surface receptors. Conversely, phenol-soluble modulins are small amphipathic peptides that directly insert into cell membranes. Lytic toxins protect *S. aureus* from phagocytosis and prevent an infected host from developing a protective adaptive immune response. Host cells can counter cytolysins by releasing *exosomes*, vesicles that act as decoys by removing cytolysins from the local environment.

TISSUE DAMAGE AND PATHOGEN DISSEMINATION

Much of the pathology associated with bacterial infection results from proinflammatory immune responses. Infected cells may continually signal in ways that alert the immune system, even though, as described above, many bacteria avoid elimination by cell-autonomous and immune cell–mediated mechanisms. In the intestine, tight junctions mediate intimate associations between epithelial cells that maintain tissue barrier function, linking the cytoskeletal networks of adjacent cells through intimate association of protein complexes across the cell membranes. Many intestinal pathogens perturb the integrity of the gut epithelium either by manipulating cell polarity or by disrupting intercellular junctions. *C. perfringens*, *V. cholerae*, pathogenic *E. coli*, *Shigella* spp., and *S. enterica* serovar Typhi all produce toxins in the gastrointestinal tract that disrupt tight junctions, consequently disrupting the barrier function of the tissue and facilitating access of the pathogen to deeper tissue. The RtxA multifunctional repeats-in-toxin (MARTX) toxin of *V. cholerae* causes cell rounding and barrier failure through actin-crosslinking activity, yet avoids eliciting substantial immune responses by simultaneously inactivating phospholipases and Rho GTPases. The serine protease autotransporters (SPATEs) of *Shigella* spp. and some pathogenic *E. coli* are typically secreted into the gut lumen or mucus layer, whereupon they cleave components of epithelial junctions and mucins in ways that facilitate tissue penetration. Tissue damage permits access to the underlying mucosal layers, the lymphatics, and the bloodstream; for some pathogens, this access enables seeding of other organs.

Transmission to New Hosts The host represents a replicative niche for bacterial pathogens, in which they multiply and are transmitted to new hosts. The mode of transmission is typically aligned with the mode of entry. For example, for respiratory pathogens, coughing induced by tissue damage in the lung aerosolizes the pathogen, enabling inhalation by and colonization of a new host. Similarly, gastrointestinal pathogens elicit diarrhea and are transmitted via the direct fecal–oral route or via contamination of crops or food with waste from an infected individual. The understanding of the spread of infectious diseases permits the institution of basic hygiene procedures that greatly diminish transmission rates—for example, hand washing, decontamination of communal surfaces, and adoption of social distancing measures.

Bacteriophages and Pathogen Lifestyle The reservoir of *V. cholerae* is aquatic environments. Disease is acquired through the ingestion of contaminated seawater or seafood. In regions where cholera is endemic, the disease displays seasonal peaks. This seasonality is associated with blooms of bacteria-targeting viruses (*bacteriophages*), which infect *V. cholerae* organisms, replicate, and lyse and kill the bacterial host. Bacterial lysis releases viral particles into the aquatic environment,

whereupon they can infect other *V. cholerae*. Consequently, the bacteriophages regulate the abundance of pathogens, with ramifications for the epidemiology of the disease. Whether bacteriophages contribute to cyclical control of other pathogens is currently unknown.

SUMMARY

Bacterial pathogens display myriad mechanisms of colonization, adhesion, invasion, dissemination, and manipulation of host pathways. Infectious diseases result when pathogens successfully establish themselves within the host. Symptoms are usually the result of ensuing fights between the pathogen and the immune system. The incredible diversity of virulence determinants highlights the success of the host in combating infection. Further elucidating how bacteria cause infection will better our understanding of both human and microbial biology and will provide new opportunities for successful therapeutic intervention against infectious and inflammatory diseases.

126 Microbial Genomics and Infectious Disease

Roby P. Bhattacharyya, Yonatan H. Grad, Deborah T. Hung

Just as microscopy opened the worlds of microbiology by providing a tool with which to visualize microorganisms, technological advances in genomics provide microbiologists with powerful methods to characterize the genetic map that underlies all microbes with unprecedented resolution, thereby illuminating their complex and dynamic interactions with each other, the environment, and human health. The field of infectious disease genomics encompasses a vast frontier of active research that is transforming public health and the clinical practice of infectious diseases. While genetics has long played a key role in elucidating the process of infection and impacting clinical infectious diseases, the ability to extend our thinking and approaches beyond the study of single genes to an examination of the sequence, structure, and function of entire genomes allows us to identify new possibilities for research and opportunities to change clinical practice and disease surveillance. From the development of diagnostics with unprecedented sensitivity, specificity, and speed to the design of novel public health surveillance tools and interventions, technical and statistical genomic innovations are reshaping our understanding of the influence of the microbial world on human health and providing us with new tools to diagnose, track, and combat infection. In this chapter, we explore the application of genomics methods to microbial pathogens and the infections they cause. We discuss innovations that are driving the development of diagnostic approaches as well as the discovery of new pathogens, providing insight into novel therapeutic approaches and paradigms, and advancing methods in infectious disease epidemiology and the study of pathogen evolution that can inform infection control measures, public health responses to outbreaks, and vaccine development. We draw on examples in current practice and from the recent scientific literature as signposts that point toward ways in which pathogen genomics may influence infectious diseases in the short and long terms, and we highlight applications to SARS-CoV-2 and the COVID-19 pandemic. **Table 126-1** provides definitions for a selection of important terms used in genomics.

MICROBIAL DIAGNOSTICS

The basic goals of a clinical microbiology laboratory are to establish the presence of a pathogen in a clinical sample, to identify the pathogen, and, when possible, to provide other information that can help guide clinical management and affect prognosis, such as antibiotic susceptibility profiles or the presence of virulence factors. To date, clinical microbiology laboratories have largely approached these goals phenotypically by growth-based assays and biochemical testing. Bacteria, for instance, were historically grouped algorithmically into species by their characteristic microscopic appearance, nutrient requirements for growth, and ability to catalyze certain reactions. Antibiotic susceptibility is still determined in most cases by assessing bacterial growth in the presence of antibiotic.

With the sequencing revolution paving the way to easy access of complete pathogen genomes, we can more systematically define the genetic basis for these observable phenotypes. Compared with traditional growth-based methods for bacterial diagnostics that dominate the clinical microbiology laboratory, nucleic acid–based diagnostics that build on this genomic information promise improved speed, sensitivity, specificity, and breadth of information. Bridging clinical and research laboratories, adaptations of genomic technologies have begun to deliver on this promise **(Table 126-2)**.

HISTORICAL LIMITATIONS AND PROGRESS THROUGH GENETIC APPROACHES

The molecular diagnostics revolution in the clinical microbiology laboratory is well under way, born of necessity in the effort to identify and characterize microbes that are refractory to traditional culture methods. Historically, diagnosis of many so-called unculturable pathogens has relied largely on serology and antigen detection. However, these methods provide only limited clinical information because of their suboptimal sensitivity and specificity, and, for serology, the long delays that diminish their utility for real-time patient management and the inability to characterize pathogens beyond identifying past exposure. Newer tests to detect pathogens based on nucleic acid content have already offered improvements in the select cases in which they have been applied.

Unlike direct pathogen detection, serologic diagnosis—measurement of the host's response to pathogen exposure—can typically be made only in retrospect, requiring both acute- and convalescent-phase serum samples. For chronic infections, distinguishing active from latent infection or identifying repeat exposure from serology alone can be difficult or impossible, depending on the syndrome. In addition, serologic diagnosis is variably sensitive, depending on the organism and the patient's immune status. For instance, tuberculosis is notoriously difficult to identify by serologic methods; tuberculin skin testing using purified protein derivative (PPD) is especially insensitive in

TABLE 126-1 Glossary of Selected Terms in Genomics

TERM	DEFINITION
Contig	A DNA sequence representing a continuous fragment of a genome, assembled from overlapping sequences; relevant for de novo assembly of sequence data that do not align to previously sequenced genomes
Genome	The entire set of heritable genetic material within an organism
Horizontal gene transfer	The transfer of genes between organisms through mechanisms other than by clonal descent, such as through transformation, conjugation, or transduction
Genomic epidemiology	An approach to inferring and reconstructing transmission events, population dynamics, and epidemiological patterns using comparative analysis of microbial genome sequences
Metagenomics	Analysis of genetic material from multiple species directly from primary samples without requiring prior culture steps
Microarray	A collection of DNA oligonucleotides ("oligos") spatially arranged on a solid surface and used to detect or quantify sequences in a sample of interest that are complementary (and therefore bind) to one or more of the arrayed oligos
Microbial genome-wide association study (GWAS)	An analytic framework to test statistical associations between microbial genotypes and phenotypes of interest, such as antibiotic resistance and virulence
Mobile genetic elements	DNA elements that can move within a genome and can be transferred between genomes through horizontal gene transfer (e.g., plasmids, bacteriophages, and transposons)
Multilocus sequence typing	A method for typing organisms based on DNA sequence fragments from a prespecified set of genes
Next-generation sequencing	High-throughput sequencing using a parallelized sequencing process that produces millions of sequences concurrently, far beyond the capacity of prior dye-terminator methods
Nucleic acid amplification test (NAAT)	A biochemical assay that evaluates for the presence of a particular string of nucleic acids through amplification by one of several methods, including polymerase and ligase chain reactions
Polymerase chain reaction (PCR)	A type of NAAT used to amplify a specific region of DNA by means of specific oligonucleotide primers and a DNA polymerase
Single-nucleotide polymorphism (SNP)	Point mutations in DNA, the number of which in different microbial isolates is a measure of their genetic distance from one another
Transcriptome	The catalog of the full set of messenger RNA (mRNA) transcripts from a cell or organism, which are typically measured by microarray or by next-generation sequencing of complementary DNA (cDNA) via a process called RNA-Seq
Whole genome sequencing (WGS)	A process that determines the full DNA sequence of an organism's genome; has been greatly facilitated by next-generation sequencing technology

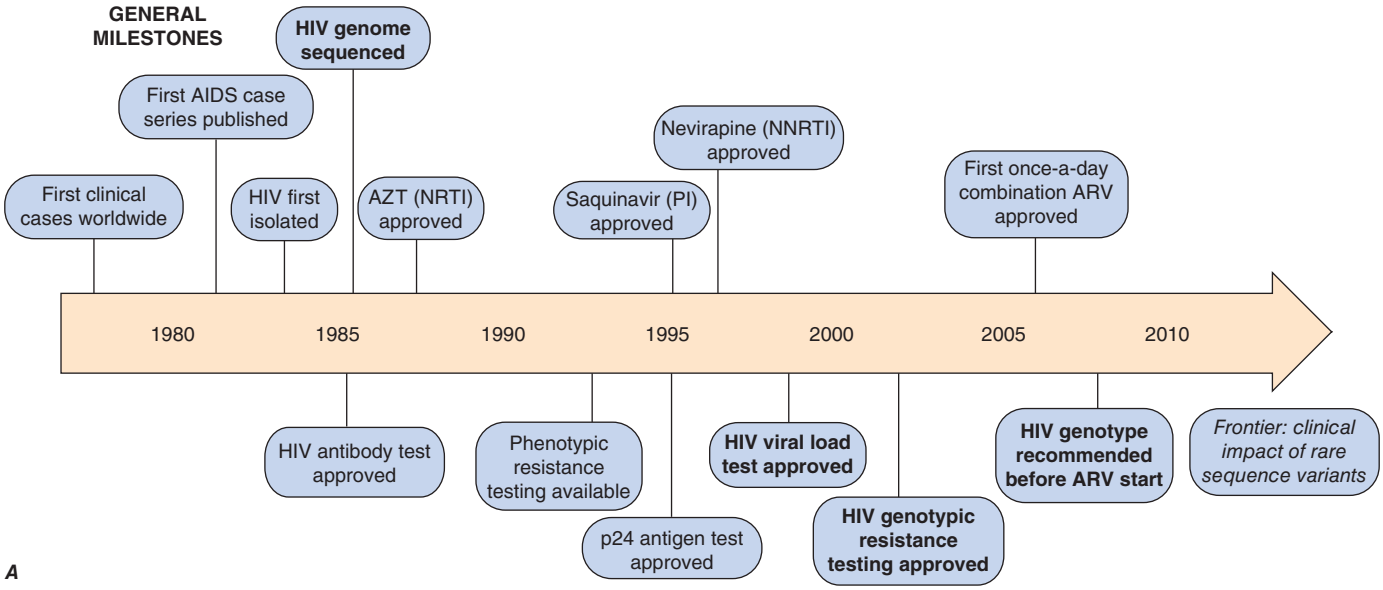
active disease and possibly cross-reactive with vaccines or other mycobacteria. Even the newer interferon γ release assays (IGRAs), which measure cytokine release from T lymphocytes in response to *Mycobacterium tuberculosis*–specific antigens in vitro, have limited sensitivity in immunodeficient hosts. Neither PPD testing nor IGRAs can distinguish latent from active infection. Serologic Lyme disease diagnostics suffer similar limitations: in patients from endemic regions, the presence of IgG antibodies to *Borrelia burgdorferi* may reflect prior exposure rather than active disease, while IgM antibodies are imperfectly sensitive and specific (50% and 80%, respectively, in early disease). The complicated nature of these tests, particularly in view of the nonspecific symptoms that may accompany Lyme disease, has had substantial implications for public perception of Lyme disease and antibiotic misuse in endemic areas. Similarly, syphilis, a chronic infection caused by *Treponema pallidum*, is notoriously difficult to stage by serology alone, requiring multiple different nontreponemal and treponemal tests (e.g., rapid protein reagin and fluorescent treponemal antibody, respectively) in conjunction with clinical suspicion. Complementing serology, antigen detection can improve sensitivity and specificity in select cases but has been validated only for a limited set of infections. Typically, structural elements of pathogens are detected, including components of viral envelopes (e.g., hepatitis B surface antigen, HIV p24 antigen, SARS-CoV-2 spike protein), cell surface markers in certain bacteria (e.g., *Streptococcus pneumoniae*, *Legionella pneumophila* serotype 1) or fungi (e.g., *Cryptococcus*, *Histoplasma*), and less specific fungal cell-wall components such as galactomannan and β-glucan (e.g., *Aspergillus* and other fungi).

Given the impracticality of culture and the lack of sensitivity or sufficient clinical information afforded by serologic and antigenic methods, the push toward nucleic acid–based diagnostics originated in pursuit of viruses and fastidious bacteria, becoming part of the standard of care for select organisms in U.S. hospitals. Such tests, including polymerase chain reaction (PCR) and other nucleic acid amplification tests (NAATs), are now widely used for many viral infections, both chronic (e.g., HIV infection, hepatitis C) and acute (e.g., influenza, SARS-CoV-2, respiratory syncytial virus). NAATs provide essential information about both the initial diagnosis and the response to therapy and, in some cases, genotypically predict drug resistance. Indeed, progression from antigen detection to PCR transformed our understanding of the natural course of HIV infection, with profound implications for treatment **(Fig. 126-1*A*)**. In the early years of the AIDS pandemic, p24 antigenemia was detected in acute HIV infection but then disappeared for years before emerging again with progression to AIDS **(Fig. 126-1*B*)**. Without a marker demonstrating viremia, the role of treatment during HIV infection prior to the development of clinical AIDS was uncertain, and assessing treatment efficacy was challenging. With the emergence of PCR as a progressively more sensitive test (now able to detect as few as 20 copies of virus per milliliter of blood), viremia was recognized as a near-universal feature of HIV infection. Given the challenges of phenotypic assays, genotypic antiviral resistance testing was also adopted early for HIV and is now the standard of care before the initiation of therapy in developed countries. These developments have been transformative in guiding therapy in early disease and, together with the development of less toxic therapies, have helped to shape policy that is moving toward ever-earlier introduction of antiretroviral therapy in HIV infection. Reverse transcriptase PCR (RT-PCR) assays are the core method for detecting SARS-CoV-2 virus in the acute phase, forming a critical component of the clinical and public health response to COVID-19, just as they were on a smaller scale for the related coronaviruses SARS-CoV and Middle East respiratory syndrome (MERS)-CoV. Tests for SARS-CoV-2 represent the largest implementation of a molecular infectious disease assay to date and play a critical role in both clinical diagnostics and public health measures to contain the COVID-19 pandemic.

As they are for viral testing, nucleic acid–based tests have become the diagnostic tests of choice for fastidious bacteria, including the common sexually transmitted bacterial pathogens *Neisseria gonorrhoeae* and *Chlamydia trachomatis* as well as the tick-borne *Ehrlichia chaffeensis* and *Anaplasma phagocytophilum*. More recently, nucleic acid amplification–based detection has offered improved sensitivity for diagnosis of the important nosocomial pathogen *Clostridioides difficile*, and NAATs have provided clinically relevant information on the presence of cytotoxins A and B as well as molecular markers of hypervirulence, such as the North American pulsotype 1 (NAP1) strain that is enriched in severe illness. The importance of genomics in selecting loci for diagnostic assays and in monitoring test sensitivity was highlighted by the emergence in Sweden of a newly recognized variant of *C. trachomatis* with a deletion that includes the gene targeted by a set of commercial NAATs. By evading detection through this deletion (and thus avoiding treatment), this strain came to be highly prevalent in some areas of Sweden. While nucleic acid–based tests remain the diagnostic approach of choice for fastidious bacteria, this example of "diagnostic escape" serves as a reminder of the need for careful development and ongoing monitoring of molecular diagnostics.

In contrast, for typical bacterial pathogens for which culture methods are well established, growth-based assays still dominate in the

TABLE 126-2 Selected Clinical Applications of Infectious Disease Genomics



APPLICATION	TECHNOLOGY	NOTES/EXAMPLES
Organism Identification		
Viral detection	PCR, RT-PCR	Identification of HIV, HBV, HCV, respiratory viruses including SARS-CoV-2 and influenza, and others for diagnosis and response to therapy
TB detection	PCR	Amplification of the *rpoB* gene for species-specific identification of *Mycobacterium tuberculosis*
Pathogen detection	PCR, RT-PCR, NAAT	Multiplexed identification of dozens of viruses, bacteria, yeasts, and parasites from a variety of clinical specimens
Bacterial detection	16S ribosomal gene sequencing	Targeted amplification and sequencing of regions of the 16S rRNA gene for identification of suspected bacterial infections undiagnosed by conventional methods
Pathogen detection	Cell-free DNA sequencing	Unbiased amplification and sequencing of cell-free nucleic acid from blood, with analytical comparison of resulting nonhuman sequences to genomes of known pathogens and contaminants, in order to identify circulating pathogen DNA; anecdotal clinical use to establish etiology of systemic or focal infection, though clinical utility and optimal use cases still evolving
Pathogen Discovery		
Bacterial pathogens	Sequencing, metagenomic assembly	Unbiased "shotgun" sequencing of isolated nucleic acid from patient samples to identify associated pathogens; proofs-of-concept: new *Bradyrhizobium* species associated with cord colitis; *Escherichia coli* O104:H4 from 2011 diarrheal outbreak in Germany; *Leptospira* species from one patient's cerebrospinal fluid; research use only at this time
Viral pathogens	Microarray, sequencing	Hybridization of clinical samples to microarrays from phylogenetically diverse known viruses identified the first SARS coronavirus and others. Direct sequencing has identified SARS-CoV-2, West Nile virus, and MERS-CoV, among others. Use is primarily in research.
Antibiotic Resistance		
MRSA detection	PCR	Detection of the *mecA* gene, the genotypic cause of methicillin resistance in *Staphylococcus aureus*
VRE detection	PCR	Detection of the *vanA* or *vanB* gene, the main genotypic causes of vancomycin resistance in *Enterococcus*
MDR-TB detection	PCR, NAAT	Detection of polymorphisms in the *rpoB* gene from *M. tuberculosis*, which account for 95% of rifampin resistance. Other probes available for *inhA* and *katG* genes can detect up to 85% of isoniazid resistance.
Carbapenemase detection	PCR	Detection of genes encoding one of several types of enzymes (KPC, NDM, OXA-48, IMP, VIM) that hydrolyze carbapenems, accounting for much but not all carbapenemase resistance in Enterobacteriaceae
HIV resistance detection	Targeted sequencing	Targeted sequencing of specific genes with known resistance-conferring mutations; now the standard of care prior to initial therapy in the United States and Europe
Epidemiology		
Outbreak and epidemic tracking	Sequencing	Application to tracking outbreaks and epidemics on local and international scales, including spread of carbapenemase-producing *Klebsiella*, *S. aureus*, *M. tuberculosis*, *E. coli*, *Vibrio cholerae*, Ebola virus, Zika virus, and influenza virus
Evolution and spread of pathogens	Sequencing	Sequencing collections of pathogens from individual patients or environmental reservoirs such as wastewater to shed light on pathogen dissemination, virulence factors, and antibiotic resistance determinants; innumerable examples, including *V. cholerae*, influenza virus, Ebola virus, Zika virus, and SARS-CoV-2

Abbreviations: HBV, hepatitis B virus; HCV, hepatitis C virus; MDR, multidrug-resistant; MERS, Middle East respiratory syndrome; MRSA, methicillin-resistant *S. aureus*; NAAT, nucleic acid amplification test; PCR, polymerase chain reaction; RT, reverse transcriptase; SARS, severe acute respiratory syndrome; TB, tuberculosis; VRE, vancomycin-resistant enterococci.

clinical laboratory. Informed by decades of clinical microbiology, these tests have served clinicians well, yet the limitations of growth-based tests—in particular, the delays associated with waiting for growth—have left opportunities for improvements. Driven by this need, mass spectrometry–based assays that offer highly accurate organism identification within a few hours of a positive blood culture are widely adopted in clinical microbiology laboratories, largely supplanting biochemical tests for organism identification in well-resourced areas. Looking ahead, molecular diagnostics, greatly informed by the vast quantity of microbial genome sequences generated in recent years, offers a way forward. First, sequencing studies can readily identify key genes (or noncoding nucleic acids) that can be developed into targets for clinical assays using PCR or hybridization assay platforms. Second, sequencing itself is becoming cheap and rapid enough to be performed on clinical specimens in certain cases, with consequent unbiased detection or characterization of pathogens.

One of the biggest drivers for the implementation of novel molecular technologies in the diagnosis of infectious diseases is the desire for more rapid—or even real-time—pathogen identification, ideally with antibiotic susceptibility information on those microbes for which resistance to the current anti-infective armamentarium is of concern. Such real-time tests have the potential to transform infectious disease management, impacting antibiotic stewardship in the outpatient setting, mortality risk in the critically ill (i.e., patients in whom early administration of effective antibiotics is the most significant factor in decreasing mortality risk), hospital admission, and length of hospital stay; the extent of this impact will depend on the economic forces that will help define the breadth of their deployment. On the public health level, such tests will likely play a role in improving antibiotic stewardship, thereby influencing the rise of antibiotic resistance and enabling surveillance of outbreaks by local, national, and international networks. In the United States and the United Kingdom, for example, public health agencies use genome sequencing to track food-borne pathogens and identify outbreaks and have rapidly expanded the routine use of genomics in identifying and characterizing other pathogens, from mycobacteria (both *M. tuberculosis* and nontuberculous mycobacteria) to *N. gonorrhoeae*. Further, international efforts to track the spread of viral diseases, particularly the vast efforts to sequence SARS-CoV-2 and monitor the emergence and spread of its variants, as well as recent work on mpox, Ebola, and Zika outbreaks and ongoing work on seasonal influenza, offer opportunities for improving interventions, surveillance, and prevention efforts, ranging from more accurate selection of the strains to include in vaccine development to improved design of trials to evaluate novel vaccines and therapies.

Technological innovations are lowering several critical barriers to the widespread adoption of genomics and other molecular methods. Specifically, for NAAT, the need for rapid thermal cycling and cold-chain storage for reagents has significantly impeded implementation

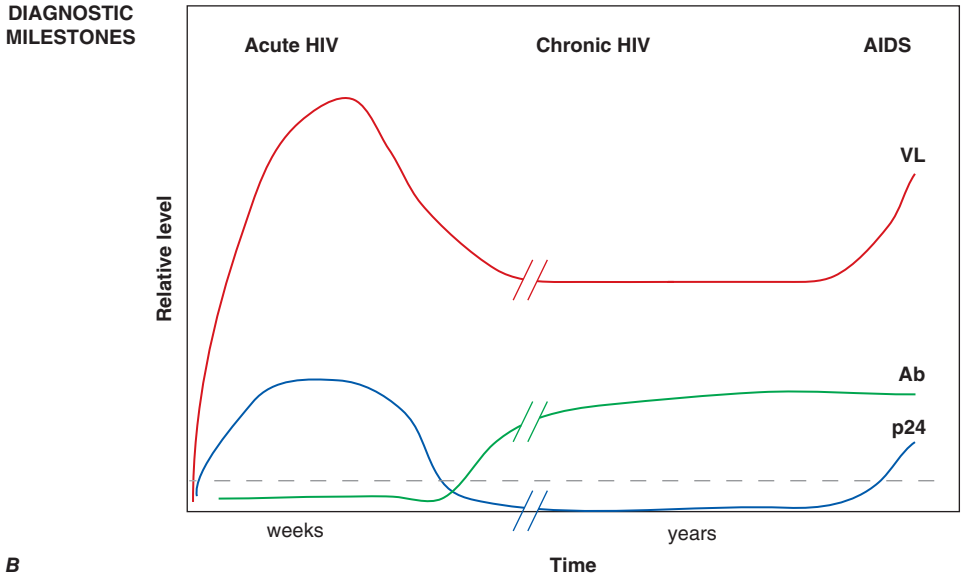


FIGURE 126-1 ***A.*** Timeline of select milestones in HIV management. Genomic advances are shown in bold type. The approvals and recommendations indicated apply to the United States. ARV, antiretroviral; AZT, zidovudine; NRTI, nucleoside reverse transcriptase (RT) inhibitor; NNRTI, nonnucleoside RT inhibitor; PI, protease inhibitor. ***B.*** Viral dynamics in the natural history of HIV infection. Three diagnostic markers are shown: HIV antibody (Ab), p24 antigen (p24), and viral load (VL). *Dashed gray line* represents limit of detection. *(Adapted from data in HH Fiebig et al: Dynamics of HIV viremia and antibody seroconversion in plasma donors: Implications for diagnosis and staging of primary HIV infection. AIDS 17:1871, 2003.)*

in resource-limited settings. Recent efforts aim to overcome these challenges by developing isothermal amplification protocols and lyophilized reagents that do not require refrigeration or sophisticated instrumentation. For clinical sequencing, (1) the cost and speed of sequencing and analysis methods continue to fall precipitously; (2) automation and miniaturization of the preparation of a sample for sequencing promise to reduce cost and minimize the expertise needed; and (3) direct sequencing technologies that eliminate the complex molecular biology required to prepare clinical samples for sequencing are improving in accuracy and robustness. Further barriers exist, including the need for careful processing of clinical samples to minimize contamination, and standardized pipelines to process data and present clinicians with easily interpretable and readily actionable results. However, as these advances give rise to rapid, accurate diagnostic tests, the ultimate goal is to inform a clinician in real time whether antibiotics are indicated and, if so, which will be effective. Real-time diagnostics will allow more efficient deployment of our precious antibiotic arsenal, thus improving both societal and patient-specific outcomes in much the same way that a rapid, sensitive troponin assay has transformed bedside management of chest pain.

ORGANISM IDENTIFICATION

To adapt nucleic acid detection to diagnostic tests and thus to identify pathogens on a wide scale, sequences must be found that are conserved enough within a species to identify the diversity of strains that may be encountered in various clinical settings, but divergent enough to distinguish one species from another. Until recently, this problem has been solved for bacteria by targeting the element of a bacterial genome that is most highly conserved within a species, the 16S ribosomal RNA (rRNA) subunit. Among many examples, this method has now been used to confirm *Mycobacterium chimaera* infections in several patients after cardiothoracic surgery, leading ultimately to recognition of a widespread outbreak. At present, 16S PCR amplification from tissue specimens can be performed by specialty laboratories, though its sensitivity and clinical utility to date have remained somewhat limited, in part because of the scarcity and relative fragility of pathogen nucleic acid in the sampled tissue, which necessitates reliable, sensitive nucleic acid amplification. As such barriers are reduced through technological advances and as the causes of culture-negative infection are clarified (perhaps in part through sequencing efforts), these tests may become both more accessible and more helpful.

With the wealth of sequencing data now available, other regions beyond 16S rRNA can be targeted for bacterial species identification. These other genomic loci can provide additional information about a clinical isolate that is relevant to patient management. For instance, detection of the presence, or potentially even the expression, of toxin genes such as *C. difficile* toxins A and B or Shiga toxin can provide clinicians with additional information that will help distinguish commensals or colonizing bacteria from pathogens and thus aid in prognostication and management as well as in diagnosis.

Beyond bacteria, one commonly used approach to PCR-based pathogen detection is so-called "syndromic panels" of multiplexed PCR to identify common causes of clinical infection syndromes, including upper respiratory infection, gastroenteritis, and meningoencephalitis. The most frequently deployed syndromic panel is the respiratory viral panel, which typically includes primer sets targeting a combination of influenza, parainfluenza, respiratory syncytial virus, adenovirus, rhinovirus, enterovirus, metapneumovirus, and common-cold coronaviruses, sometimes in conjunction with unculturable bacteria such as *Mycoplasma*, *Chlamydophila*, and *Bordetella* species. With the advent of the COVID-19 pandemic, SARS-CoV-2 was quickly added to this multiplex PCR panel within months of its development as a stand-alone PCR test. The goal of such panels is to capture common infectious causes of these syndromes in a single, standardized diagnostic test, ideally streamlining the diagnostic evaluation. The ready identification of a plausible etiologic agent may offer diagnostic clarity if judiciously used and carefully considered in the clinical context of each patient. The widespread adoption of SARS-CoV-2 PCR testing in the earliest days of the COVID-19 pandemic underscored the crucial role of precise etiologic pathogen diagnosis in patient care, triage, infection control, and epidemiology.

One challenge with PCR-based assays is the relative complexity of the molecular biology and consequent need for advanced technology for implementation, including instruments and reagents. Several recent approaches have advanced the molecular biology of nucleic acid detection with the aim of increasing deployability of NAATs for use in resource-limited or even field settings. These methods couple nucleic acid detection to an enzymatic readout, enabling catalytic signal amplification. Several such approaches build on the intrinsic sensitivity, specificity, and amplification of the CRISPR (*c*lustered, *r*egularly *i*nterspaced *s*hort *p*alindromic *r*epeats) effectors Cas12a and Cas13a as nucleic acid sensors. Distinct from the famous gene editing CRISPR effector Cas9, these robust and versatile enzymes recognize short nucleic acid targets with high specificity and transduce this binding event into "collateral cleavage" of nearby nucleic acids that can be engineered to create a signal using fluorescent reporter constructs. Crucially, this biotechnology can be made to work in conjunction with isothermal enzymatic preamplification steps to achieve remarkable sensitivity, all robustly enough to withstand lyophilization that enables long-term storage before being reconstituted in the field. Such assays are still in the early stages of development, but they have shown promise and could play a critical role in global diagnostics and surveillance.

While amplification tests such as PCR and other NAATs exemplify one approach to nucleic acid detection, other approaches exist, including detection by hybridization. Although not currently used in the clinical realm, techniques for multiplexed detection and identification of pathogens by hybridization to microarrays or in solution are being developed for other purposes. Of note, these different detection techniques require different degrees of conservation. Highly sensitive amplification methods require a high degree of sequence identity between PCR primer pairs and their short, specific target sequences; even a single base-pair mismatch (particularly near the 3′ end of the primer) may interfere with detection. In contrast, hybridization-based tests are more tolerant of mismatch and thus can be used to detect important regions that may be less precisely conserved within a species, thus potentially allowing detection of clinical isolates from a given species with greater diversity between isolates. Such assays take advantage of the predictable binding interactions of nucleic acids and do not require enzymology, broadening the range of conditions under which such assays are feasible, including directly on primary clinical specimens. The applicability of hybridization-based methods toward either DNA or RNA opens the possibility of expression profiling, which can uncover phenotypic information from nucleic acid content.

Both PCR and hybridization methods target specific, known organisms. At the other extreme, as sequencing costs decline, metagenomic sequencing from patient samples is increasingly feasible. This shotgun sequencing approach is unbiased—i.e., can detect any microbial sequence, however divergent or unexpected. In one example, a clinical sample of cerebrospinal fluid from an immunocompromised patient with signs and symptoms of chronic meningitis was found through metagenomic sequencing and analysis to contain small amounts of *Leptospira* DNA. In light of this information, retrospective PCR testing confirmed the diagnosis of neuroleptospirosis, which had been missed prior to the sequencing result. The patient was treated with penicillin G and clinically recovered. Increasingly, efforts are under way to bring whole genome sequencing to other clinical samples, including sputum and blood, to more readily identify pathogens. One such assay certified for clinical use in the United States—a shotgun metagenomic sequencing approach applied to cell-free DNA circulating in the bloodstream that aims to identify pathogens both in blood and other body sites—is gaining adoption in cases where traditional culture-based methods fail to identify a pathogen in patients with symptoms consistent with infection. This new approach brings its own set of challenges, however, including the need to recognize pathogenic sequences against a background of expected host and commensal sequences and to distinguish true pathogens from either colonizers or laboratory contaminants. The burgeoning field of microbiome research is driving technology development for sequencing and analyzing complex microbial communities. Lessons from this field will inform diagnostic efforts.

PATHOGEN DISCOVERY

In addition to clinical diagnostic applications, novel genomic technologies, including whole genome sequencing, are being applied to clinical research specimens with a goal of identifying new pathogens in a variety of circumstances. The tremendous sensitivity and unbiased nature of sequencing is also ideal in searching clinical samples for unknown or unsuspected pathogens.

Causal inference in infectious diseases has progressed since the time of Koch, whose historical postulates provided a rigorous framework for attributing a disease to a microorganism. To modernize Koch's postulates, an organism, whether it can be cultured or not, should induce disease upon introduction into a healthy host if it is to be implicated as a causative pathogen. Current sequencing technologies are ideal for advancing this modern version of Koch's postulates because they can identify candidate causal pathogens with unprecedented sensitivity and in an unbiased way, unencumbered by limitations such as culturability. Yet, as direct sequencing on primary patient samples greatly expands our ability to recognize associations between microbes and disease states, critical thinking and experimentation will remain vital in establishing causality.

Virus discovery in particular has been greatly facilitated by new nucleic acid technology. These frontiers were first notably explored with high-density microarrays containing spatially arrayed sequences from a phylogenetically diverse collection of viruses. Despite bias toward those with homology to known viruses, novel viruses in clinical samples were successfully identified on the basis of their ability to hybridize to these prespecified sequences. This methodology famously contributed to identification of the coronavirus causing severe acute respiratory syndrome (SARS). Once discovered, the SARS coronavirus was rapidly sequenced: the full genome was assembled in April 2003, <6 months after recognition of the first case.

With the advent of next-generation sequencing, unbiased pathogen discovery is now addressed through a process known as *metagenomic assembly* **(Fig. 126-2)**, largely supplanting other methods. Sequences of random nucleotide fragments can be generated from clinical specimens with no a priori knowledge of pathogen identity through a process called *shotgun sequencing*. This collection of sequences can then be computationally aligned to host (i.e., human) sequences, with aligned sequences removed and remaining sequences compared with other

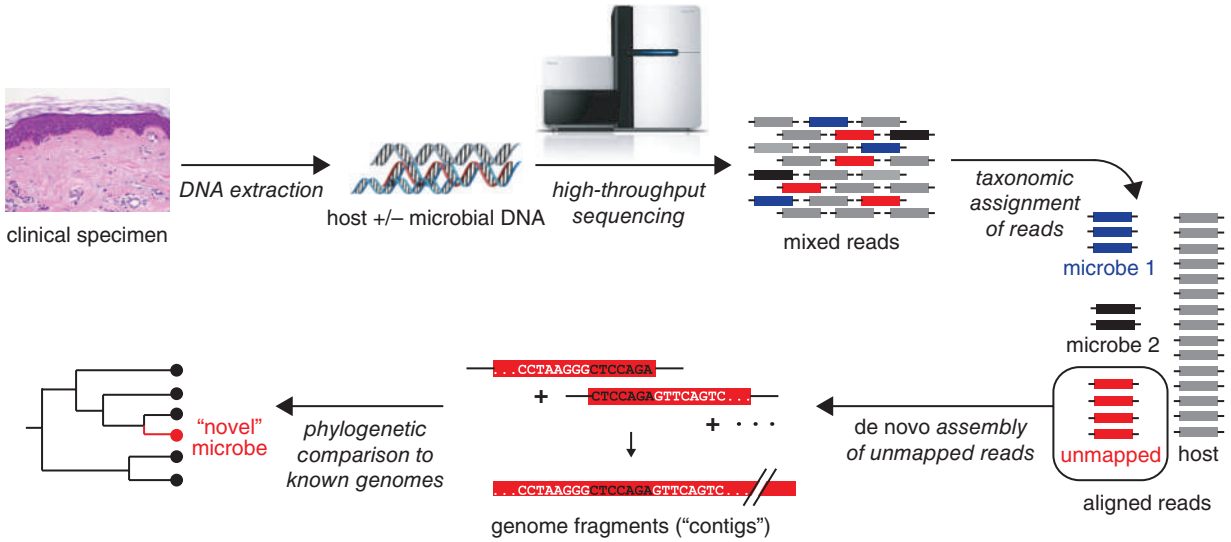

FIGURE 126-2 Workflow of metagenomic assembly for pathogen discovery. DNA is isolated from a specimen of interest (e.g., tissue, body fluid) containing a mixture of host DNA and nucleic acids from coexisting microbes, either commensal or pathogenic. All DNA (and RNA, if a reverse transcription step is added) is then sequenced, yielding a mixture of DNA sequence fragments ("reads") from the organisms present. Except for reads that do not align ("map") to any known sequence, these reads are aligned to existing reference genomes for the host or any known microbes. The unmapped reads are computationally assembled de novo into the largest contiguous stretches of DNA possible ("contigs"), representing fragments of previously unsequenced genomes. These genome fragments (contigs) are then mapped onto a phylogenetic tree based on their sequence. Some may represent known but as-yet-unsequenced organisms, while others will represent novel species. *(Figure prepared with valuable input from Dr. Ami S. Bhatt, personal communication.)*

known genomes to detect the presence of known microorganisms. Sequence fragments that remain unaligned suggest the presence of an additional organism that cannot be matched to a known, characterized genome; these reads can be assembled into contiguous nucleic acid stretches that can be compared with known sequences to construct the genome of a potentially novel organism. Assembled genomes (or parts of genomes) can then be compared with known genomes to infer the phylogeny of new organisms and identify related classes or traits. Thus, not only can this process identify unanticipated pathogens, but it can even identify undiscovered organisms.

The emergence of COVID-19 provides a dramatic example that illustrates advances in pathogen discovery technology in the intervening 16 years since SARS-CoV was discovered: the causal coronavirus, SARS-CoV-2, was identified through metagenomic sequencing within about 1 month of the first known case and just weeks after the outbreak was first recognized. Sequencing and assembly were completed within 5 days of the discovery of the new virus, and a NAAT was released 1 day later. Given the ensuing ravages of COVID-19 and the cost of delays of even a few weeks in implementing this new diagnostic test in some locations, it is sobering to contemplate the added harm had this outbreak occurred even a decade earlier. This timeline illustrates the advancing power and speed of new diagnostic technologies but also underscores the pressing need for continued progress.

As metagenomic sequencing and assembly techniques become more robust, this technology holds great promise for identifying microorganisms that are associated with clinical conditions of unknown etiology. Conventional methods already have unexpectedly linked numerous conditions with specific agents of infection—e.g., cervical and oropharyngeal cancers with human papillomavirus (HPV), Kaposi's sarcoma with human herpesvirus 8, and certain lymphomas and, more recently, multiple sclerosis with Epstein-Barr virus. Recently, Zika virus, first described in the 1940s, was found to be increasing in incidence as a cause of febrile syndromes, particularly in Central and South America. A concurrent increase in the incidence of microcephaly was noted that temporally and geographically matched the Zika epidemics. Zika was suspected to be neurotropic because of a previously recognized association with Guillain-Barré syndrome, but the strongest link between Zika virus and microcephaly came when the virus itself was detected by both quantitative reverse transcription PCR (RT-qPCR) and whole genome sequencing in postmortem fetal brain tissue from microcephalic infants. An argument for causality was built on the foundation of epidemiologic evidence and direct viral detection, both of which were built on nucleic acid detection and genome sequencing. Sequencing techniques offer unprecedented sensitivity and specificity for identifying foreign nucleic acid sequences that may suggest other such pathogen-associated conditions—from malignancies to inflammatory conditions to unexplained fevers or other clinical syndromes—associated with organisms from viruses to bacteria to parasites. Caution is needed, though: in the absence of the ability to fulfill Koch's postulates, sequence-based identification of a microbe from patient specimens is not, on its own, sufficient to ascribe pathogenicity. The increasing sensitivity of these methods warrants greater rigor and care in defining what is "noise" and what represents a pathogen.

As sequencing-based discovery expands, microbes may be found to be associated with conditions not classically thought of as infectious, such as the link between maternal Zika virus infection and fetal microcephaly. Studies of bowel flora in laboratory animals and even humans already suggest correlations between microbe composition and various aspects of metabolic and cardiovascular health. Improved methods for pathogen detection will continue to uncover unexpected correlations between microbes and disease states, but the mere presence of a microbe does not establish causality. Fortunately, once the relatively laborious and computationally intensive metagenomic sequencing and assembly efforts have identified a pathogen, further detection can more easily be undertaken with targeted methods such as PCR or hybridization, which may be more scalable and amenable to in situ confirmation. This capacity should facilitate the additional careful investigation that will be required to progress beyond correlation and to draw causal inference.

ANTIBIOTIC RESISTANCE

At present, antibiotic resistance in bacteria and fungi is conventionally determined by isolating a single colony from a cultured clinical specimen and testing its growth in the presence of drug. The requirement for multiple growth steps in these conventional assays has several consequences. First, only culturable pathogens can be readily processed. Second, this process requires considerable infrastructure to support the sterile environment needed for culture-based testing of diverse organisms. Finally, and perhaps most significantly, even the fastest-growing organisms require 1–2 days of processing for identification and 2–3 days for determination of susceptibilities. Some slow-growing organisms take even longer; for instance, weeks must pass before

drug-resistant *M. tuberculosis* can be identified by growth phenotype. Given the clinical imperative in serious illness to begin effective therapy early, this inherent delay in susceptibility determination has obvious implications for empirical antibiotic use: broad-spectrum antibiotics often must be chosen up front in situations where it is later shown that preferred narrower-spectrum drugs would have been effective or even that no antibiotics were appropriate (i.e., in viral infections). Even with this strategy, as resistant organisms become more common, the empirical choice can be incorrect, often with devastating consequences. Real-time identification of the infecting organism and information on its susceptibility profile would guide initial therapy and support judicious antibiotic use, ideally improving patient outcomes while aiding in the ever-escalating fight against antibiotic resistance by reserving the use of broad-spectrum agents for cases in which they are truly needed.

Molecular diagnostics and sequencing offer a way to accelerate detection of a pathogen's antibiotic susceptibility profile. If a genotype that confers resistance can be identified, this genotype can be targeted for molecular detection. In infectious disease, this approach has most comprehensively come to fruition for HIV (Fig. 126-1*A*). (In a conceptually parallel application of genomic analysis, molecular detection of certain resistance determinants in cancers informs selection of targeted chemotherapy.) Extensive sequencing of HIV strains and correlations drawn between viral genotypes and phenotypic resistance have delineated the majority of mutations in key HIV genes, such as reverse transcriptase, protease, and integrase, that confer resistance to the antiretroviral agents that target these proteins. For instance, the single amino acid substitution K103N in the HIV reverse transcriptase gene predicts resistance to the first-line nonnucleoside reverse transcriptase inhibitor efavirenz, and its detection informs a clinician to choose a different agent. The effects of these common mutations on HIV susceptibility to various drugs—as well as on viral fitness—are curated in publicly available databases. Thus, genotypes are now routinely used to predict drug resistance in HIV, as phenotypic resistance assays are far more cumbersome than targeted sequencing. Though it was not implemented at the level of individual patients, sequencing-based detection of circulating SARS-CoV-2 variants predicted susceptibility to monoclonal antibodies due to changes in the spike protein and, thus, informed decisions made by the U.S. Food and Drug Administration (FDA) on granting and rescinding approval for such COVID-19 therapies as the pandemic progressed. As new therapies are introduced, this targeted sequencing–based approach to drug resistance will likely prove important in other viral infections.

The challenge of predicting drug susceptibility from genotype is more daunting for bacteria than for HIV, yet considerable progress has been made toward sequencing-based determination of bacterial antibiotic susceptibility. Bacteria have far more complex genomes than viruses, with thousands of genes on their chromosomes (many of which can functionally interact in ways that escape a priori prediction) and the capacity to acquire many more through horizontal gene transfer of plasmids and mobile genetic elements within and between species. Thus, the task of comprehensively defining all possible genetic resistance mechanisms is orders of magnitude more complex in bacteria than in viruses, which typically have far more limited genomes. Despite these challenges, considerable progress has been made in recent years. In select cases where biological factors appear to have constrained the genotypic basis for resistance to a small, well-defined set of mutations, genotypic assays for antibiotic resistance are already being integrated into clinical practice. One important example is the detection of methicillin-resistant *Staphylococcus aureus* (MRSA). *S. aureus* is one of the most common and serious bacterial pathogens of humans, particularly in health care settings. Resistance to methicillin—the most effective class of antistaphylococcal antibiotics—is common, even in community-acquired strains. Vancomycin—an alternative drug to methicillin—is effective against MRSA but is measurably inferior to methicillin against methicillin-susceptible *S. aureus* (MSSA). Analysis of clinical MRSA isolates has demonstrated that the molecular basis for resistance to methicillin in essentially all cases stems from the expression of an alternative penicillin-binding protein (PBP2A) encoded by the gene *mecA*, which is found within a transferable genetic element called *mec*. This mobile cassette has spread rapidly through the *S. aureus* population via horizontal gene transfer and selection from widespread antibiotic use. Because methicillin resistance is essentially always due to the presence of the *mecA* gene, MRSA is particularly amenable to molecular detection. A PCR test for the *mecA* gene, which saves hours to days compared with standard culture-based methods, has been approved by the FDA to augment (but not replace) traditional culture-based susceptibility testing. Similar to MRSA, vancomycin-resistant enterococci (VRE) harbor one of a limited number of *van* genes found to be responsible for resistance to this important antibiotic, which occurs through alteration of the mechanism for cell wall cross-linking that vancomycin inhibits. Detection of one of these genes by PCR indicates resistance. More recently, multiplexed PCR assays targeting carbapenemase genes (those encoding the KPC, NDM, OXA-48, IMP-1, and VIM carbapenemases), which are responsible for a significant fraction of carbapenem resistance (though not all instances), can predict some resistance to this crucial antibiotic class, though they are not comprehensive enough to confirm susceptibility if absent. Despite these caveats, such assays to detect even a limited set of high-value resistance genes are gaining use in high-resourced settings. Finally, a PCR assay targeting the highly conserved RNA polymerase gene serves not only to detect *M. tuberculosis* directly in sputum samples but also to detect resistance to rifampin, since the determinants of resistance to this RNA polymerase inhibitor map almost exclusively to a short region of this gene. Since rifampin resistance is epidemiologically associated with, though not causal for, multidrug resistance, this assay identifies strains at high risk for multidrug resistance, enhancing its value. This test has transformed tuberculosis testing where available, improving sensitivity and providing a limited measure of susceptibility testing to guide therapy.

Although identification and rapid detection of monogenic resistance determinants have improved, bacteria typically evolve multiple, diverse resistance mechanisms to most antibiotics; thus, outside of these edge cases, resistance prediction often requires probing for and integration of multiple genetic lesions, targets, or mechanisms. For instance, at least five distinct modes of resistance to fluoroquinolones are known: reduced import, increased efflux, target site mutation, drug modification, and shielding of the target sites by expression of another protein. These mechanisms are typically present in combination in clinically resistant isolates; thus, the problem of detecting genetic resistance is often a combinatorial one. In another clinically important example, while carbapenem resistance in Enterobacteriaceae is often explained by the presence of carbapenemases, resistance may also develop when other, less broad-spectrum β-lactamases are found in combination with porin mutations or upregulated efflux pumps. These more complex mechanisms prevent PCR-based carbapenemase detection assays from identifying other mechanisms of carbapenem resistance. Additionally, plasmids and transposable elements, which often are enriched for antibiotic resistance determinants, may be more technically and analytically challenging to sequence, although newer long-read sequencing technologies are beginning to address these challenges. To further complicate genetic prediction, changes in gene expression (which may be detectable through mutations in promoter regions or regulatory genes without coding mutations in known resistance determinants) and even gene copy number (which may occur without changes in primary sequence) of resistance determinants play critical roles in some cases of genetic resistance. Thus, while predicting resistance when determinants are found is rapidly becoming feasible, the more clinically relevant task of predicting *susceptibility* when no known resistance determinants are found remains more difficult.

To build on early successes with the goal of advancing beyond binary detection of monogenic resistance determinants, the ultimate frontier for genetic prediction of bacterial antibiotic resistance lies in more comprehensive prediction of a resistance phenotype from sequence information—a task similar to HIV resistance prediction. Yet there is no comprehensive compendium of genetic elements conferring resistance and their pairwise and higher-order interactions with each other and with the genetic background of bacterial pathogens. Non-viral genomes are much larger than viral ones, and their abundance

and diversity are such that thousands of genetic differences often exist between clinical isolates of the same species, of which perhaps only one or a few may contribute to resistance. In addition, new mechanisms may emerge in the face of antibiotic deployment or with the release of new drugs, and genetic prediction of resistance will inevitably lag behind the emergence of unforeseen mechanisms. While confident prediction of bacterial antibiotic resistance from sequencing determinants may therefore seem daunting, the vast expansion of microbial sequencing capacity, combined with analytic methods such as microbial genome-wide association studies and machine learning algorithms, offers powerful analytical approaches to this "needle in a haystack" problem and has permitted remarkable advances in the predictive power of sequence determinants to date. Particularly in *M. tuberculosis*, where horizontal gene transfer is minimal and the pathogen is essentially restricted to human hosts to facilitate more representative sampling, a remarkable fraction of phenotypic resistance can be explained by known genetic determinants. Because of these biologic advantages, as well as the slow and laborious growth process that impedes traditional phenotypic assessment, whole genome sequencing has proven quite effective at predicting susceptibility profiles in this organism, to the point that the United Kingdom now routinely performs whole genome sequencing in parallel with phenotypic antibiotic susceptibility testing for *M. tuberculosis* in what some hope will be a precursor to fully whole genome sequencing–based antibiotic susceptibility testing. Even in more highly variable pathogens, with sequencing of sufficient numbers of susceptible and resistant pathogens, and more sophisticated analytical algorithms, sequence-based prediction methods are improving in predictive accuracy, at least within the geographic region from which the test samples have been sequenced.

It is important to note that genotype-based analytical methods largely identify correlates, not necessarily surrogates or determinants, of resistance. In HIV diagnostics, surrogates (i.e., causal determinants of resistance) were found to be more reliable predictors than mere correlates in expanding sequencing-based resistance prediction to the general population. Without a mechanistic understanding of genetic resistance, a correlative relationship may be lineage-specific and less generalizable. Especially with multiple possible mechanisms of resistance to a given antibiotic and ongoing evolutionary pressure resulting in the development and acquisition of new modes of resistance, a genotypic approach to diagnosing antibiotic resistance is likely to remain challenging and to require ongoing vigilance in constantly correlating genotypic with more traditional phenotypic methods. An important corollary benefit of a genomic approach to resistance prediction, anchored in phenotypic validation, could be the systematic identification of outliers with unexplained resistance. These strains can form the basis for understanding newly emerging resistance mechanisms, which can in turn inform new drug development endeavors. Understanding resistance mechanisms may also help direct infection control efforts. For instance, the first identification of the *mcr-1* (mobilized colistin resistance) gene on a plasmid, together with other antibiotic resistance determinants, heightened concern about colistin-resistant Enterobacterales identified first in China and later elsewhere because it implied transferrable multidrug resistance. Early recognition of these potentially dangerous strains elucidated the immediate need for strict containment protocols. Furthermore, metagenomic studies have highlighted the silent carriage of resistance genes in the microbiomes of returning travelers and their subsequent spread to household contacts.

In parallel with advancing sequencing technologies, progress in computational techniques, bioinformatics and statistics, and data storage, as well as experimental confirmatory testing of hypotheses, will be needed to advance toward the ambitious goal of a comprehensive compendium of global antibiotic resistance determinants. Open sharing and careful curation of new sequence information will be of paramount importance, as will iterative or even continuous comparison of predictions with ongoing phenotypic testing to assess performance and allow prediction algorithms to keep up with newly evolving or emerging resistance mechanisms.

We continuously observe the accumulation of new or unanticipated modes of resistance from ongoing evolutionary pressure caused by the widespread clinical use of antibiotics. Even with MRSA, perhaps the best-studied case of antibiotic resistance and a model of relative simplicity with a single known monogenic resistance determinant (*mecA*), a genotype-based approach to resistance detection proved imperfect. One limitation was a recall of the initial commercial genotypic resistance assay that was deployed for the identification of MRSA. A clinical isolate of *S. aureus* that emerged in Belgium expressed a variant of the *mec* cassette not detected by the assay's PCR primers. New primers were added to detect this new variant, and the assay was reapproved for use. This example illustrates the need for ongoing monitoring of any genotypic resistance assay. A second limitation is that a contradiction can occur between genotypic and phenotypic evidence for resistance. Up to 5% of MSSA strains have been reported to carry a copy of the *mecA* gene that is either nonfunctional or not expressed. Thus, the erroneous identification of these strains as MRSA by genotypic detection would lead to administration of the inferior antibiotic vancomycin rather than the preferred β-lactam therapy.

These examples illustrate one of the prime challenges of moving beyond growth-based assays: genotype is merely a proxy for the resistance phenotype that directly informs patient care. Alternative approaches currently under development attempt to circumvent the limitations of genotypic resistance testing by returning to phenotypic assays, albeit more rapid ones. One such approach is informed by genomic methods: transcriptional profiles serve as a rapid phenotypic signature for antibiotic response. Conceptually, since dying cells are transcriptionally distinct from cells fated to survive, susceptible bacteria enact different transcriptional profiles after antibiotic exposure than resistant ones, independent of the mechanism of resistance. These differences can be measured and, since transcription is one of the most rapid responses to cell stress (minutes to hours), can be used to determine whether cells are resistant or susceptible much more rapidly than is possible if growth in the presence of antibiotics is awaited (days). Like DNA, RNA can be readily detected through predictable rules governing base pairing via either amplification or hybridization-based methods. Changes in a carefully selected set of transcripts form an expression signature that can represent the total cellular response to antibiotic without requiring full characterization of the entire transcriptome. Preliminary proof-of-concept studies suggest that this approach may identify antibiotic susceptibility based on transcriptional phenotype much more quickly than is possible with growth-based assays. Other rapid phenotype-based approaches to antibiotic susceptibility testing, including automated microscopy, ultrafine measurements of mass fluctuations, and others, are under development as well, with the former approved for clinical use.

Because of its sensitivity in detecting even very rare nucleic acid fragments, sequencing provides an unprecedented depth of study into complex populations of cells and tissues. The strength of this depth and sensitivity applies not only to the detection of rare, novel pathogens in a sea of host signal but also to the identification of heterogeneous pathogen subpopulations in a single host that may differ, for example, in drug resistance profiles or pathogenesis determinants. For instance, recent studies have highlighted the diversification of pathogens in chronic bacterial infections, such as *Pseudomonas* in the lungs of patients with cystic fibrosis or *M. tuberculosis* in disseminated infection, perhaps allowing for niche specialization within the host. Such diversification has long been recognized in chronic viral populations, as exemplified by HIV. Future studies will be needed to elucidate the clinical significance of these variable subpopulations, even as deep sequencing is now providing unprecedented levels of detail about majority and minority members of this population.

HOST-BASED DIAGNOSTICS

While pathogen-based diagnostics continue to be the mainstay for confirming infection, serologic testing and nonspecific biomarkers—such as erythrocyte sedimentation rate, C-reactive protein level, and even total white blood cell and neutrophil counts—have long been the basis of a strategy for measuring host responses to aid in the diagnosis of infection. Even recently identified host biomarkers of bacterial infection, such as procalcitonin, have fallen short in their versatility, with

positive and negative predictive values that are thus far adequate for only a few narrow applications but inadequate for generalized clinical use. Here, too, the application of genomics is now being explored to improve upon this approach, given the previously described limitations of serologic testing and the lack of specificity of protein biomarkers identified to date. Rather than using antibody responses as a retrospective biomarker for infection, recent efforts have focused on transcriptomic analysis of the host response as a new direction with diagnostic implications for human disease.

For instance, while pathogen-based diagnostic tests to distinguish active from latent tuberculosis infection have proven elusive, the transcriptional profile of circulating white blood cells exhibits a differential pattern of expression of nearly 400 transcripts that distinguish active from latent tuberculosis; this expression pattern is driven in part by changes in interferon-inducible genes in the myeloid lineage. In a validation cohort, this transcriptional signature was able to distinguish patients with active versus latent disease, to distinguish tuberculosis infection from other pulmonary inflammatory states or infections, and to track responses to treatment in as little as 2 weeks, with normalization of expression toward that of patients without active disease over 6 months of effective therapy. Such a test could play an important role not only in the management of patients but also as a marker of efficacy in clinical trials of new therapeutic agents. More recently, a distilled three-transcript signature has shown promise for distinguishing active from latent tuberculosis, raising hopes of a deployable assay in the near term.

Similarly, considerable progress has been made toward identifying host transcriptional signatures in circulating blood cells that distinguish viral from bacterial causes of upper respiratory infection, with better performance characteristics than current clinical parameters or available protein biomarkers. Additional host signatures have been reported that distinguish among bacterial infection, viral infection, and inflammatory states; identify Lyme disease; identify influenza; and even distinguish between gram-positive and gram-negative bacterial infections. In some cases, results have been extended to different host populations—including adults and children, and those with varying immune function—which obviously will be critical for generalizing such an approach. Thus, profiling of host transcriptional dynamics could augment the information obtained from studies of pathogens, both enhancing diagnosis and monitoring the progression of illness and the response to therapy. The frontier of genomic applications to understand host response to infection, with the potential of identifying biomarkers or even underlying disease biology, continues to rapidly advance, incorporating novel technological and computational approaches such as single-cell host transcriptional profiling of infected patients, to understand complex processes such as sepsis.

In this era of genome-wide association studies and attempts to move toward personalized medicine, genomic approaches are also being applied to the identification of host genetic loci and factors that contribute to infection susceptibility. Such loci will have undergone strong selection among populations in which the disease is endemic. Through identification of the beneficial genetic alleles among individuals who survive in such settings, markers for susceptibility or resistance are being discovered; these markers can be translated to diagnostic tests to identify susceptible individuals to implement preventive or prophylactic interventions. Further, such studies may offer mechanistic insight into the pathogenesis of infection and inform new methods of therapeutic intervention. Such beneficial genetic associations were recognized long before the advent of genomics, as in the protective effects of the negative Duffy blood group or heterozygous hemoglobin abnormalities against *Plasmodium* infection. Genomic approaches allow more systematic and widespread application of this principle to identify not only people with increased susceptibility to prevalent diseases (e.g., HIV infection, tuberculosis, and cholera) but also host factors that contribute to and thus might predict the severity of disease. In one recent example, polymorphisms in certain genetic loci, or specific circulating autoantibodies, were found to be associated with severe COVID-19.

THERAPEUTICS

Genomics has the potential to impact infectious disease therapeutics in two ways. By transforming the speed or type of diagnostic information that can be attained, it can influence therapeutic decision-making. Alternatively, by opening new avenues to a better understanding of pathogenesis, providing new ways to disrupt infection, and delineating new approaches to antibiotic discovery or characterization of vaccine targets, it has the potential to facilitate the development of new therapeutic agents.

GENOMIC DIAGNOSTICS INFORMING THERAPEUTICS

Efforts at antibiotic discovery are declining, with few new agents in the pipeline and even fewer new drugs (in particular, few agents with new mechanisms of action) entering the market. This phenomenon is due in part to the lack of economic incentives for the private sector; however, it is also attributable in part to the enormous challenges involved in the discovery and development of antibiotics. Most recent efforts have focused on broad-spectrum antibiotics; the development of a chemical entity that works across an extremely diverse set of organisms (i.e., species more divergent from each other than a human is from an amoeba) is far more challenging than the development of an agent that is designed to target a single bacterial species. Nevertheless, the concept of narrow-spectrum antibiotics has heretofore been rejected because of the lack of early diagnostic information that would guide the selection of such agents. Thus, rapid diagnostics providing antibiotic susceptibility information that can guide antibiotic selection in real time has the potential to alter and simplify antibiotic strategies by allowing a paradigm shift away from broad-spectrum drugs and toward narrow-spectrum agents. Such a paradigm shift clearly would have additional implications for antibiotic resistance, helping to limit selective pressure applied to pathogens and commensal bacteria during therapy.

In yet another diagnostic paradigm with the potential to impact therapeutic interventions, genomics is opening new avenues to a better understanding not only of different host susceptibilities to infection but also of different host responses to therapy. For example, the role of glucocorticoids in tuberculous meningitis has long been debated. Recently, polymorphisms in the human genetic locus *LTA4H*, which encodes a leukotriene-modifying enzyme, were found to modulate the inflammatory response to tuberculosis. Patients with tuberculous meningitis who were homozygous for the proinflammatory *LTA4H* allele were most helped by adjunctive glucocorticoid treatment, while those who were homozygous for the anti-inflammatory allele were negatively affected by steroid treatment. Steroids have become part of the standard of care in tuberculous meningitis, but this study suggests that perhaps only a subset of patients benefit from this anti-inflammatory adjunct (while others may be harmed) and further suggests a genetic means of prospectively identifying this subset. Thus, genomic diagnostic tests may eventually approach the goal of personalized medicine, informing diagnosis, prognosis, and treatment decisions by revealing the pathogenic potential of the microbe and by detecting individualized host responses to both infection and therapy.

GENOMICS IN DRUG AND VACCINE DEVELOPMENT

Genomic technologies are dramatically changing research on host–pathogen interactions, with a goal of increasingly influencing the process of therapeutic discovery and development. Sequencing offers several possible avenues into antimicrobial therapeutic discovery. First, genome-scale molecular methods have paved the way for comprehensive identification of all essential genes encoded by a pathogen, thereby systematically identifying critical vulnerabilities within a pathogen that could be targeted therapeutically. Second, genome-scale methodologies offer rapid ways to address the mechanism of action of newly identified hits from compound screens. Whole genome sequencing offers a rapid, unbiased way to detect mutations arising in resistant mutants during selection. Similarly, transcriptional profiling can provide insights into mechanisms of action of new candidate drugs. For instance, the

transcriptional signature of cell wall disruptors (e.g., β-lactams) is distinct from that of DNA-damaging agents (e.g., fluoroquinolones) or protein synthesis inhibitors (e.g., aminoglycosides). Either approach can thus suggest a mechanism of action or flag compounds for prioritization because of a potentially novel activity. In an alternative strategy for determining mechanisms of action, genome-wide RNA interference or CRISPR screens can be used to identify genes required for antimicrobial efficacy. This approach provided new insights into the mechanism of action of drugs that have been in use for decades for human African trypanosomiasis. Third, sequencing can readily identify the most conserved regions of a pathogen's genomes and corresponding gene products; this information is invaluable in narrowing antigen candidates in vaccine development. These surface proteins can be expressed recombinantly and tested for the ability to elicit a serologic response and protective immunity. This process, termed *reverse vaccinology*, has proved particularly useful for pathogens that are difficult to culture or poorly immunogenic. After decades of development, the utility of this approach became dramatically apparent with the rapid development of mRNA vaccines targeting conserved regions of the SARS-CoV-2 genome, fueling the most rapid development of a vaccine in history. Comparative genomics informed by prior coronavirus sequences enabled the first mRNA vaccine design to begin within days of the first SARS-CoV-2 sequence being made publicly available, and now annual updates are guided by ongoing sequencing of circulating variants, as discussed in detail below.

Genomics has been employed in both developing vaccines and defining their impact on microbial epidemiology and ecology. Examples include recent studies of influenza, malaria, *S. pneumoniae*, and HPV following vaccine introduction. Extensive sequencing of influenza viruses has been valuable in understanding the modest efficacy of seasonal influenza vaccination, and the combination of genomics and antigenic cartography is used to select strains to include in subsequent influenza vaccines. Beyond this, sequence conservation informs efforts to design more robust pan-influenza or pan-coronavirus vaccines. The RTS,S/AS01 malaria vaccine was analyzed by targeted sequencing of parasites from vaccinated and control populations during a phase 3 trial conducted at 11 sites in Africa; these analyses revealed reduced vaccine efficacy against parasites with amino acid mutations in the circumsporozoite protein targeted by the vaccine. Similarly, studies of the more established pneumococcal vaccines (the 7- and 13-valent polysaccharide conjugate vaccines, PCV-7 and PCV-13) documented serotype replacement: strains targeted by the vaccine have dramatically decreased in prevalence following widespread vaccination campaigns. Given that specific serotypes of HPV (e.g., types 16 and 18) clearly are more strongly associated than others with carcinogenesis, HPV vaccines have capitalized on serotype replacement, targeting vaccine strains to specifically prevent infection with the more dangerous serotypes. Such a strategy, informed by pathogen genomics, aims to protect individuals and ideally to decrease the circulating burden of more virulent strains within society.

Large-scale gene content analysis from sequencing or expression profiling enables new research directions that provide novel insights into the interplay of pathogen and host during infection or colonization. One important goal of such research is to suggest new therapeutic approaches to disrupt this interaction in favor of the host. Indeed, one of the most immediate applications of next-generation sequencing technology has come from simply characterizing human pathogens and related commensal or environmental strains and then finding genomic correlates for pathogenicity. For instance, as *Escherichia coli* varies from a simple nonpathogenic, lab-adapted strain (K-12) to a Shiga toxin–producing enterohemorrhagic gastrointestinal pathogen (O157:H7), it displays up to a 25% difference in gene content, though it is classified as the same species. Similarly, some isolates of *Enterococcus*—a genus notorious for its increasing incidence of resistance to common antibiotics such as ampicillin, vancomycin, and aminoglycosides—also contain recently acquired genetic material comprising up to 25% of the genome on mobile genetic elements. This fact suggests that horizontal gene transfer plays an important role in the organisms' adaptation as nosocomial pathogens. On closer study, this genome expansion is associated with loss of CRISPR elements, which protect the bacterial genome from invasion by certain foreign genetic material, and may thus facilitate the acquisition of antibiotic resistance–conferring genetic elements. While loss of this regulation appears to impose a competitive disadvantage in antibiotic-free environments, these drug-resistant strains thrive in the presence of even some of the best antienterococcal therapies. In addition to insights gained from genome sequencing, transcriptomic and proteomic profiling of pathogens under various conditions that mimic colonization or infection, including existence as biofilms or in polymicrobial communities, intracellular infection models, antibiotic exposure, and nutrient starvation, has begun to reveal novel biologic features that may be targeted by the next generation of therapies. At the cutting edge of the host–pathogen interface, single-cell transcriptomic methodologies are rapidly increasing in feasibility and extent, revealing previously unknown heterogeneity in the potential outcomes of intracellular infection.

Thus, genomic studies are transforming our understanding of infection, offering evidence of virulence factors or toxins and providing insight into ongoing evolution of pathogenicity and drug resistance. One goal of such studies is to identify therapeutic agents that can disrupt the pathogenic process. There is currently much interest in the theoretical concept of antivirulence drugs that inhibit virulence factors rather than killing the pathogen outright as a means to intervene in infection. Further, with sequencing ever more accessible and efficient, ongoing large-scale studies have unprecedented statistical power to associate clinical outcomes with pathogen and host genotypes and thus to further reveal vulnerabilities in the infection process that can be targeted for disruption. Although this is just the beginning, such studies point to a tantalizing future in which the clinician is armed with genomic predictors of infection outcome and therapeutic response to guide clinical decision-making.

EPIDEMIOLOGY OF INFECTIOUS DISEASES

Epidemiologic studies of infectious diseases have several main goals: to identify and characterize outbreaks, to describe the pattern and dynamics of an infectious disease as it spreads through populations, and to identify interventions that can limit or reduce the burden of disease. One classic, paradigmatic example is John Snow's elucidation of the origin of the 1854 London cholera outbreak. Snow used careful geographic mapping of cases to determine that the likely source of the outbreak was contaminated water from the Broad Street pump, and by removing the pump handle, he aborted the outbreak. Whereas that effort was undertaken without knowledge of the causative agent of cholera, advances in microbiology and genomics have expanded the purview of epidemiology to consider not just the disease but also the pathogen and its genetic variants, its virulence factors, and the complex relationships between microbial and host populations.

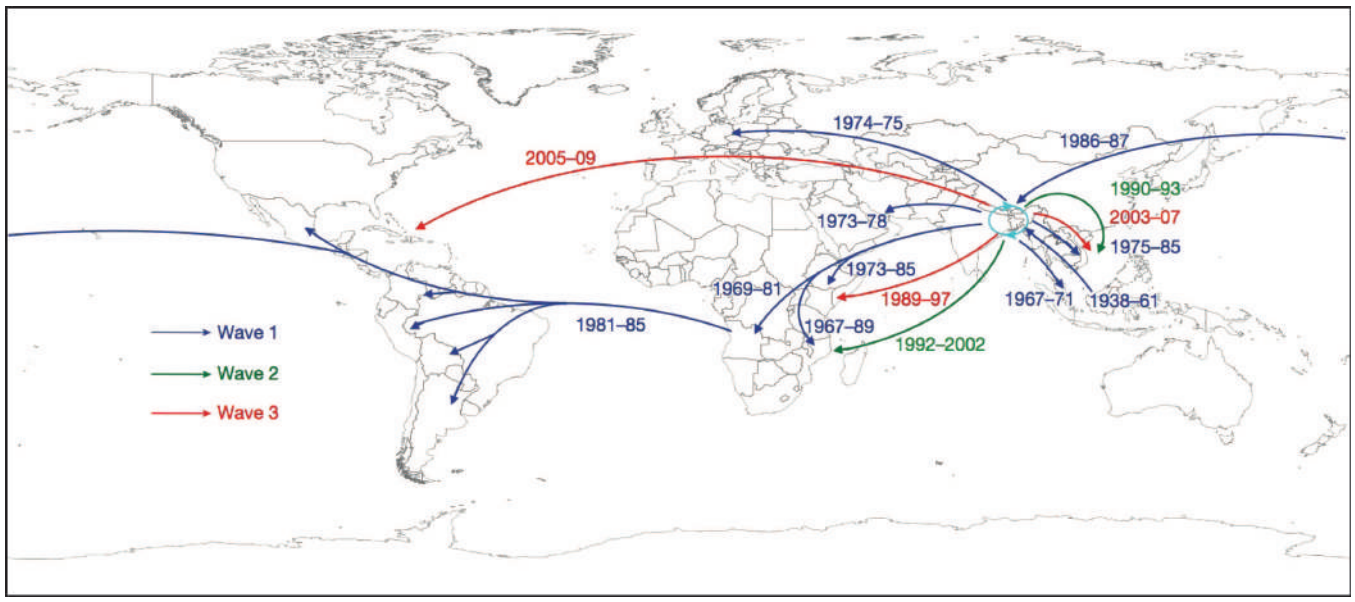
Through use of genomic tools such as high-throughput sequencing, the diversity of a microbial population can be rapidly described with unprecedented resolution, with discrimination between isolates that have single-nucleotide differences across the entire genome and advancement beyond prior approaches that relied on phenotypes (such as antibiotic susceptibility profiles) or genetic markers (such as multilocus sequence typing). The development of statistical methods grounded in molecular genetics and evolutionary theory has established analytical approaches that translate descriptions of microbial population diversity and structure into descriptions of the origin and history of pathogen spread. By linking phylogenetic reconstruction with epidemiologic and demographic data, genomic epidemiology presents the opportunity to track transmission from person to person and across demographic and geographic boundaries, to infer transmission patterns of both pathogens and sequence elements that confer phenotypes of interest, and to estimate the transmission dynamics of outbreaks.

TRANSMISSION NETWORKS

Whole genome sequencing of pathogen genomes can be used to infer transmission and identify point-source outbreaks. As reported in a seminal paper in 2010, a study of MRSA in a Thai hospital demonstrated

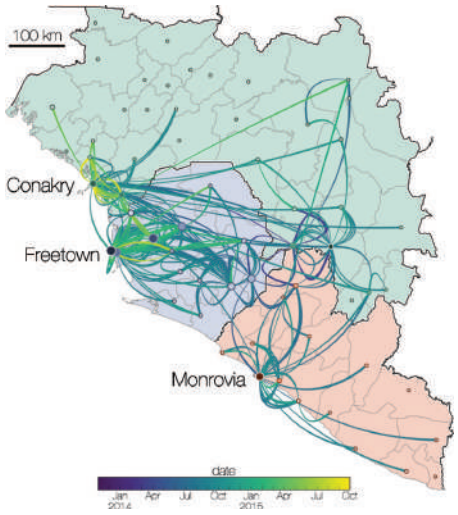
the use of whole genome sequencing in reconstructing the transmission of a pathogen from patient to patient by integrating the analysis of accumulation of mutations over time with the dates and hospital locations of the infected individuals. Since then, multiple instances of the use of whole genome sequencing to define and motivate interventions aimed at interrupting transmission chains have been reported. In another MRSA outbreak in a special-care baby unit in Cambridge, United Kingdom, whole genome sequencing extended the traditional infection control analysis, which relies on typing organisms by their antibiotic susceptibilities, to sequencing of isolates from clinical samples. This approach identified an otherwise unrecognized outbreak of a specific MRSA strain that was occurring against a background of the usual pattern of infection caused by a diverse circulating population of MRSA strains. The analysis showed evidence of transmission among mothers within the special-care baby unit and in the community and demonstrated the key role of MRSA carriage in a single health care provider in the persistence of the outbreak. In yet another example, in response to the observation of 18 cases of infection by carbapenemase-producing *Klebsiella pneumoniae* over 6 months at the National Institutes of Health Clinical Research Center, genome sequencing of the isolates was used to discriminate between the possibilities that these cases represented multiple, independent introductions into the health care system or a single introduction with subsequent transmission. On the basis of network and phylogenetic analysis of genomic and epidemiologic data, the authors reconstructed the likely relationships among the isolates from patient to patient, demonstrating the nosocomial spread of a single resistant *Klebsiella* strain. Similar approaches have elucidated the extent to which presumed nosocomial *C. difficile*, VRE, and carbapenem-resistant Enterobacterales represent within-hospital transmission—of bacterial strains or of plasmids and mobile genetic elements—versus independent acquisitions of unrelated pathogens. With these demonstrations of the potential contribution of genomics to hospital infection-control efforts, an important avenue of research seeks to develop statistical methods with which to ascertain when such tools are useful and their cost-effectiveness when compared with that of current nongenomic approaches.

Genome sequencing of clinical specimens of viruses has been used to understand their patterns of spread and the clinical and epidemiologic implications of genetic variants. As RNA viruses use an error-prone RNA-dependent RNA polymerase, they accumulate mutations at a rapid rate, facilitating inferences about the dynamics and patterns of spread. These tools have been applied to the study of outbreaks of well-known viruses, such as recent outbreaks of yellow fever in South America and mumps in the United States, as well as recent zoonotic pathogens, such as the coronaviruses MERS-CoV and SARS-CoV. The sequencing of SARS-CoV-2 in the context of the pandemic has offered a powerful example of the contributions that genomic epidemiology can make to, and its increasingly central role in, tracking the spread of a pathogen both locally and globally and informing policy and public health decision-making. Moreover, tracking variants and combining the genome sequences with epidemiologic line-list data enable investigation of the extent to which new variants cause differing symptom profiles and levels of severe disease.



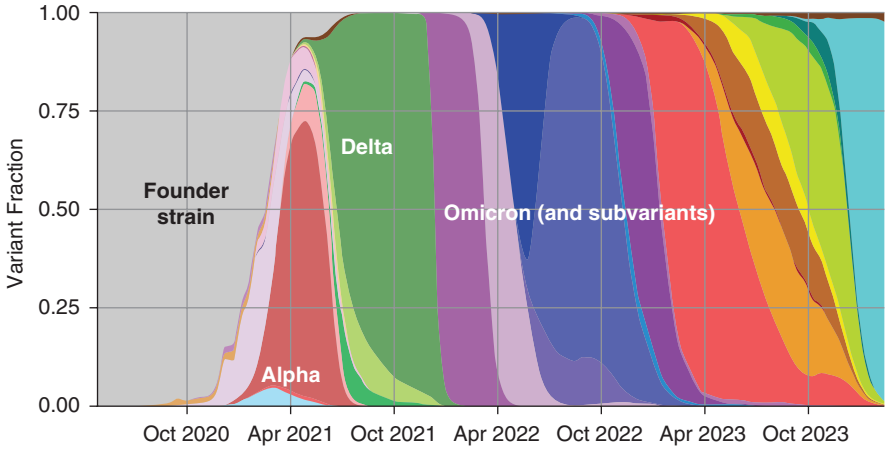
The uncovering of unexpected transmission events by genomic epidemiology studies is motivating investigations into pathogen ecology and modes of transmission. Whole genome sequencing established the clonality of several high-profile outbreaks, enabling the discovery of dangerous contaminants such as *Burkholderia pseudomallei* in aromatherapy spray, *Pseudomonas* in eyedrops, *Exserohilum* in injectable corticosteroids, *Fusarium* in epidural anesthetic preparations, *E. coli* O157:H7 in beef, and *Mycobacterium chimaera* in the temperature-control systems used during cardiac bypass. Each of these outbreaks caused considerable morbidity and in some cases mortality before being localized and prevented on the basis of investigations informed and accelerated by genomic epidemiology.

As more studies aim to carefully define the origins and spread of infectious agents using the high-resolution lens of whole genome sequencing, fundamental questions arise about the diversity of infecting and colonizing microbial populations. Traditional microbiologic methods include taking a single colony from a growth plate as representative of the population. However, the more diverse the colonizing or infecting pathogen population, the less representative these individual isolates are and the greater the possibility for introducing error into whole genome sequencing–based methods while reconstructing transmission. Sequencing studies of multiple colonies of an *S. aureus* strain colonizing a single individual showed a "cloud" of diversity. What is the clinical significance of this diversity? What are the processes that generate and limit it? What amount of diversity is transmitted under different conditions and routes of transmission? How do the answers to these questions vary by infectious organism, type of infection, host, and response to treatment? More comprehensive descriptions of diversity, population dynamics, transmission bottlenecks, and the forces that shape and influence the growth and spread of microbial populations will be a critically important focus of future investigations.



ORIGINS AND DYNAMICS OF PATHOGEN SPREAD

In addition to reconstructing the transmission chains of local outbreaks, genomics-based epidemiologic methods reveal broad-scale geographic and temporal spread of pathogens. Four examples include the origins of cholera in Haiti, the history of HIV-1 group M, the spread of Ebola in West Africa, and the timing and nature of spread of the zoonotic COVID-19 pandemic, which brought genomic tracking of pathogen variants to the forefront of public consciousness for a time. Cholera, a dehydrating diarrheal illness caused by infection with *Vibrio cholerae*, first spread worldwide from the Indian subcontinent in the 1800s and has since caused seven pandemics; the seventh pandemic has been ongoing since the 1960s. An investigation into the geographic patterns of cholera spread in the seventh pandemic used genome sequences from a global collection of 154 *V. cholerae* strains representing isolates from 1957 to 2010. This investigation revealed that the seventh pandemic has comprised at least three overlapping waves spreading out from the Indian subcontinent **(Fig. 126-3*A*)**. Further, analysis of the genome of an isolate of *V. cholerae* from the 2010 outbreak of cholera in Haiti showed it to be more closely related to isolates from South Asia than to isolates from neighboring Latin America, supporting the hypothesis that the outbreak was derived from *V. cholerae* introduced into Haiti by human travel (likely from Nepal) rather than by environmental or more geographically proximal sources. A subsequent study that dated the time to the most recent common ancestor of a population of *V. cholerae* isolates from Haiti provided further support for a single point-source introduction from Nepal. Application of similar methods that integrate pathogen genome sequences, mutation rates, geographic locations, and phylogenetic inference to HIV-1 group M dated the origin of the virus to the 1920s and the city of Kinshasa (then called Leopoldville), the capital of the Democratic Republic of the Congo (then called the Belgian Congo). This work established an understanding of how a boom in industry and a city with extensive railroad connections provide a scaffolding along which a virus can rapidly spread geographically.



Genome sequencing has proven invaluable in understanding the geographic, demographic, climatic, and administrative factors that drove, sustained, and limited the 2013–2016 Ebola outbreak that ravaged West Africa **(Fig. 126-3*B*)** as well as the factors and patterns of transmission of Zika virus in the Americas and most recently the timing and origins of SARS-CoV-2 transmission in human populations. With the rapid availability of the SARS-CoV-2 viral genome sequence, data from a set of cases from early in the pandemic enabled inference of the time to the most recent common ancestor, supporting that SARS-CoV-2 entered circulation in human populations in Wuhan, China, sometime in late November to early December of 2019. Subsequently, large, coordinated sequencing networks have been able to recreate its patterns of global spread, discover new variants, and monitor as these variants disseminate. For the first time, scientists and even the public were able to watch viral evolution through a population in almost real time. First, a single-nucleotide polymorphism (D614G in the viral spike protein) displaced the original strain in early 2020, followed in subsequent years by other variants such as Alpha, Delta, Omicron, and then various Omicron sublineages becoming dominant either

FIGURE 126-3 ***A.*** Transmission events inferred from phylogenetic reconstruction of 154 *Vibrio cholerae* isolates from the seventh cholera pandemic. Date ranges represent estimated time to the most recent common ancestor for strains transmitted from source to destination locations, based on a Bayesian model of the phylogeny. *(Reprinted by permission from the Nature Publishing Group, Nature 477:462. Evidence for several waves of global transmission in the seventh cholera pandemic, A Mutreja et al © 2011.)* ***B.*** Inferred Ebola virus spread in West Africa (Liberia, *red*; Guinea, *green*; and Sierra Leone, *blue*) by phylogeographic methods using virus genome sequences, dates, and an evolutionary model. The lines reflect spread between population centroids of each administrative region, going from the thin end to the thick end and colored by a time scale. *(Reprinted by permission from Nature Publishing Group, Nature 544:309. Virus genomes reveal factors that spread and sustained the Ebola epidemic, G Dudas et al © 2017.)* ***C.*** SARS-CoV-2 variant proportions in the United States from the start of the COVID-19 pandemic through March 6, 2024. Each major variant family that rose to dominance in the United States is labeled. *(Variant proportions are taken from https://covariants.org, accessed April 21, 2024, which derives underlying variant data from the Global Initiative on Sharing All Influenza Data [GISAID].)*

regionally or globally (Fig. 126-3*C*) as their mutation profile conferred advantages in increasingly immune populations.

One compelling area of innovation in molecular epidemiology is the development of wastewater-based surveillance. Wastewater surveillance has been used to monitor for the appearance of poliovirus, among others, but its widespread and widely publicized use for SARS-CoV-2 in "nowcasting" quantitative estimates of epidemic trends has galvanized interest in using wastewater to monitor disease trends and pathogens and their characteristics. The U.S. Centers for Disease Control and Prevention has sought to establish a national wastewater surveillance system, building on the SARS-CoV-2 work. These tools can help provide a population-level view of the first appearance of a pathogen, variant, or antibiotic resistance determinant and can also help monitor the population burden and hence the epidemic curve. Work remains to develop robust, repeatable, and accurate methods across many pathogens, particularly those that can replicate or exchange DNA in wastewater environments. Nonetheless, this data source has great promise for providing early signals to decision-makers to help inform public health actions.

These efforts illustrate the remarkable promise of genome sequencing in improving outbreak response strategies by elucidating previously hidden origins and paths of disease spread and details of the forces that shape epidemics. The combination of in-the-field sequencing with portable sequencing platforms, rapid data sharing, and rapid open analysis through sites such as *nextstrain.org* offers a paradigm by which real-time genomic epidemiology, including wastewater-based epidemiology, may contribute to "weather maps," enabling prediction of epidemic patterns in space and time and thus providing guidance for public health interventions to slow or control their spread.

Increasing numbers of investigations into the spread of many pathogens are contributing to a growing atlas of maps describing routes, patterns, and tempos of microbial diversification and dissemination,

not just for agents of emerging infectious diseases but for common pathogens as well. Such studies will create a vast amount of data that can be used to investigate the diversity and microbiologic links within distinct niches and the patterns of spread from one niche to another. The increasingly broad adoption of genome sequencing by health care and public health institutions ensures that the available catalog of genome sequences and associated epidemiologic data will grow very rapidly. For example, updating from the pulsed-field gel electrophoresis techniques that have been used to define strains of food-borne pathogens since the late 1980s, PulseNet—the U.S. Centers for Disease Control and Prevention network for monitoring these pathogens—has instituted routine genome sequencing. The COVID-19 pandemic further underscores the importance of building a new global public health infrastructure in which sequencing plays a central role to facilitate early disease discovery, rapid and close tracking of spread, and development of diagnostics and targeted effective interventions. With higher-resolution description of microbial diversity and of the dynamics of that diversity over time and across epidemiologic and demographic boundaries and evolutionary niches, we will gain even greater insights into the relationships of transmission routes and patterns of historical spread.

EPIDEMIC POTENTIAL

Defining pathogen transmissibility is a critical step in the development of public health surveillance and intervention strategies because this information can help to predict the epidemic potential of an outbreak. Transmissibility can be estimated by a variety of methods, including inference from the growth rate of an epidemic and the generation time of an infection (the mean interval between infection of an index case and infection of the people infected by that index case). Genome sequencing and analysis of a well-sampled population provide another method by which to derive similar fundamental epidemiologic parameters. One key measure of transmissibility is the basic reproduction number, defined as the number of secondary infections generated from a single primary infectious case. When the basic reproduction number is >1, an outbreak has epidemic potential; when it is <1, the outbreak will become extinct. On the basis of sequences from influenza virus samples obtained from infected patients very early in the 2009 H1N1 influenza pandemic, the basic reproduction number was estimated through a population genomic analysis at 1.2; this result provided greater confidence to estimates derived by traditional epidemiologic data, which ranged from 1.4 to 1.6. In addition, with the assumption of a molecular clock model, sequences of H1N1 samples together with information about when and where the samples were obtained have been used to estimate the date and location of the pandemic's origin, providing insight into disease origins and dynamics. Integrating viral genomics with other types of data—such as the timing and nature of mitigation efforts and the impact of those efforts on mobility—will expand the toolkit with which to assess the impact of public health interventions on slowing and controlling disease spread. These tools may also be applied to institutional infection control: with the development of return-to-work protocols, sequencing offers one option to help learn the extent to which infections arose from within-institution spread. Because the magnitude and intensity of the public health response are guided by the predicted size of an outbreak, the ability of genomic methods to cast light on a pathogen's origin and epidemic potential adds an important dimension to the contributions of these methods to infectious disease epidemiology.

PATHOGEN EVOLUTION

Beyond describing transmission and dynamics, pathogen genomics can provide insight into the evolution of pathogens and the interactions of selective pressures, the host, and pathogen populations, which can have implications for clinical decision-making and the development of vaccines and therapeutics. From a clinical perspective, this process is central to the acquisition of antibiotic resistance, the generation of increasing pathogenicity or new virulence traits, the evasion of host immunity and clearance (leading to chronic infection), and vaccine efficacy.

Microbial genomes evolve through a variety of mechanisms, including mutation, duplication, insertion, deletion, recombination, and horizontal gene transfer. Segmented viruses (e.g., influenza virus) can reassort gene segments within multiply infected cells. The pandemic 2009 H1N1 influenza A virus, for example, appears to have been generated through reassortment of several avian, swine, and human influenza strains. Such potential for the evolution of novel pandemic strains has precipitated concern about the possible evolution to transmissibility of virulent strains that have been associated with high mortality rates but have not yet exhibited efficient human infectivity. Experiments with H5N1 avian influenza, for example, have defined five mutations that render it transmissible, at least in ferrets—the animal model system for human influenza. Studies that examine the genomes of pathogens collected longitudinally from individual infections have similarly demonstrated their evolution as they adapt to host environments and new immune and therapeutic pressures.

The continuous antigenic evolution of seasonal influenza offers an example of how studies of pathogen evolution can impact surveillance and vaccine development. Frequent updates to the annual influenza vaccine are needed to ensure protection against the dominant strains. These updates are based on anticipating which viral populations from a pool of substantial locally and globally diverse circulating viruses will predominate in the upcoming season. Toward that end, sequencing-based studies of influenza virus dynamics have shed light on the global spread of influenza, providing concrete data on patterns of spread and helping to elucidate the origins, emergence, and circulation of novel strains. Through analysis of >1000 influenza A H3N2 virus isolates over the 2002–2007 influenza seasons, Southeast Asia was identified as the usual site from which diversity originates and spreads worldwide. Further studies of global isolate collections have shed further light on the diversity of circulating virus, showing that some strains persist and circulate outside of Asia for multiple seasons. Similar studies with SARS-CoV-2, including genome sequences from orders of magnitude more clinical specimens than the aforementioned influenza study, have helped identify where new SARS-CoV-2 variants have emerged and informed vaccine composition.

Not only do genomic epidemiology studies have the potential to help guide vaccine selection and development, but they also help to track what happens to pathogens circulating in the population in response to vaccination. By describing pathogen evolution under the selective pressure of a vaccinated population, such studies can play a key role in surveillance and identification of virulence determinants and perhaps may even help to predict the future evolution of escape from vaccine protection. The seven-valent pneumococcal conjugate vaccine (PCV-7) targeted the seven serotypes of *S. pneumoniae* responsible for the majority of invasive disease at the time of its introduction in 2000; since then, PCV-7 has dramatically reduced the incidence of pneumococcal disease and mortality. However, sequencing of >600 Massachusetts pneumococcal isolates from 2001 to 2007 has shown that, in the pneumococcal population, previously rare nonvaccine serotypes are replacing vaccine serotypes and that some vaccine strains have persisted despite vaccination by recombining the vaccine-targeted capsule locus with a cassette of capsule genes from non-vaccine-targeted serotypes. Studying the virulence of these persistently circulating strains can help to rationally update vaccine composition.

The large collections of pathogen genome sequences are driving development of tools to decipher the genetic basis for antibiotic resistance, virulence, and infection risk. Some pathogens have distinct types of clinical manifestations, the basis for which we are just beginning to unravel with the aid of genomics. For example, *Listeria* is a food-borne pathogen that can cause both central nervous system infections and maternal/neonatal infections. Although all *Listeria* isolates are treated the same from a public health perspective, variation in outcomes exists and appears to be linked to the strains' genomic background. Molecular analysis of a national reference laboratory's collections of well-characterized specimens, based on the fraction of immunocompetent people in which they caused disease, revealed that some clonal complexes of *Listeria* appear to be more virulent than others. Linking epidemiology and comparative genomics then enabled enumeration

of putative virulence factors that contribute to the clinical phenotypes as well as identification and confirmation of a novel gene cluster that mediates central nervous system tropism. This approach illustrates progress toward a future in which we can link pathogen identification with risk, thereby informing resource use and allocation.

GLOBAL CONSIDERATIONS

While cutting-edge genomic technologies are largely implemented in the developed world, their application to infectious diseases perhaps offers the biggest potential impact in less developed regions where the burden of these infections is greatest. This globalization of genomic technology and its extensions has already begun in each of the areas of focus highlighted in this chapter; it has occurred both through the application of advanced technologies to samples collected in the developing world and through the adaptation and importation of technologies directly to the developing world for on-site implementation as they become more globally accessible.

Genomic characterization of the pathogens responsible for such important global illnesses, such as tuberculosis, malaria, trypanosomiasis, cholera, and COVID-19, has led to insights in diagnosis, treatment, and infection control. For instance, with the increasing burden of drug-resistant tuberculosis in the developing world, a molecular diagnostic test has been developed to detect rifampin-resistant tuberculosis. The genetic basis for rifampin resistance has been well defined by targeted sequencing: characteristic mutations in the molecular target of rifampin, RNA polymerase, account for the vast majority of instances of rifampin resistance. At least in areas that can afford to implement it, a rapid, automated PCR assay that can detect both *M. tuberculosis* and a rifampin-resistant allele of RNA polymerase directly in clinical samples has been implemented in parts of Africa and Asia, transforming the recognition and management of incident tuberculosis and multidrug resistance where they are most prevalent. Since rifampin resistance frequently accompanies resistance to other antibiotics, this test can suggest the presence of multidrug-resistant *M. tuberculosis* within hours instead of weeks, without the infrastructure required for culture.

High-resolution genomic tracking of the spread of epidemics—from cholera to Ebola to Zika to COVID-19—has yielded insights into which public health measures may prove most effective in controlling local epidemics. Many genomic tracking efforts have involved close collaborations with local scientists and public health officials, and considerable investment in sequencing infrastructure in sub-Saharan Africa has made on-location epidemic tracking in the event of another such outbreak feasible. Such investment can not only enable real-time outbreak recognition and tracking but also provide the infrastructure needed to capitalize on the many other benefits of high-throughput sequencing as they are developed. The early returns of such investments are exemplified by the rapid reporting of genome sequences for SARS-CoV-2, with substantial insights from sequencing efforts across the world; perhaps most notably, the Omicron variant was first identified in South Africa, enabling preparations for what became a global sweep in the subsequent weeks. Overall, sequencing efforts have become cheaper and have moved closer to point-of-care with each passing year. As these technologies synergize with efforts to globalize information-technology resources, global implementation of genomic methods promises to spread state-of-the-art methods for diagnosis, treatment, and epidemic tracking of infections to areas that need these capabilities the most.

GENOMICS AND THE COVID-19 PANDEMIC

The COVID-19 pandemic, which began in 2019 and spread worldwide in 2020, resulted in hundreds of millions of documented infections and millions of deaths and serves as a prime example of the pandemic potential of infectious pathogens. It also demonstrated the central role that genomic tools now play in response to infectious outbreaks, ranging from enabling diagnostics and vaccines to tracking evolution, virulence, and transmissibility of the pathogen. The rapid discovery of SARS-CoV-2 and sequencing of its genome was complete within weeks of the recognition of the clinical syndrome. The rapid public sharing of this genome sequence led directly to two key interventions: diagnostic assay development via RT-qPCR and vaccine design. Crucially, vaccine development was informed by homology of the SARS-CoV-2 sequence to SARS and MERS coronaviruses. The dominant antigen of those viruses, the surface protein Spike, was well characterized, enabling the design of the first SARS-CoV-2 vaccines to begin the day after the genome sequence was shared. The progress of the most rapidly developed and validated vaccine in human history was unquestionably accelerated by genomic technology. Whole genome sequencing has also played a large role in outbreak tracking and confirmation of case clusters in institutional settings such as hospitals or congregate living facilities, in helping to distinguish reinfections from recrudescence or prolonged viral shedding, in monitoring spread through societies, and in tracking pathogen evolution, including the emergence of new variants of concern with altered transmissibility, severity, and/or partial evasion of the immune response generated to prior versions of the virus, vaccines, or monoclonal antibody therapeutics. Finally, cutting edge genomic methods including single-cell transcriptional profiling and genome-wide association studies are contributing to our understanding of the wide variability in outcomes of SARS-CoV-2 infection, ranging from asymptomatic carriage to death. Overall, just as the global response to the COVID-19 pandemic underscores the indispensable role that genomics methods have come to play in the clinical and public health management of infectious diseases, the devastating impact of this pandemic reveals the urgent need for further development and implementation of tools for disease surveillance and response.

SUMMARY

By illuminating the genetic information that encodes the most fundamental processes of life, genomic technologies are transforming many aspects of medicine. In infectious diseases, methods such as next-generation sequencing and genome-scale expression analysis offer information of unprecedented depth about individual microbes as well as microbial communities. This information is expanding our understanding of the interactions of microorganisms with each other, their human hosts, and the environment. Despite technological and financial barriers that slow the widespread adoption of large-scale pathogen sequencing in clinical and public health settings, genomic methodologies have utterly transformed the research landscape in infectious disease and are beginning to make meaningful inroads into clinical settings. As even vaster amounts of data are generated, innovations in data storage, development of bioinformatics tools to manipulate the data, standardization of methods, and training of end-users in both the research and clinical realms will be required. The cost-effectiveness and applicability of whole genome sequencing, particularly in the clinic, remain to be studied, and studies of the impact of genome sequencing on patient outcomes will be needed to clarify the contexts in which these new methodologies can make the greatest contributions to patient well-being. The ongoing efforts to overcome limitations through collaboration, teaching, and reduction of financial obstacles should be applauded and expanded. With advances in genomic technologies and computational analysis, our ability to detect, characterize, treat, monitor, prevent, and control infections has advanced rapidly in recent years and will continue to do so, with the hope of heralding a new era where the clinician is better armed to combat infection and promote human health.

127 Approach to the Acutely Ill Infected Febrile Patient

Tamar F. Barlam

The physician treating the acutely ill febrile patient must be able to recognize infections that require emergent attention. If such infections are not adequately evaluated and treated at initial presentation, the opportunity to alter an adverse outcome may be lost. In this chapter, the clinical presentations of and approach to patients with infectious disease emergencies are discussed. These infectious processes and their treatments are discussed in detail in other chapters.

APPROACH TO THE PATIENT

Acute Febrile Illness

Before the history is elicited and a physical examination is performed, an immediate assessment of the patient's general appearance can yield valuable information. The perceptive physician's subjective sense that a patient is septic or toxic often proves accurate. Visible agitation or anxiety in a febrile patient can be a harbinger of critical illness.

HISTORY

Presenting symptoms are frequently nonspecific. Detailed questions should be asked about the onset and duration of symptoms and about changes in severity or rate of progression over time. Host factors, such as extremes of age and comorbid conditions, may increase the risk of infection with certain organisms or of a more fulminant course than is usually seen. Lack of splenic function, alcoholism with significant liver disease, IV drug use, HIV infection, diabetes, malignancy, morbid obesity, organ transplantation, and chemotherapy all predispose to specific infections and frequently to increased severity. The patient should be questioned about factors that might help identify a nidus for invasive infection, such as recent upper respiratory tract infections, influenza, or varicella; prior trauma; disruption of cutaneous barriers due to lacerations, burns, surgery, body piercing, or decubiti; and the presence of foreign bodies or prosthetic devices. Travel, presence during a natural disaster such as a hurricane or tsunami, contact with pets or other animals, or activities that might result in tick or mosquito exposure can lead to diagnoses that would not otherwise be considered. Recent dietary intake, medication use, social or occupational contact with ill individuals, vaccination history, recent sexual contacts, and menstrual history may be relevant. Pregnancy might increase the risk and severity of some illnesses, such as influenza or COVID-19, or increase the risk of significant morbidity for the fetus, as in *Listeria* or Zika virus infection. A detailed review of systems should include any neurologic signs or sensorium alterations, rashes or skin lesions, and focal pain or tenderness.

PHYSICAL EXAMINATION

A complete physical examination should be performed, with special attention to several areas that are sometimes given short shrift in routine examinations such as assessment of the patient's general appearance and a detailed skin, soft tissue, and neurologic evaluation.

The patient may appear either anxious and agitated or lethargic and apathetic. Fever is usually present, although elderly patients and compromised hosts (e.g., patients who are uremic or cirrhotic and those who are taking glucocorticoids or nonsteroidal anti-inflammatory drugs) may be afebrile despite serious underlying infection. Critically ill patients may be hypothermic, with a high risk of organ failure and mortality. Mortality at 30 days decreases with increasing temperature at presentation. Measurement of blood pressure, heart rate, and respiratory rate and oxygen saturation helps determine the degree of hemodynamic and metabolic compromise.

The etiologic diagnosis may become evident in the context of a thorough skin examination **(Chap. 21)**. Petechial rashes are typically seen with meningococcemia or Rocky Mountain spotted fever (RMSF; **see Fig. A1-16**); erythroderma is associated with toxic shock syndrome (TSS). On soft tissue and muscle examination, areas of erythema or duskiness, edema, and tenderness may indicate underlying necrotizing fasciitis, myositis, or myonecrosis. The neurologic examination must include a careful assessment of mental status for signs of early encephalopathy. Evidence of nuchal rigidity or focal neurologic findings should be sought.

DIAGNOSTIC WORKUP

After a quick clinical assessment, diagnostic material should be obtained rapidly and antibiotic and supportive treatment begun. Blood (for cultures; baseline complete blood count with differential; measurement of serum electrolytes, blood urea nitrogen, serum creatinine, and serum glucose; liver function tests and serum lactate; and D-dimer) can be obtained at the time an IV line is placed and before antibiotics are administered. Three sets of blood cultures should be performed for patients with possible acute endocarditis. Blood smears from patients at risk for severe parasitic disease, such as malaria or babesiosis **(Chaps. 231, 232, and A2)**, must be examined for the diagnosis and quantitation of parasitemia. Blood smears may also be diagnostic in ehrlichiosis and anaplasmosis. Testing of a nasopharyngeal sample for COVID-19 or influenza may be indicated.

Patients with possible meningitis should have cerebrospinal fluid (CSF) obtained before the initiation of antibiotic therapy. Focal findings, depressed mental status, or papilledema should be evaluated by brain imaging prior to lumbar puncture, which, in this setting, could initiate herniation. *Antibiotics should be administered before imaging but after blood for cultures has been drawn.* If CSF cultures are negative, blood cultures will provide the diagnosis in 50–70% of cases. Molecular diagnostic techniques (e.g., broad-range 16S rRNA gene polymerase chain reaction testing for bacterial meningitis pathogens) are of increasing importance in the rapid diagnosis of life-threatening infections.

CT or MRI may be necessary to evaluate focal processes that require urgent surgical intervention. Other diagnostic procedures, such as wound cultures, should not delay the initiation of treatment for more than minutes. Once emergent evaluation, diagnostic procedures, and (if appropriate) surgical consultation (see below) have been completed, other laboratory tests can be conducted. Appropriate radiography; CT and/or MRI imaging; urinalysis; measurement of the erythrocyte sedimentation rate, C-reactive protein, and/or procalcitonin; and transthoracic or transesophageal echocardiography all may prove important.

TREATMENT

The Acutely Ill Patient

In the acutely ill patient, empirical antibiotic therapy for presumed bacterial or fungal infection is critical and should be administered without undue delay in addition to fluid resuscitation and vasopressor support as needed. Increased prevalence of antibiotic resistance in community-acquired bacteria must be considered when antibiotics are selected. **Table 127-1** lists first-line empirical regimens for infections considered in this chapter. In addition to the rapid initiation of antibiotic therapy, several of these infections require urgent surgical attention. Neurosurgical evaluation for subdural empyema, otolaryngologic surgery for possible mucormycosis, and cardiothoracic surgery for critically ill patients with acute endocarditis are as important as antibiotic therapy. For infections such as necrotizing fasciitis and clostridial myonecrosis, rapid surgical intervention supersedes other diagnostic or therapeutic maneuvers.

Adjunctive treatments may reduce morbidity and mortality rates and include dexamethasone for bacterial meningitis or IV immunoglobulin for TSS. Adjunctive therapies should usually be initiated within the first hours of treatment; however, dexamethasone for bacterial meningitis must be given before or at the time of the first dose of antibiotic. Glucocorticoids may also be harmful—e.g., when given in the setting of cerebral malaria or viral hepatitis.

SPECIFIC PRESENTATIONS

The infections considered below according to common clinical presentation can have rapidly catastrophic outcomes, and their immediate recognition and treatment can be life-saving.

SEPSIS WITHOUT AN OBVIOUS FOCUS OF PRIMARY INFECTION

Patients initially have a brief prodrome of nonspecific symptoms and signs that progresses quickly to hemodynamic instability with hypotension, tachycardia, tachypnea, respiratory distress, and altered mental status. Disseminated intravascular coagulation (DIC) with clinical evidence of a hemorrhagic diathesis is a poor prognostic sign.

Septic Shock (See also Chap. 315) Patients with bacteremia leading to septic shock may have a primary site of infection (e.g., pneumonia, pyelonephritis, or cholangitis) that is not evident initially. Elderly patients who may have atypical presentations and often have comorbid conditions, hosts compromised by malignancy and neutropenia, and patients who have recently undergone a surgical procedure or hospitalization are at increased risk for an adverse outcome. Gram-negative bacteremia with organisms such as *Pseudomonas aeruginosa* or *Escherichia coli* and gram-positive infection with organisms such as *Staphylococcus aureus* (including methicillin-resistant *S. aureus* [MRSA]) or group A streptococci can present as intractable hypotension and multiorgan failure. Treatment can usually be initiated empirically on the basis of the presentation, host factors **(Chap. 315)**, and local patterns of bacterial resistance. Outcomes are worse when antimicrobial treatment is delayed or when the responsible pathogen ultimately proves not to be susceptible to the initial regimen. The increasing prevalence of multidrug-resistant organisms makes this especially relevant. Broad-spectrum antimicrobial agents are therefore recommended and should be instituted rapidly, preferably within the first hours after presentation with septic shock. Pharmacodynamics are altered in sepsis due to increased volume of distribution and renal clearance, so it is important to adequately dose antimicrobials. Risk factors for fungal infection should be assessed, as the incidence of fungal septic shock is increasing. Nonbacterial causes of shock, such as dengue virus infection, should be considered in endemic areas. Glucocorticoids are often considered for patients with severe sepsis who do not respond to fluid resuscitation and vasopressor therapy, but conclusive evidence for efficacy in this setting is lacking.

Overwhelming Infection in Asplenic Patients (See also Chap. 315) Patients without splenic function are at risk for overwhelming bacterial sepsis compared with the general population. The median interval between splenectomy and sepsis is 4–6 years, with a range of 1–19 years. Almost 50% or more of these infections occur within the first l or 2 years, but the increased risk persists throughout life. Encapsulated bacteria cause the majority of infections. *Streptococcus pneumoniae* is the most common isolate, causing 40–70% of cases. Children less than 5 years of age are at 15 times higher risk of invasive pneumococcal disease than adults, who are more likely to have antibody to these organisms. The risk of infection with *Haemophilus influenzae* or *Neisseria meningitidis* also is greater in patients without splenic function, but reported cases are declining. Severe clinical manifestations of infections due to other organisms, such as *E. coli*, *S. aureus*, *Bordetella holmesii*, *Capnocytophaga*, *Babesia*, and *Plasmodium* species, have been described.

Babesiosis (See also Chap. 232) A history of recent travel to endemic areas raises the possibility of infection with *Babesia*. Cases are increasing in the United States, particularly in the Northeast. Between 1 and 4 weeks after a tick bite, the patient experiences chills, fatigue, anorexia, myalgia, arthralgia, shortness of breath, nausea, and neurologic symptoms such as headache, confusion, delirium or impaired consciousness; ecchymosis and/or petechiae are occasionally seen. The tick that most commonly transmits *Babesia*, *Ixodes scapularis*, also transmits *Borrelia burgdorferi* (the agent of Lyme disease) and *Anaplasma*; co-infection can occur and may result in more severe disease. Infection with the European species *Babesia divergens* is more frequently fulminant than that due to the U.S. species *Babesia microti*. *B. divergens* causes a febrile syndrome with hemolysis, jaundice, hemoglobinemia, and renal failure and is associated with a mortality rate as high as 40%. Severe babesiosis is especially common in asplenic hosts but does occur in hosts with normal splenic function, particularly those >60 years of age and those with underlying immunosuppressive conditions such as HIV infection or malignancy. Complications include renal failure, acute respiratory failure, heart failure, DIC, and splenic rupture.

Other Sepsis Syndromes Tularemia **(Chap. 175)** has been reported in every U.S. state except Hawaii. This disease is associated with wild rabbit, tick, horse-fly, and tabanid fly contact. It can be transmitted by arthropod bite, handling of infected animal carcasses, consumption of contaminated food and water, or inhalation. The typhoidal form can be associated with gram-negative septic shock and a mortality rate of >30%, especially in patients with underlying comorbid or immunosuppressive conditions. Plague occurs infrequently in the United States **(Chap. 176)**, primarily after contact with ground squirrels, prairie dogs, or chipmunks, but is endemic in other parts of the world; >90% of all cases occur in Africa with Madagascar especially affected. The septic form is particularly rare and is associated with shock, multiorgan failure, and a 30% mortality rate. Pneumonic plague is rapidly progressive and fatal without treatment. These infections should be considered in the appropriate epidemiologic setting. The Centers for Disease Control and Prevention (CDC) lists *Francisella tularensis* and *Yersinia pestis* (the agents of tularemia and plague, respectively) along with *Bacillus anthracis* (the agent of anthrax) as important organisms that might be used for bioterrorism **(Chap. S4)**.

SEPSIS WITH SKIN MANIFESTATIONS (SEE ALSO CHAP. 21)

Sepsis can be associated with diverse skin findings. In one study, almost 18% of patients with severe sepsis had secondary skin findings, such as purpura, petechiae, or ecchymoses. Maculopapular rashes may reflect early meningococcal or rickettsial disease but are usually associated with nonemergent infections. Exanthems are usually viral. Primary HIV infection commonly presents with a rash that is typically maculopapular and involves the upper part of the body but can spread to the palms and soles. The patient is usually febrile and can have lymphadenopathy, severe headache, dysphagia, diarrhea, myalgias, and arthralgias. Recognition of this syndrome provides an opportunity to prevent transmission and to institute early treatment.

TABLE 127-1 Empirical Treatment for Common Infectious Disease Emergencies[a]

CLINICAL SYNDROME	POSSIBLE ETIOLOGIES	TREATMENT	COMMENTS	SEE CHAP(S)
Sepsis without a Clear Focus				
Septic shock	*Pseudomonas* spp., gram-negative enteric bacilli, *Staphylococcus* spp., *Streptococcus* spp.	Vancomycin (15 mg/kg q12h)[b] ***plus either*** Piperacillin/tazobactam (4.5 g) q8h via extended infusion (EI)[c] *or* cefepime (2 g) q8h via EI	Empirical therapy should be tailored to local resistance patterns. Carbapenem or aminoglycoside antibiotics should be considered for empirical therapy when rates of multidrug-resistant gram-negative organisms are high or for patients with risk factors for resistant organisms. Adjust treatment when culture data become available.	152, 153, 166, 170, 315
Overwhelming post-splenectomy sepsis	*Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis*	Ceftriaxone (2 g q12h) *plus* vancomycin (15 mg/kg q12h)[b]	If a β-lactam–sensitive strain is identified, vancomycin can be discontinued and a narrower-spectrum agent, such as penicillin, considered based on susceptibility testing.	315
Babesiosis	*Babesia microti* (U.S.), *B. divergens* (Europe)	Atovaquone (750 mg q12h) *plus* azithromycin (500 mg q24h)	Clindamycin (600 mg q8h) *plus* quinine (650 mg q8h) can be used in severe disease not responding to atovaquone and azithromycin. Treatment with doxycycline (100 mg bid) for potential co-infection with *Borrelia burgdorferi* or *Anaplasma* spp. may be prudent.	229, 232
Sepsis with Skin Findings				
Meningococcemia	*N. meningitidis*	Ceftriaxone (2 g q12h) or penicillin (4 mU q4h)	Ceftriaxone eradicates nasopharyngeal carriage of the organism. Close contacts require chemoprophylaxis with rifampin (600 mg q12h for 2 days) or ciprofloxacin (a single dose, 500 mg).	160
Rocky Mountain spotted fever (RMSF)	*Rickettsia rickettsii*	Doxycycline (100 mg bid)	If both meningococcemia and RMSF are being considered, use ceftriaxone (2 g q12h) *plus* doxycycline (100 mg bid). If RMSF is diagnosed, ceftriaxone can be discontinued.	192
Purpura fulminans	*S. pneumoniae, H. influenzae, N. meningitidis*	Ceftriaxone (2 g q12h) *plus* vancomycin (15 mg/kg q12h)[b]	If a β-lactam-sensitive strain is identified, vancomycin can be discontinued.	151, 160, 162, 315
Erythroderma: toxic shock syndrome	Group A *Streptococcus, Staphylococcus aureus*	Vancomycin (15 mg/kg q12h)[b] *plus* clindamycin (600 mg q8h)	If a penicillin- or oxacillin-sensitive strain is isolated, these agents are superior to vancomycin (penicillin, 2 mU q4h; or oxacillin, 2 g IV q4h). The site of toxigenic bacteria should be debrided; IV immunoglobulin can be used in severe cases.[d]	152, 153
Sepsis with Soft Tissue Findings				
Necrotizing fasciitis	Group A *Streptococcus,* mixed aerobic/anaerobic flora	Vancomycin (15 mg/kg q12h)[b] *plus* piperacillin/tazobactam (4.5 q q8h via EI)[c] *plus* clindamycin (600 mg q8h)	Urgent surgical evaluation is critical. Empirical therapy should be tailored to local resistance patterns. For mixed aerobic/anaerobic infections, clindamycin can be discontinued. Adjust treatment when culture data become available.	134, 152, 153
Clostridial myonecrosis	*Clostridium perfringens*	Penicillin (2 mU q4h) *plus* clindamycin (600 mg q8h)	Urgent surgical evaluation is critical.	159
Neurologic Infections				
Bacterial meningitis	*S. pneumoniae, N. meningitidis*	Ceftriaxone (2 g q12h) *plus* vancomycin (15 mg/kg q12h)[b]	If a β-lactam–sensitive strain is identified, vancomycin can be discontinued. If the patient is >50 years old or has comorbid disease, add ampicillin (2 g q4h) for *Listeria* coverage. Dexamethasone (10 mg q6h for 4 days) started before, or at the time of, the first dose of antibiotic improves outcome in adults with meningitis (especially pneumococcal).	143
Brain abscess, suppurative intracranial infections	*Streptococcus* spp., *Staphylococcus* spp., anaerobes, gram-negative bacilli	Vancomycin (15 mg/kg q12h)[b] *plus* metronidazole (500 mg q8h) *plus* ceftriaxone (2 g q12h)	Urgent surgical evaluation is critical. If a penicillin- or oxacillin-sensitive strain is isolated, these agents are superior to vancomycin (penicillin, 4 mU q4h; *or* oxacillin, 2 g q4h).	143
Cerebral malaria	*Plasmodium falciparum*	Artesunate (2.4 mg/kg IV at 0, 12, and 24 h; then once daily)	Avoid glucocorticoids. Until IV artesunate is available, treatment can be initiated with oral artemether-lumefantrine. Atovaquone-proguanil, quinine, and mefloquine are other options.	229, 231
Spinal epidural abscess	*Staphylococcus* spp., gram-negative bacilli	Vancomycin (15 mg/kg q12h)[b] ***plus either*** Piperacillin/tazobactam (4.5 g q8h via EI) *or* cefepime (2 g q8h via EI)[c]	Surgical evaluation is essential. If a β-lactam–sensitive strain is isolated, oxacillin, 2 g q4h or cefazolin 2 gm IV q8h is superior to vancomycin.	453
Focal Infections				
Acute bacterial endocarditis	*S. aureus,* β-hemolytic streptococci, HACEK group,[e] *Neisseria* spp., *S. pneumoniae*	Ceftriaxone (2 g q12h) or cefepime (2 g q8h via EI)[c] *plus* vancomycin (15 mg/kg q12h)[b]	Adjust treatment when culture data become available. Evaluation by cardiology and cardiothoracic surgery is essential.	133

[a]These empirical regimens include coverage for gram-positive pathogens that are resistant to β-lactam antibiotics. Local resistance patterns should be considered and may alter the need for empirical vancomycin or for expanded coverage for antibiotic-resistant gram-negative pathogens. [b]A vancomycin loading dose of 20–25 mg/kg can be considered in critically ill patients. Dosing must be adjusted based on pharmacokinetic/pharmacodynamic monitoring. Daptomycin (10 mg/kg once daily) can be considered in place of vancomycin as alternate coverage for β-lactam resistant gram-positive organisms. Data for use in central nervous system infections are limited but emerging. [c]EI, extended infusion. β-Lactam antibiotics may exhibit unpredictable pharmacodynamics in sepsis. Prolonged or continuous infusions are often used. [d]The optimal dose of IV immunoglobulin has not been determined, but the median dose in observational studies is 2 g/kg (total dose administered for 1–5 days). [e]*Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium hominis, Eikenella corrodens,* and *Kingella kingae.*

Petechial rashes caused by viruses are seldom associated with hypotension or a toxic appearance, although there can be exceptions (e.g., severe measles or arboviral infection). Petechial rashes limited to the distribution of the superior vena cava are rarely associated with severe disease. In other settings, petechial rashes require more urgent attention.

Meningococcemia (See also Chap. 160) Almost three-quarters of patients with *N. meningitidis* bacteremia have a rash. Meningococcemia most often affects young children (i.e., those 6 months to 5 years old). In sub-Saharan Africa, the high prevalence of serogroup A meningococcal disease has been a threat to public health for more than a century. Thousands of deaths occur annually in this area, which is known as the "meningitis belt," and large epidemic waves occur approximately every 8–12 years. In the setting of aggressive vaccination programs against serogroup A, disease due to other serogroups, such as serogroups C, W135, and X, are increasing. Outside Africa, outbreaks for the past 50 years reported in the United States and Europe are caused primarily by serogroup C (approximately 60%) followed by serogroup B (29%). In the United States, sporadic cases and outbreaks occur in day-care centers, schools (grade school through college, particularly among college freshmen living in residential halls), and army barracks. Outbreaks have also been described in people experiencing homelessness. People with underlying comorbidities, such as cancer, renal or liver disease, or solid organ transplant recipients, are at increased risk. Household contacts of index cases are at 400–800 times greater risk of disease than the general population. Patients may have fever, headache, nausea, vomiting, myalgias, changes in mental status, and meningismus. However, the rapidly progressive form of disease is not usually associated with meningitis. The rash is initially pink, blanching, and maculopapular, appearing on the trunk and extremities, but then becomes hemorrhagic, forming petechiae. Petechiae are first seen at the ankles, wrists, axillae, mucosal surfaces, and palpebral and bulbar conjunctiva, with subsequent spread on the lower extremities and to the trunk. A cluster of petechiae may be seen at pressure points—e.g., where a blood pressure cuff has been inflated. In rapidly progressive meningococcemia (10–20% of cases), the petechial rash quickly becomes purpuric **(see Fig. A1-41)**, and patients develop DIC, multiorgan failure, and shock; 50–60% of these patients die, and survivors often require extensive debridement or amputation of gangrenous extremities. Hypotension with petechiae for <12 h is associated with significant mortality. Cyanosis, coma, oliguria, metabolic acidosis, and elevated partial thromboplastin time also are associated with a fatal outcome. Antibiotics given in the office by the primary care provider before hospital evaluation and admission may improve prognosis; this observation suggests that early initiation of treatment may be lifesaving. Members of the patient's household and other persons with close contact should receive antibiotic prophylaxis with ciprofloxacin, rifampin, or ceftriaxone. Meningococcal conjugate vaccines are protective against serogroups A, C, Y, and W135 and are recommended for children 11–12 years of age with a booster dose at 16 years of age, and for other high-risk patients. Vaccines active against serogroup B are recommended for high-risk individuals ≥10 years of age and may be appropriate for teens and young adults (16 through 23 years of age).

Rocky Mountain Spotted Fever and Other Rickettsial Diseases (See also Chap. 192) RMSF is a tickborne disease that occurs throughout North and South America. It is caused primarily by *Rickettsia rickettsii* but can be caused by other rickettsiae (e.g., *R. parkeri*, *R. akari*). Up to 40% of patients do not report a history of a tick bite, but a history of travel or outdoor activity (e.g., camping in tick-infested areas) can often be ascertained. For the first 3 days, headache, fever, malaise, myalgias, nausea, vomiting, and anorexia are documented. By day 3, half of patients have skin findings. Blanching macules develop initially on the wrists and ankles and then spread over the legs and trunk. The lesions become hemorrhagic and are frequently petechial. The rash spreads to palms and soles later in the course. The centripetal spread is a classic feature of RMSF but occurs in a minority of patients. Moreover, 10–15% of patients with RMSF never develop a rash. The patient can be hypotensive and develop noncardiogenic pulmonary edema, confusion, lethargy, and encephalitis progressing to coma. The CSF contains 10–100 cells/μL, usually with a predominance of mononuclear cells. The CSF glucose level is often normal; the protein concentration may be slightly elevated. Renal and hepatic injury as well as bleeding secondary to vascular damage are noted. Delayed recognition and treatment are associated with a greater risk of death; mortality rates are 20–35% if treatment is delayed or not prescribed compared with ~4% when treated with doxycycline within 5 days of onset. Native Americans, Alaskan natives, Pacific Islanders, children 5–9 years of age, adults >70 years old, and persons with underlying immunosuppression are at increased risk of death as well.

Other rickettsial diseases cause significant morbidity and mortality worldwide. *Mediterranean spotted fever* caused by *Rickettsia conorii* is found in Africa, southwestern and south-central Asia, and southern Europe. Patients have fever, flu-like symptoms, and an inoculation eschar at the site of the tick bite. A maculopapular rash develops within 1–7 days, involving the palms and soles but sparing the face. Elderly patients or those with diabetes, alcoholism, uremia, or congestive heart failure are at risk for severe disease characterized by neurologic involvement, respiratory distress, and gangrene of the digits or purpura fulminans. Mortality rates associated with this severe form of disease approach 50% without treatment, but a single day of doxycycline is associated with much improved outcomes. *Epidemic typhus*, caused by *Rickettsia prowazekii*, is transmitted in louse-infested environments and emerges in conditions of extreme poverty, war, refugee camps, and natural disaster. Patients experience a sudden onset of high fevers, severe headache, cough, myalgias, and abdominal pain. A maculopapular rash develops (primarily on the trunk) in more than half of patients and can progress to petechiae and purpura. Serious signs include delirium, coma, seizures, noncardiogenic pulmonary edema, skin necrosis, and peripheral gangrene. Mortality rates approached 60% in the preantibiotic era and continue to exceed 10–15% in contemporary outbreaks. *Scrub typhus*, caused by *Orientia tsutsugamushi* (a separate genus in the family Rickettsiaceae), is transmitted by larval mites or chiggers and is one of the most common infections in southeastern Asia and the western Pacific. The organism is found in areas of heavy scrub vegetation (e.g., along riverbanks) and most common in rural areas among farming communities. Patients may have an inoculation eschar and may develop a maculopapular rash, lymphadenopathy, and dyspnea. Severe cases progress to pneumonia, meningoencephalitis, myocarditis, DIC, and renal failure. Mortality rates range from 1% to 70% and vary by location, increasing age, myocarditis, delirium, pneumonitis, or signs of hemorrhage.

If recognized in a timely fashion, rickettsial disease is very responsive to tetracycline-based treatment. Doxycycline (100 mg twice daily for 1–14 days) is the treatment of choice for both adults and children. Combination therapy with doxycycline and azithromycin reduces complications and death in patients with severe scrub typhus.

Purpura Fulminans (See also Chaps. 160 and 315) Purpura fulminans is the cutaneous manifestation of DIC and presents as large ecchymotic areas and hemorrhagic bullae. Progression of petechiae to purpura, ecchymoses, and gangrene is associated with congestive heart failure, septic shock, acute renal failure, acidosis, hypoxia, hypotension, and death. Purpura fulminans has been associated primarily with *N. meningitidis* but, in splenectomized patients, may be associated with *S. pneumoniae*, *H. influenzae*, and *S. aureus*.

Ecthyma Gangrenosum Septic shock caused by *P. aeruginosa* or, less often, *Aeromonas hydrophila* or other gram-negative organisms, can be associated with ecthyma gangrenosum **(see Figs. 170-1 and A1-34)**: hemorrhagic vesicles surrounded by a rim of erythema with central necrosis and ulceration, most frequently located on the legs and trunk. Echthyma gangrenosum is most common among patients with neutropenia, extensive burns, and hypogammaglobulinemia.

Other Infections Associated with Rash *Vibrio vulnificus* and other noncholera *Vibrio* bacteremic infections **(Chap. 173)** can cause focal skin lesions and overwhelming sepsis in hosts with chronic liver

disease, heavy alcohol consumption, iron storage disorders, diabetes, renal insufficiency, hematologic disease, or malignancy or other immunocompromising conditions. More than 95% of the cases are in the subtropical Pacific and Atlantic Oceans coastal regions in the Northern Hemisphere. After ingestion of contaminated raw shellfish (typically oysters from the Gulf Coast in U.S. cases), there is a sudden onset of malaise, chills, fever, and hypotension. The patient develops bullous or hemorrhagic skin lesions, usually on the lower extremities, and 75% of patients have leg pain. The mortality rate can be as high as 35–60%, particularly when the patient presents with hypotension and septicemia. Outcomes are improved when patients are treated with fluoroquinolones with or without cephalosporins or with tetracycline-containing regimens. Other infections, caused by agents such as *Aeromonas*, *Klebsiella*, and *E. coli*, can cause hemorrhagic bullae and death due to overwhelming sepsis in cirrhotic patients. *Capnocytophaga canimorsus* can cause septic shock in asplenic or cirrhotic patients. Infection typically follows a dog bite. Serovars A–C appear more virulent, constituting 92% of human infections but only 7.6% of canine isolates. Patients present with fever, chills, myalgia, vomiting, diarrhea, dyspnea, confusion, and headache. Findings can include an exanthem or erythema multiforme **(see Figs. 59-9 and A1-24A)**, cyanotic mottling or peripheral cyanosis, petechiae, and ecchymosis. About one-third of patients with sepsis develop septic shock, and 11–30% of patients with this fulminant form die of overwhelming sepsis and DIC. Survivors may require amputation because of gangrene.

Erythroderma TSS **(Chaps. 152 and 153)** is usually associated with erythroderma. The patient presents with fever, malaise, myalgias, nausea, vomiting, diarrhea, and confusion. There is a sunburn-type rash that may be subtle and patchy but is usually diffuse and is found on the face, trunk, and extremities. Erythroderma, which desquamates after 1–2 weeks, is more common in *Staphylococcus*-associated than in *Streptococcus*-associated TSS. Hypotension develops rapidly—often within hours—after the onset of symptoms. Early renal failure may precede hypotension and distinguishes this syndrome from other septic shock syndromes. There may be no indication of a primary focal infection, although possible cutaneous or mucosal portals of entry for the organism can be ascertained through a careful history. Colonization rather than overt infection of the vagina or a postoperative wound, for example, is typical with staphylococcal TSS, and the mucosal areas appear hyperemic but not infected. Streptococcal TSS is more often associated with skin or soft tissue infection (including necrotizing fasciitis), and patients are more likely to be bacteremic. TSS caused by *Clostridium sordellii* is associated with childbirth or with skin injection of black-tar heroin. The diagnosis of TSS is defined by the clinical criteria of fever, rash, hypotension, and multiorgan involvement, although fever is typically absent when TSS is caused by *C. sordellii*. The mortality rate is 5% for menstruation-associated TSS, 10–15% for nonmenstrual TSS, 30–70% for streptococcal TSS, and up to 90% for obstetric *C. sordellii* TSS. Clindamycin improves outcomes when included in the treatment regimen. The use of IV immunoglobulin is associated with improved survival in some studies, in conjunction with clindamycin therapy.

Viral Hemorrhagic Fevers Viral hemorrhagic fevers **(Chaps. 215 and 216)** are zoonotic illnesses caused by viruses that reside in either animal reservoirs or arthropod vectors. These diseases occur worldwide and are restricted to areas where the host species live. They are caused by four major groups of viruses: Arenaviridae (e.g., Lassa fever in Africa), Bunyaviridae (e.g., Rift Valley fever in Africa; hantavirus hemorrhagic fever with renal syndrome in Asia; and Crimean-Congo hemorrhagic fever, which has an extensive geographic distribution), Filoviridae (e.g., Ebola and Marburg virus infections in Africa), and Flaviviridae (e.g., yellow fever in Africa and South America and dengue in Asia, Africa, and the Americas). Lassa fever and Ebola and Marburg virus infections are also transmitted from person to person. The vectors for most viral fevers are found in rural areas; dengue and yellow fever are important exceptions. After a prodrome of fever, myalgias, and malaise, patients develop evidence of vascular damage, petechiae, and local hemorrhage. Shock, multifocal hemorrhaging, and neurologic signs (e.g., seizures or coma) predict a poor prognosis. Dengue **(Chap. 215)** is the most common arboviral disease worldwide. More than 100–400 million cases occur each year, ~25% of which are symptomatic with at least 12,000–20,000 deaths. Patients have a triad of symptoms: hemorrhagic manifestations, evidence of plasma leakage, and platelet counts of <100,000/μL. Mortality rates are 10–20%. If dengue shock syndrome develops, which is associated with severe hepatitis and neurologic involvement, mortality rates can reach 40%. Ebola infection has been associated with outbreaks with high mortality rates. From 1976 to 2022, 35 outbreaks were reported with an average case fatality rate of approximately 50%. Symptoms can appear 2–21 days after exposure, but most patients become ill within 9 days. The patient first presents with fatigue, fever, headache, and muscle pains, and the illness can progress to multiorgan failure and hemorrhaging. Careful volume-replacement therapy to maintain blood pressure and intravascular volume is key to survival in these infections.

Other viral illnesses with rash, such as measles, can be associated with significant mortality rates, especially in patients who develop organ complications such as pneumonia, pancreatitis or encephalitis. Measles continues to be responsible for more than 100,000 deaths per year worldwide, and to cause outbreaks in populations with low vaccination rates.

SEPSIS WITH A SOFT TISSUE/MUSCLE PRIMARY FOCUS

See also Chap. 134.

Necrotizing Fasciitis This infection is characterized by extensive necrosis of the subcutaneous tissue and fascia. It may arise at a site of minimal trauma or surgical incision and may also be associated with recent varicella, childbirth, or muscle strain. Diabetes mellitus, IV drug use, chronic liver or renal disease, and malignancy are associated risk factors. The most common causes of necrotizing fasciitis are group A streptococci alone **(Chap. 153)** and a mixed facultative and anaerobic flora **(Chap. 134)**. The incidence of group A streptococcal necrotizing fasciitis has been increasing for the past quarter-century; surveillance in the United States links 13% of the cases to active IV drug use or homelessness. Physical findings are initially minimal except for soft tissue edema and mild erythema compared with the severity of pain and the degree of fever. The infected area is red, hot, shiny, swollen, and exquisitely tender. In untreated infection, the overlying skin develops blue-gray patches after 36 h, and cutaneous bullae and necrosis develop after 3–5 days. Necrotizing fasciitis due to a mixed flora, but not that due to group A streptococci, can be associated with gas production. Without treatment, pain decreases because of thrombosis of the small blood vessels and destruction of the peripheral nerves—an ominous sign. The mortality rate is 11–34% overall and increases when in association with TSS. With surgery, outcomes are significantly better. Necrotizing fasciitis may also be due to *Clostridium perfringens* **(Chap. 159)**; in this condition, the patient is extremely toxic and the mortality rate is high. Within 48 h, rapid tissue invasion and systemic toxicity associated with hemolysis and death ensue. The distinction between this entity and clostridial myonecrosis is made by muscle biopsy.

Clostridial Myonecrosis (See also Chap. 159) Myonecrosis is often associated with trauma or surgery but can develop spontaneously. The incubation period is usually 12–24 h long, and massive necrotizing gangrene develops within hours of onset. Systemic toxicity, shock, and death can occur within 12 h. The patient's pain and toxic appearance are out of proportion to physical findings. On examination, the patient is febrile, apathetic, tachycardic, and tachypneic and may express a feeling of impending doom. Hypotension and renal failure develop later, and hyperalertness is evident preterminally. The skin over the affected area is bronze-brown, mottled, and edematous. Bullous lesions with serosanguineous drainage and a mousy or sweet odor can develop. Crepitus can occur secondary to gas production in muscle tissue. The mortality rate is >65% for spontaneous myonecrosis, which is often associated with *Clostridium septicum* or *C. tertium* and underlying malignancy. The mortality rates associated with trunk and

limb infection are 63% and 12%, respectively, and any delay in surgical treatment increases the risk of death.

NEUROLOGIC INFECTIONS WITH OR WITHOUT SEPTIC SHOCK

Bacterial Meningitis (See also Chap. 143) Bacterial meningitis is one of the most common infectious disease emergencies involving the central nervous system. Although hosts with cell-mediated immune deficiency (including transplant recipients, diabetic patients, elderly patients, and cancer patients receiving certain chemotherapeutic agents) are at particular risk for *Listeria monocytogenes* meningitis, most cases in adults are due to *S. pneumoniae* (30–60%) and *N. meningitidis* (10–35%). The classic presentation of fever, meningismus, and altered mental status is seen in only one-third to one-half of patients and is more common in adults over 60 years of age, although the elderly can also present without fever or meningeal signs. Cerebral dysfunction is evidenced by confusion, delirium, and lethargy that can progress to coma. In some cases, the presentation is fulminant, with sepsis and brain edema; papilledema at presentation is unusual and suggests another diagnosis (e.g., an intracranial lesion). Focal signs, including cranial nerve palsies (IV, VI, VII), can be seen in 10–20% of cases; 50–70% of patients have bacteremia. A poor outcome is associated with coma, seizures, hypotension, a purpuric rash, a pneumococcal etiology, respiratory distress, a CSF glucose level of <0.6 mmol/L (<10 mg/dL), a CSF protein level of >2.5 g/L, and peripheral leukopenia or thrombocytopenia. Rapid initiation of treatment is essential; the odds of an unfavorable outcome may increase by 30% for each hour that treatment is delayed. Dexamethasone is an adjunctive treatment for meningitis in adults, especially for infections caused by *S. pneumoniae,* but is not recommended for *Listeria* meningitis. It must be given before or with the first dose of antibiotics; otherwise, it is unlikely to improve outcomes.

Suppurative Intracranial Infections (See also Chap. 145) Suppurative intracranial infections present along with sepsis and hemodynamic instability. Rapid recognition of the toxic patient with central neurologic signs is crucial to improvement of the prognosis of these entities. Patients with diabetes or hematologic disease may be at increased risk for these infections. *Subdural empyema* arises from the paranasal sinus in 60–70% of cases. Microaerophilic streptococci and staphylococci are the predominant etiologic organisms. The patient is toxic, with fever, headache, and nuchal rigidity. Of all patients, 75% have focal signs and 6–20% die. Despite improved survival rates, 15–44% of patients are left with permanent neurologic deficits. *Septic cavernous sinus thrombosis* follows a facial or sphenoid sinus infection; 70% of cases are due to staphylococci (including MRSA), and the remainder are due primarily to aerobic or anaerobic streptococci. Fungi have been common in some series. A unilateral or retro-orbital headache progresses to a toxic appearance and fever within days. Three-quarters of patients have unilateral periorbital edema that becomes bilateral and then progresses to ptosis, proptosis, ophthalmoplegia, and papilledema. The mortality rate is as high as 30% in older studies with frequent neurologic sequelae but recent reports indicate improved survival as high as 90%. *Septic thrombosis of the superior sagittal sinus* spreads from the ethmoid or maxillary sinuses and is caused by *S. pneumoniae*, other streptococci, and staphylococci. The fulminant course is characterized by headache, nausea, vomiting, rapid progression to confusion and coma, nuchal rigidity, and brainstem signs. Broad-spectrum antibiotics and early surgical intervention at the primary site of infection may improve outcomes. Anticoagulation or steroids are of uncertain benefit.

Brain Abscess (See also Chap. 145) Brain abscess often occurs without systemic signs. Almost half of patients are afebrile, and presentations are more consistent with a space-occupying lesion in the brain; 70% of patients have headache and/or altered mental status, 50% have focal neurologic signs, and 25% have papilledema. Abscesses can present as single or multiple lesions resulting from contiguous foci or hematogenous infection, such as endocarditis, or after surgery or trauma. The infection progresses over several days from cerebritis to an abscess with a mature capsule. More than one-fourth to one-half of infections are polymicrobial, with an etiology consisting of aerobic bacteria (primarily streptococcal species) and anaerobes. Abscesses arising hematogenously are especially apt to rupture into the ventricular space, causing a sudden and severe deterioration in clinical status and a high mortality rate. Otherwise, mortality is low (<20%) but morbidity is high (30–55%). Patients presenting with stroke and a parameningeal infectious focus, such as sinusitis or otitis, may have a brain abscess; physicians must maintain a high level of suspicion. Prognosis worsens in patients with a fulminant course, delayed diagnosis, abscess rupture into the ventricles, multiple abscesses, or abnormal neurologic status at presentation. Patients who receive medical therapy alone, compared with those receiving combined medical and surgical interventions, have higher mortality and a greater chance of neurologic sequelae.

Cerebral Malaria (See also Chap. 231) This entity should be urgently considered for inhabitants of, or recent travelers to, areas endemic for malaria. Any patient with a change in mental status or repeated seizure in the setting of fulminant malaria has cerebral malaria. Fulminant malaria is caused by *Plasmodium falciparum* and is associated with temperatures of >40°C (>104°F), hypotension, jaundice, acute respiratory distress syndrome, and bleeding. Patients present with a febrile illness and lethargy or other neurologic signs, In adults, this nonspecific febrile illness progresses to coma over several days; occasionally, coma occurs within hours and death within 24 h. Nuchal rigidity and photophobia are rare. On physical examination, symmetric encephalopathy is typical, and upper motor neuron dysfunction with decorticate and decerebrate posturing can be seen in advanced disease. Unrecognized infection results in a 20–30% mortality rate. Intravenous artesunate is associated with better outcomes. Children with neurologic deficit at hospital discharge, seizure recurrence during treatment, and/or ischemic neural injury on MRI are at particular risk for neurologic and mental health sequelae.

Intracranial and Spinal Epidural Abscesses (See also Chap. 453) Spinal and intracranial epidural abscesses (SEAs and ICEAs) can result in permanent neurologic deficits, sepsis, and death. At-risk patients include those with diabetes mellitus; IV drug use; chronic alcohol abuse; recent spinal trauma, surgery, or epidural anesthesia; and other comorbid conditions, such as HIV infection. Fungal epidural abscess and meningitis have been linked to epidural or paraspinal glucocorticoid injections. In the United States and Canada, where early treatment of otitis and sinusitis is typical, ICEA is rare but the number of cases of SEA is on the rise. ICEAs typically present as fever, mental status changes, and neck pain, while SEAs often present as fever, localized spinal tenderness, and back pain. ICEAs are typically polymicrobial, whereas SEAs are most often due to hematogenous seeding, with staphylococci the most common etiologic agent. Early diagnosis and treatment, which may include surgical drainage, minimize rates of mortality and permanent neurologic sequelae. Outcomes are worse for SEA due to MRSA, for infection at a higher vertebral-body level, for impaired neurologic status on presentation, and for dorsal rather than ventral abscess location. Elderly patients and persons with renal failure, malignancy, and other comorbidities also have less favorable outcomes.

OTHER FOCAL SYNDROMES WITH A FULMINANT COURSE

Infection at virtually any primary focus (e.g., osteomyelitis, pneumonia, pyelonephritis, or cholangitis) can result in bacteremia and sepsis. Rapid clinical deterioration and death can be associated with destruction of the primary site of infection, as is seen in endocarditis and in infections of the oropharynx (e.g., Ludwig's angina or epiglottitis, in which edema suddenly compromises the airway). TSS has been associated with focal infections such as septic arthritis, peritonitis, sinusitis, and wound infection. Lemierre's syndrome is jugular septic thrombophlebitis primarily caused by *Fusobacterium necrophorum,* but it can be caused by other *Fusobacterium* spp., anaerobic streptococci and other bacteria. Lemierre's syndrome is associated with metastatic infectious emboli (primarily to the lung but sometimes to the liver or

other organs) and sepsis, with mortality rates of >15%. *Fusobacterium* bloodstream infections have been associated with occult gastrointestinal or genitourinary malignancy.

Rhinocerebral Mucormycosis (See also Chap. 224) Individuals with diabetes or immunocompromising conditions such as solid organ transplants or hematologic malignancies are at risk for invasive rhinocerebral mucormycosis. Patients present with low-grade fever, dull sinus pain, diplopia, decreased mental status, decreased ocular motion, chemosis, proptosis, dusky or necrotic nasal turbinates, and necrotic hard-palate lesions that respect the midline. Without rapid recognition, surgical intervention, and antifungal therapy, the process continues on an inexorable invasive course, with mortality rates of 50–85% or greater. Uncontrolled diabetes and increasing age are negative prognostic factors.

Acute Bacterial Endocarditis (See also Chap. 133) This entity presents with a much more aggressive course than subacute endocarditis. Bacteria such as *S. aureus*, *S. pneumoniae*, *L. monocytogenes*, *Haemophilus* species, and streptococci of groups A, B, and G attack native valves. Native-valve endocarditis caused by *S. aureus* (including MRSA strains) is increasing. Mortality rates range from 10% to 40%. The host may have comorbid conditions such as underlying malignancy, diabetes mellitus, IV drug use, or alcoholism. Rheumatic valvular disease remains the most prevalent risk factor in Africa but is much less common in the United States. The patient presents with fever, fatigue, and malaise <2 weeks after onset of infection. On physical examination, a changing murmur and congestive heart failure may be noted. Hemorrhagic macules on palms or soles (*Janeway lesions*) sometimes develop. Petechiae, Roth's spots, splinter hemorrhages, and splenomegaly are unusual. Rapid valvular destruction, particularly of the aortic valve, results in pulmonary edema and hypotension. Myocardial abscesses can form, eroding through the septum or into the conduction system and causing life-threatening arrhythmias or high-degree conduction block. Large friable vegetations can result in major arterial emboli, metastatic infection, or tissue infarction including stroke. Older patients with *S. aureus* endocarditis are especially likely to present with nonspecific symptoms—a circumstance that delays diagnosis and worsens prognosis. Rapid intervention is crucial for a successful outcome.

Inhalational Anthrax (See also Chap. S4) Inhalational anthrax, the most severe form of disease caused by *B. anthracis*, had not been reported in the United States for more than 25 years until the use of this organism as an agent of bioterrorism in 2001. Patients presented with malaise, fever, cough, nausea, drenching sweats, shortness of breath, and headache. Rhinorrhea was unusual. All patients had abnormal chest roentgenograms at presentation. Pulmonary infiltrates, mediastinal widening, and pleural effusions were the most common findings. Hemorrhagic meningitis was documented in 38% of these patients. Survival was more likely when antibiotics were given during the prodromal period and when multidrug regimens with at least two bacteriocidal antibiotic agents were used. In the absence of urgent intervention with antimicrobial agents and supportive care, inhalational anthrax progresses rapidly to hypotension, cyanosis, and death.

Viral Respiratory Tract Illness Viral respiratory tract illnesses can cause severe disease; several new syndromes have been described in the past decade. For patients who present with a respiratory illness and a relevant exposure and travel history, these viral illnesses must be considered and appropriate infection control measures instituted in addition to supportive care.

Avian and Swine Influenza (See also Chap. 206) Human cases of avian influenza have occurred primarily in Southeast Asia, particularly Vietnam (H5N1) and China (H7N9). Avian influenza should be considered in patients with severe respiratory tract illness, particularly if they have been exposed to poultry. Patients present with high fever, an influenza-like illness, and lower respiratory tract symptoms; this illness can progress rapidly to bilateral pneumonia, acute respiratory distress syndrome, multiorgan failure, and death. Younger age appears to be associated with a lower risk of complications. Early antiviral treatment with neuraminidase inhibitors should be initiated along with aggressive supportive measures. Unlike avian influenza, whose human-to-human transmission has so far been rare and has not been sustained, influenza caused by a novel swine-associated A(H1N1) virus emerged in 2009 and caused more than 60 million cases and 12,000 deaths in 1 year. Patients most at risk of severe disease were children <5 years of age, elderly persons, patients with underlying chronic conditions, and pregnant women. Obesity also has been identified as a risk factor for severe illness. The virus continues to circulate as a seasonal influenza virus, along with A(H1N1) strains. Although influenza cases dropped during the peak of the COVID-19 pandemic, they are again increasing and cause 3–5 million cases of severe illness and 300,000–650,000 deaths each year.

SARS, COVID-19, and MERS (See Chaps. 204 and 205) Novel betacoronaviruses have now been identified as the cause of severe acute respiratory syndrome (SARS, caused by SARS-CoV-1), Middle East respiratory syndrome (MERS, caused by MERS-CoV), and COVID-19 (caused by SARS-CoV-2). Although the three viruses have many similarities, they differ in degree of contagion and case fatality rates. SARS and MERS "super-spreaders" are very symptomatic and typically critically ill, hospitalized patients. This is in contrast to COVID-19 where patients with highly transmissible virus are often asymptomatic or have mild disease. SARS emerged in 2002 in China and was diagnosed in several countries, primarily in Asia. Possible animal reservoirs include bats and civets. SARS-CoV-1 is characterized by efficient human transmission but relatively low mortality. The potential SARS-CoV-1 pandemic was controlled through identification and isolation of infected patients. There have been no reported cases since 2004.

MERS likely has a bat reservoir and was first recognized in 2012 in Saudi Arabia. Human cases have been associated with direct and indirect contact with dromedary camels. Unlike SARS and COVID-19, MERS exhibits inefficient human transmission but carries a high mortality rate. As of 2023, >2600 cases had been confirmed, most in the Arabian Peninsula, with 35% mortality. MERS ranges from asymptomatic infection to acute respiratory distress syndrome, multiorgan failure, and death. Elderly men with comorbidities appear to be at highest risk for poor outcomes. Despite little documented human-to-human transmission in the community, nosocomial infection must be prevented by adherence to strict infection control practices. MERS is currently a low-level public health threat and is likely to remain so unless the virus mutates and its transmissibility increases.

COVID-19 caused by SARS-CoV-2 resulted in a pandemic of historic proportion. Originally linked to cases in China, SARS-CoV-2 spread internationally at a rapid pace. As of December 2023, cases approached 773 million worldwide with almost 7 million confirmed deaths; the United States has reported more than 103 million cases and over 1.1 million deaths. Actual infection may exceed reported cases by 8–10 fold. The primary mode of transmission of COVID-19 is through direct person-to-person contact via respiratory droplets; transmission by the airborne route or by contact with contaminated surfaces is much less common. Greatest risk of infection is associated with close and prolonged contact such as in household or congregate settings. Rates of secondary infection among household contacts are high: >50% in studies early in the pandemic.

Although ~80% of patients with symptomatic COVID-19 infection have mild disease such as cough, sore throat, fever, gastrointestinal symptoms, and taste and smell alterations, ~5% of patients develop respiratory failure, shock, and multiorgan system failure. Patients typically have been symptomatic for 5–7 days before progression to severe pneumonia and hypoxemia. Shock, often in the setting of cardiac injury/myocarditis, arrhythmias or cardiomyopathy, and thromboembolic complications such as pulmonary emboli or stroke, can occur. Other manifestations include acute kidney or liver injury. Laboratory findings include lymphopenia, elevated lactate dehydrogenase, and often evidence of a cytokine-release type syndrome with elevated C-reactive protein, D-dimer, ferritin, and proinflammatory cytokines such as interleukin 6 (IL-6). Chest radiographs and CT imaging reveal

diffuse ground-glass opacities. Consolidation, predominantly in the lower lobes and peripherally, is a frequent finding. Mortality rates for patients requiring intensive care and mechanical ventilation have improved significantly over the course of the pandemic but remain ≥20% for patients who progress to that disease severity. Risk factors for severe disease and poor outcomes include age ≥65 years, morbid obesity, diabetes, cardiovascular or cerebrovascular disease, hypertension, chronic obstructive lung disease, and chronic kidney disease. Severe disease and mortality is also increased in males and pregnant women.

Treatment currently includes supportive care, antiviral therapy, anti-inflammatory therapy, and anticoagulation prophylaxis or treatment. Patients with respiratory distress are hypoxemic but maintain pulmonary mechanical functioning; thus, invasive mechanical ventilation should be delayed until other interventions have been exhausted. In a meta-analysis, dexamethasone or other glucocorticoids reduced 28-day mortality in patients with severe COVID-19 disease compared with standard care: 32% and 40%, respectively (odds ratio, 0.66; 95% confidence interval, 0.53–0.82). Thus, dexamethasone (6 mg IV/PO daily) is indicated for patients with hypoxemia. IL-6 inhibitors such as tocilizumab may be indicated for patients with rapidly escalating oxygen requirements. Secondary bacterial pneumonia in COVID-19 is not common, and antibacterial agents should not be routinely prescribed. With the availability of highly effective vaccines, prevention is the most important strategy to control COVID-19. Vaccination has reduced progression to severe disease and hospitalization. In addition, treatment with antiviral agents such as nirmatrelvir/ritonavir or remdesivir can reduce risk of progression to severe disease and hospitalization for patients with mild symptoms.

Hantavirus Pulmonary Syndrome **(See also Chap. 215)**

Hantavirus pulmonary syndrome has been documented in the United States since 1993 (primarily the southwestern states, west of the Mississippi River), Canada, and South America. Most cases occur in rural areas and are associated with exposure to rodents. Patients present with a nonspecific viral prodrome of fever, malaise, myalgias, nausea, vomiting, and dizziness that may progress to pulmonary edema, respiratory failure, and death. Hantavirus pulmonary syndrome causes myocardial depression and increased pulmonary vascular permeability; therefore, careful fluid resuscitation and use of pressor agents are crucial. Use of venoarterial extracorporeal membrane oxygenation (ECMO) for severe Hantavirus pulmonary syndrome has been successful and should be considered. Aggressive cardiopulmonary support during the first few hours of illness can be life-saving in this high-mortality syndrome. The early onset of thrombocytopenia may help distinguish this syndrome from other febrile illnesses in an appropriate epidemiologic setting.

SUMMARY

Acutely ill febrile patients with the syndromes discussed in this chapter require close observation, aggressive supportive measures, and—in most cases—admission to intensive care units. The most important task of the physician is to distinguish these patients from other infected febrile patients whose illness will not progress to fulminant disease. The alert physician must recognize the acute infectious disease emergency and proceed with appropriate urgency.

128 Principles of Immunization

Kathleen M. Neuzil, Kathryn M. Edwards

The birth of vaccinology is often ascribed to Edward Jenner's observation in the 18th century that infection of milkmaids with cowpox, termed *vaccinia* and hence the term *vaccination*, conferred protection against smallpox. This discovery catalyzed a sequence of events that ultimately led to the eradication of smallpox, one of the most disfiguring and lethal infections of humans. Vaccination programs are among the most impactful and cost-effective health interventions. Considered to be one of the greatest achievements in public health, vaccines are estimated to have averted more than 37 million deaths globally between 2000 and 2019. This represents a 45% reduction in deaths compared with a scenario of no vaccination.

Vaccines are defined as inactivated or attenuated pathogens or components of a pathogen (nucleic acid, protein) that, when administered to the host, stimulate a protective response by the cells of the immune system **(Table 128-1)**. Adjuvants may be added to vaccines to nonspecifically boost the immune response. Vaccination is the act of introducing a vaccine into the body to induce protection from a specific disease. Immunization is a process by which a person becomes resistant to a particular infectious disease or pathogen, usually by vaccination. However, immunity may also be conferred passively.

IMMUNE RESPONSES TO VACCINES

While **Chapter 360** provides an overview of immune responses, a few additional concepts are relevant to vaccines. Vaccines targeted for new infectious pathogens, such as SARS-CoV-2 at the onset of the pandemic, or vaccines given to infants and young children without prior exposure to a pathogen, will trigger a primary immune response with peak antibody titers achieved several weeks after administration. It may take several doses of a vaccine to induce a priming response, particularly if the vaccine is inactivated or a toxoid. Live, attenuated vaccines generate more robust responses and generally only require one or two doses. Subsequent booster doses of vaccines trigger a secondary response with rapid induction of antibody within several days to a week. Vaccines administered against common pathogens, such as influenza, will trigger secondary booster responses since all older children and adults would have encountered influenza virus and/or will have received past influenza vaccines. Immune responses to vaccines are generally measured in terms of serum antibody levels, but mucosal antibodies, cellular responses, and memory cells also are stimulated after vaccination and function to prevent disease and sustain immunity.

Passive Immunity Vaccines stimulate active immunity—inducing an immune response by the host to the vaccine antigen—and will be the focus of most of this section. Passive immunity also serves an important role in prophylaxis. Passive immunity results from the exogenous introduction of antibodies. Originally, such antibodies came from another person or animal and were relatively short-lived. Examples included hepatitis A, tetanus, and rabies immunoglobulins. The more recent capability to generate monoclonal antibodies to infectious pathogens, along with methods to extend the half-life of antibodies, has expanded their prophylactic use. Monoclonal antibodies targeted to SARS-CoV-2 strains were beneficial during the pandemic, particularly in populations who did not mount robust immune responses to vaccines. Currently, monoclonal antibodies are routinely used in infants and young children for the prevention of respiratory syncytial virus (RSV) infections, and their use in adults will likely continue or increase in the years ahead. These agents are evaluated for their safety and efficacy using similar methodology as in vaccine studies but will not be discussed extensively in this chapter.

Another type of passive antibody protection is maternal immunization, whereby vaccines are given to the pregnant person and the

TABLE 128-1 Categories and Characteristics of Approved Vaccines and Adjuvants

VACCINES

TECHNOLOGY	DESCRIPTION	EXAMPLES OF APPROVED VACCINES	ADVANTAGES	DISADVANTAGES
Live attenuated	Weakened or attenuated form of the pathogen that causes disease	Measles, mumps, rubella, varicella, oral poliomyelitis, nasal influenza vaccine, oral rotavirus	Mimics natural infection Effective priming with durable immunity Large-scale manufacturing capabilities Single or two doses often sufficient	Difficult to reach desired level of attenuation Safety concerns for certain populations (e.g., pregnant women, immunocompromised patients) Stability
Inactivated	Pathogens or toxins rendered nonreplicating through heat or chemical processes (may be entire pathogen or parts of it)	Inactivated poliomyelitis, hepatitis A, whole-cell pertussis, tetanus and diphtheria toxoids	Induces broad immune response to multiple antigens Large-scale manufacturing capabilities	Reactogenic Multiple doses needed May require adjuvant
Purified protein-based (split or subunit)	Specific parts of the pathogen are produced in culture	Influenza, acellular pertussis, recombinant shingles	Highly specific immune response Noninfectious Low reactogenicity Ease of production	Multiple doses may be needed May require adjuvant Limited cross-protective immunity
Polysaccharide–protein conjugates	Type of subunit vaccine that combines a polysaccharide antigen with a protein carrier to improve immune responses	Pneumococcal, meningococcal, typhoid, Hib	Conjugate protein may also provide immunity (e.g., tetanus) Strong immune responses in all ages, including infants	Technically difficult and costly to produce Individual conjugate required for each vaccine serotype
Virus-like particles	One or more proteins arranged to closely resemble viruses	Hepatitis B, HPV	Broad and robust immunity Noninfectious	Technically difficult to produce Lower stability
Replicating viral vector	Replicating, nonpathogenic viruses deliver nucleic acid to host for in vivo production of antigen	Vesicular stomatitis virus–based Ebola vaccine	Induces broad immune response High manufacturing scalability	Immunity to vector may dampen immune response Safety of vector—may not be suitable for certain immunocompromised populations
Nonreplicating viral vector	Replication-deficient nonpathogenic viruses deliver nucleic acid to host for in vivo production of antigen	Chimp adenovirus–based COVID-19 vaccine	Induces broad immune response High manufacturing scalability	Immunity to vector may dampen immune response
Nucleic acid (DNA, RNA)	Lipid nanoparticles deliver nucleic acid to host for in vivo production of antigen	COVID-19 mRNA vaccines	Rapid development and manufacturing timelines Effective and safe for majority of population	May require several doses/boosters to maintain immunity Reactogenic

ADJUVANTS

TECHNOLOGY	EXAMPLES	CURRENT USE	MECHANISM OF ACTION
Alum	Aluminum hydroxide or aluminum phosphate	Multiple vaccines—e.g., HPV, hepatitis A, DTaP	Possible depot effect; increases antibody production
Oil-in-water emulsion	AS03, MF59	Influenza	Increases recruitment of innate immune cells and enhanced antigen uptake
Toll-like receptor (TLR) agonists	Monophosphoryl lipid A (MPL) Cytosine-phosphate-guanine (CpG)	HPV (AS04—MPL and alum) Shingles (MPL and QS21) Hepatitis B (CPG)	Activates TLR to enhance antigen presentation and enhance adaptive immune responses
Saponins	QS-21, Matrix-M	Malaria vaccines (MPL, QS21, and Matrix-M) COVID-19 (Matrix M)	Prolongs antigen bioavailability and enhances antigen signals
Delivery platforms	Lipid nanoparticle (LNP)	COVID-19 mRNA vaccines	Improved lymphatic transport enhances antigen uptake and presentation

antibody generated by their immune system is transferred to the fetus through the placenta. Examples of vaccines given to the pregnant person, largely for the protection of the baby, include tetanus, acellular pertussis, and RSV vaccines. Other vaccines given to pregnant persons for protection of both the mother and the baby include influenza and COVID-19.

VACCINE FORMULATIONS

Vaccine formulations have evolved over time (Fig. 128-1). In the late 19th to mid-20th century, methods to inactivate whole bacteria and detoxify bacterial toxins led to early whole-cell typhoid and cholera vaccines, as well as diphtheria and tetanus toxoids. The discovery that repeated passage of organisms in unnatural hosts could select for avirulent strains provided the foundation for Bacille Calmette-Guérin (BCG) vaccine for tuberculosis and yellow fever vaccines. The ability to grow viruses in cell culture informed the development of live attenuated vaccines against poliomyelitis, measles, mumps, rubella, and varicella viruses between 1950 and 1980. During the next three decades, the fields of biotechnology and molecular genetics burgeoned. New vaccines that circumvented poor immune responses to bacterial polysaccharides by their conjugation to proteins included pneumococcal, *Haemophilus influenzae* type b, and meningococcal vaccines. The development of recombinant DNA technology allowed antigens to be expressed in cell lines, leading to hepatitis B and human papillomavirus (HPV) vaccines.

With the COVID-19 pandemic, a new generation of vaccines and platform technologies emerged with unprecedented speed. While many of these new technologies had been in development for years, the public health need and the influx of government resources propelled these technologies through the approval and deployment phases at an accelerated pace. The gene-based (e.g., mRNA) and vector-based technological advancements have been most visible. For years,

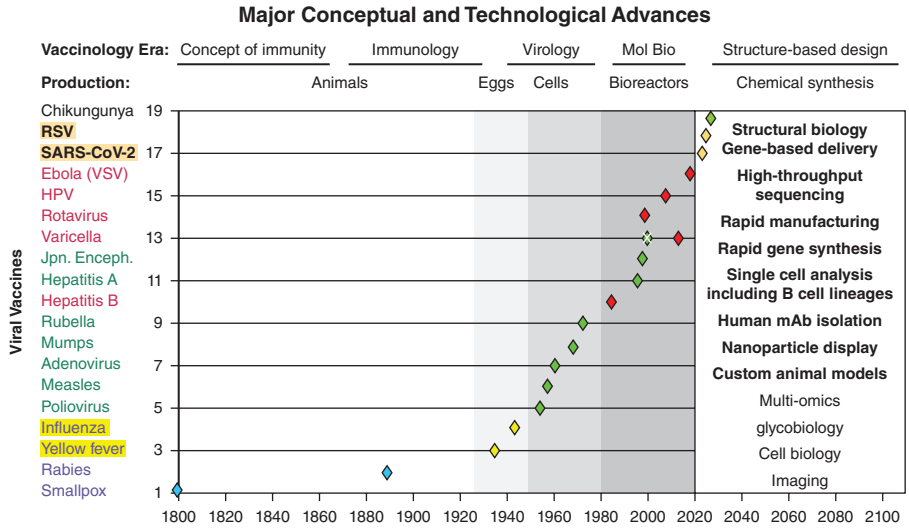

FIGURE 128-1 Major conceptual and technological advances for viral vaccines in the vaccinology era. *(Reproduced with permission from Barney Graham.)*

mRNA technology was limited by its instability and inefficiency of in vivo transfection, until the lipid nanoparticle (LNP) delivery system improved the RNA-based vaccine delivery. Further, new adjuvants and structure-guided antigen design of the SARS-CoV-2 spike protein transformed the field. These technological advances were accompanied by innovations in trial design, real-time safety surveillance and effectiveness evaluations at a massive scale, transmission modeling, and sophisticated analysis of immunologic correlates of protection.

Adjuvants Adjuvants are substances that are added to vaccines to enhance the immune responses to the antigen. Replicating viral vaccines generally do not need adjuvants, but they are often needed in inactivated or protein-based vaccines. Early emulsions, such as Freund's adjuvant, stimulated humoral and cellular responses but were very reactogenic. Alum, the oldest adjuvant formulated as aluminum hydroxide or phosphate, has been in use for more than 90 years. It promotes humoral immune responses, has an excellent safety record, and is included in many of the vaccines administered to infants and young children. As the understanding of molecular mechanisms involved in immune responses progressed, new adjuvants were developed. Oil-in-water emulsions, including MF59 and AS03, contain squalene as a vehicle and enhance innate and adaptive immune responses. They are approved in combination with certain influenza vaccines. As Toll-like receptors were discovered, adjuvants were developed to combine with the newer, more purified protein and subunit vaccines. The Toll-like receptor agonists TLR4 and TLR9 have been included in licensed vaccines. These include monophosphoryl lipid A (MPL) with alum (AS04) for HPV and cytosine-phosphate-guanine (CpG) for hepatitis B. More recently, MPL has been combined with a natural saponin component, QS-21, for use in the recombinant shingles vaccine and the RTS,S malaria vaccine. Likewise, a saponin-based adjuvant, Matrix-M, is approved for use in the recombinant COVID-19 vaccine and the R21 malaria vaccine. In addition to enhancing delivery of mRNA vaccines, LNPs induce inflammation and have an adjuvanting effect. Additional adjuvants are being studied in experimental vaccines, and others will likely be included in licensed products in the future.

VACCINE DEVELOPMENT

The pathway from vaccine discovery to population impact encompasses a broad set of components summarized in Fig. 128-2. These steps include understanding of the burden of the pathogen to be prevented and the immune factors involved in protection; antigen discovery; preclinical animal studies advancing to human trials assessing immune responses, safety, and efficacy; vaccine licensure and policy-making; implementation; and finally monitoring of vaccine uptake, impact, and safety after implementation. Well-established systems and processes, both pre- and postlicensure, ensure that vaccines are safe and effective.

Establishing the Need for an Immunization Generally, before extensive resources are expended to formulate and develop vaccines, it is important to establish the burden of disease, the population at risk for the disease, and the mechanisms involved in protection. Much of this can be done through existing surveillance systems, such as those at the Centers for Disease Control and Prevention (CDC), that measure the burden of disease and the population at risk. In certain situations, vaccines are developed before their potential benefit is fully known, based on the theoretical risk to the population. Examples of these vaccines are those directed against potentially pandemic influenza strains or other pandemic threats.

Phases of Vaccine Development Like the development of pharmaceutical agents, vaccine development progresses through preclinical and three distinct clinical stages: phases 1, 2, and 3. Under specific circumstances where phase 3 trials may be delayed or challenging, controlled human infection models (CHIM) may be part of the development pathway.

Initially, research focuses on the identification of an antigen or antigens with the potential to stimulate a protective immune response that will prevent disease upon encounter with the pathogen. For most vaccines the generation of an antibody directed to an important component of the pathogen is associated with protection. Examples are vaccines directed against the attachment proteins such as the spike in SARS-CoV-2 vaccines or against toxins such as the tetanus or diphtheria vaccines. These proposed vaccines are administered in *preclinical* studies to small animals, often mice; their immune responses are measured, and safety established. Generation of immunity against the pathogen must be demonstrated, or the vaccine will not undergo further testing. Toxicity studies are conducted in animals to detect safety signals, and some vaccinated animals are challenged with wild-type pathogens after vaccination to establish protection.

Phase 1, 2, and 3 Clinical Trials When preclinical studies in animals demonstrate that the vaccine stimulates an immune response and there are no toxicity concerns, vaccines then undergo *phase 1 clinical trials*. In the United States, prior to the onset of phase 1 studies, the vaccine manufacturer must submit an Investigational New Drug (IND) application to the U.S Food and Drug Administration (FDA) that outlines the vaccine approach prior to the start of the study. When the IND is approved, phase 1 trials can begin. These trials enroll limited numbers of healthy participants, usually fewer than 100 individuals and generally between the ages of 18 to approximately 55 years, primarily to test the safety of the new experimental vaccine, although immunogenicity also is measured. Subjects enrolled in phase 1 studies are well informed about the risks and the potential benefits of the vaccines and are screened for their ability to be monitored closely and to adhere to rigorous safety assessments. These assessments include daily

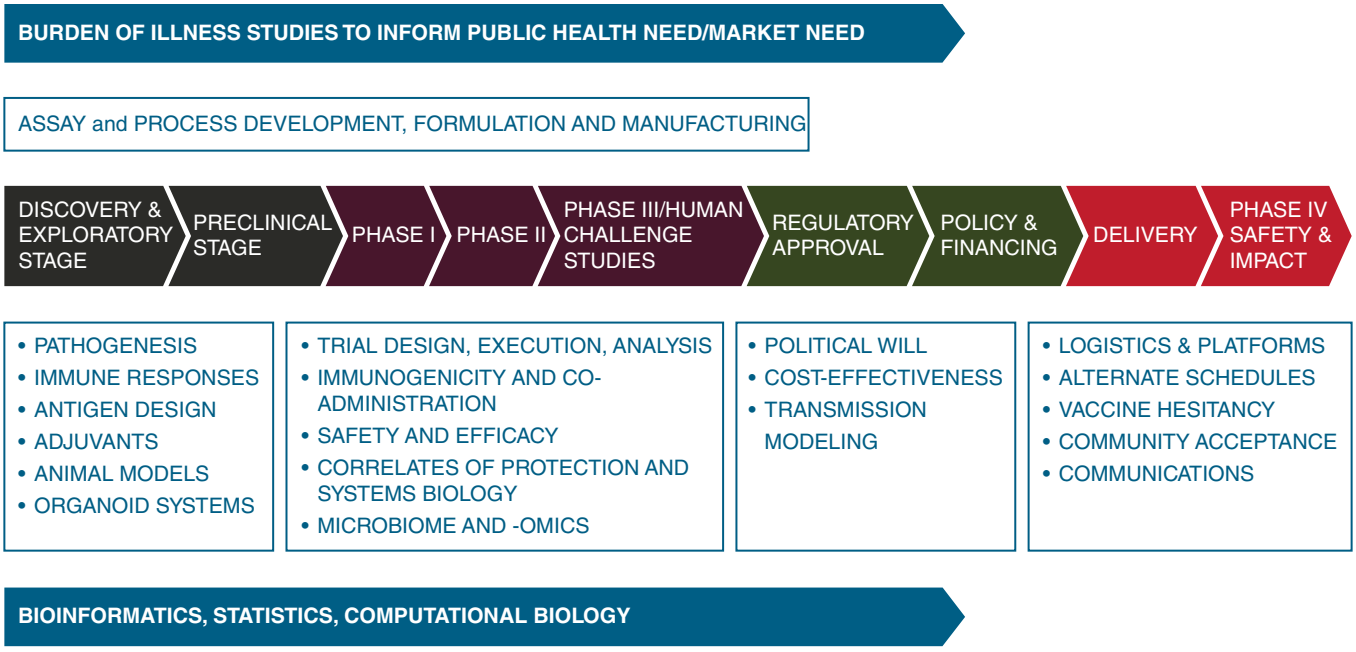

FIGURE 128-2 Vaccine development: a continuum from antigen discovery to population impact. *(Figure created by Kathleen M. Neuzil, MD, MPH.)*

monitoring of local and systemic adverse events with measurement of temperature and size of redness and swelling at the injection site, and with detailed assessments of systemic reactions that may result in limitations of normal activities after vaccine administration. Phase 1 studies often involve a dose-ranging component such that the first enrolled subjects are administered the lowest doses of vaccine, and, if tolerated, the doses are increased. Many phase 1 studies have independent Data Safety and Monitoring Committees (DSMCs) composed of vaccine- and pathogen-specific experts, independent of the study site investigators and sponsors of the study, who assess the reactions and approve the advancing of the dose level based on the safety profile of the administered vaccines. Phase 1 studies have halting rules such that if severe reactions are seen, the study will be stopped. These halting rules might include hospitalization for a vaccine-related adverse event, or a severe reaction attributed to the vaccine in several participants. All participants in the phase 1 trials will have immunologic studies performed as well to determine the magnitude of the antibody responses and, in some situations, the function of the antibody generated and/or T lymphocyte responses to the vaccines. At the conclusion of the phase 1 trial, the safety and immunogenicity data are reviewed and presented to the FDA for approval to advance to phase 2 studies.

Phase 2 studies involve several hundred subjects and often have a larger age range than that evaluated in phase 1. They expand the safety profile and assess immune responses in larger numbers of subjects. Again, meticulous attention to safety assessment is included in these studies, often with independent DSMCs to assess the reaction profile. Finally, if phase 2 studies confirm safety and immunogenicity in the expanded populations and with approval of the FDA, phase 3 trials can begin.

Phase 3 trials are designed to determine whether the vaccines will prevent a predefined endpoint, generally the prevention of laboratory-confirmed disease with the vaccine-directed pathogen. Subjects enrolled in phase 3 studies are randomized and blind to the receipt of either another irrelevant vaccine or a control agent, usually consisting of a placebo. Subjects and investigators are blind to group assignment and remain so throughout the phase 3 trial. After administration of the vaccine, study participants are followed closely, and if they develop predefined symptoms of disease they are tested for the presence of the pathogen. The determination of the primary endpoint of the study and the level of vaccine efficacy is the study goal. When feasible, one of the additional outcomes of the phase 3 trial is the determination of a serologic correlate of protection. For example, a correlate could be an antibody level associated with protection from disease. This would facilitate evaluation of additional vaccines in population groups not involved in the original trial and would not require assessment of actual protection from disease. While this is a highly sought-after endpoint, it is often not possible to determine. Prior to submission of the vaccine for licensure there will need to be lot-consistency assessments that determine that several lots of the vaccines can be made that are consistent in their safety and immunogenicity endpoints.

Controlled Human Infection Models (CHIMs) CHIMs may be part of the development pathway of a vaccine. Such models involve intentionally infecting healthy participants with a pathogen and following them carefully for development of disease. The evaluation of vaccines in these models may provide unique immunologic insights into correlates of protection, may establish a rapid pathway for downselection of candidates to move to later-phase trials or to endemic areas, and may inform vaccine approval. For example, an oral cholera vaccine for travelers in the United States was approved by the FDA based on a controlled human challenge study that established efficacy against clinical cholera. The determination to use CHIM is made in consultation with the FDA and based on the premise that the size, complexity, and expense of a study—for example, a study of a cholera vaccine with a disease endpoint in travelers—would render a phase 3 trial infeasible and significantly delay the approval of the vaccine. Other well-established CHIMs that are used to assess vaccines include those for influenza, typhoid fever, shigellosis, and malaria.

Vaccine Licensure At the conclusion of the phase 3 efficacy trials and consistency lot testing, data are presented to the national regulatory authorities who ultimately will decide whether the vaccine will be licensed. In the United States, the FDA will require that the product be labeled for how it will be used, based on the data generated in the phase 3 clinical trial. They will seek the guidance of a standing advisory group of experienced clinicians, vaccine experts, epidemiologists, and other subject matter experts, called the Vaccine and Related Biological Products Advisory Committee (VRBPAC), to advise whether the vaccine should be licensed. The FDA poses specific questions to the VRBPAC that relate to both vaccine efficacy and safety. All the adverse events reported in clinical trials are comprehensively presented and discussed with the committee. Any significant safety concerns raised may delay licensure, and additional safety studies may be proposed. Ultimately, although the FDA will seek the guidance of the VRBPAC, it will decide independently whether to license the vaccine and what requirements will be placed on that license. The inclusion of children and pregnant women in vaccine licensure will generally not occur unless the vaccines

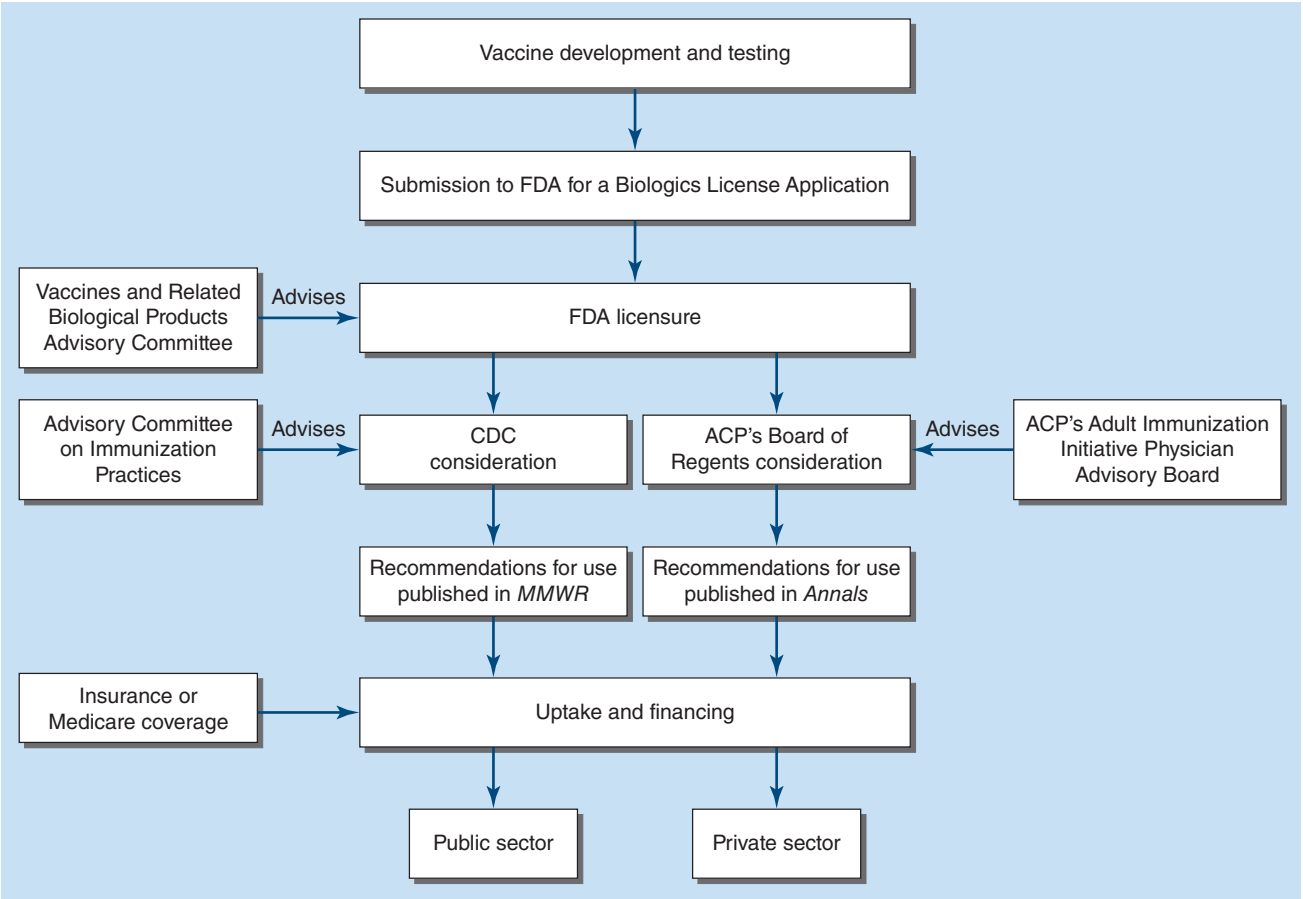

FIGURE 128-3 Development and dissemination of vaccine recommendations and policies for adults. ACP, American College of Physicians. *(From Annals of Internal Medicine, JC Smith et al: Immunization Policy Development in the United States: The Role of the Advisory Committee on Immunization Practices, Vol. 150, No. 1. have been specifically studied in those populations for their safety and immunogenicity. This process is outlined in Fig. 128-3.

The Advisory Committee on Immunization Practices (ACIP) Process Following licensure of vaccines by the FDA, the group that has played the major role in determining recommendations for vaccination in the United States is the Advisory Committee on Immunization Practices (ACIP) of the CDC. The ACIP provides recommendations for the use of vaccines in children, adolescents, and adults and issues a yearly vaccination schedule for all age groups and clinical conditions. Since 1995, the ACIP, American Academy of Pediatrics, American Academy of Family Physicians, American College of Physicians, American College of Obstetricians and Gynecologists, and other professional organizations have worked together to coordinate vaccine schedules and policies.

Members of the ACIP have expertise in a variety of disciplines related to the charge to the committee, including clinical medicine, epidemiology, vaccinology, public health, implementation science, and economic evaluations. The ACIP charter states, "Committee deliberations on use of vaccines to control disease in the U.S. shall include consideration of disease epidemiology and burden of disease, vaccine efficacy and effectiveness, vaccine safety, the quality of evidence reviewed, analyses and implementation issues." The committee may revise or withdraw their recommendation(s) regarding a particular vaccine as new information on disease epidemiology, effectiveness or safety, economic considerations, or other issues becomes available. Once approved by the CDC Director, the ACIP recommendations are published in the *Morbidity and Mortality Weekly Report (MMWR)* and become official CDC immunization use policy. Among the responsibilities of the ACIP is prioritizing use in settings where there are shortages of vaccines so that the highest-priority groups for whom vaccine might be recommended can receive them.

The immunization delivery system in the United States consists of both public and private providers. Since 1993 the Vaccines for Children (VFC) Program provides vaccines to children whose parents or guardians may not be able to afford them. Serving as one of the nation's most important contributors to health equity, the program helps ensure that all children have a better chance of getting their recommended vaccinations on schedule and staying healthy. In contrast, most vaccines for adults are delivered by private healthcare providers, although many of the vaccines are purchased using federal or other government funds. This may contribute to the relatively low coverage of adult vaccines compared with childhood vaccines. The Affordable Care Act requires private insurers to cover ACIP-recommended vaccines at in-network providers.

Vaccine Policy and Postlicensure Surveillance Once a vaccine is licensed for use in the United States and recommendations are made by the ACIP, systems need to be put in place to provide access to vaccines and to remove barriers to access, such as cost. Ongoing monitoring of vaccine effectiveness and safety are critical to evaluate issues such as waning immunity, to identify groups at heightened risk for vaccine failure, and to determine adverse events following vaccination that are causally related, especially rare events that could not be detected in prelicensure trials. Estimations of the burden of causally vaccine-related adverse events can then be weighed against the benefits of the vaccine to determine if any changes in recommendations are warranted. Disease surveillance is crucial to determine who continues to acquire disease, risk factors for disease, and the role of vaccine failure versus failure to vaccinate in disease prevention.

After Vaccine Implementation Prelicensure clinical trials usually enroll thousands of participants. However, there are questions that cannot be answered in these studies. These questions include (1) What is the duration of protection from disease, and is there a need for boosters? (2) What is the effectiveness of the vaccine in population groups not evaluated in the clinical trials? Effectiveness can be measured in observational studies post-licensure by comparing disease incidence in vaccinees

versus nonvaccinees; (3) Are there rare causally related adverse events? If so, what is the incidence rate, and are there risk factors for developing the adverse event that could lead to vaccine contraindications? and (4) What is the impact of vaccination in protecting the community (i.e., herd immunity) by preventing or reducing transmission? Answering these questions requires a comprehensive surveillance system to detect and determine characteristics of disease in the postvaccine era and whether such disease is the result of failure to vaccinate or vaccine failure. If the former, what measures can be taken to enhance vaccine uptake, or should recommendations for vaccination be broadened if substantial numbers of cases are occurring in groups for whom vaccine is not recommended? If there is evidence of vaccine failure, is it the result of vaccine mishandling (e.g., improper storage) or is the rate of failure within expected levels (e.g., the measured vaccine effectiveness is within levels expected based on the prelicensure trials)? If effectiveness is low, are there groups at higher risk for vaccine failure, and if so, would additional doses of vaccines or alternative schedules reduce that risk?

Assessing Vaccine Safety Adequately assessing vaccine safety is critical to the success of immunization programs and requires an existing comprehensive system to monitor safety. In the United States, there are several systems in place to assess safety in the postlicensure setting. The Vaccine Adverse Event Reporting System (VAERS) allows providers, parents, and patients to report adverse events. The VAERS program functions more to raise hypotheses about whether receipt of a vaccine or vaccines causes an adverse event than it does to evaluate causation. The Vaccine Safety Datalink (VSD) is a collaborative project between CDC's Immunization Safety Office (ISO) and eight health care organizations. The VSD was initiated in 1990 and continues to monitor safety of vaccines over large populations and to conduct studies to assess rare and serious adverse events following immunization. The Clinical Immunization Safety Assessment (CISA) Project is a national network of vaccine safety experts from the CDC's ISO, seven medical research centers, and other partners, which provides a comprehensive vaccine safety public health service to the nation.

Vaccine Injury Compensation Most vaccine-preventable diseases are transmitted person-to-person. Thus, when individuals are vaccinated, they are protected from disease and indirectly are protecting others in society who either cannot be vaccinated (e.g., have medical contraindications to vaccine) or fail to make an adequate immune response. Therefore, if someone is injured by vaccine, society should provide that person compensation. This is the basis of the National Vaccine Injury Compensation Program (NVICP). This program offers compensation for the injured vaccine recipient and reduces the risk of liability for the vaccine provider and the manufacturer, as persons who receive vaccines covered by the NVICP must first go through this compensation process before suing the provider or manufacturer.

Vaccine Hesitancy Over the past decade there has been an increase in vaccine hesitancy. Reasons for vaccine hesitancy are multifactorial and include concerns over vaccine safety, questioning whether specific vaccines are needed to prevent disease, and mistrust of the public health sector and medical professionals recommending the vaccines. This hesitancy has increased since the COVID-19 pandemic coincident with the proliferation of antivaccine tropes and with concern over loss of autonomy of individuals to make decision for themselves. These concerns can often be alleviated or lessened by addressing the specific questions raised by the hesitant individual and by a presumptive approach where vaccines are presented as the standard of care. A strong recommendation for a vaccine by a trusted health care provider is one proven mechanism to reduce vaccine hesitancy. Websites maintained by the CDC, NIH, and various specialty and subspeciality organizations have extensive information about vaccines, and providers should refer their patients to these credible sources.

SUMMARY

Few programs have had the impact of vaccines in reducing health burdens. This is the result of a rigorous system to ensure that recommended vaccines are safe and effective, and of an equally rigorous system to ensure that persons for whom vaccines are recommended receive them. With the development and introduction of new vaccines, public health gains are expected to increase in coming years as long as high vaccine coverage levels can be maintained.

129 Immunization Principles and Vaccine Use

Sarah Meyer, Amanda Cohn, Georgina Peacock

Few medical interventions of the past century can rival the effect that immunization has had on longevity, economic savings, and quality of life. Twenty-one diseases are now preventable through vaccines routinely administered to children and adults in the United States **(Table 129-1)**, and most vaccine-preventable diseases of childhood are at historically low levels **(Table 129-2)**. In the past few years, the adult immunization landscape has changed substantially with an increased number of recommended routine vaccines.

The COVID-19 pandemic identified a need for improved infrastructure to ensure adult vaccination, especially for those who are uninsured and who have limited access to health systems. Health care providers in a variety of settings deliver the vast majority of vaccines in the United States and therefore play an integral role in the nation's public health system.

VACCINE IMPACT

Direct and Indirect Effects Many immunizations against specific infectious diseases protect individuals against infection and thereby prevent symptomatic illnesses. In addition, specific vaccines may blunt the severity of clinical illness (e.g., rotavirus vaccines and severe gastroenteritis) or reduce complications (e.g., zoster vaccines and

TABLE 129-1 Diseases Preventable with Vaccines Routinely Administered in the United States to Children and/or Adults

CONDITION	TARGET POPULATION(S) FOR ROUTINE USE
Pertussis	Children, adolescents, adults
Diphtheria	Children, adolescents, adults
Tetanus	Children, adolescents, adults
Poliomyelitis	Children
Measles	Children
Mumps	Children
Rubella, congenital rubella syndrome	Children
Hepatitis B	Children and high-risk adults
Haemophilus influenzae type b infection	Children and high-risk adults
Hepatitis A	Children and high-risk adults
Influenza	Children, adolescents, adults
Varicella	Children
Pneumococcal disease	Children, older adults, and high-risk adults[a]
Serogroups A, C, W, Y meningococcal disease	Adolescents and high-risk children and adults
Serogroup B meningococcal disease	High-risk children and adults[a]
Rotavirus infection	Infants
Human papillomavirus infection, cervical and anogenital cancers	Adolescents and young adults[a]
Zoster	Older adults and high-risk adults
Respiratory syncytial virus	Infants, high-risk children, pregnant persons[a]
COVID-19	Children, adolescents, adults
Dengue	High-risk children (i.e., those living in endemic areas and with laboratory confirmation of prior infection)
Mpox	High-risk adults

[a]Others in certain age groups may be vaccinated based on shared clinical decision-making.

TABLE 129-2 Decline in Vaccine-Preventable Diseases in the United States following Widespread Implementation of National Vaccine Recommendations

CONDITION	ANNUAL NO. OF PREVACCINE CASES (AVERAGE)	NO. OF CASES REPORTED IN 2023[a]	REDUCTION (%) IN CASES AFTER WIDESPREAD VACCINATION
Smallpox	29,005	0	100
Diphtheria	21,053	2	>99
Measles	530,217	47	>99
Mumps	162,344	429	>99
Pertussis	200,752	5611	97
Polio (paralytic)	16,316	0	100

postherpetic neuralgia). Some immunizations also reduce transmission of infectious disease agents from immunized persons to others, thereby reducing the impact of infection spread. This indirect impact is known as *herd immunity*. The level of immunization in a population that is required to achieve indirect protection of unimmunized persons varies substantially with the specific vaccine and disease. For example, because of how transmissible measles is, an estimated 95% of the population needs to be vaccinated to achieve herd immunity, whereas with polio, an estimated 80% coverage is needed.

Over the past 30 years, due to the implementation of the Vaccines for Children Program, children have had broad access to routine childhood vaccines, regardless of insurance status. For routinely recommended vaccines in the United States, major declines in rates of vaccine-preventable diseases among both children and adults have become evident (Table 129-2). For example, vaccination of children <5 years of age against *Streptococcus pneumoniae* has led to not only a 96% reduction in invasive pneumococcal disease, but also substantial reductions in incidence among adults through herd immunity. Among children born during 1994–2023, the childhood vaccination series will prevent 508 million illnesses and 1,129,000 deaths over the course of their lifetime and save nearly $2.7 trillion in societal costs (U.S.).

Control, Elimination, and Eradication of Vaccine-Preventable Diseases Immunization programs are associated with the goals of controlling, eliminating, or eradicating a disease. *Control* of a vaccine-preventable disease reduces poor illness outcomes and often limits the disruptive impacts associated with outbreaks of disease in communities, schools, and institutions. Control programs can also reduce absences from work for ill persons and for parents caring for sick children, decrease absences from school, and limit health care utilization associated with treatment visits.

Elimination of a disease is a more demanding goal than control, usually requiring the reduction to zero of cases in a defined geographic area but sometimes defined as reduction in the indigenous sustained transmission of an infection in a geographic area. As of 2024, the United States had eliminated indigenous transmission of measles, rubella, poliomyelitis, and diphtheria. Importation of pathogens from other parts of the world continues to be important, and public health efforts are intended to respond promptly to such cases in order to limit forward spread of the infectious agent.

Eradication of a disease is achieved when its elimination can be sustained without the need to continue interventions. The only vaccine-preventable disease of humans that has been globally eradicated thus far is smallpox. Although smallpox vaccine is no longer given routinely, the disease has not reemerged naturally because all chains of human transmission were interrupted through earlier vaccination efforts and humans were the only natural reservoir of the virus. Currently, a major health initiative is targeting the global eradication of polio. Two of the three wild poliovirus types (types 2 and 3) have been eradicated globally. However, endemic transmission of wild poliovirus type 1 continues in Afghanistan and Pakistan, and circulating vaccine-derived polioviruses have been detected in areas of the world where poliovirus had been eliminated, including a case of vaccine-derived poliovirus type 2 in New York in 2022. Detection of a case of disease that has been targeted for eradication or elimination is considered a sentinel event that could permit the infectious agent to become reestablished in the community or region. Therefore, such episodes must be promptly reported to public health authorities.

Epidemic and Pandemic Preparedness and Response Clusters of cases of a vaccine-preventable disease detected in an institution, a medical practice, or a community may signal important changes in the pathogen, vaccine, or environment. Several factors can give rise to increases in vaccine-preventable disease, including (1) low rates of immunization that result in an accumulation of susceptible persons (e.g., measles resurgence among vaccination abstainers); (2) changes in the infectious agent that permit it to escape vaccine-induced protection (e.g., non-vaccine-type pneumococci); (3) waning of vaccine-induced immunity (e.g., pertussis among adolescents and adults vaccinated in early childhood); and (4) point-source introductions of large inocula (e.g., food-borne exposure to hepatitis A virus). Reporting episodes of outbreak-prone diseases to public health authorities can facilitate recognition of clusters that require further interventions.

The COVID-19 pandemic highlighted the importance of a strong immunization program: robust surveillance systems to detect emerging infectious disease threats; public–private partnerships to accelerate the development of novel vaccines; and systems in place to rapidly implement a vaccination program and monitor vaccine safety and effectiveness. On a global scale, the "100 Days Mission" is being explored by the Coalition for Epidemic Preparedness Innovations (CEPI) and partners as a response to the next "Disease X" to make safe, effective vaccines, therapeutics, and diagnostics within 100 days of identification.

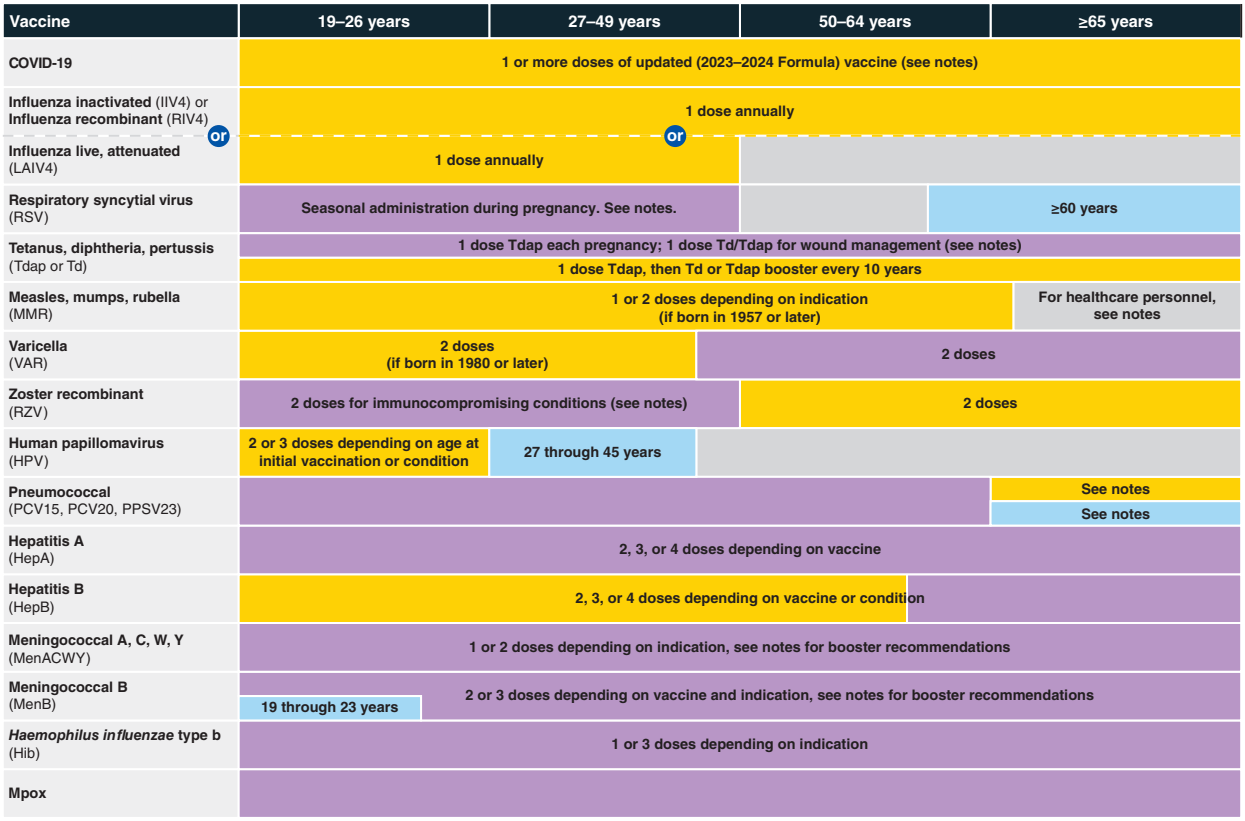
PUBLIC HEALTH REPORTING Recognition of suspected cases of diseases targeted for elimination or eradication—along with other diseases that require urgent public health interventions, such as contact tracing, administration of chemo- or immunoprophylaxis, or epidemiologic investigation for common-source exposure—is typically associated with special reporting requirements. Many diseases against which vaccines are routinely used, including measles, pertussis, and *Haemophilus influenzae* type b invasive disease, are nationally notifiable. Clinicians and laboratory staff have a responsibility to report some vaccine-preventable disease occurrences to local or state public health authorities according to specific case-definition criteria. All providers should be aware of state or city disease-reporting requirements and the best ways to contact public health authorities. A prompt response to vaccine-preventable disease outbreaks can greatly enhance the effectiveness of control measures.

GLOBAL CONSIDERATIONS Vaccinations are estimated to prevent 3.5–5 million deaths every year on a global scale. The COVID-19 pandemic led to disruptions of routine vaccination programs, resulting in declines in vaccine coverage in more than 100 countries. Although there have been promising signs of recovery, with diphtheria-pertussis-tetanus (DPT) coverage in 2022 nearly recovered to 2019 levels, gaps remain for other vaccines. For example, 22 million children missed their first dose of measles vaccine in 2022 compared with 19 million in 2019. As a result, the World Health Organization, the United Nations Children's Fund, Gavi, the Vaccine Alliance, and the Bill & Melinda Gates Foundation launched "The Big Catch-Up" to support recovery of childhood vaccination rates to at least prepandemic levels.

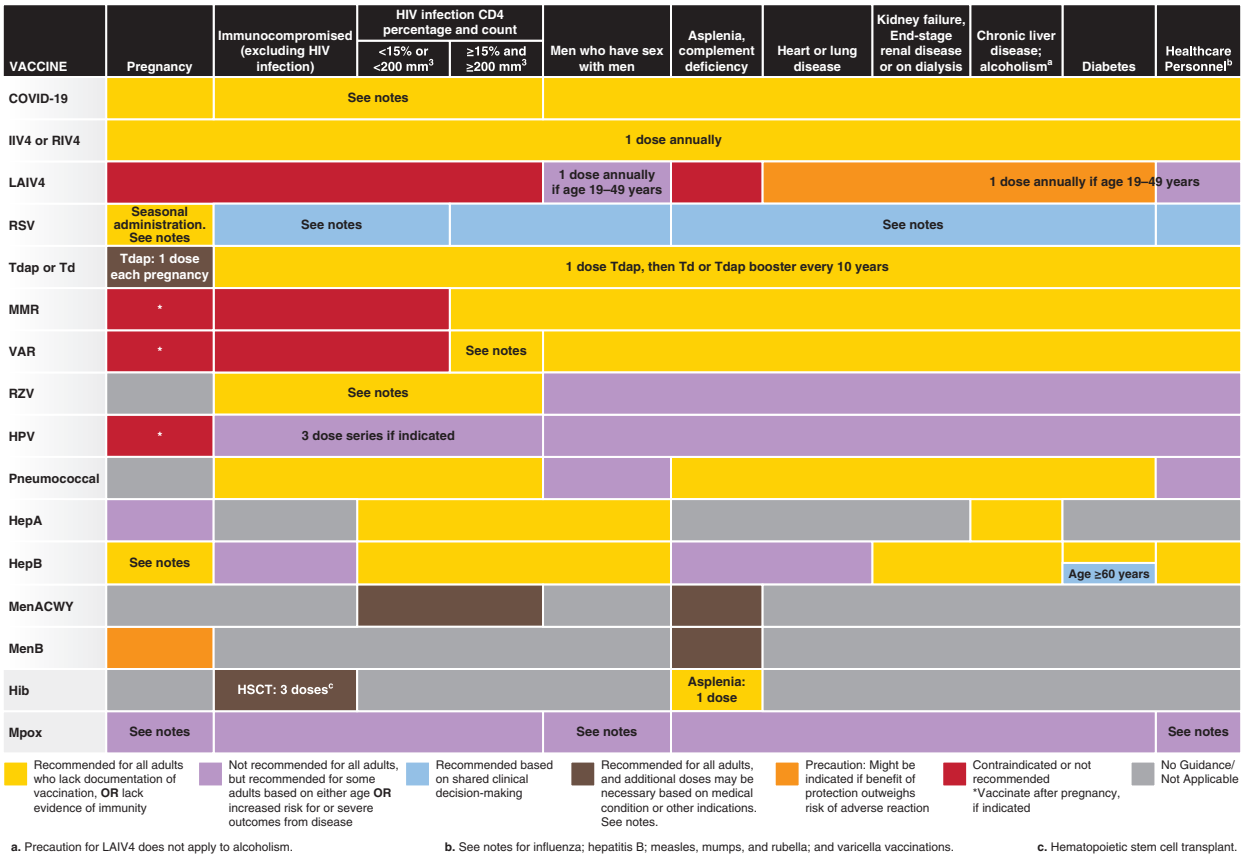
Enhancing Immunization in Adults Although immunization has become a centerpiece of routine pediatric medical visits, it has not been as well integrated into routine health care for adults. This chapter focuses on immunization principles and vaccine use in adults. Accumulating evidence suggests that immunization coverage can be increased through efforts directed at consumer-, provider-, institution-, and system-level factors. The literature suggests that the application of multiple strategies is more effective at raising coverage rates than is the use of any single strategy.

RECOMMENDATIONS FOR ADULT IMMUNIZATIONS The CDC's Advisory Committee on Immunization Practices (ACIP) makes recommendations for administration of vaccines approved or authorized by the U.S. Food and Drug Administration (FDA) for use in children and adults in the U.S. civilian population. The ACIP is a federal advisory committee that consists of up to 20 voting members (experts in fields associated with immunization) appointed by the Secretary of the U.S. Department of Health and Human Services, as well as ex officio members representing federal agencies and nonvoting representatives of various liaison organizations, including major medical societies and managed-care organizations. ACIP recommendations are available at *www.cdc.gov/acip-recs/hcp/vaccine-specific/*.

ACIP makes several types of recommendations. Routine, catch-up, and risk-based recommendations are those in which everyone in a particular age or risk group is recommended to receive vaccination. Examples include recombinant zoster vaccination for adults age ≥50 years and hepatitis B vaccination for adults age 19–59 years. Shared clinical decision-making recommendations are individually based and informed by a decision process between the health care provider and patient. With shared clinical decision-making recommendations, the decision to vaccinate is informed by the best available evidence on who may benefit from vaccination; the individual's characteristics, values, and preferences; the health care provider's clinical discretion; and the characteristics of the vaccine being considered. Examples of shared clinical decision-making recommendations include human papillomavirus vaccination of adults age 27-45 years and serogroup B meningococcal vaccination of adolescents and young adults age 16-23 years.



ADULT IMMUNIZATION SCHEDULES Immunization schedules for adults in the United States are updated regularly, through an addendum after ACIP votes on a new recommendation as well as an annual update, and can be found online (*www.cdc.gov/vaccines/hcp/imz-schedules/adult-age.html*). The adult immunization schedule is also approved by seven provider organizations and published annually in *Annals of Internal Medicine* and *Morbidity and Mortality Weekly Report* (*www.cdc.gov/mmwr*). The adult immunization schedules for 2024 are summarized in **Fig. 129-1**. Additional information and specifications are contained in the footnotes to these schedules.



IMMUNIZATION PRACTICE STANDARDS

Administering immunizations to adults involves a number of processes, such as deciding whom to vaccinate, assessing vaccine contraindications and precautions, providing vaccine information statements (VISs), ensuring appropriate storage and handling of vaccines, administering vaccines, and maintaining vaccine records. In addition, provider reporting of adverse events that follow vaccination is an essential component of the vaccine safety monitoring system. In 2014, the Standards for Adult Immunization Practice were revised to help providers take steps to ensure that their patients are fully immunized, including assessing the immunization status of patients at every clinical encounter, strongly recommending vaccines that patients need, administering vaccines or referring the patient to a vaccination provider, and documenting vaccines received by the patient.

Deciding Whom to Vaccinate Every effort should be made to ensure that adults receive all indicated vaccines as expeditiously as possible. When adults present for care, their immunization history should be assessed and recorded, and this information should be used to identify needed vaccinations according to the most current version of the adult immunization schedule. Decision-support tools incorporated into electronic health records can provide prompts for needed vaccinations. Standing orders, which are often used for routinely indicated vaccines (e.g., influenza and zoster vaccines), permit a nurse or another approved licensed practitioner to administer vaccines without a specific physician order, thus lowering barriers to adult immunization.

Assessing Contraindications and Precautions Before vaccination, all patients should be screened for contraindications and precautions. A *contraindication* is a condition that increases the risk of a serious adverse reaction to vaccination. A vaccine should not be administered when a contraindication is documented. For example, a history of an anaphylactic reaction to a dose of vaccine or to a vaccine component is a contraindication for further doses. A *precaution* is a condition that may increase the risk of an adverse event or that may compromise the ability of the vaccine to evoke immunity (e.g., administering measles vaccine to a person who has recently received immune globulins or other blood products and may consequently have transient passive immunity to measles virus). Normally, a vaccine is

a. Precaution for LAIV4 does not apply to alcoholism.

b. See notes for influenza; hepatitis B; measles, mumps, and rubella; and varicella vaccinations.

c. Hematopoietic stem cell transplant.

FIGURE 129-1 Recommended adult immunization schedules, United States, 2024. Additional information, including footnotes for each vaccine, contraindications, and precautions, can be found at *www.cdc.gov/vaccines/hcp/imz-schedules/adult-age.html*. The recommendations in this schedule were approved by the Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP), the American Academy of Family Physicians (AAFP), the American College of Physicians (ACP), the American College of Obstetricians and Gynecologists (ACOG), and the American College of Nurse-Midwives (ACNM). For complete statements by the ACIP, visit *www.cdc.gov/acip-recs/hcp/vaccine-specific/*.

not administered when a precaution is noted. However, situations may arise when the benefits of vaccination outweigh the estimated risk of an adverse event, and the provider may decide to vaccinate the patient despite the precaution.

In some cases, contraindications and precautions are temporary and may lead to mere deferral of vaccination until a later time. For example, moderate or severe acute illness with or without fever is generally considered a transient precaution to vaccination and results in postponement of vaccine administration until the acute phase has resolved; thus, the superimposition of adverse effects of vaccination on the underlying illness and the mistaken attribution of a manifestation of the underlying illness to the vaccine are avoided. Contraindications and precautions to vaccines licensed in the United States for use in adults are summarized in **Table 129-3**. It is important to recognize conditions that are *not* contraindications in order not to miss opportunities for vaccination. For example, in most cases, mild acute illness (with or without fever) or a history of a mild to moderate local reaction to a previous dose of the vaccine are not contraindications to vaccination.

History of Immediate Hypersensitivity to a Vaccine Component A severe allergic reaction (e.g., anaphylaxis) to a previous dose of a vaccine or to one of its components is a contraindication to vaccination. While most vaccines have many components, substances to which individuals are most likely to have had a severe allergic reaction include egg protein, gelatin, and yeast. In addition, although natural rubber (latex) is not a vaccine component, some vaccines are supplied in vials or syringes that contain natural rubber latex. These vaccines can be identified by the product insert and should not be administered to persons who report a severe (anaphylactic) allergy to latex unless the benefit of vaccination clearly outweighs the risk for a potential allergic reaction. The much more common local or contact hypersensitivity to latex, such as to medical gloves (which contain synthetic latex that is not linked to allergic reactions), is *not* a contraindication to administration of a vaccine supplied in a vial or syringe that contains natural rubber latex.

SPECIFIC ADULT POPULATIONS

Pregnant Persons Several vaccines are recommended for pregnant persons in the United States: tetanus and diphtheria toxoids and acellular pertussis (Tdap), inactivated influenza, COVID-19, and respiratory syncytial virus (RSV) vaccine, as well as hepatitis B vaccine (if not already vaccinated). Tdap and RSV vaccine are administered to pregnant persons specifically to prevent severe pertussis and RSV disease, respectively, in their infants, while influenza, COVID-19, and hepatitis B (HepB) vaccines are given to protect both the pregnant person and infant.

Tdap vaccine is recommended during each pregnancy at the 27th through 36th week of gestation (preferably during the earlier part of this time period), regardless of prior vaccination status, in order to prevent pertussis in young infants. Annual influenza vaccination is recommended for everyone age ≥6 months, including pregnant persons in any trimester, ideally during September or October. Vaccination during July or August can be considered for pregnant persons in their third trimester if vaccine is available. Staying up to date with COVID-19 vaccination is recommended for everyone age ≥6 months, including pregnant persons in any trimester. It is recommended that every infant receive protection against severe RSV disease, either through maternal RSV vaccination during the 32nd through 36th week of gestation (during September to January) or through infant administration of nirsevimab, a long-acting monoclonal antibody.

Pregnant persons may need additional vaccines as well, such as HepB vaccine if not already vaccinated, since all adults age 19 through 59 years are recommended to receive HepB vaccination. Pregnancy is not a contraindication to administration of most other inactivated vaccines when otherwise indicated or when the benefits of vaccination are judged to outweigh potential risks (e.g., serogroup B meningococcal vaccination); it is recommended that human papillomavirus (HPV) and recombinant zoster vaccination are delayed until after pregnancy. Live-virus vaccines (e.g., measles, mumps, and rubella [MMR], varicella) are contraindicated during pregnancy because of the hypothetical risk that vaccine virus replication will cause congenital infection or have other adverse effects on the fetus. Patients who are breast-feeding or trying to get pregnant should stay up to date on all recommended vaccines, especially as certain congenital infections (e.g., rubella) are preventable through vaccination.

Immunocompromised Persons Immunocompromised persons are at increased risk for severe outcomes from infectious diseases. Therefore, staying up to date on recommended vaccines is important for this population. Immunocompromised patients may need to receive vaccines at an earlier age than the general population (e.g., pneumococcal and zoster at age ≥19 years instead of age ≥50 years), receive additional doses of a recommended vaccine (e.g., three-dose primary series and additional doses of COVID-19), receive vaccines based on a particular type of immunocompromising condition (e.g., meningococcal vaccination for those with complement deficiency), or have different vaccine recommendations based on degree of immune suppression, particularly for live-virus vaccines. Live-virus vaccines elicit an immune response due to replication of the attenuated (weakened) vaccine virus that is contained by the recipient's immune system. In persons with compromised immune function, enhanced replication of vaccine viruses is possible and could lead to disseminated infection with the vaccine virus. For this reason, live-virus vaccines are contraindicated for persons with severe immunosuppression, the definition of which may vary with the vaccine. Severe immunosuppression may be caused by many disease conditions, including hematologic or other malignancy. In some of these conditions, all affected persons are severely immunocompromised. In others (e.g., HIV infection), the degree to which the immune system is compromised depends on the severity of the condition, which in turn depends on the stage of disease or treatment. For example, MMR vaccine may be given to HIV-infected persons with CD4 percentage of ≥15 and count of ≥200/μL.

Older Adults As age increases, the ability to mount adaptive and innate immune responses declines, resulting in increased susceptibility to infectious diseases and reduced responses after vaccination. This immunosenescence, along with increased rates of underlying conditions, increases the risk of severe outcomes of infectious diseases in older adults. Long-term care facility residents among this age group are potentially at even greater risk due to increased frailty as well as risk of transmission associated with congregate settings. In addition to staying up to date on all recommended vaccines (e.g., COVID-19, Td/Tdap), there are specific vaccine recommendations for older adults: zoster vaccine in adults age ≥50 years, pneumococcal conjugate vaccine for adults age ≥50 years, and RSV vaccine in all adults aged ≥75 years and in those age 60–74 years at increased risk for severe RSV. Furthermore, adults age ≥65 years are recommended to receive a higher-dose influenza vaccine (i.e., high-dose, adjuvanted, or recombinant vaccine) rather than the standard-dose vaccine.

Health Care Workers Health care workers are recommended to stay up to date with all vaccines recommended for them based on age or underlying condition (including influenza and COVID-19 vaccines), and they may be recommended to receive additional vaccines due to their occupational exposure (e.g., meningococcal vaccine for laboratory personnel who handle *Neisseria meningitidis* isolates). As part of their participation in the Centers for Medicare and Medicaid Services' Hospital Inpatient Quality Reporting program, acute-care hospitals and select other facilities are required to report the proportion of their health care personnel who have received seasonal influenza and COVID-19 vaccination. Some institutions and jurisdictions have added mandates on influenza vaccination of health care workers and have expanded on earlier requirements related to vaccination or proof of immunity for hepatitis B, measles, mumps, rubella, and varicella.

VACCINE INFORMATION STATEMENTS

A Vaccine Information Statement (VIS) is a one-page (two-sided) information sheet produced by the CDC that informs vaccine

TABLE 129-3 Contraindications and Precautions for Commonly Used Vaccines in Adults

VACCINE FORMULATION	CONTRAINDICATIONS AND PRECAUTIONS
All vaccines	**Contraindication** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component **Precaution** Moderate or severe acute illness with or without fever. Defer vaccination until illness resolves.
Td	**Precautions** GBS within 6 weeks after a previous dose of TT-containing vaccine History of Arthus-type hypersensitivity reactions after a previous dose of TD- or DT-containing vaccines (including MenACWY). Defer vaccination until at least 10 years have elapsed since the last dose.
Tdap	**Contraindication** History of encephalopathy (e.g., coma or prolonged seizures) not attributable to another identifiable cause within 7 days of administration of a vaccine with pertussis components, such as DTaP or Tdap **Precautions** GBS within 6 weeks after a previous dose of TT-containing vaccine Progressive or unstable neurologic disorder, uncontrolled seizures, or progressive encephalopathy. Defer vaccination until a treatment regimen has been established and the condition has stabilized. History of Arthus-type hypersensitivity reactions after a previous dose of TT- or DT-containing vaccines (including MenACWY). Defer vaccination until at least 10 years have elapsed since the last dose.
HPV	**Contraindications** History of immediate hypersensitivity to yeast Pregnancy (vaccinate after pregnancy if indicated)
MMR	**Contraindications** History of immediate hypersensitivity reaction to gelatin[a] or neomycin Pregnancy (vaccinate after pregnancy if indicated) Known severe immunodeficiency (e.g., hematologic and solid tumors; chemotherapy; congenital immunodeficiency; long-term immunosuppressive therapy; severe immunocompromise due to HIV infection) Family history of altered immunocompetence (i.e., congenital or hereditary immunodeficiency in a first-degree relative), unless the immune competence of the potential vaccine recipient has been substantiated clinically or verified by a laboratory **Precautions** Recent receipt (within 11 months) of antibody-containing blood product History of thrombocytopenia or thrombocytopenic purpura Need for tuberculin skin testing or interferon γ release assay (IGRA) testing
Varicella	**Contraindications** Pregnancy (vaccinate after pregnancy if indicated) Known severe immunodeficiency History of immediate hypersensitivity reaction to gelatin[a] or neomycin Family history of altered immunocompetence (i.e., congenital or hereditary immunodeficiency in a first-degree relative), unless the immune competence of the potential vaccine recipient has been substantiated clinically or verified by a laboratory **Precaution** Recent receipt (within 11 months) of antibody-containing blood product Receipt of specific antiviral drugs (acyclovir, famciclovir, or valacyclovir) 24 h before vaccination Use of aspirin or aspirin-containing products
Influenza, inactivated, injectable	**Precaution**[b] History of GBS within 6 weeks after a previous influenza vaccine dose
Influenza, live attenuated nasal spray	**Contraindications**[b] Pregnancy Immunosuppression, including that caused by medications or by HIV infection; known severe immunodeficiency (e.g., hematologic and solid tumors; chemotherapy; congenital immunodeficiency; long-term immunosuppressive therapy; severe immunocompromise due to HIV infection) Close contact with severely immunosuppressed persons who require a protected environment, such as isolation in a bone marrow transplantation unit Receipt of oseltamivir or zanamivir within 48 h before vaccination, peramivir within the previous 5 days, or baloxavir within the previous 17 days. Active cerebrospinal fluid/oropharyngeal communications/leaks Cochlear implants Anatomic or functional asplenia (e.g., sickle cell disease) **Precautions** History of GBS within 6 weeks of a previous influenza vaccine dose Medical conditions that might predispose to higher risks of complications from influenza, such as diabetes mellitus; chronic pulmonary disease (including asthma); chronic cardiovascular disease (except hypertension); renal, hepatic, neurologic/neuromuscular, hematologic, or metabolic disorders

(*Continued*)

TABLE 129-3 Contraindications and Precautions for Commonly Used Vaccines in Adults (Continued)

VACCINE FORMULATION	CONTRAINDICATIONS AND PRECAUTIONS
Pneumococcal polysaccharide	None, other than those listed for all vaccines
Pneumococcal conjugate	None, other than those listed for all vaccines
Hepatitis A	**Contraindication** History of immediate hypersensitivity to neomycin
Hepatitis B	**Contraindications** History of immediate hypersensitivity to yeast (for Engerix-B and Recombivax-HB) Pregnancy: Heplisav-B and PreHevbrio are not recommended; use other hepatitis B vaccines if indicated
Meningococcal conjugate	None, other than those listed for all vaccines
Serogroup B meningococcal	**Precaution** Pregnancy (vaccination may be indicated if benefits of protection outweigh risks of adverse reaction)
Zoster	**Precaution** Current herpes zoster infection
COVID-19	**Precaution** Diagnosed nonsevere allergy (e.g., urticaria beyond the injection site) or nonsevere, immediate (onset <4 h) allergic reaction after administration of a previous dose Myocarditis or pericarditis within 3 weeks after a dose Multisystem inflammatory syndrome in children (MIS-C) or multisystem inflammatory syndrome in adults (MIS-A)
Respiratory syncytial virus	None, other than those listed for all vaccines
Mpox	None, other than those listed for all vaccines

[a]Extreme caution must be exercised in administering MMR, varicella, or live zoster vaccine to persons with a history of anaphylactic reaction to gelatin or gelatin-containing products. Before administration, skin testing for sensitivity to gelatin can be considered. However, no specific protocols for this purpose have been published. [b]History of severe allergic reaction (e.g., anaphylaxis) to egg is a labeled contraindication to the use of inactivated influenza vaccine and live attenuated influenza vaccine. However, CDC's Advisory Committee on Immunization Practices recommends that any licensed, recommended, and appropriate inactivated influenza vaccine or recombinant influenza vaccine may be administered to persons with egg allergy of any severity (*www.cdc.gov/acip-recs/hcp/vaccine-specific/flu.html*).

Abbreviations: DT, diphtheria toxoid; DTaP, diphtheria, tetanus, and pertussis; GBS, Guillain-Barré syndrome; HPV, human papillomavirus; MenACWY, quadrivalent meningococcal conjugate vaccine; MMR, measles, mumps, and rubella; Td, tetanus and diphtheria toxoids; Tdap, tetanus and diphtheria toxoids and acellular pertussis; TT, tetanus toxoid.

recipients (or their parents or legal representatives) about the benefits and risks of a vaccine. VISs are mandated by the National Childhood Vaccine Injury Act (NCVIA) of 1986 and—whether the vaccine recipient is a child or an adult—must be provided for any vaccine covered by the Vaccine Injury Compensation Program (VICP). As of February 2024, vaccines that are covered by the NCVIA and that are licensed for use in adults include tetanus, diphtheria, hepatitis A, hepatitis B, HPV, influenza, MMR, pneumococcal conjugate, meningococcal, polio, and varicella vaccines. When combination vaccines for which no separate VIS exists are administered (e.g., hepatitis A and B combination vaccine), all relevant VISs should be provided. In addition, although provision of a VIS is not specifically mandated under the Public Readiness and Emergency Preparedness (PREP) Act, which authorizes the Countermeasures Injury Compensation Program (CICP), CDC has published VISs for the approved or authorized vaccines currently covered under the CICP, including COVID-19 and mpox vaccines. The CICP provides compensation for injuries that occur after the administration of certain countermeasures.

VISs also exist for some vaccines not covered by the VICP or CICP, such as pneumococcal polysaccharide, Japanese encephalitis, rabies, herpes zoster, typhoid, and yellow fever vaccines. The use of these VISs is encouraged but is not mandated.

All current VISs are available at two websites: the CDC's Vaccine Information Statements site (*www.cdc.gov/vaccines/hcp/vis/*) and the Immunization Action Coalition's site (*www.immunize.org/vaccines/vis/about-vis/*). (The latter site also includes translations of the VISs.) VISs from these sites can be downloaded and printed.

STORAGE AND HANDLING

Injectable vaccines are packaged in multidose vials, single-dose vials, or manufacturer-filled single-dose syringes. The live attenuated nasal-spray influenza vaccine is packaged in single-dose sprayers. Oral typhoid vaccine is packaged in capsules. Some vaccines, such as MMR and varicella, come as lyophilized (freeze-dried) powders that must be reconstituted (i.e., mixed with a liquid diluent) before use. The lyophilized powder and the diluent come in separate vials. Diluents are not interchangeable but rather are specifically formulated for each type of vaccine; only the specific diluent provided by the manufacturer for each type of vaccine should be used. Once lyophilized vaccines have been reconstituted, their shelf-life is limited and they must be stored under appropriate temperature and light conditions. For example, varicella must be protected from light and administered within 30 min of reconstitution; recombinant zoster and MMR vaccines likewise must be protected from light but can be used up to 6 and 8 h after reconstitution, respectively.

Vaccines are stored either at refrigerator temperature (2–8°C) or at freezer temperature (–15°C or colder). In general, inactivated vaccines (e.g., inactivated influenza, pneumococcal polysaccharide, and meningococcal conjugate vaccines) are stored at refrigerator temperature, while vials of lyophilized-powder live-virus vaccines (e.g., varicella, MMR vaccines) are stored at freezer temperature. Diluents for lyophilized vaccines may be stored at refrigerator or room temperature. Live attenuated influenza vaccine—a live-virus liquid formulation administered by nasal spray—is stored at refrigerator temperature.

Vaccine storage and handling errors can result in the loss of vaccines worth millions of dollars, and administration of improperly stored vaccines may elicit inadequate immune responses or adverse events in patients. To improve the standard of vaccine storage and handling practices, the CDC has published detailed guidance (available at *www.cdc.gov/vaccines/hcp/admin/storage/toolkit/storage-handling-toolkit.pdf*). For vaccine storage, the CDC recommends stand-alone units—i.e., self-contained units that either refrigerate or freeze but do not do both—as these units maintain the required temperatures better than combination refrigerator/freezer units. Dormitory-style combined refrigerator/freezer units should never be used for vaccine storage.

The temperature of refrigerators and freezers used for vaccine storage must be monitored and recorded at least twice each workday. Ideally, continuous thermometers that measure and record temperature all day and all night are used, and minimal and maximal temperatures are read and documented each workday. The CDC recommends the use of calibrated digital thermometers with a probe in thermal-buffered material; more detailed information on specifications of storage units and temperature-monitoring devices is provided at the link given above.

ADMINISTRATION OF VACCINES

Most parenteral vaccines recommended for routine administration to adults in the United States are given by either the intramuscular (IM) or the subcutaneous (SC) route; one influenza vaccine formulation approved for use in persons 2–49 years of age is given intranasally. Some vaccines can be given by multiple routes; for example, MMRV vaccine, one of the MMR vaccines (M-M-R II), and 23-valent pneumococcal polysaccharide vaccine can be given by either IM or SC route, and the mpox vaccine can be given intradermally or subcutaneously.

Vaccines given to adults by the SC route are administered with a 5/8-inch needle into the upper outer-triceps area. Vaccines administered to adults by the IM route are injected into the deltoid muscle **(Fig. 129-2)** with a needle whose length should be selected on the basis of the recipient's sex and weight to ensure adequate penetration into the muscle. Current guidelines indicate that, for men and women weighing <152 lb (<70 kg), a 1-inch needle is sufficient; for women weighing 152–200 lb (70–90 kg) and men weighing 152–260 lb (70–118 kg), a 1- to 1.5-inch needle is needed; and for women weighing >200 lb (>90 kg) and men weighing >260 lb (>118 kg), a 1.5-inch needle is required. Additional illustrations of vaccine injection locations and techniques may be found at *www.immunize.org/wp-content/uploads/catg.d/p2020.pdf*.

Aspiration, the process of pulling back on the plunger of the syringe after skin penetration but prior to injection, is not necessary because no large blood vessels are present at the recommended vaccine injection sites.

Multiple vaccines can be administered at the same visit; indeed, administration of all needed vaccines at one visit is encouraged. Studies have shown that in general, vaccines are as effective when administered simultaneously as they are individually, and simultaneous administration of multiple vaccines is not associated with an increased risk of adverse effects and may increase uptake due to not needing to return for subsequent vaccinations. If more than one vaccine must be administered in the same limb, the injection sites should be separated by 1–2 inches so that any local reactions can be differentiated. If a vaccine and an immune globulin preparation are administered simultaneously (e.g., Td vaccine and tetanus immune globulin), a separate anatomic site should be used for each injection.

For certain vaccines (e.g., hepatitis B vaccine), multiple doses are required for an adequate and persistent antibody response. The recommended vaccination schedule specifies the interval between doses. Many adults who receive the first dose in a multiple-dose vaccine series do not complete the series or do not receive subsequent doses within the recommended interval; this lack of adherence to protocol compromises vaccine efficacy and/or the duration of protection. Providers should implement recall systems that will prompt patients to return for subsequent doses in a vaccination series at the appropriate intervals. With some exceptions (e.g., oral typhoid vaccine), an interruption in the schedule does not require restarting of the entire series or the addition of extra doses.

Syncope may follow vaccination, especially in adolescents and young adults. Serious injuries, including skull fracture and cerebral hemorrhage, have occurred. Adolescents and adults should be seated or lying down during vaccination. The majority of reported syncope episodes after vaccination occur within 15 min. The CDC recommends that vaccine providers consider observing vaccine recipients, particularly adolescents, with patients seated or lying down for 15 min after vaccination to decrease the risk of injury should they develop syncope. If syncope develops, patients should be observed until the symptoms resolve.

Anaphylaxis is a rare complication of vaccination. All facilities providing immunizations should have an emergency kit containing aqueous epinephrine for administration in the event of a systemic anaphylactic reaction.

MAINTENANCE OF VACCINE RECORDS

All vaccines administered should be fully documented in the patient's permanent medical record. Documentation should include the date of administration, the name or common abbreviation of the vaccine, the vaccine lot number and manufacturer, the administration site, the VIS edition, the date the VIS was provided, and the name, address, and title of the person who administered the vaccine. Increasing use

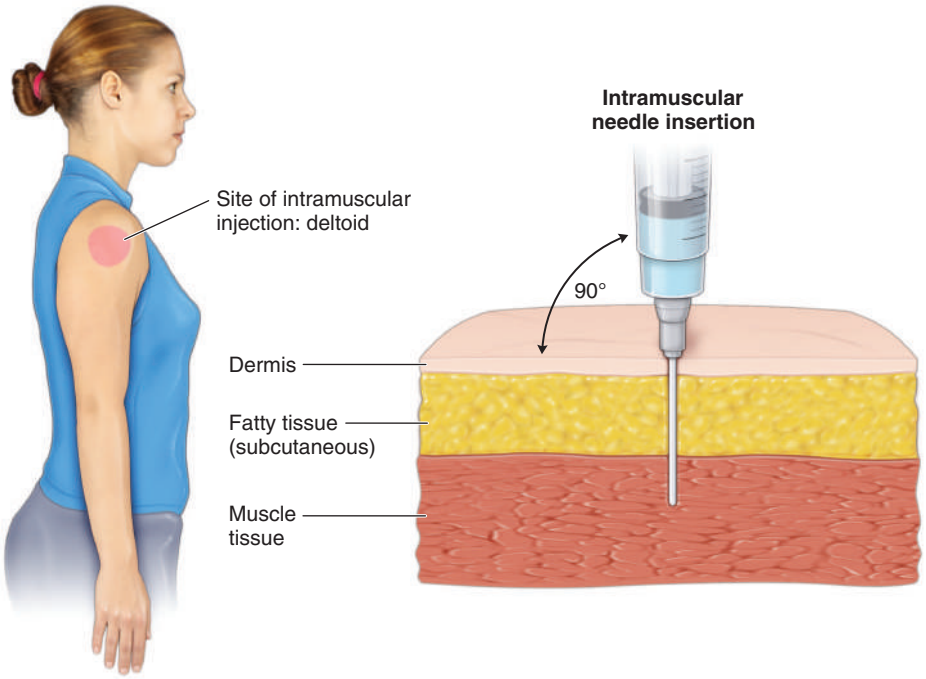


FIGURE 129-2 Technique for IM administration of vaccine.

of two-dimensional bar codes on vaccine vials and syringes that can be scanned for data entry into compatible electronic medical records and immunization information systems may facilitate more complete and accurate recording of required information.

VACCINE SAFETY MONITORING AND ADVERSE EVENT REPORTING

Prelicensure Evaluations of Vaccine Safety Before vaccines are licensed by the FDA, they are evaluated in clinical trials with volunteers. These trials are conducted in three progressive phases. Phase 1 trials are small, usually involving <100 volunteers. Their purposes are to provide a basic evaluation of safety and to identify common adverse events. Phase 2 trials, which are larger and may involve several hundred participants, collect additional information on safety and are usually designed to evaluate immunogenicity as well. Data gained from phase 2 trials can be used to determine the composition of the vaccine, the number of doses required, and a profile of common adverse events. Vaccines that appear promising are evaluated in phase 3 trials, which typically involve several hundred to several thousand volunteers and are generally designed to demonstrate vaccine efficacy and provide additional information on vaccine safety.

Postlicensure Monitoring of Vaccine Safety After licensure, a vaccine's safety is assessed by several mechanisms. The NCVIA of 1986 requires health care providers to report certain adverse events that follow vaccination. As a mechanism for that reporting, the Vaccine Adverse Event Reporting System (VAERS) was established in 1990 and is jointly managed by the CDC and the FDA. This safety surveillance system collects reports of adverse events associated with vaccines currently approved or authorized in the United States. *Adverse events* are defined as untoward events that occur after immunization and that might be caused by the vaccine product or vaccination process. While the VAERS was established in response to the NCVIA, reporting of any adverse event following vaccination—whether in a child or an adult, and whether or not it is believed to have actually been caused by vaccination—is encouraged through the VAERS. The adverse events that health care providers are required to report are listed in the reportable-events table at *vaers.hhs.gov/docs/VAERS_Table_of_Reportable_Events_Following_Vaccination.pdf*. The number of VAERS reports submitted varies each year. In 2019, VAERS received more than 48,000 reports. Approximately 85–90% of the reports described mild side effects such as fever, arm soreness, or mild irritability; the remaining reports are classified as serious. However, a report to VAERS does not mean that a vaccine caused an adverse event.

Anyone can file a VAERS report, including health care providers, manufacturers, and vaccine recipients or their parents or guardians. VAERS reports may be submitted online or in paper form (*vaers.hhs.gov/reportevent.html*); additional information can be obtained by email (*info@vaers.org*) or phone (800-822-7967). The VAERS form asks for the following information: the type of vaccine received; the timing of vaccination; the time of onset of the adverse event; and the recipient's current illnesses or medications, history of adverse events following vaccination, and demographic characteristics (e.g., age and sex). This information is entered into a database. The individual who reported the adverse event then receives a confirmation letter by mail with a VAERS identification number that can be used if additional information is submitted later. In selected cases of serious adverse reaction, the patient's recovery status may be followed up at 60 days and 1 year after vaccination. The FDA and the CDC have access to VAERS data and use this information to monitor vaccine safety and conduct research studies. VAERS data (minus personal information) are also available to the public.

While the VAERS provides useful information on vaccine safety, this passive reporting system has important limitations. One is that events following vaccination are merely reported; the system cannot assess whether a given type of event occurs more often than expected after vaccination. A second is that event reporting is incomplete and is biased toward events that are believed to be more likely to be due to vaccination and that occur relatively soon after vaccination. To obtain more systematic information on adverse events occurring in both vaccinated and unvaccinated persons, the Vaccine Safety Datalink project was initiated in 1991. Directed by the CDC, this project includes 11 managed-care organizations in the United States; member databases include information on immunizations, medical conditions, demographics, laboratory results, and medication prescriptions. In addition to these systems, CDC, FDA, and other federal partners use multiple other systems and data sources to conduct comprehensive vaccine safety monitoring, including CDC's V-safe system, FDA's Biologics Effectiveness and Safety (BEST) system, CMS's Medicare claims database, and the Department of Defense's Vaccine Adverse Event Clinical System. In addition, postlicensure evaluations of vaccine safety may be conducted by the vaccine manufacturer. In fact, such evaluations are often required by the FDA as a condition of vaccine licensure.

CONSUMER ACCESS TO AND DEMAND FOR IMMUNIZATION

By removing barriers to the consumer or patient, providers and health care institutions can improve vaccine use. Financial barriers have traditionally been important constraints. Fortunately, some progress has been made to mitigate out-of-pocket costs for vaccination of adults. The Affordable Care Act enacted in 2010 requires that most private insurance plans provide coverage for immunizations that appear on the approved immunization schedules without deductibles or copays when administered by an in-network provider. In addition, as of 2023, the Inflation Reduction Act eliminated out-of-pocket costs for ACIP-recommended vaccines for patients with Medicare prescription drug coverage and requires state Medicaid programs to cover and pay for ACIP-recommended adult vaccines without cost-sharing. However, barriers to vaccination remain for uninsured adults. A comprehensive Vaccines for Adults program to provide vaccines to uninsured adults has been proposed but has not yet been authorized for funding. To help ensure access to COVID-19 vaccines for uninsured and underinsured adults, CDC launched the Bridge Access Program for COVID-19 vaccines in 2023; this program ended in 2024.

In addition to removing financial barriers, other strategies that enhance patients' access to vaccination include extended office hours (e.g., evening and weekend hours) and scheduled vaccination-only clinics where waiting times are reduced. In recent years, pharmacies have become an increasingly important venue for adult vaccination and have helped improve equitable access to vaccines, given that the majority of the adult population lives within 5 miles of a pharmacy. Other locations outside the "medical home" (e.g., through occupational clinics, universities, and retail settings) also can expand access for adults who do not make medical visits frequently.

Health promotion efforts aimed at increasing the demand for immunization are common. Direct-to-consumer advertising by pharmaceutical companies has been used for some newer adolescent and adult vaccines. Efforts to raise consumer demand for vaccines have not increased immunization rates unless implemented in conjunction with other strategies that target strengthening of provider practices or reduction of consumer barriers. Attitudes and beliefs related to vaccination can be considerable impediments to consumer demand. Many adults view vaccines as important for children but are less familiar with vaccinations targeting disease prevention in adults. Several vaccines are recommended for adults with certain medical risk factors, but self-identification as a high-risk individual is relatively rare. Communication research suggests that adults are motivated to get vaccines to protect their own health and many would get vaccinated to protect loved ones. Adults with chronic conditions are more likely to be aware that they need to protect their own health.

STRATEGIES FOR PROVIDERS AND HEALTH CARE FACILITIES

Recommendation from the Provider Health care providers can have great influence on patients with regard to immunization. Studies repeatedly show that a health care provider is the most trusted source of vaccine information, and patients who receive a strong vaccine recommendation from a provider are more likely to get vaccinated than

those who do not. Strong provider recommendations using a presumptive approach (e.g., "You're due for the flu shot today" vs "What do you want to do about the flu shot?") have been shown to improve vaccine acceptance **(Chap. 3)**. Providers should be well informed about vaccine risks and benefits so that they can address patients' common concerns. The CDC and seven provider organizations review and update the schedule for adult immunization on an annual basis and have developed educational materials to facilitate provider–patient discussions about vaccination (*www.cdc.gov/vaccines/hcp/*).

System Supports Medical offices can incorporate a variety of methods to ensure that providers consistently offer specific immunizations to patients with indications for specific vaccines. Decision-support tools have been incorporated into some electronic health records to alert the provider when specific vaccines are indicated. Manual or automated reminders and standing orders have been discussed (see "Deciding Whom to Vaccinate," above) and have consistently improved vaccination coverage in both office and hospital settings. Most clinicians' estimates of their own performance diverge from objective measurements of their patients' immunization coverage; quantitative assessment and feedback have been shown in pediatric and adolescent practices to increase immunization performance significantly. Some health plans have instituted incentives for providers with high rates of immunization coverage. Specialty providers, including obstetrician–gynecologists, may be the only providers serving some high-risk patients with indications for selected vaccines (e.g., pneumococcal polysaccharide vaccine, zoster vaccine for immunocompromised adults) as well as for other routine vaccinations (e.g., influenza, COVID-19).

Immunization Requirements Vaccination against selected communicable diseases is required for attendance at many universities and colleges as well as for service in the U.S. military and in some occupational settings (e.g., child care, laboratory, veterinary, and health care). Immunizations are recommended and sometimes required for travel to certain countries **(Chap. 130)**.

VACCINATION SETTINGS

Vaccination of adults occurs in a variety of settings. While the "medical home" remains a critical setting for vaccination of adults, other settings such as pharmacies have become an increasingly important venue for adult vaccination and help to expand equitable access and convenience to vaccination. Other vaccination settings outside the medical home include health department venues, workplaces, and schools or colleges.

Regardless of setting, it remains important for standards of immunization practice to be followed. Consumers should be provided with information on the vaccine and how to report adverse events (e.g., via provision of a VIS), and procedures should ensure that documentation of vaccine administration is forwarded to the primary care provider and the state or city public health immunization registry. Detailed documentation may be required for employment, school attendance, and travel. Personalized health records can help consumers keep track of their immunizations, and some occupational health clinics have incorporated automated immunization reports that help employees stay up to date with recommended vaccinations. Some pharmacy chain establishments are using automated systems to report immunization information to the state or local immunization information system.

PERFORMANCE MONITORING

Tracking of immunization coverage at national, state, institution, and practice levels can yield feedback to practitioners and programs and facilitate quality improvement. Healthcare Effectiveness Data and Information Set (HEDIS) measures related to adult immunization facilitate comparison of health plans. CDC utilizes a number of surveys to monitor vaccination coverage among adults and track progress toward achievement of Healthy People 2030 targets for immunization coverage. These sources include the National Health Interview Survey, the Behavioral Risk Factor Surveillance System, the National Immunization Surveys, Internet panel surveys, and other sources. Vaccination coverage among adults remains suboptimal, and state-specific immunization coverage for certain vaccines reveals substantial geographic variation in coverage. There are persistent disparities in adult immunization coverage rates by race and ethnicity, as well as other sociodemographic factors. In contrast, racial and economic disparities in immunization of young children have been dramatically reduced during the past 30 years. Much of this progress is attributed to the Vaccines for Children Program, which since 1994 has entitled eligible children, including those who are uninsured or underinsured, to receive free vaccines.

FUTURE TRENDS

Although most vaccines developed in the twentieth century targeted common acute infectious diseases of childhood, more recently developed vaccines prevent chronic conditions prevalent among adults. Hepatitis B vaccine prevents hepatitis B–related cirrhosis and hepatocellular carcinoma, HPV vaccine prevents some types of cervical cancer, genital warts, and anogenital cancers and may also prevent some oropharyngeal cancers, and the herpes zoster subunit vaccine protects against zoster and postherpetic neuralgia. New targets of vaccine development and research may further broaden the definition of vaccine-preventable disease. Research is ongoing on vaccines to prevent insulin-dependent diabetes mellitus, nicotine addiction, and Alzheimer's disease. Expanding strategies for vaccine development are incorporating molecular approaches such as RNA, DNA, vector, and peptide vaccines. New technologies, such as the use of transdermal and other needle-less routes of administration, are being applied to vaccine delivery.

Acknowledgment

The authors thank Anne Schuchat, MD, Lisa A. Jackson, MD, and Nancy Messonnier, MD, for their significant contributions to this chapter in the previous editions.

130 Health Recommendations for International Travel

Jesse Waggoner, Henry M. Wu

In recent decades, international travel has increased dramatically with globalization and greater access to international flights. According to the United Nations World Tourism Organization, international tourist arrivals increased 50.3% from 2010 to 2019; arrivals exceeded 1.4 billion in 2019, with the highest rate of growth in arrivals to destinations in Asia and the Pacific. In 2018, according to the United Nations Conference on Trade and Development, total global merchandise exports reached

a record 19.5 trillion U.S. dollars, a nearly threefold increase over the previous two decades. Although travel in 2020 dropped drastically during the COVID-19 pandemic, there has been recovery since 2021, resuming prepandemic growth trends.

International travel has brought social, economic, and cultural benefits to the world; however, travel also widens the range of infections to which an individual may be exposed. The speed of air travel has been a major factor in the ease with which emerging infectious diseases have quickly spread worldwide in recent years. In the nineteenth century, intercontinental travel took long enough that travelers often recovered or perished from acute infections before arrival at their destinations. However, in the jet age, the time required to circumnavigate the globe has decreased to <24 h. This duration is shorter than the incubation periods for almost all infections, increasing the likelihood that infected travelers can arrive at their destinations prior to symptom onset. Epidemics can result; examples include severe acute respiratory syndrome (SARS) in 2003, Ebola virus disease in 2014, and the COVID-19 pandemic in 2020. Furthermore, introduction of pathogens into vulnerable regions can subsequently lead to infections becoming endemic, as was observed with the reintroduction of dengue throughout much of the Americas beginning in the 1970s and the global spread of HIV infections in the 1980s.

Additional challenges include the increasing diversity of travelers. While tourism, business travel, and mission work continue to be popular, recent decades have seen increasing numbers of other types of travelers, including students, migrants, medical tourists, and persons visiting their countries of origin ("visiting friends and relatives" [VFR] travelers). Furthermore, an increasing range of individuals with risk factors for illness or injury are traveling internationally, including elderly persons, infants, pregnant women, and persons with chronic medical conditions (e.g., immunocompromising conditions). Whether practicing travel medicine, primary care, or other specialties, providers will encounter patients who travel internationally. This chapter outlines key considerations and preventive measures for international travelers, particularly those traveling to low- and middle-income countries.

EPIDEMIOLOGY OF TRAVEL-RELATED CONDITIONS

Unanticipated medical problems during travel are common. Although reported rates of travel-related morbidity and mortality vary widely by destination, traveler type, and study methodology, as many as 43–79% of travelers report developing a travel-related illness. Most illnesses are minor, with diarrhea often the most commonly reported and fewer than 1–3% of travelers reporting hospitalization. Among vaccine-preventable infections in travelers to lower-income countries, influenza historically has been the most commonly reported, although COVID-19 has also become common among travelers since 2020. Typhoid and hepatitis A are reported much less often, but typically are still reported more frequently than other infections commonly discussed in travel medicine but not frequently diagnosed in travelers, including cholera, Japanese encephalitis, meningococcal disease, rabies, poliomyelitis, and yellow fever. However, outbreaks such as the emergence of yellow fever in coastal southeastern Brazil in 2017–2018 or cholera associated with the 2010 earthquake in Haiti can result in an increased incidence of travel-associated cases. Among causes of death in travelers, studies suggest that cardiovascular events (likely associated with preexisting cardiac conditions) and injury are much more common than infections. Among U.S. citizens, the injuries most commonly causing deaths during international travel in 2016–2017 were motor vehicle accidents, homicide, drowning and maritime injuries, and suicide. Stressors encountered during travel can also exacerbate or uncover psychiatric disorders, and psychological conditions such as depression and anxiety are a common reason for medical evacuation.

GENERAL APPROACH TO ADVISING INTERNATIONAL TRAVELERS

Whether advising travelers in a travel clinic or in a primary care setting, providers must cover a few key elements in a pretravel consultation **(Table 130-1)**. These include (1) a trip risk assessment based on detailed review of the itinerary and the traveler's medical profile; (2) immunizations; (3) prevention of arthropod-borne infections, including malaria chemoprophylaxis (when indicated); (4) food and water precautions and travelers' diarrhea management; and (5) prevention of injuries and other conditions associated with travel.

A detailed itinerary, including cities and areas in a country to be visited, activities, and type of accommodations, is critical for assessment of the risks of the trip and determination of the indications for specific vaccinations, malaria prophylaxis, and other preventive measures. Trip duration, sequence of countries visited, and transit stops are important considerations, especially in the assessment of immunization requirements such as those for yellow fever. Numerous online resources offer recommendations for immunizations and malaria prophylaxis, which vary significantly among countries or even within certain countries **(Table 130-2)**. The U.S. Centers for Disease Control and Prevention (CDC) travelers' health website (*www.cdc.gov/travel*) is a source of comprehensive, up-to-date, country-specific recommendations on numerous topics, including immunizations, malaria chemoprophylaxis, and travel health notices for outbreaks and emerging infections. Because recommendations and requirements can change unexpectedly, providers are advised to routinely review guidance for each country prior to making recommendations.

Consideration of the traveler's medical profile is critical to recommendations for appropriate preventive measures. Key considerations include the patient's age, medical and vaccination histories, current medications, allergies (drug, food, and environmental), and pregnancy status. Although any chronic medical problem can be relevant to travel, common issues that can require particular attention include immunocompromising conditions (including HIV infection and treatment with immunosuppressive and immunomodulatory medications), cardiac and pulmonary conditions, pregnancy status, and severe allergies. Significant hepatic and renal impairment due to any etiology can affect the choice of malaria prophylaxis.

Although travel clinics with providers specializing in travel medicine—e.g., those with a Certificate in Travelers' Health issued by the International Society of Travel Medicine—are now common in many cities worldwide, many travelers do not seek pretravel consultations, often because of an underappreciation of travel risks or a lack of awareness of the resource. Primary care providers are encouraged to routinely ask their patients about upcoming travel. Although some travel-specific vaccinations are often available only at specialized clinics, many recommended vaccines are available from general practitioners or pharmacies. Reasons to refer a patient to a travel specialist include the need for vaccines used exclusively for travel, complex itineraries or traveler medical histories, or unfamiliarity with recommended immunizations or malaria chemoprophylaxis. Because several vaccines are given as a series and all vaccines theoretically take a week or more to induce protective immunity, referral to a travel clinic at least 4–6 weeks before travel is ideal. However, when this time frame is not possible, consultations can still provide much benefit.

While the decision of whether to travel is ultimately that of the traveler, travel medicine providers play a key role in helping travelers identify the risks of a trip so that they can make an informed decision based on their personal risk tolerance. Occasionally, some situations can warrant advice against travel, including trips to areas with dangerous outbreaks or security situations or trips by a traveler who is unable to undertake critical preventive measures (e.g., travel to highly malarious areas without chemoprophylaxis). Unfortunately, travel-related vaccinations and chemoprophylactic medications can be expensive and often are not covered by health insurance. To assist travelers on a limited budget, providers can prioritize preventive measures according to degree of risk so that decisions to decline a recommendation are not based on cost alone.

IMMUNIZATIONS FOR TRAVELERS

Historically, the field of travel medicine considered immunizations as routine, recommended, or required. Because infections prevented by *routine* immunizations for children and adults are encountered worldwide, travelers should be up to date with these immunizations.

TABLE 130-1 Overview of the Pretravel Consultation

CONSULTATION ELEMENT	ITEMS TO BE COVERED	INTERVENTIONS, ADVICE
Risk Assessment		
Itinerary	• Destination countries and regions • Timing • Duration of trip • Mode of travel • Accommodations • Reason for travel and anticipated activities • Altitude	• Risk assessment that considers the itinerary, traveler, and ability to implement recommended preventive measures • Shared decision-making regarding whether to travel
Traveler	• Medical history, medications • Allergies • Pregnancy status and planning • General risk tolerance	
Immunizations		
Itinerary	Recommended and required vaccinations for itinerary	• Administration of vaccines to meet recommendations and requirements • Provision of official documentation (ICVP[a]) for required immunizations
Traveler	• Immunization history • Precautions and contraindications for specific vaccines	
Malaria and Arthropod-borne Infection Prevention		
Itinerary	• Malaria and other arthropod-borne infection risk at destination • Accommodations and activities • Local malaria resistance to chemoprophylaxis drugs	• Prescription of malaria chemoprophylaxis when indicated • Administration of vaccines for arthropod-borne infections when indicated and available • Arthropod-bite avoidance advice • Advice on early recognition of malaria symptoms
Traveler	• Precautions and contraindications to specific malaria chemoprophylaxis agents • Drug–drug interactions of regular medications with malaria chemoprophylaxis	
Gastrointestinal Illness		
Itinerary	• Destination hygienic standards and water quality • Source of meals (e.g., restaurants, street vendors, home-cooking)	See **Fig. 130-2**
Traveler	• Travel style • Adventurous eating habits • Drug–drug interactions of regular medications with self-treatment antibiotics	
Other Possible Topics to Address		
	• Waterborne infection (schistosomiasis, leptospirosis) prevention • Injury and crime avoidance • Animal bite and rabies prevention • Sexually transmitted infections • Altitude illness • Venous thromboembolism • Jet lag • Motion sickness • Severe food, insect sting, and environmental allergies • Travel health and medical evacuation insurance • Traveler health kits and travel with medications • Mental health and cultural adaptation	

[a]ICVP, International Certificate of Vaccine Prophylaxis ("yellow card").

Recommended travel vaccines in adults are those that are not included in routine schedules but that should be considered because of anticipated risks during travel. *Required* immunizations are those that are mandated by international regulations or specific countries for entry or exit. These three categories are not mutually exclusive or fixed, as many vaccinations that originally were used exclusively for travel (e.g., hepatitis A vaccine) are now given routinely in the United States.

For required travel immunizations, proof of vaccination is provided on the International Certificate of Vaccination Prophylaxis (ICVP, commonly called the "yellow card") issued by travel medicine providers. When appropriate, medical waivers for required vaccinations can be granted and documented on the ICVP. While enforcement of vaccine requirements can be unpredictable, travelers without proof or medical waiver for a required immunization can be subject to entry barriers, vaccination upon arrival, quarantine, or other penalties. In some situations, a vaccine may not be routinely recommended for a specific country but is still required for entry. The most common of these situations involves yellow fever vaccination, when a traveler who has recently been in an endemic country enters certain nonendemic countries (see "Yellow Fever," below).

Abbreviation: CDC, Centers for Disease Control and Prevention.

All vaccines that are commonly administered for travel can generally be given on the same day; however, oral typhoid vaccine should be administered at least 8 h after oral cholera vaccine. Limited evidence on immunogenicity suggests that the response to live virus vaccines may be impaired if they are given on different days <28 days apart. For this reason, live virus vaccines (i.e., yellow fever, measles–mumps–rubella [MMR], live attenuated influenza, and varicella) should be given on the same day or spaced at least 28 days apart. If neither of these schedules is possible, the recommendation is to repeat the second vaccination after at least 28 days. Table 130-3 outlines common immunizations for travel in adults.

IMMUNIZATIONS FOR TRAVELERS TO MOST DESTINATIONS

Hepatitis A Hepatitis A is one of the more commonly reported vaccine-preventable infections in travelers. Transmission occurs primarily through direct person-to-person contact (fecal–oral transmission) or contaminated food and water, and travel is among the most common risk factors for infection among cases reported in the United States. Travelers are at highest risk in countries with inadequate sanitation and hygienic practices; levels of hepatitis A endemicity are highest in South Asia and sub-Saharan Africa. Although hepatitis A immunization is now routinely recommended for persons with certain medical conditions and for all children in the United States, many adults have not been vaccinated. A single dose of monovalent hepatitis A vaccine is considered protective for younger, healthy adults when given prior to travel, and a booster vaccine dose given 6–18 months after the primary dose confers lifelong immunity. For persons >40 years old, immunocompromised persons, and other individuals with chronic medical conditions that might impair immune response, administration of hepatitis A immune globulin (0.1 mL/kg) at a separate site at the time of primary vaccination can be considered. No efficacy data are available to support single-dose use of hepatitis A/B combined vaccine (Twinrix) before travel.

Hepatitis B Hepatitis B is transmitted through contact with contaminated blood, blood products, or other bodily fluids. Travelers are strongly advised against high-risk activities, including tattooing, body piercing, and unprotected sexual intercourse. Even when avoiding activities that pose a high risk of exposure to hepatitis B, travelers seeking health care can be exposed through inadequate infection-control measures or blood-product screening. While all travelers may benefit from hepatitis B vaccination, ensuring immunity to hepatitis B is particularly important for long-term travelers, health care workers, and persons who have sexual encounters. Nonimmune travelers who are departing too soon to complete the standard schedule for recombinant hepatitis B vaccine can consider the rapid hepatitis A/B combined vaccine (Twinrix) series or the recombinant hepatitis B vaccine with novel adjuvant (Heplisav-B).

Influenza and COVID-19 Since respiratory infections such as seasonal influenza and COVID-19 are the most common vaccine-preventable infections acquired during travel, travelers should be advised to be up to date with routine seasonal influenza and COVID-19 vaccinations. Because of variations in influenza seasons worldwide and

TABLE 130-3 Common Travel Immunizations

VACCINE	PRIMARY SERIES IN UNVACCINATED ADULTS	BOOSTER INTERVAL	PREGNANCY CONSIDERATIONS
Consider for Most Destinations			
Hepatitis A, inactivated (Havrix, Vaqta)	2 doses 6–12 months apart (Havrix); 2 doses 6–18 months apart (Vaqta)	None recommended	Limited data, generally considered safe, use if protection recommended
Hepatitis A/B combined (Twinrix)	3 doses at 0, 1, and 6 months; accelerated series: 3 doses on days 0, 7, and 21–30	Not recommended except booster at 12 months after accelerated primary series	Limited data, generally considered safe, use if protection recommended
Hepatitis B, recombinant and recombinant with novel adjuvant (Heplisav-B)	Recombinant, 3 doses at 0, 1, and 6 months; recombinant with novel adjuvant, 2 doses at 0 and 1 month	Not recommended after routine vaccination schedule	Recombinant vaccine, 3-dose schedule not contraindicated; Heplisav-B, no data
Measles, mumps, and rubella (MMR)	2 doses (≥28 days apart)	None recommended	Contraindicated
Specific Destinations or Activities			
Chikungunya vaccine, live	1 dose	Undetermined	Inadequate data, precaution advised
Cholera, live attenuated (Vaxchora), inactivated oral (Dukoral)	1 dose (Vaxchora); 2 doses 1–6 weeks apart (Dukoral)	Undetermined for Vaxchora; 2 years for Dukoral	Inadequate data, not recommended
Japanese encephalitis, inactivated Vero cell culture–derived (IXIARO)	2 doses on days 0 and 7–28	≥1 year after primary series	Inadequate data, precaution advised against use unless risk of infection outweighs theoretical vaccine risk
Meningococcal meningitis, quadrivalent conjugate	1 dose	5 years	May be used if indicated
Poliomyelitis, inactivated	3 doses if previously unvaccinated	Single lifetime adult booster for persons who received primary series as children	May be used if indicated
Rabies, human diploid cell (HDCV), purified chick embryo cell (PCECV)	2 doses on days 0 and 7	A third dose (21 days to 3 years after initial series) or titer check (1–3 years after primary series) recommended for travelers with ongoing (>3 year) exposure risk[a]	May be used if indicated
Tick-borne encephalitis vaccine, inactivated	3 doses; second dose 14 days to 3 months after the first, and third dose 5–12 months after the second[b]	≥3 years after primary series	Inadequate data; consider if risk of infection outweigh potential risks
Typhoid, Vi capsular polysaccharide and oral live attenuated	1 dose	2 years for Vi capsular polysaccharide; 5 years for oral live attenuated	Inadequate data; use Vi polysaccharide if protection needed
Yellow fever	1 dose	None routine; 10-year boosters recommended for certain groups	Precaution

[a]Readers are advised to refer to the Centers for Disease Control and Prevention *Yellow Book* or Advisory Committee on Immunization Practices (ACIP) 2022 guidance on rabies vaccination for detailed rabies preexposure prophylaxis recommendations based on exposure risk categories. [b]Travelers unable to receive the third dose before travel should receive two doses before travel.

year-round risk in tropical regions, influenza vaccine should be offered to unvaccinated travelers even when the influenza season has already peaked locally. Travel medicine providers can reinforce the importance of these immunizations for all travelers by emphasizing that even uncomplicated infection can disrupt travel and put their contacts at risk. Preventing infections among those at higher risk for severe illness (e.g., the elderly and persons with immunocompromising conditions) is particularly important, since the availability of appropriate treatments and supportive care can be limited in many destinations. For this reason, other vaccines for respiratory infections not typically associated with travel, including pneumococcus and respiratory syncytial virus, are potentially important for certain travelers at higher risk of severe illness. Other preventative advice for respiratory infections (wearing masks in high-risk situations or avoiding crowded, poorly ventilated areas) can be important for persons at high risk for infection.

For travelers at high risk for complicated influenza or COVID-19 infections, providing a course of antivirals for self-treatment might be considered for travel to areas with limited access to treatment. However, travelers must be counseled on the proper use of antivirals, i.e., reserving their use for confirmed or strongly suspected infections. In addition to available SARS-CoV-2 home test kits, rapid multiplex influenza and SARS-CoV-2 tests are now available for home use in the United States. These kits are useful for travelers; however, at-home tests are not sufficiently sensitive to rule out an infection and travelers should seek formal medical evaluation whenever possible.

Measles, Mumps, and Rubella According to the World Health Organization (WHO), numbers of measles cases have increased globally in recent years, with more cases worldwide in 2019 than in any other year since 1996 **(Chap. 211)**. In the past decade, countries at all income levels have had major outbreaks. Although endemic measles transmission was eliminated in the United States in 2000, cases have increased in recent years because of outbreaks initiated by infected travelers, mostly those who were unvaccinated or undervaccinated. Unfounded vaccine hesitancy **(Chap. 3)** directed against measles vaccines is not uncommon in the United States and Europe, contributing to a recent worldwide resurgence. Disruption of vaccination programs during the COVID-19 pandemic has also contributed to recent outbreaks. Transmission events in airports and aboard aircraft have been reported, so all nonimmune travelers are potentially at risk. Travelers should have evidence of immunity to measles. For U.S. adults, acceptable criteria include (1) documented vaccination with two doses of live measles virus–containing vaccine given at least 28 days apart; (2) serologic evidence of immunity; (3) laboratory-confirmed illness; or (4) birth before 1957. Although two doses of measles virus–containing vaccine have been recommended for children in the United States since 1989, a significant number of older U.S. travelers born after 1956 may have received only one dose. In this country, the only measles vaccine available for use in adults is the combined MMR vaccine. Travelers should also have evidence of immunity to mumps and rubella; the criteria for immunity to these diseases are similar to those for measles except that a single dose of rubella virus–containing vaccine is considered adequate.

Tetanus, Diphtheria, and Pertussis Travelers should be up to date with age-appropriate tetanus, diphtheria, and pertussis

vaccinations (Chap. 129). While the risk of tetanus and pertussis exists worldwide, diphtheria is endemic or epidemic primarily in countries without adequate levels of vaccination. Because a tetanus booster is recommended for tetanus-prone injuries if the preceding booster dose was received >5 years earlier, some experts consider an early booster (before 10 years) for travelers engaging in activities with a high risk of injury in destinations with limited access to health care. A diphtheria booster within 5 years of travel is also recommended for travelers going to countries experiencing a diphtheria outbreak.

Typhoid Fever Typhoid fever, caused by *Salmonella enterica* serotype Typhi, is transmitted through ingestion of contaminated food and water. Most cases of typhoid fever reported in the United States are diagnosed in travelers after being acquired in South Asia. Africa and Southeast Asia also are considered high risk. East Asia, South America, and the Caribbean are considered lower risk. As with other food- and waterborne infections, travelers to endemic areas are at increased risk when consuming food or drink under unhygienic conditions. The risk of typhoid fever is usually lower than the risk of travelers' diarrhea and hepatitis A; however, rising levels of antimicrobial resistance in endemic regions (particularly in South Asia) have increased the importance of prevention. Two vaccines are approved for travelers: injectable Vi capsular polysaccharide vaccine and oral live attenuated vaccine. Oral vaccine is contraindicated for immunocompromised persons, and completion of the vaccination course requires 1 week (four doses separated by 48 h). Neither vaccine provides protection against paratyphoid fever (caused by *S. enterica* subtype Paratyphi A, B, or C), which is less commonly reported in U.S. travelers.

Varicella Travelers should have evidence of varicella immunity. For most U.S. travelers, this immunity can consist of documented receipt of two doses of varicella vaccine, laboratory evidence of immunity, confirmation of prior varicella or herpes zoster by a health care provider, or birth in the United States before 1980.

IMMUNIZATIONS FOR CERTAIN REGIONS OR SITUATIONS

Yellow Fever Yellow fever is endemic in much of sub-Saharan Africa and South America (Fig. 130-1). Requirements for yellow fever immunization are among the most common entry rules encountered by travelers. Some endemic countries require proof of immunization for all international arrivals. Other countries, including many nonendemic countries that are prone to epidemics, require proof of immunization for arriving travelers who have recently (i.e., within 10 days prior to arrival) traveled to endemic countries. Transit stops for ≥12 h in an endemic country also can result in a requirement for proof of immunization. The United States has no requirement regarding yellow fever immunization for travelers entering the country. Country-specific recommendations and requirements for yellow fever immunization are available from the CDC Travelers' Health website (Table 130-2).

Yellow fever vaccine is available only through state-authorized official yellow fever vaccination clinics, and its administration is recorded on the ICVP. Yellow fever immunization is considered valid for entry purposes beginning 10 days after administration and extending for the lifetime of the vaccinee. Evidence indicates that a single dose of yellow fever vaccine provides most recipients with long-term protection; therefore, the previous requirement for boosting every 10 years was removed by the WHO from the International Health Regulations in 2016. Booster doses of yellow fever vaccine are still recommended after 10 years for certain individuals, including women who were pregnant during primary immunization, persons who were infected with HIV at the time of vaccination, and persons who received a hematopoietic stem cell transplant after immunization (provided they are sufficiently immunocompetent). Booster doses are also recommended for travelers who will be at particularly high risk of yellow fever during travel, including travel to areas experiencing epidemics, prolonged stays in highly endemic areas, or travel during peak transmission seasons.

All licensed yellow fever vaccines are live attenuated products. Contraindications include severe immunosuppression (e.g., during immunosuppressive or immunomodulatory therapy, in primary immunodeficiencies, or with symptomatic HIV infection or a CD4+ T lymphocyte count of <200/μL), malignant neoplasms, thymus gland disorders, and severe egg allergies. Precautions in adults include an age of ≥60 years, pregnancy, breastfeeding, and asymptomatic HIV infection with a CD4+ T lymphocyte count of 200–499/μL. Although medical waivers can be issued by yellow fever clinics, travelers must also consider the risks of traveling to endemic areas without vaccination. Common mild adverse reactions to vaccination include fevers, body aches, lymphadenopathy, localized swelling, and rash. Rare severe adverse events include anaphylaxis, neurologic complications (e.g., meningitis, encephalitis, Guillain-Barré syndrome), and yellow fever vaccine–associated viscerotropic disease (YEL-AVD). YEL-AVD is similar to yellow fever and can result in death. The risk of YEL-AVD is estimated to be ~0.3 case per 100,000 doses administered, with increased risk among immunosuppressed and elderly persons.

Poliomyelitis Although wild-type poliovirus has been eradicated from most of the world, poliomyelitis caused by circulating vaccine-derived poliovirus has been sporadically reported in numerous countries in Africa, the Middle East, and Asia where immunization rates are inadequate. For adults who have had the primary childhood polio vaccination series and are traveling to countries with reported wild-type or circulating vaccine-derived poliovirus transmission in the previous 12 months, a single booster of inactivated poliovirus vaccine before travel is recommended. This recommendation is sometimes extended to countries bordering those with poliovirus transmission when the risk of imported cases is high, especially for health care or humanitarian aid workers. Travelers who stay >4 weeks in certain countries considered high risk for exporting polio can also be subject to exit requirements for proof of recent vaccination (4 weeks to 12 months before departure). Because the list of countries with recommendations for polio booster doses is continually updated, providers should routinely review current polio booster guidance in online resources (Table 130-2).

Cholera Most countries at risk for cholera are in Africa and Asia, with the exception of the island of Hispaniola in the Americas. In 2022, an upsurge in cases was observed worldwide, and this trend continued into 2023. Transmission occurs mostly through consumption of contaminated water, although contaminated food or person-to-person contact also can be responsible. The risk to travelers is extremely low when safe food and water precautions are followed. Cholera vaccination can be considered for travelers to endemic regions, particularly those visiting areas experiencing outbreaks, health care workers, or travelers who cannot adhere to strict hygienic practices. Individuals at higher risk for severe disease (e.g., those with type O blood or comorbid conditions) and those who will be in situations where access to health care will be difficult also might consider vaccination. A single-dose live attenuated oral cholera vaccine (Vaxchora) is approved for travelers in the United States and the European Union. This vaccine had an efficacy of 90% at 10 days and 80% at 3 months after administration; the duration of protection and the need for booster doses remain to be determined. Oral killed cholera vaccines are available outside the United States.

Meningococcal Disease Endemic and epidemic meningococcal disease can occur worldwide; however, immunization is primarily recommended for high-risk travelers, including those going to countries in the African "meningitis belt" during the dry season (December to June), when large-scale epidemics can take place. Historically, meningococcal disease in the meningitis belt was caused by serogroup A; however, more recently, serogroups C, W-135, and X have caused outbreaks following the successful serogroup A vaccination program (Meningitis Vaccine Project, *https://www.path.org/our-impact/articles/about-meningitis-vaccine-project/*). Travelers should receive quadrivalent meningococcal vaccine, which protects against serogroups A, C, Y, and W-135. Conjugated meningococcal vaccines are generally preferred over polysaccharide vaccines because of their increased immunogenicity and the reduced carriage of meningococci by vaccinees; in fact, the polysaccharide vaccines are no longer available in the

A

B

FIGURE 130-1 Yellow fever recommendations in (*A*) Africa and (*B*) the Americas. Vaccination of travelers to areas with low exposure risk (designated in green) is not routinely recommended but can be considered for travelers at increased risk due to high exposure to mosquitoes or prolonged travel. Recommendations current as of November 2022. See Centers for Disease Control and Prevention Travelers' Health website for current recommendations. *(Reproduced with permission from J Nemhauser et al [eds]: Yellow Book 2024 Health Information for International Travel. New York, Oxford University Press; 2023.)*

United States. Pilgrims traveling to the Kingdom of Saudi Arabia for the Hajj and Umrah pilgrimages are required to demonstrate proof of vaccination with quadrivalent meningococcal vaccine within the preceding 3 years. Vaccination against serogroup B meningococcal disease is not recommended for travelers except in specific outbreak situations.

Japanese Encephalitis Japanese encephalitis is a potentially severe viral infection passed to humans by evening-biting mosquitoes in much of Asia and parts of the western Pacific **(Chap. 215)**. Although the WHO estimates that as many as 68,000 cases occur each year in Asia, the risk to travelers from nonendemic areas is estimated to be <1 case per 1 million travelers. However, certain travelers are at increased risk, such as long-term expatriates, persons traveling in rural areas during peak transmission seasons, and those with increased outdoor exposure (particularly during the evening). Short-term travelers to urban areas appear to be at lowest risk. In addition to mosquito avoidance measures, vaccination can be considered for travelers at risk for infection. Multiple Japanese encephalitis vaccines are available worldwide. An inactivated Vero cell culture–derived vaccine (IXIARO) is available in the United States and Europe and can be given to adults as a two-dose primary series, with doses administered 7–28 days apart.

Rabies Rabies **(Chap. 214)** is endemic to all continents except Antarctica and to numerous islands worldwide. Although many mammalian species can be infected with rabies virus, terrestrial carnivores and bats are the main reservoirs. In countries without animal control or routine pet vaccination, bites from infected dogs are often the most common source of rabies infection. Management of animal bites carrying a rabies risk is a common reason travelers seek urgent health care during or after travel. Individuals at higher risk for exposure may include children, long-term travelers, travelers whose activities will put them at higher risk of animal contact (e.g., field biologists, cavers), and travelers to remote areas. All travelers should be advised about animal bite avoidance and management of bite and scratch injuries (even minor), including thorough washing of the wound with soap and water (or povidone iodine) and immediate medical evaluation to determine whether rabies postexposure prophylaxis is indicated. The CDC-recommended postexposure prophylaxis regimen requires administration of rabies immune globulin and a rabies vaccination series. Rabies preexposure immunization series can be considered for travelers at higher risk of exposure, particularly those to destinations where access to rabies immune globulin can be difficult. Individuals receiving the rabies preexposure vaccination series should be advised that they will require urgent postexposure booster doses of vaccine following potential exposures. In the United States, the rabies preexposure vaccination series was revised in 2022, and a two-dose series (7 days apart) is now approved for travelers with risk of exposure. A third dose (between 21 days and 3 years after the initial series) or confirmation of protective titer (1–3 years after the initial series) is recommended for travelers who will be at risk for >3 years (see detailed discussion in the CDC *Yellow Book*, Table 130-2).

Tick-Borne Encephalitis Tick-borne encephalitis **(Chap. 215)** is endemic to parts of Europe and Asia, ranging from France to northern Japan. The infection is transmitted primarily through the bite of an infected *Ixodes* tick. Transmission is also possible through ingestion of unpasteurized dairy products from infected goats, sheep, or cows. Travelers to endemic regions who engage in outdoor activities in forested areas should consider vaccination prior to travel. An inactivated tick-borne encephalitis vaccine is approved in the United States, given with a three-dose primary series (second dose 14 days to 3 months after the first, and the third dose 5–12 months after the second). For short-term travelers unable to receive the third dose before travel, evidence suggests that vaccine efficacy following the initial two doses is sufficient enough to warrant vaccination with two doses. All travelers should use personal protective measures against tick bites (see "Prevention of Arthropod-Borne Infections," below).

Dengue Dengue **(Chap. 215)** is the most common arthropod-borne virus (arbovirus) worldwide, transmitted by *Aedes* mosquitoes. It is the leading cause of fever in travelers returning from most tropical and subtropical destinations outside of sub-Saharan Africa, where malaria is most common. While most travel-related cases are uncomplicated, severe dengue can occur in travelers, including dengue hemorrhagic fever and dengue shock syndrome. There is currently no U.S. Food and Drug Administration (FDA)-approved dengue vaccine in the United States for travelers, since the only FDA-approved vaccine (Dengvaxia; tetravalent live-attenuated dengue vaccine) has indications limited to individuals residing in regions of endemicity with evidence of a past dengue virus infection. In the European Union (and some other non-U.S. countries), a newer tetravalent live attenuated dengue vaccine (Qdenga) is approved for persons aged 4 and older. It can be considered for use in travelers, although questions remain regarding its ability to elicit protection against all dengue virus serotypes, specifically in seronegative recipients. All travelers should use personal protective measures against mosquito bites (see "Prevention of Arthropod-Borne Infections," below).

Chikungunya Chikungunya virus **(Chap. 215)** is an arbovirus transmitted by *Aedes* mosquitoes that has spread worldwide in recent decades. Approximately 100–200 chikungunya cases are reported annually in U.S. travelers. The highest risk of infection is among travelers to countries experiencing outbreaks. Chikungunya causes an acute febrile illness, and although life-threatening illness is rare, many patients develop severe arthralgias that might become chronic. A live chikungunya vaccine was approved in the United States in 2023 with an indication for individuals 18 years of age and older at increased risk of exposure to chikungunya virus. The vaccine is given as a single dose and is contraindicated in immunocompromised persons. In these trials, ~12% of individuals developed chikungunya-like symptoms. While most reactions were mild or moderate in severity and short-lived, 1.6% of vaccine recipients developed more significant symptoms or fever ≥39°C. New guidance on its use in travelers has been recently released (*https://www.cdc.gov/chikungunya/hcp/vaccine/index.html*).

PREVENTION OF ARTHROPOD-BORNE INFECTIONS

MALARIA PREVENTION

Malaria **(Chap. 231)** results from infection with one or more of five species of protozoan parasites: *Plasmodium falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. The disease remains a significant cause of morbidity and mortality worldwide, and it is the leading cause of life-threatening infections in travelers. The majority of the disease burden, both in endemic populations and in travelers, occurs in regions of sub-Saharan Africa where *P. falciparum* is endemic. In 2018, nearly all of the 1823 malaria cases reported in the United States were acquired during travel to endemic countries. In most cases, the patient had not taken chemoprophylaxis, had adhered to the regimen inconsistently, or had taken an incorrect regimen. Among cases in U.S. residents, visiting friends or relatives was the most common reason for travel.

Although there have been significant recent developments in malaria vaccines for use in endemic countries, these vaccines are not approved for travelers. Key elements of malaria prevention in travelers include mosquito avoidance, chemoprophylaxis, and early recognition of infection to prevent the development of severe disease. *Plasmodium* species are transmitted by *Anopheles* mosquitoes, which typically bite from dusk until dawn. Limiting activities to enclosed or well-screened areas during these hours is recommended. Travelers should wear long-sleeved shirts and long pants to limit the amount of exposed skin and should apply a recommended insect repellent to any skin that remains exposed. Both the CDC and the WHO provide lists of reliable insect repellents, with products that contain DEET (20–50%) as the active ingredient being preferred by most experts. Travelers may also wear permethrin-treated clothing to increase protection. If sleeping areas are not well screened, it is recommended that individuals sleep under insecticide-treated bed nets. Indoor insecticide sprays or spatial repellents should be used with caution; the efficacy of these measures in

malaria prevention has not been proven, and there may be risks from direct inhalation.

In addition to mosquito avoidance, chemoprophylaxis to prevent symptomatic disease is recommended for travelers to higher-risk regions. Current drugs used for malaria chemoprophylaxis include atovaquone-proguanil (Malarone), chloroquine (and hydroxychloroquine), doxycycline, mefloquine, primaquine, and tafenoquine (see **Chap. 231** for detailed regimens). Chemoprophylaxis recommendations should be based on careful review of the traveler's itinerary to determine malaria risk, predominant malaria species, and drug resistance patterns. The CDC and other travel medicine resources (Table 130-2) provide current country-specific risk assessments and chemoprophylaxis recommendations. Other important considerations include the traveler's medical history and routine medications; this information is essential in assessing for contraindications to specific drugs or drug–drug interactions. Primaquine and tafenoquine are active against the dormant liver stages of *P. vivax* and *P. ovale,* and both drugs are useful as prophylaxis in persons without glucose-6-phosphate dehydrogenase (G6PD) deficiency traveling to areas where these species are more common. Primaquine can also be used for presumptive antirelapse therapy in returned travelers without G6PD deficiency who had a prolonged risk of exposure to *P. vivax* or *P. ovale* and did not use primaquine or tafenoquine for chemoprophylaxis. Currently approved regimens are well tolerated, and concerns that severe side effects are common are not supported by clinical evidence (e.g., hepatitis with atovaquone-proguanil or psychosis with mefloquine). Providers should emphasize that malaria chemoprophylaxis can be life-saving and that, when prophylaxis is indicated, the benefits outweigh the low risk of serious adverse reactions.

After the onset of malaria, progression to severe disease can be rapid; therefore, early recognition of symptoms is crucial. Febrile travelers should seek evaluation as soon as possible during or after travel to malarious areas. Although the CDC does not recommend that travelers carry malaria treatment medications for standby emergency therapy as an alternative to chemoprophylaxis, this approach is accepted by some authorities for some travelers to lower-risk areas instead of chemoprophylaxis. However, because chemoprophylaxis failures can occur and locally acquired antimalarial agents can be substandard, prescription of a "reliable-supply" treatment course can be considered (in addition to chemoprophylaxis), to be used as needed under the advice of a medical professional. In the United States, atovaquone-proguanil and artemether-lumefantrine (Coartem) are available oral treatments for malaria, although atovaquone-proguanil should not be prescribed as a reliable-supply treatment course when it is being used for chemoprophylaxis.

PREVENTION OF OTHER ARTHROPOD-BORNE INFECTIONS

Arthropod-borne infections are present worldwide, and arboviral infections are particularly numerous. Risk of arbovirus acquisition may vary from year to year and by season (rainy vs dry). In addition, risk can increase dramatically during outbreak periods, as witnessed during recent outbreaks of infection with chikungunya virus and Zika virus in the Americas. While dengue, chikungunya, and Zika infections result from the bite of infected *Aedes* mosquitoes, arboviruses may also be transmitted by non-*Aedes* mosquitoes (Japanese encephalitis virus, Mayaro virus, o'nyong-nyong virus), ticks (tick-borne encephalitis virus, Powassan virus), and biting midges (Oropouche virus). In addition to arboviral illness, travelers are at risk for numerous other arthropod-borne infections, including—but not limited to—leishmaniasis (sand flies), filariasis (mosquitoes), African trypanosomiasis (tsetse flies), Chagas disease (triatomine bugs), and many tick-borne infections such as rickettsial diseases (e.g., African tick bite fever, scrub typhus) and Lyme disease.

Travel immunizations for arthropod-borne infections are limited to yellow fever, Japanese encephalitis, tick-borne encephalitis, dengue, and chikungunya vaccines, although availability of these vaccines can vary worldwide. Many arboviral infections have no approved vaccines, and furthermore, some travelers might be unable to receive certain vaccines due to cost or medical barriers (precautions or contraindications). For these reasons, arthropod bite avoidance remains a cornerstone of arthropod-borne infection prevention. Recommendations for avoiding arthropod bites in general are similar to those provided for *Anopheles* mosquito avoidance to prevent malaria. However, in contrast to malaria, many disease-transmitting arthropods bite during the day and may be encountered across a wider range of environments. Travelers at risk for tick bites can tuck pants into socks and perform daily self-inspections for attached ticks. Avoidance of sleeping in mud or thatch housing in areas endemic for Chagas disease is recommended.

GASTROINTESTINAL ILLNESS

Depending on the itinerary and season, as many as 30–70% of travelers report travelers' diarrhea (TD). Symptoms can include urgently passed loose stools, abdominal pain, fever, and vomiting, and more severe cases can result in volume depletion or bloody diarrhea (dysentery). The majority (~80%) of TD cases result from bacterial infections, with the most common pathogens being *Escherichia coli* and *Campylobacter*, *Shigella*, and *Salmonella* species. A minority of cases are caused by viruses, preformed bacterial toxins, and protozoa (most commonly *Giardia*). Although travelers may develop gastrointestinal illness during travel to any destination, TD is most likely to occur in low- and middle-income countries, where unhygienic food preparation practices constitute the greatest risk for development of disease.

Precautions Recommendations for the prevention of TD center on appropriate food and beverage selection as well as hand hygiene. Food is safest when cooked and served hot. Uncooked fruits and vegetables, unless they can be washed and peeled by the traveler, are considered risky. Dairy products should be pasteurized. Travelers are advised to drink bottled or purified water during travel and to avoid drinking beverages with ice, which may be made with water from unsafe sources. Before drinking any bottled or canned beverage, travelers should confirm that the factory seal is intact, as refilling of bottles with untreated water or questionable beverages is common. Street-side vendors can be particularly risky. Individuals traveling to more remote areas without access to bottled water can use one of a number of methods to purify water, including boiling, chemical treatments, filtration, or ultraviolet irradiation devices.

Prophylaxis For prophylaxis of TD, bismuth subsalicylate can be considered for short-term use. This medication, taken as two tablets (or 2 oz of liquid) four times daily, has been shown to decrease TD incidence by 50% in Mexico. The safety of bismuth subsalicylate prophylaxis when used for >21 days has not been established. Furthermore, the high dosing frequency of this regimen, common side effects (constipation, black tongue), and potential drug interactions (e.g., with acetazolamide or warfarin) limit its utility. No recommendation can be made for probiotics for TD prevention given the limited number of studies and varied results, which may vary by specific strain of probiotic used. Likewise, data supporting prebiotics for TD prevention are limited and inconclusive. Prophylactic antibiotics generally are not recommended for TD prevention given increasing concerns about adverse reactions, colonization or infection with multidrug-resistant pathogens, and development of *Clostridioides difficile* infection. However, short-term antibiotic prophylaxis (with rifaximin favored over fluoroquinolones) can be considered in rare situations for travelers at high risk for complications from TD. Oral killed cholera vaccine (Dukoral, available in Europe and Canada) shows some cross-protection against enterotoxigenic *E. coli*; however, given the wide range of TD pathogens, the protection conferred by this vaccine against TD is likely to be minimal.

Self-Treatment In general, TD is a self-limited illness, with symptoms resolving in 3–7 days for bacterial infections. Recovery times are typically shorter for infections with viral pathogens and may be prolonged for parasitic infections. For travelers who develop TD, initiation of self-treatment should be based on the patient-assessed functional impact of illness **(Fig. 130-2)**. TD can be considered *mild* (not distressing and has no impact on activities), *moderate* (distressing and may interfere with planned activities), or *severe* (incapacitating

*Azithromycin is preferred as first line for severe diarrhea or diarrhea acquired in areas with widespread quinolone resistance including Southeast and South Asia. Quinolones and rifaximin may be considered second-line treatment in moderate diarrhea or severe diarrhea without dysentery or high fever.

FIGURE 130-2 Management of travelers' diarrhea. *(Adapted from MS Riddle et al: Guidelines for the prevention and treatment of travelers' diarrhea: A graded expert panel report. J Travel Med 24:S63, 2017.)*

or prevents participation in planned activities). All dysenteric TD is considered severe. For all levels of severity, replacement of fluid and electrolyte losses resulting from diarrhea and/or vomiting is a mainstay of treatment. In severe cases, replacement with oral rehydration solution (available over the counter) is ideal; however, milder cases can be managed with any potable liquid. In addition, for patients with mild or moderate TD, self-treatment with antimotility agents alone (e.g., loperamide) can be considered.

Antibiotic treatment can decrease the duration of TD to 1–2 days, with potential further benefits from adjunctive loperamide. However, the risks of adverse effects, drug–drug interactions, and alterations in the traveler's microbiota are increasingly recognized in patients treated with antibiotics. Consequences of an altered microbiota can include *C. difficile* colitis and acquisition of multidrug-resistant organisms. Studies have shown that international travelers, particularly those who take antibiotics during travel, are at risk for becoming colonized with multidrug-resistant organisms, including extended-spectrum β-lactamase–producing Enterobacteriaceae. Travelers colonized with multidrug-resistant organisms may be at elevated risk for drug-resistant infections (e.g., urinary tract infection). The role of travelers in the global spread of multidrug-resistant organisms is uncertain. Given these concerns, routine self-treatment with antibiotics is recommended only in severe TD. Self-treatment with antibiotics, with or without antimotility agents, can be considered for moderate TD cases. Increasing quinolone resistance, most clearly documented in *Campylobacter* in Southeast and South Asia, has limited the utility of this antibiotic class for TD. The authors' preferred antibiotic regimen for TD self-treatment is azithromycin at a dose of 500 mg daily for 3 days, although a single 1000-mg dose also is effective. Rifaximin or rifamycin SV can also be considered, especially for persons unable to take other antibiotics because of drug–drug interactions. However, *Campylobacter* species are resistant to rifamycins, and their efficacy against dysentery has not been established. Treatment regimens for TD are covered in detail in **Chap. 138**. Empirical treatment of acute TD with antiprotozoal agents such as metronidazole is not recommended.

A small proportion of individuals develop prolonged symptoms (≥14 days), which may result from persistent infection (most often secondary to protozoa), secondary infection (*C. difficile*), or postinfectious irritable bowel syndrome. Antibiotic treatment for acute TD has not been proven to reduce the incidence of postinfectious irritable bowel syndrome, and patients with protracted symptoms should undergo a thorough evaluation.

PREVENTION OF OTHER TRAVEL-RELATED PROBLEMS

ACTIVITY-SPECIFIC INFECTION RISKS

Travelers should avoid direct contact with freshwater bodies (lakes, ponds, rivers) because of possible risks of leptospirosis and schistosomiasis. Schistosomiasis is endemic in Africa, Asia, and South America. Diving in African Rift Valley lakes (especially Lake Malawi) and rafting on the Nile River are popular activities that put travelers at risk for schistosomiasis. Appropriate footwear is important in tropical countries to prevent infection with *Strongyloides stercoralis* and hookworm as well as snakebites. Animals of all types (wild, stray, or even pets) are best avoided to minimize bite risk.

Travelers who engage in casual sex, including that with commercial sex workers, should be aware that the risk of sexually transmitted infections **(Chap. 141)** can be high, especially when barrier protections are not used. The multinational outbreak of mpox in 2022 was spread through close (skin-to-skin) contact, largely among networks of men who have sex with men (MSM). Given the continued transmission of mpox worldwide, vaccination against mpox should be considered for travelers who may engage in high-risk activity. Injection drug use, tattooing, and even acupuncture in unhygienic settings can pose a high risk for blood-borne infections such as HIV infection and hepatitis B and C.

VENOUS THROMBOEMBOLISM

Travelers are at risk for venous thromboembolism **(Chap. 122)**, particularly after long-haul flights or other extended periods of limited mobility. General precautions for prevention include ambulation during travel, calf exercises, and aisle seating. Travelers at increased risk for venous thromboembolism may benefit from graduated compression stockings. Anticoagulation may be considered for high-risk individuals.

ALTITUDE ILLNESS

Travelers to high-altitude destinations (>2500 m) should be counseled on altitude illness, and the prescription of medications for prophylaxis, such as acetazolamide, may be indicated **(Chap. 475)**. Popular high-altitude destinations include Cusco, Peru (the usual gateway to Machu

Picchu), mountains that attract climbers (e.g., Mt. Kilimanjaro), and Nepal (trekking).

MOTION SICKNESS

Motion sickness triggered by various modes of transportation can be significant for many travelers. Nonpharmacologic interventions can be helpful, such as avoiding known triggers, staying hydrated, getting adequate rest, and optimizing positions in vehicles near windows. For travelers with significant motion sickness history, over-the-counter and prescription antihistamines (e.g., dimenhydrinate, cyclizine, promethazine) can be effective in preventing and treating motion sickness; however, sedation and anticholinergic effects can limit their use. Nonsedating antihistamines appear to be less effective. A prescription for transdermal scopolamine patches can be helpful for susceptible travelers who anticipate prolonged risk periods (e.g., on cruises or extended bus trips), although like the antihistamines, anticholinergic and central nervous system effects are a concern with scopolamine, particularly in elderly travelers. While the evidence supporting complementary and integrative health approaches to prevent and treat motion sickness is limited or anecdotal, approaches such as acupressure bands or ginger are relatively simple to use and might have some benefit for individual travelers. Travelers should be counseled about potential drug–drug interactions between supplements and their routine medications.

JET LAG

Jet lag **(Chap. 33)** occurs when travel across time zones causes the traveler's circadian rhythm to become asynchronous with the local time zone. Symptoms are most significant with travel across more than three time zones and can result in poor sleep, daytime sleepiness (with poor physical and mental performance), gastrointestinal symptoms, and altered mood. Strategies to help circadian rhythms adjust to new time zones include shifting of sleep schedules prior to travel, timed light exposures after arrival, and melatonin use. Online resources to assist travelers in timing interventions to minimize jet lag are available (Table 130-2), although none has been validated in clinical trials. While caffeine use can reduce daytime drowsiness, it can also disrupt sleep. Prescription of hypnotics (e.g., zolpidem) for travel-related insomnia should generally be avoided, since adverse effects, including excessive fatigue and impaired cognition upon awakening, can be problematic during travel. When used, the lowest effective dose of a hypnotic medication should be used, and travelers should be cautioned about use during flights (when extended immobilization is problematic) or any situation when a full course of sleep is not possible. Sedative-hypnotic and anxiolytic medications are among the classes of drugs that are potentially restricted by certain countries (see "Traveling with Prescription Medications," below).

INJURIES

International travel presents numerous factors that contribute a higher risk of injuries and death. Travelers may face unfamiliar environments and language barriers and rely heavily on other people (e.g., drivers and tour operators) for protection. Furthermore, in low- and middle-income countries, safety protections that are typical in high-income countries are often less stringent, unenforced, or nonexistent. Travelers often exhibit increased risk-taking behaviors during travel, frequently in association with the use of alcohol. When injuries do occur, access to adequate trauma care can be limited. Motor vehicle accidents are a common cause of injury deaths in travelers. In addition to poor road conditions, traffic rules are often less strictly enforced overseas. Riding on motorbikes (especially without a helmet), on overcrowded public transit, in improperly maintained vehicles, and in vehicles without seatbelts should be avoided. Drowning prevention and crime avoidance are important safety topics. The U.S. State Department provides country-specific safety and security advice for U.S. travelers (Table 130-2).

TRAVELERS WITH PREEXISTING MEDICAL CONDITIONS

Travel is increasingly common for persons with chronic medical conditions. Risks vary depending on the condition, destination, and activities. Travelers with chronic medical conditions are encouraged to plan their trips carefully and to consult with their physicians to assess fitness for travel. Notably, cardiovascular events are a frequent cause of in-flight emergencies and death during travel. Travel across time zones and changes in diet can create challenges in conditions—e.g., diabetes mellitus—that require regulation of diet and consistent medication timing. Providers can assist travelers by providing copies of prescriptions (or medication lists), a medical problems list, and a baseline electrocardiogram.

Adverse events caused by drug–drug interactions can be difficult to manage during travel, especially in destinations with limited emergency care. Therefore, providers should review the traveler's medication list for potential drug interactions when prescribing prophylactic or self-treatment medications. Azithromycin and quinolones prescribed for travelers' diarrhea self-treatment can cause additive QT interval prolongation when used with some antidepressant and antiarrhythmic medications. Malaria prophylaxis medications can affect the international normalized ratio in patients who are taking warfarin.

IMMUNOCOMPROMISED TRAVELERS

An increasing number of immunocompromised persons are traveling, including organ transplant recipients, HIV-infected persons, cancer patients, persons with asplenia, and persons receiving immunosuppressive therapies (e.g., biologic agents, antimetabolites, or chronic high-dose glucocorticoids). Although each of these conditions has unique risks, general concerns include increased susceptibility to infection, decreased vaccine efficacy, and—for patients with severe immunosuppression—contraindications to live virus vaccines. Routinely recommended precautions (e.g., food and water hygiene, insect bite avoidance) are particularly important for travelers with immunocompromising conditions.

Conditions associated with severe immunocompromise that preclude use of live virus vaccines include active leukemia or lymphoma, generalized malignancy, graft-versus-host disease, HIV/AIDS (with a CD4+ count of <200 cells/μL), and congenital immunodeficiencies. Immunosuppressive therapies that preclude live virus vaccines include high-dose glucocorticoid treatment (defined as ≥20 mg of prednisone or the equivalent daily for ≥2 weeks), alkylating agent administration, antimetabolite therapy (e.g., azathioprine, methotrexate), transplant-related immunosuppression, cancer chemotherapy, radiation therapy, and treatment with biologic agents, including tumor necrosis factor blockers, checkpoint inhibitors, and lymphocyte-depleting agents. If possible, travel immunizations should be administered prior to iatrogenic immunosuppression (≥2 weeks for inactivated vaccines and ≥4 weeks for live vaccines). The duration of immunosuppression after discontinuation of immunosuppressive therapies can be prolonged, particularly for biologic agents. Travelers unable to receive a required yellow fever vaccine because of immunosuppression should be given a medical waiver if travel cannot be avoided. Providers are advised to review the detailed guidance for immunizing immunocompromised travelers provided in the CDC *Yellow Book* (Table 130-2) and other resources.

HIV-INFECTED TRAVELERS

Infection risk in HIV-infected individuals generally correlates with the level of immunosuppression (i.e., the CD4+ T-cell count). Adults with HIV infection and CD4+ counts of >500 cells/μL are generally considered to have levels of risk similar to those faced by travelers without immunocompromising conditions. Live MMR and varicella vaccines can generally be administered to HIV-infected travelers with a CD4+ count of >200 cells/μL for ≥6 months. Guidance for yellow fever immunization of HIV-infected persons is reviewed above. Oral live attenuated typhoid and live attenuated influenza vaccines should not be administered to HIV-infected persons, given the availability of polysaccharide and inactivated versions of these vaccines, respectively.

The number of countries that restrict the entry of HIV-infected persons has decreased in recent years, particularly for short-term travelers and tourists. However, HIV-infected travelers should review the policies of their destination, especially when they plan to work abroad or stay for longer terms. Unnecessary disclosures of HIV status to customs

or immigration officials should be avoided. Resources include embassies in destination countries, the U.S. State Department, and online resources for travelers with HIV infection (Table 130-2).

PREGNANT TRAVELERS

Travel medicine providers should assess pregnancy status and the possibility of conception during travel. The pregnant traveler faces numerous unique risks. These include limited availability of emergency care for pregnancy complications, increased risk of certain infections, and exposure to specific infections that can result in pregnancy complications. Although most airlines will allow pregnant women to travel up to 36 weeks of pregnancy, the American College of Obstetrics and Gynecology recommends travel during the middle period of pregnancy (weeks 14–28), when morning sickness has improved, before mobility becomes impaired, and when the risk of spontaneous abortion or premature labor is minimal. Pregnancy-related contraindications and relative contraindications to travel are numerous and are reviewed in the CDC *Yellow Book* (Table 130-2).

Pregnant travelers are at increased risk of various infections (e.g., malaria, influenza, hepatitis E, listeriosis) and/or severity of illness when traveling. Some infections, notably Zika virus disease, toxoplasmosis, and rubella, can result in birth defects or fetal death. Pregnant travelers should contemplate the infectious risks of their destination and consider delaying travel to areas where particularly dangerous infections, such as malaria or Zika, are present. Currently, only mefloquine and chloroquine are approved for malaria chemoprophylaxis in pregnancy, and plasmodial resistance to these drugs can further limit options. Travel immunizations considered safe during pregnancy also are limited (Table 130-3). When used as directed, insect repellents registered by the Environmental Protection Agency, such as DEET, are considered safe during pregnancy.

TRAVELERS WITH SEVERE ALLERGIES

Travelers with severe allergies to food, insect stings, and environmental allergens can be at increased risk during travel, particularly in destinations without adequate emergency care. Avoidance of food allergens can be challenging, particularly when eating in restaurants or catered settings. Language barriers can present difficulties in avoiding exposures to allergens in food or medications. Regional variations in culinary practices and ingredients can lead to unexpected food allergen exposure. Outdoor activities can increase the risk of stings by hymenopterous insects (bees, wasps, ants). Solo travelers can face particular challenges when experiencing severe allergies.

Providers should ensure that travelers have an emergency care plan for severe allergies and an adequate supply of emergency self-treatment, including epinephrine auto-injectors and antihistamines. For travelers who will have no immediate access to health care, it can be prudent to bring other medications that might be indicated, including rescue bronchodilator inhalers (for individuals with asthma) and short courses of glucocorticoids. Written documentation of the allergic disorder and self-treatment medications should be carried, especially when injectable medications are involved. Travelers with severe food allergies should alert restaurants and hosts. Printable food allergy alert cards in various languages are available online (Table 130-2).

OTHER PRETRAVEL PREPARATIONS

TRAVEL HEALTH KITS

A carefully planned travel health kit can minimize the need to seek care for self-treatable conditions. The ideal contents depend on the destination, duration, and activities during travel as well as on individual health issues. Routine and trip-specific prescription medications (e.g., malaria prophylaxis, travelers' diarrhea self-treatment antibiotics) should be carried in original labeled prescription bottles to aid in identification. A digital thermometer and typically used over-the-counter medications, such as analgesics and antipyretics, antidiarrheal medications, medications for motion sickness, antacids, laxatives, oral rehydration salts, antihistamines, and topical steroid creams, can be important. Basic first-aid items, such as gloves, bandages, tape, antibiotic ointment, and tweezers, are helpful. Critical medications should always be carried and not packed in checked luggage; however, travelers must consider any restrictions about flying with sharp objects or liquids, particularly in their carry-on baggage.

TRAVELING WITH PRESCRIPTION MEDICATIONS

Carrying copies of prescriptions (or a signed medication list from a physician's office) is recommended. Many countries, particularly in Asia, the Middle East, and Africa, have stringent restrictions on certain drugs that are less restricted in the United States. These regulations can include controlled substances such as opioid analgesics, anxiolytics and sedatives, and medications for attention deficit hyperactivity disorder. Even some over-the-counter medications such as pseudoephedrine and diphenhydramine are restricted in certain countries. Requirements for traveling with restricted medications can include carrying copies of prescriptions or even obtaining advance approval from the destination country's health ministry. Levels of enforcement and penalties for violations vary widely. Travelers who plan to carry potentially restricted medications should contact the embassy of their destination to review policies. The International Narcotics Control Board also maintains a listing of regulations for travelers carrying controlled medications to specific countries (Table 130-2). Travelers taking antiviral medications for HIV preexposure prophylaxis going to countries that restrict entry to persons living with HIV/AIDS might take specific precautions to avoid challenges when entering (see online resource for HIV-infected travelers, Table 130-2). Travelers should carry amounts appropriate for the duration of their itinerary, including a limited number of extra doses for use in cases of a delay in return.

Although many medications that require prescription in the United States are available over the counter overseas, the quality of locally acquired pharmaceuticals can vary. Counterfeit medications, particularly antimalarials, are common in much of the world. Whenever possible, travelers are cautioned to avoid obtaining critical medications such as malaria chemoprophylaxis during travel.

HEALTH CARE OVERSEAS AND TRAVEL HEALTH INSURANCE

Travelers should consider where they would seek urgent or emergency health care, particularly if they have chronic health conditions, are pregnant, or will participate in activities with a high risk of injury or illness (e.g., altitude sickness). International travelers should be aware that most countries do not accept routine health insurance from other countries and that such insurance is unlikely to cover out-of-pocket health care costs or to provide assistance in identifying providers overseas. Travelers are advised to review their health insurance policies before travel to assess the scope of international coverage (including emergency care, hospitalization, psychiatric care, and obstetric care, if applicable) and the availability of 24-h physician-backed support.

For many travelers, supplemental insurance coverage of some type is prudent. *Travel insurance* usually consists of coverage for financial losses due to trip cancellation (e.g., due to unexpected illness) or lost baggage. *Supplemental travel health insurance* policies cover health care costs overseas and typically provide 24-h support centers. *Medical evacuation (medevac) insurance* can be a part of a travel health insurance policy or a stand-alone policy and covers medical evacuation when it is determined that the local level of care is inadequate. Further information on travel health insurance is available from online resources listed in Table 130-2.

SPECIAL TRAVEL POPULATIONS

Travelers are increasingly diverse in their reasons for and types of travel, each of which poses unique risks and challenges **(Table 130-4)**. A major challenge in travel medicine is presented by VFR travelers who are visiting their countries of origin. VFR travelers face increased risks for travel-related infections, as they often travel to areas not frequented by tourists, stay in local homes, and adopt local food and transportation habits. Immunity resulting from malaria infection is not long-term, but immigrants from malaria-endemic countries often incorrectly assume that they are immune. Barriers to appropriate

TABLE 130-4 Risks and Prevention Strategies in Special Travel Populations

GROUP	RISKS AND CHALLENGES	PREVENTION STRATEGIES
Travelers visiting friends and relatives (VFR)	• Greater likelihood of visiting areas outside usual travel destinations • Frequent adoption of food, accommodation, and transportation habits similar to those of locals • May underestimate importance of travel immunizations or malaria prophylaxis • Financial or cultural barriers to seeking pretravel advice or immunization	• Questions about planned travel during routine care visits • Prioritization of vaccines and prophylaxis for highest-risk infections when resources are limited
Budget travelers	• Financial barriers to seeking pretravel advice or immunization • Lower quality of accommodations, transportation, and food establishments	• Prioritization of vaccines and prophylaxis for highest-risk infections when resources are limited • Education about high-risk activities (e.g., motorbike taxis)
Last-minute travelers	• Minimal advance notice for pretravel consultations or immunizations	• Several vaccines are effective with a single dose. • Some vaccination series can be accelerated. • Some malaria chemoprophylaxis can be started 1 day prior to entering risk areas. • Consider broad immunization coverage and standing malaria chemoprophylaxis supply for aircrews or other travelers with unpredictable, last-minute trips.
Long-term travelers	• Increased risk of infection and injury due to longer duration • Increased likelihood of adopting local food, accommodation, and transportation standards • Potential need for extended supply of malaria chemoprophylaxis	• Increased emphasis on importance of certain vaccines, such as hepatitis B, rabies, typhoid, or Japanese encephalitis (in endemic areas) • Long-term malaria chemoprophylaxis
Health care workers on medical missions	• Risk of infections acquired through patient care because of inadequate infection-control standards • Potentially high prevalence of untreated transmissible infections in patients • Limited or no access to urgent postexposure prophylaxis for HIV infection and hepatitis B • Exposure to emerging infections and outbreaks	• Ensure that traveler has received recommended immunizations for health care workers. • Advise traveler to assess availability of adequate personal protective equipment and medications for HIV postexposure prophylaxis and to consider potential need to bring own supplies. • Advise traveler against working with organizations inexperienced in delivering care in the destination area.
Medical tourists	• Nosocomial infections and other complications of medical procedures overseas • Substandard accreditation, infection control, safety guidelines, drugs, and blood-product screening • Increased risk of thromboembolism following surgery	• Advise traveler on potential risks. • Direct tourist to internationally accredited facilities and providers. • Tourist should acquire a copy of medical records for providers who will provide follow-up care. • See CDC *Yellow Book* (Table 130-2) for specific resources.

Abbreviation: CDC, Centers for Disease Control and Prevention.

pretravel advice can include financial and language issues or a lack of trust in the medical system.

POSTTRAVEL MEDICAL CARE

Acute febrile illness in returning travelers can represent a potentially life-threatening illness, such as malaria, typhoid fever, or leptospirosis. Early diagnosis and treatment can be critical and potentially life-saving for many travel-related infections. Although most acute febrile illnesses have incubation periods of <14 days, infections including typhoid, malaria, leptospirosis, and acute schistosomiasis can have prolonged incubation periods. Travelers should be advised to always inform their health care providers of their travel history, even when their travel does not immediately precede illness onset. Exposure risk occurring as much as a year prior to illness onset should be considered for malaria. Providers unfamiliar with infections common to a region recently visited by an acutely ill traveler should consult with infectious disease or travel medicine specialists and/or their local public health departments.

OUTBREAKS AND EMERGING INFECTIOUS DISEASES

Emerging and reemerging infectious diseases create challenges for international travel. During outbreaks of novel or emerging infections (e.g., the 2020 COVID-19 pandemic, recent Ebola virus disease epidemics in western and central Africa, or the emergence of Zika in the Americas in 2015–2016), information can be limited or can rapidly change. Significant travel disruption can also occur when outbreaks of well-known infections take place in previously unaffected areas, such as the 2017–2018 yellow fever outbreak in southeastern Brazil, which included the metropolitan areas of Rio de Janeiro and São Paolo, two major travel destinations for which vaccination had not previously been recommended. Providers counseling travelers can help them make informed decisions by carefully reviewing available travel health notices, surveillance reports, and potential risks to travelers. Individuals may be advised against travel to certain areas when risks are significant.

Section 2 Clinical Syndromes: Community-Acquired Infections

131 Pneumonia

Lionel A. Mandell,
Michael S. Niederman

DEFINITION

Pneumonia is an infection of the pulmonary parenchyma. Despite significant morbidity and mortality, it is often misdiagnosed, mistreated, and underestimated. Pneumonia has usually been classified as community-acquired (CAP), hospital-acquired (HAP), or ventilator-associated (VAP). A fourth category, healthcare-associated pneumonia, should be discontinued because it did not reliably predict infection with resistant pathogens and was associated with increased use of broad-spectrum antibiotics. Rather than relying on a predefined subset of pneumonia cases, it is better to assess patients individually based on risk factors for infection with a resistant organism, such as certain comorbid illnesses, recent hospitalization, or recent antibiotic therapy.

Pneumonia caused by macroaspiration of oropharyngeal or gastric contents, usually referred to as aspiration pneumonia, is best thought of as a point on the continuum that includes CAP and HAP. Estimates suggest that aspiration pneumonia accounts for 5–15% of CAP cases, but reliable figures for HAP are unavailable. The airways or pulmonary parenchyma may be involved, and patients usually represent a clinical phenotype with risk factors for macroaspiration and involvement of characteristic anatomic pulmonary locations.

In this chapter, we will not be dealing with pneumonia in immunocompromised hosts.

PATHOPHYSIOLOGY

Pneumonia is the result of the proliferation of microbial pathogens in the alveoli and the host's response to them. Until recently, it was thought that the lungs were sterile and that pneumonia resulted from the introduction of potential pathogens into this sterile environment. Typically, this introduction occurred through microaspiration of oropharyngeal organisms into the lower respiratory tract. The overcoming of innate and adaptive immunity by such microorganisms could result in the clinical syndrome of pneumonia.

A complex and diverse community of bacteria in the lungs constitutes the lung microbiota. Awareness of this microbiota has prompted a rethinking of how pneumonia develops. Mechanical factors, such as the hairs and turbinates of the nares, the branching tracheobronchial tree, mucociliary clearance, and gag and cough reflexes, play roles in host defense but are insufficient to effectively block bacterial access to the lower airways. In the absence of a sufficient barrier, microorganisms may reach the lower respiratory tract by a variety of pathways, including inhalation, microaspiration, and direct mucosal dispersion.

The constitution of the lung microbiota is determined by three factors: microbial entry into the lungs, microbial elimination, and regional growth conditions for bacteria, such as pH, oxygen tension, and temperature. The key question, however, is how a dynamic homeostasis among bacterial communities results in acute infection. Pneumonia therefore does not appear to be the result of the invasion of a sterile space by a particular microorganism but is more likely an emergent phenomenon dependent upon a number of mechanisms, including self-accelerating positive feedback loops.

A possible model for pneumonia is as follows. An inflammatory event resulting in epithelial and/or endothelial injury results in the release of cytokines, chemokines, and catecholamines, some of which may selectively promote the growth of certain bacteria, such as *Streptococcus pneumoniae* and *Pseudomonas aeruginosa*. This cycle of inflammation, enhanced nutrient availability, and release of potential bacterial growth factors may result in a positive feedback loop that further accelerates inflammation and the growth of particular bacteria, which may then become dominant. In cases of CAP and HAP, the trigger may be a viral infection compounded by microaspiration of oropharyngeal organisms. In cases of true aspiration pneumonia, the trigger may possibly be the macroaspiration event itself.

Once triggered, innate and adaptive immune responses can help contain potential pathogens and prevent the development of pneumonia. However, in the face of continuing inflammation (and especially if a positive feedback loop becomes sustainable), the process may proceed to a full-fledged pneumonia syndrome. Inflammatory mediators such as interleukin 6 and tumor necrosis factor result in fever, and chemokines such as interleukin 8 and granulocyte colony-stimulating factor increase local neutrophil numbers. Mediators released by macrophages and neutrophils may create an alveolar capillary leak, resulting in impaired oxygenation, hypoxemia, and radiographic infiltrates. Bacteria themselves may produce toxins that further amplify the inflammatory response. Moreover, some bacterial pathogens appear to interfere with the hypoxic vasoconstriction that would normally occur with fluid-filled alveoli, possibly resulting in severe hypoxemia. Decreased compliance due to capillary leak, hypoxemia, increased respiratory drive, increased secretions, and occasionally infection-related bronchospasm all lead to worsening dyspnea. If severe enough, changes in lung mechanics secondary to reductions in lung volume, compliance, and intrapulmonary shunting of blood may cause respiratory failure.

PATHOLOGY

Classic pneumonia evolves through a series of stages. The initial stage is edema with a proteinaceous exudate and often bacteria in the alveoli. Next is a rapid transition to the red hepatization phase. Erythrocytes in this intraalveolar exudate give this stage its name. In the third phase, gray hepatization, erythrocytes have been lysed and degraded. The neutrophil is the predominant cell, fibrin deposition is abundant, and bacteria have disappeared. This phase corresponds with the successful containment of the infection and improvement in gas exchange. In the final phase, resolution, the macrophage reappears as the dominant cell in the alveolar space and the debris of neutrophils, bacteria and fibrin has been cleared, as has the inflammatory response.

This pattern has been described best for lobar pneumococcal pneumonia but may not apply to pneumonia of all etiologies. In VAP, respiratory bronchiolitis may precede the development of a radiologically apparent infiltrate. A bronchopneumonia pattern is most common in nosocomial pneumonias, whereas a lobar pattern is more common in bacterial CAP. Despite the radiographic appearance, viral and *Pneumocystis* pneumonias represent alveolar rather than interstitial processes.

COMMUNITY-ACQUIRED PNEUMONIA

ETIOLOGY

Numerous microbes may cause CAP, including a variety of bacteria, viruses, fungi, and protozoa.

Newer viral pathogens include metapneumoviruses, the coronaviruses responsible for severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS), and the SARS-CoV-2 coronavirus. First described in December 2019, SARS-CoV-2 and its associated clinical disease, COVID-19, reached pandemic proportions and are a cause of significant morbidity and mortality. The COVID-19 pandemic has changed the etiologic profile of CAP, and the ultimate role that the SARS-CoV-2 virus will play as a cause of CAP remains to be seen. The virus and the disease are discussed in detail in **Chap. 205**.

Although most CAP cases are caused by relatively few pathogens, an accurate determination of their prevalence is difficult because laboratory testing methods are often insensitive and indirect **(Table 131-1)**. Separation of potential agents into "typical" bacterial pathogens and "atypical" organisms may be helpful, although both types of pathogens can lead to similar clinical syndromes. The former group includes *S. pneumoniae*, *Haemophilus influenzae*, and, in selected patients, *Staphylococcus aureus* and gram-negative bacilli such as *Klebsiella pneumoniae* and *P. aeruginosa*. The "atypical" organisms include *Mycoplasma pneumoniae*,

TABLE 131-2 Epidemiologic Factors Suggesting Possible Causes of Community-Acquired Pneumonia

FACTOR	POSSIBLE PATHOGEN(S)
Alcoholism	*Streptococcus pneumoniae*, oral anaerobes, *Klebsiella pneumoniae*, *Acinetobacter* spp., *Mycobacterium tuberculosis*
COPD and/or smoking	*Haemophilus influenzae*, *Pseudomonas aeruginosa*, *Legionella* spp., *S. pneumoniae*, *Moraxella catarrhalis*, *Chlamydia pneumoniae*
Structural lung disease (e.g., bronchiectasis)	*P. aeruginosa*, *Burkholderia cepacia*, *Staphylococcus aureus*
Dementia, stroke, decreased level of consciousness	Oral anaerobes, gram-negative enteric bacteria
Lung abscess	CA-MRSA, oral anaerobes, endemic fungi, *M. tuberculosis*, nontuberculous mycobacteria
Travel to Ohio or St. Lawrence river valley	*Histoplasma capsulatum*
Travel to southwestern United States	Hantavirus, *Coccidioides* spp.
Travel to Southeast Asia	*Burkholderia pseudomallei*, avian influenza virus
Stay in hotel or on cruise ship in previous 2 weeks	*Legionella* spp.
Local influenza activity	Influenza virus, *S. pneumoniae*, *S. aureus*
Exposure to infected humans	SARS-CoV-2
Exposure to birds	*H. capsulatum*, *Chlamydia psittaci*
Exposure to rabbits	*Francisella tularensis*
Exposure to sheep, goats, parturient cats	*Coxiella burnetii*

Abbreviations: CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; COPD, chronic obstructive pulmonary disease; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

Chlamydia pneumoniae, and *Legionella* species as well as respiratory viruses such as influenza, adenoviruses, human metapneumoviruses, respiratory syncytial virus, and coronaviruses. With the increasing use of pneumococcal vaccine, the incidence of pneumococcal pneumonia is decreasing. *M. pneumoniae* plays more of a role in ambulatory cases, whereas *Legionella* tends to be associated with more serious cases and can be found in outbreaks, as well. *C. pneumoniae* now appears to account for <1% of CAP cases. Viruses are recognized as increasingly important in pneumonia, and polymerase chain reaction (PCR)–based testing indicates their presence in the respiratory tract of 20–30% of healthy adults and in the same percentage of pneumonia patients, including those who are severely ill. The most common are influenza, parainfluenza, and respiratory syncytial viruses. Whether they are true etiologic pathogens, co-pathogens, or simply colonizers cannot always be determined. Atypical organisms cannot be cultured on standard media or seen on Gram stain, but their frequency and importance have significant implications for therapy. They are intrinsically resistant to all β-lactam antibiotics and require treatment with a macrolide, fluoroquinolone, or a tetracycline. In the 10–15% of CAP cases that are polymicrobial, the etiology usually includes a combination of typical and atypical pathogens.

Earlier literature suggested that aspiration pneumonia was caused primarily by anaerobes, with or without aerobic pathogens. A shift, however, has been noted recently: if aspiration pneumonia is acquired in a community or hospital setting, the likely pathogens are those usually associated with CAP or HAP. Anaerobes may still play a role, especially in patients with poor dentition, lung abscess, necrotizing pneumonia, or empyema.

S. aureus pneumonia is known to complicate influenza virus infection. However, methicillin-resistant *S. aureus* (MRSA) has been reported as a primary etiologic agent of CAP. Although cases caused by MRSA are relatively uncommon, clinicians must be aware of its potentially serious consequences, such as necrotizing pneumonia. Two factors have led to this problem: the spread of MRSA from the hospital setting to the community and the emergence of genetically distinct MRSA strains in the community associated with bacterial toxin production. Community-associated MRSA (CA-MRSA) strains may infect healthy individuals who have had no association with health care.

Despite a careful history, physical examination, and radiographic studies, the causative pathogen is often difficult to predict with certainty, and in more than half of cases, a specific etiology is not determined. Nevertheless, epidemiologic and risk factors may suggest certain pathogens **(Table 131-2)**.

EPIDEMIOLOGY

It is estimated that 7 million or more CAP cases occur annually in the United States. The annual incidence in adults ranges from 16 to 23 per 1000 population. The incidence of hospitalization is 650/100,000 but rises dramatically to 2000/100,000 yearly in the elderly. Overall, approximately 30% of patients are hospitalized, resulting in 1.5 million admissions. Along with influenza, CAP is the eighth leading cause of death in the United States, resulting in >60,000 deaths annually. The mortality rate among outpatients is usually <5% but ranges from ~12 to 40% among hospitalized patients. The exact rate depends on whether treatment takes place in or outside the intensive care unit (ICU). In the United States, CAP is the leading cause of death from infection among patients >65 years of age. Moreover, 18% of hospitalized CAP patients are readmitted within 1 month of discharge. The overall yearly CAP cost is estimated at $17 billion.

Risk factors for CAP in general and pneumococcal pneumonia in particular have implications for treatment. They include alcoholism, asthma, immunosuppression, institutionalization, and age >70 years. In the elderly, decreased cough and gag reflexes and reduced antibody and Toll-like receptor responses increase the likelihood of pneumonia. Risk factors for pneumococcal pneumonia include dementia, seizure disorders, heart failure, cerebrovascular disease, alcoholism, tobacco smoking, chronic obstructive pulmonary disease (COPD), and HIV infection. CA-MRSA pneumonia is more likely in patients with skin colonization or infection with CA-MRSA at other sites, and after viral infection. Enterobacteriaceae tend to infect patients recently hospitalized, given antibiotics, or who have comorbidities such as alcoholism, heart failure, or renal failure. *P. aeruginosa* is a particular problem in patients with severe structural lung disease (e.g., bronchiectasis, cystic fibrosis, or severe COPD). Risk factors for *Legionella* infection include diabetes, hematologic malignancy, cancer, severe renal disease, HIV infection, smoking, male gender, and a recent hotel stay or cruise ship trip.

CLINICAL MANIFESTATIONS

The clinical presentation of pneumonia can vary from indolent to fulminant and from mild to fatal. Manifestations of worsening severity include both constitutional findings and those limited to the lung and associated structures. The patient is frequently febrile and/or tachycardic and may experience chills and/or sweats. Cough may be nonproductive or productive of mucoid, purulent, or blood-tinged sputum. Gross hemoptysis is suggestive of necrotizing pneumonia (e.g., that due to CA-MRSA). Depending on severity, shortness of breath may be present, and pleural involvement may result in chest pain. Up to 20% of

patients may have gastrointestinal symptoms such as nausea, vomiting, or diarrhea. Other symptoms may include fatigue, headache, myalgias, and arthralgias.

Findings on physical examination vary with the degree of pulmonary consolidation and the presence or absence of a significant pleural effusion. An increased respiratory rate and use of accessory muscles of respiration are common. Palpation may reveal increased or decreased tactile fremitus, and the percussion note can vary from dull to flat, reflecting underlying consolidated lung and pleural fluid, respectively. Crackles, bronchial breath sounds, and possibly a pleural friction rub may be heard. The clinical presentation may be less obvious in the elderly, who may initially display new-onset or worsening confusion, or worsening of a chronic illness, but few other manifestations. Severely ill patients may have septic shock and organ failure. In cases of CAP, symptoms can range from almost nonexistent to severe, and in those with aspiration pneumonia, chest radiographic findings are often in gravity-dependent parts of the lung.

DIAGNOSIS

When confronted with possible CAP, the physician must ask two questions: Is this pneumonia, and, if so, what is the likely pathogen? The former question is answered by clinical and radiographic methods, whereas the latter requires laboratory techniques.

Clinical Diagnosis The differential diagnosis includes infectious and noninfectious entities, including acute bronchitis, exacerbations of chronic bronchitis, heart failure, and pulmonary embolism. The importance of a careful history cannot be overemphasized. The diagnosis of CAP requires a compatible history, such as cough, sputum production, fever and dyspnea, and a new infiltrate on chest radiography.

Unfortunately, the sensitivity and specificity of physical examination findings are only 58% and 67%, respectively. Chest radiography is often unable to differentiate CAP from other conditions. Radiographic findings may suggest increased severity (e.g., cavitation or multilobar involvement) and occasionally suggest an etiologic diagnosis, such as pneumatoceles in *S. aureus* infection or an upper-lobe cavitating lesion in tuberculosis. Computed tomography (CT) may be of value in suspected loculated effusion or cavitary cases or in postobstructive pneumonia caused by a tumor or foreign body. For outpatients, clinical and radiologic assessments are usually all that is required before treatment is started since most laboratory results are not available soon enough to influence initial management. In certain cases, the availability of rapid point-of-care outpatient tests can be important, such as for rapid diagnosis of influenza infection, and can prompt specific anti-influenza treatment and secondary prevention measures.

Etiologic Diagnosis The etiology of pneumonia usually cannot be determined solely on the basis of clinical or radiographic presentation. Data from >17,000 emergency department CAP cases showed an etiologic determination in only 7.6%. Except for CAP patients admitted to the ICU, no data exist showing that treatment directed at a specific pathogen is statistically superior to empirical therapy. The benefit of establishing a microbial etiology may be questioned, particularly in light of the cost of diagnostic testing. However, a number of reasons exist for attempting an etiologic diagnosis. Identification of a specific or unexpected pathogen allows focusing of the initial empirical regimen, with a consequent decrease in antibiotic selection pressure and the risk of resistance. Pathogens with important public safety implications, such as *Mycobacterium tuberculosis,* influenza, and SARS-CoV-2 viruses, may be found. Finally, without susceptibility data, trends in resistance cannot be followed accurately, and appropriate empirical therapeutic regimens are harder to devise.

GRAM STAIN AND CULTURE OF SPUTUM The main purpose of the sputum Gram stain is to ensure suitability of a specimen for culture. To be suitable, a sputum sample must have >25 neutrophils and <10 squamous epithelial cells per low-power field. However, staining may also identify certain pathogens (e.g., *S. pneumoniae*, *S. aureus*, and gram-negative bacteria). The sensitivity and specificity of the sputum Gram stain and culture are highly variable. Even in cases of proven bacteremic pneumococcal pneumonia, the positive sputum cultures are ≤50%.

Many patients, particularly elderly individuals, may be unable to produce an appropriate sputum sample. Others may be taking antibiotics that interfere with culture results. Inability to produce sputum can be caused by dehydration, whose correction may result in increased sputum production and a more obvious infiltrate on chest radiography. For patients admitted to the ICU and intubated, a deep-suction aspirate or bronchoalveolar lavage sample has a high yield on culture when sent to the laboratory as soon as possible. Since pathogens in severe and mild CAP may differ (Table 131-1), the greatest benefit of staining and culturing respiratory secretions is to alert the physician to unexpected and/or resistant pathogens and to permit appropriate modification of therapy. Other stains and cultures (e.g., for *M. tuberculosis* or fungi) may be useful as well. The sputum Gram stain and culture are recommended only for hospitalized CAP patients, particularly those with severe cases or those with risks of MRSA or *P. aeruginosa* infection.

BLOOD CULTURES The yield from blood cultures, even when samples are collected before antibiotic therapy, is disappointingly low. Only 5–14% of cultures from hospitalized CAP patients are positive, and the most common pathogen is *S. pneumoniae* followed by *S. aureus* and *P. aeruginosa.* Since recommended empirical regimens all provide pneumococcal coverage, a blood culture positive for this pathogen has little, if any, effect on clinical outcome. However, susceptibility data may allow narrowing of antibiotic therapy in appropriate cases, and such data help to track microbial resistance patterns on a national basis. Because of the low yield and lack of significant impact on outcome, blood cultures are not considered *de rigueur* for all hospitalized CAP patients. Certain high-risk patients should have blood cultured, including those with neutropenia secondary to pneumonia, asplenia, complement deficiencies, chronic liver disease, or severe CAP and those at risk of MRSA or *P. aeruginosa* infection.

URINARY ANTIGEN TESTS Two commercially available tests detect pneumococcal and *Legionella* urinary antigens. The *Legionella pneumophila* test detects only serogroup 1, which accounts for most community-acquired cases of Legionnaires' disease in the United States. Its sensitivity and specificity are 70% and 99%, respectively. The pneumococcal urine antigen test also is quite sensitive and specific (70% and >90%, respectively). Although false-positive results can be obtained for pneumococcus-colonized children, the test is generally reliable. Both tests can detect antigen even after initiation of appropriate antibiotic therapy. Testing for urinary pneumococcal antigen can be reserved for severe cases; *Legionella* antigen can be sought in severe cases and when relevant epidemiologic factors are present.

POLYMERASE CHAIN REACTION PCR tests amplify a microorganism's DNA or RNA, and multiplex PCR panels test for a number of viral and bacterial pathogens. These tests dramatically improve response times, compared to standard cultures, but the contamination of respiratory specimens by upper-airway flora may make semiquantitative or quantitative assays necessary for best results. PCR of nasopharyngeal swabs has become the standard for diagnosis of respiratory viral infection, including influenza and coronaviruses. PCR can also detect the nucleic acid of *Legionella* species, *M. pneumoniae*, *C. pneumoniae*, and mycobacteria. The cost-effectiveness of PCR testing, however, has not been definitively established.

SEROLOGY A fourfold rise in specific IgM antibody titer between acute- and convalescent-phase serum samples is generally considered diagnostic of infection with a particular pathogen. Until recently, serologic tests were used to help identify atypical pathogens as well as selected unusual organisms such as *Coxiella burnetii.* However, these tests have fallen out of favor because of the delays in obtaining convalescent phase results and difficulties with interpretation.

BIOMARKERS Two of the most commonly used markers are C-reactive protein (CRP) and procalcitonin (PCT). Levels of these acute-phase reactants increase in the presence of an inflammatory response, particularly to bacterial pathogens. Nevertheless, PCT is insufficiently accurate for use in the diagnosis of bacterial CAP, and initial serum

PCT levels should not be used as a basis for withholding initial antibiotic treatment. CRP is considered even less sensitive than PCT for detecting bacterial pathogens. These tests should not be used alone but, in conjunction with findings from the history, physical examination, radiography, and laboratory tests, may facilitate antibiotic stewardship and appropriate management of seriously ill CAP patients.

TREATMENT

Community-Acquired Pneumonia

SITE OF CARE

The decision to hospitalize a patient with CAP has considerable implications. The cost of inpatient management exceeds outpatient treatment by a factor of 20, and hospitalization accounts for most CAP-related expenditures. However, late admission to the ICU is associated with increased mortality rates. The choice can be difficult: some patients can be managed at home, while others require hospitalization. Tools that objectively assess the risk of adverse outcomes, including severe illness and death, can help to minimize unnecessary hospitalizations. The two most frequently used are the Pneumonia Severity Index (PSI), a prognostic model that identifies patients at low risk of dying, and the CURB-65 criteria, which yield a severity-of-illness score.

To determine the PSI, points are given for 20 variables, including age, coexisting illness, and abnormal physical and laboratory findings. Based on the score, patients are assigned to one of five classes with these mortality rates: class 1, 0.1%; class 2, 0.6%; class 3, 2.8%; class 4, 8.2%; and class 5, 29.2%. Using the PSI results in lower admission rates for class 1 and 2 patients. Class 3 patients could ideally be admitted to an observation unit pending further decisions.

The CURB-65 criteria include five variables: confusion (C); urea >7 mmol/L (U); respiratory rate ≥30/min (R); blood pressure—systolic ≤90 mmHg or diastolic ≤60 mmHg (B); and age ≥65 years. Patients with a score of 0 (a 30-day mortality rate of 1.5%) can be treated as outpatients. With a score of 1 or 2, the patient should be hospitalized unless the score is entirely or in part attributable to an age of ≥65 years; in such cases, hospitalization may not be necessary. Among patients with scores of ≥3, mortality rates are 22% overall; these patients may require ICU admission. The PSI score has greater efficacy and has been more robustly validated than the CURB-65 criteria but is more difficult to calculate.

In general, if a patient is unable to maintain oral intake, if compliance may be an issue when assessed on the basis of mental condition or living situation (e.g., cognitive impairment or homelessness), or if the patient's O_2 saturation on room air is <92%, hospitalization is necessary. If these considerations do not apply, clinical judgment in conjunction with a prediction rule should be used to determine the site of care.

Neither PSI nor CURB-65 is accurate in determining the need for ICU admission. Patients with septic shock requiring vasopressors or with acute respiratory failure requiring intubation and mechanical ventilation should be admitted directly to an ICU **(Table 131-3)**, and those with three of the nine minor criteria listed in the latter table should be admitted to an ICU or a high-level monitoring unit. Mortality rates were higher among less ill patients who were admitted to a medical floor but then deteriorated than among equally ill patients initially monitored in the ICU.

TABLE 131-3 Criteria for Severe Community-Acquired Pneumonia

Minor criteria
Respiratory rate ≥30 breaths/min
PaO_2/FiO_2 ratio ≤250
Multilobar infiltrates
Confusion/disorientation
Uremia (BUN level ≥20 mg/dL)
Leukopenia (WBC count <4000 cells/μL)
Thrombocytopenia (platelet count <100,000 cells/μL)
Hypothermia (core temperature <36°C)
Hypotension requiring aggressive fluid resuscitation
Major criteria
Respiratory failure requiring invasive mechanical ventilation
Septic shock requiring vasopressors

Abbreviations: BUN, blood urea nitrogen; PaO_2/FiO_2, arterial oxygen pressure/fraction of inspired oxygen; WBC, white blood cell.

ANTIBIOTIC RESISTANCE

Antimicrobial resistance is a significant problem that threatens to diminish our therapeutic armamentarium. Antibiotic misuse results in increased antibiotic selection pressure that can affect resistance locally and globally by clonal dissemination. For CAP, the main resistance issues currently involve *S. pneumoniae* and CA-MRSA.

S. pneumoniae In general, pneumococcal resistance to β-lactams is acquired by (1) direct DNA incorporation and remodeling of penicillin-binding proteins through contact with closely related oral commensal bacteria (e.g., viridans group streptococci), (2) the process of natural transformation, or (3) mutation of certain genes.

Susceptibility to penicillins depends upon treatment with intravenous (IV) or oral agents.

For IV: Susceptible: minimum inhibitory concentration (MIC) ≤2 μg/mL

Intermediate: MIC >2 and ≤4 μg/mL
Resistant: MIC ≥4 μg/mL

For oral: Susceptible: MIC ≤0.06 μg/mL

Intermediate: MIC >0.06 and ≤1 μg/mL
Resistant: MIC >1 μg/mL

For non–central nervous system pneumococcal infections, decreased susceptibility to penicillin is mitigated by usual doses. In the United States, only 0.6% of pneumococci are resistant to ceftriaxone and cefotaxime. Risk factors for penicillin-resistant pneumococcal infection include recent antimicrobial therapy, age of <2 or >65 years, attendance at a day-care center, recent hospitalization, and HIV infection.

In contrast to penicillin resistance, macrolide resistance is increasing in *S. pneumoniae* through several mechanisms. *Target-site modification* caused by ribosomal methylation in 23S rRNA encoded by the *ermB* gene results in high-level resistance (MIC, ≥64 μg/mL) to macrolides, lincosamides, and streptogramin B–type antibiotics. The *efflux mechanism* encoded by the *mef* gene (*M phenotype*) is usually associated with low-level resistance (MIC, usually <16 μg/mL). These two mechanisms account for ~40% and ~60%, respectively, of resistant pneumococcal isolates in the United States. High-level resistance to macrolides is more common in Europe, whereas lower-level resistance predominates in North America. The prevalence of macrolide-resistant *S. pneumoniae* exceeds 25% in some countries; in Canada, it is ~22%, and in the United States approximately 40%. Much of this resistance is high-level, and treatment failures may result. In these situations, a macrolide should not be used as empirical monotherapy. In the United States and Canada, 87.5% of pneumococci are susceptible to doxycycline.

The rate of pneumococcal resistance to fluoroquinolones (e.g., levofloxacin, moxifloxacin, and gemifloxacin) is usually <2%. Changes can occur in one or both target sites (topoisomerases II and IV) and are attributable to mutations in the *gyrA* and *parC* genes, respectively. An efflux pump may also play a role in pneumococcal resistance to fluoroquinolones.

Isolates resistant to drugs from three or more antimicrobial classes with different mechanisms of action are considered multidrug-resistant (MDR) strains. The propensity for an association of pneumococcal resistance to penicillin with reduced susceptibility to other drugs, e.g. macrolides, tetracyclines, and trimethoprim-sulfamethoxazole, is of concern. In the United States, 58.9% of

penicillin-resistant pneumococcal blood isolates are also resistant to macrolides.

The most important risk factor for antibiotic-resistant pneumococcal infection is use of a specific antibiotic within the previous 3 months. A history of prior antibiotic treatment is a critical factor in avoiding the use of an inappropriate antibiotic.

CA-MRSA CAP due to MRSA may be caused by the classic hospital-acquired strains or by genotypically and phenotypically distinct community-acquired strains. Most infections with the former are acquired either directly or indirectly during contact with the health care environment. However, in some hospitals, CA-MRSA strains are displacing the classic hospital-acquired strains, suggesting that the newer community-acquired strains may be more robust.

Methicillin resistance in *S. aureus* is determined by the *mecA* gene, which encodes for resistance to all β-lactam drugs At least five staphylococcal chromosomal cassette *mec* (SCC*mec*) types have been described. The typical hospital-acquired strain usually has a type II or III SCC*mec* element, whereas CA-MRSA has type IV. CA-MRSA isolates tend to be less resistant than the older hospital-acquired strains and are often susceptible to trimethoprim-sulfamethoxazole, clindamycin, and tetracycline in addition to vancomycin and linezolid. CA-MRSA strains also carry genes for superantigens such as enterotoxins B and C and Panton-Valentine leukocidin; the latter is a membrane-tropic toxin that can create cytolytic pores in neutrophils, monocytes, and macrophages. Risk factors for MRSA include colonization or prior infection and MRSA as suggested by gram-positive cocci in clusters on sputum Gram stain. Other factors that may raise suspicion of MRSA infection include recent antibiotics, hospitalization, influenza, cavitary or necrotizing pneumonia, or empyema.

M. pneumoniae Macrolide-resistant *M. pneumoniae* has been reported in a number of countries, including Germany (3%), Japan (30%), China (95%), and France and the United States (5–13%). *Mycoplasma* resistance to macrolides is increasing as a result of binding-site mutation in domain V of 23S rRNA.

Gram-Negative Bacilli A detailed discussion of resistance among gram-negative bacilli is beyond the scope of this chapter **(see Chap. 166)**. Fluoroquinolone resistance among community isolates of *Escherichia coli* is increasing. *Enterobacter* species are typically resistant to cephalosporins, and the drugs of choice to treat these organisms are usually fluoroquinolones or carbapenems. Similarly, when infections due to bacteria producing extended-spectrum β-lactamases (ESBLs) are documented or suspected, a carbapenem should be considered.

INITIAL ANTIBIOTIC MANAGEMENT

Since the etiology of CAP is rarely known at the outset of treatment, initial therapy is usually empirical and designed to cover the likeliest pathogens. In all cases, treatment should be initiated as expeditiously as possible. CAP treatment guidelines in the United States from the American Thoracic Society (ATS) and the Infectious Diseases Society of America (IDSA) consider the likely pathogens, risk of antimicrobial resistance, severity of illness, site of care, and risk of infection with specific bacteria such as MRSA and *P. aeruginosa* **(Fig. 131-1, Tables 131-4 and 131-5)**. In the figure and the tables, the antibiotics are not listed in order of preference.

The approach to treatment of aspiration pneumonia is based on a number of factors, including site of acquisition (community vs hospital), normal or abnormal chest radiograph, and additional variables such as illness severity, state of dentition, and risk of infection with an MDR pathogen. Routine coverage of anaerobes is unnecessary unless dentition is poor or there is a lung abscess or necrotizing pneumonia.

Our approach to CAP treatment (Tables 131-4 and 131-5) is very similar to the CAP guidelines with the exceptions listed below.

Outpatients The exceptions to the CAP guidelines that we follow in treating patients are as follows:

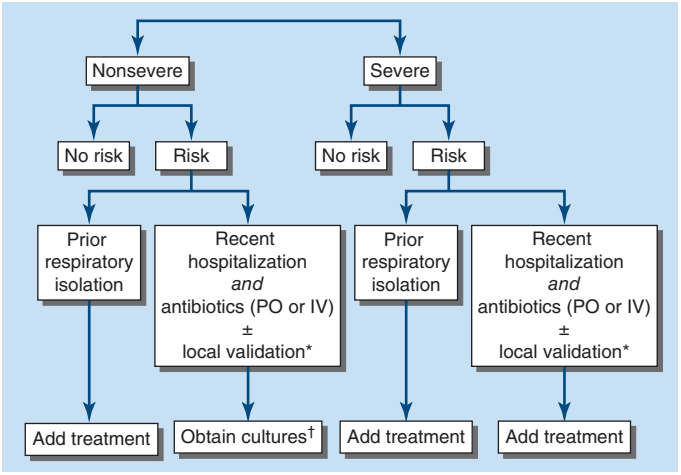

FIGURE 131-1 Algorithm for assessment of inpatient risk of infection with methicillin-resistant *Staphylococcus aureus* (MRSA) or *Pseudomonas aeruginosa*. Underlying lung disease (e.g., bronchiectasis or very severe chronic obstructive pulmonary disease) are also risks for *P. aeruginosa* infection. *Local validation consists of information on local prevalence, resistance, and risk factors. †Can also use MRSA rapid nasal polymerase chain reaction (PCR) if available. IV, intravenous; PO, oral.

- We usually initiate coverage that includes atypical organisms as well as *S. pneumoniae.*
- Generally, we do not consider the risk of infection with *P. aeruginosa* or MRSA particularly significant in outpatients.
- Prior antibiotic use should include both oral and parenteral agents.

Patients are stratified into two groups: those without comorbidity or risk factors for antibiotic resistance and those with comorbidities (e.g., chronic heart, lung, liver, or kidney disease; diabetes; alcoholism; malignancy; or asplenia) with or without risk factors for resistance (Table 131-4). As a general rule, if patients have been treated with a drug from a particular class of antibiotics within the previous 3 months, drugs from a different class should be used to minimize resistance issues.

For those without comorbidity or resistance risk factors, amoxicillin alone or doxycycline is recommended in the guidelines. Monotherapy with amoxicillin is based on evidence of its efficacy in the treatment of hospitalized CAP patients. This recommendation is a change from the 2007 IDSA/ATS CAP guidelines. As a rule, however, we usually tend to initiate treatment that includes coverage for S. *pneumoniae* as well as the atypical pathogens (Table 131-4).

TABLE 131-4 Initial Treatment Strategies for Outpatients with Community-Acquired Pneumonia

STATUS	STANDARD REGIMEN
No comorbidities or risk factors for antibiotic resistance[a]	Combination therapy with amoxicillin (1 g tid) + either a macrolide[b] or doxycycline (100 mg bid)
	or
	Monotherapy with doxycycline (100 mg bid)
	or
	Monotherapy with a macrolide[b,c]
With comorbidities[d] ± risk factors for antibiotic resistance[a]	Combination therapy with
	amoxicillin/clavulanate[e] or a cephalosporin[f] + either a macrolide[b] or doxycycline (100 mg bid)
	or
	Monotherapy with a respiratory fluoroquinolone[g]

[a]Antibiotic treatment within the past 3 months or contact with the health care system. [b]Azithromycin (500 mg on day 1, then 250 mg/d for 4 days), clarithromycin (500 mg bid), or clarithromycin ER (1000 mg/d). [c]If local prevalence of pneumococcal resistance is <25%. [d]Including chronic heart, lung, liver, or kidney disease; diabetes mellitus; alcoholism; malignancy; or asplenia. [e]500/125 mg tid or 875/125 mg bid. [f]Cefpodoxime (200 mg bid) or cefuroxime (500 mg bid). [g]Levofloxacin (750 mg/d), moxifloxacin (400 mg/d), or gemifloxacin (320 mg/d).

TABLE 131-5 Initial Treatment for Inpatients with or without Risk Factors for Infection with MRSA or *Pseudomonas aeruginosa*

DISEASE SEVERITY, RISK STATUS	REGIMEN
Nonsevere	
No risk factors	A β-lactam[a] + a macrolide[b] *or* A respiratory fluoroquinolone[c]
Prior respiratory isolation	Add coverage for MRSA[d] or *Pseudomonas aeruginosa*[e]
Recent hospitalization, antibiotic treatment, ± LV[f]	Add coverage for MRSA[d] or *P. aeruginosa*[e] only if cultures are positive
Severe	
No risk factors	A β-lactam[a] + a macrolide[b] *or* A β-lactam[a] + respiratory fluoroquinolone[c]
Prior respiratory isolation	Add coverage for MRSA[d] or *P. aeruginosa*[e]
Recent hospitalization, antibiotic treatment ± LV[f]	Add coverage for MRSA[d] or *P. aeruginosa*[e]

[a]Ampicillin-sulbactam (1.5–3 g q6h), ceftriaxone (1–2 g/d), cefotaxime (1–2 g q8h), ceftaroline (600 mg q12h), or ertapenem (1 g/d). [b]Azithromycin (500 mg/d) or clarithromycin (500 mg bid). [c]Levofloxacin (750 mg/d), moxifloxacin (400 mg/d), or gemifloxacin (320 mg/d). [d]Vancomycin (15 mg/kg q12h, with adjustment based on serum levels) or linezolid (600 mg q12h). [e]Piperacillin-tazobactam (4.5 g q6h), cefepime (2 g q8h), ceftazidime (2 g q8h), imipenem (500 mg q6h), meropenem (1 g q8h), or aztreonam (2 g q8h). [f]Obtain cultures. MRSA rapid nasal polymerase chain reaction can also be used if available.

Abbreviations: LV, local validation (local prevalence, resistance, risk factors); MRSA, methicillin-resistant *Staphylococcus aureus*.

Monotherapy with a macrolide is recommended in the guidelines only if there are contraindications to amoxicillin or doxycycline and there is documented low risk of macrolide resistance (<25%). Otherwise, outpatient treatment is quite similar to the regimens recommended in the 2007 IDSA/ATS guidelines. Two relatively newer agents, lefamulin (a pleuromutilin) and omadacycline (a tetracycline) are possible options for CAP patients unable to take β-lactams and/or wanting to avoid the fluoroquinolones. They are available in the United States but not in Canada. Treatment of influenza **(Chap. 206)** and COVID-19 **(Chap. 205)** is discussed in their own chapters.

Inpatients Our exceptions to the recommendations in the CAP guidelines are as follows:

- As a general rule, when initiating treatment for infection with *P. aeruginosa*, we use double coverage.
- The presence of all three risk factors is not required for drug resistance (recent hospitalization, recent oral or IV antibiotic treatment, ± local validation) (Fig. 131-1, Table 131-5).

The main considerations for determining initial empirical treatment of hospitalized CAP patients are clinical severity and risk of infection with drug-resistant pathogens such as MRSA or *P. aeruginosa*. Hospitalization alone is not now considered a significant risk factor for these pathogens. Hospitals should collect local data on MRSA and *P. aeruginosa* regarding prevalence, risk factors for infection, and antibiotic susceptibilities. Patients can be categorized as having nonsevere or severe CAP (Table 131-3), and those in each category may or may not have risk factors for MRSA or *P. aeruginosa* (Fig. 131-1). In scenarios involving these variables in hospitalized CAP patients, empirical treatment for either of these pathogens should be added to standard therapy in those previously colonized or infected with these pathogens, but not in the patient who is considered nonsevere and whose only risk factors are recent hospitalization and antibiotic treatment ± local validation data (Fig. 131-1). In this setting, if we begin treatment, we try to de-escalate if appropriate. In most patients, cultures should be performed but treatment usually withheld unless culture results or rapid nasal PCR results for MRSA are positive.

Nonsevere, No Risk Factors For patients with nonsevere infection and no risk factors, treatment should consist of either a combination of a β-lactam and a macrolide or monotherapy with a respiratory fluoroquinolone (Table 131-5). In the event of contraindications to macrolides and fluoroquinolones, a β-lactam plus doxycycline may be used. Treatment with a β-lactam plus macrolide combination or a fluoroquinolone alone results in lower mortality than monotherapy with a β-lactam.

Severe, No Risk Factors Patients with severe infection but no risk factors should receive combination therapy with either a β-lactam plus macrolide or a β-lactam and a respiratory fluoroquinolone (Table 131-5). Observational studies suggest that combination therapy with a β-lactam plus macrolide may be preferable to a β-lactam plus fluoroquinolone.

Nonsevere and Severe, with Risk Factors To date, there are no prediction rules reliably identifying patients who should be started empirically on treatment for MRSA or *P. aeruginosa*. Current risk factors for infection with these pathogens are hierarchical. Prior isolation of these organisms, especially from the respiratory tract within the previous year, is a more robust risk factor than recent hospitalization and exposure to parenteral antibiotics. For *P. aeruginosa*, underlying lung disease (e.g., bronchiectasis or very severe COPD) also is an important risk factor. If MRSA or *P. aeruginosa* has been isolated previously, appropriate empirical therapy should be started in both severe and nonsevere cases (Table 131-5). We prefer linezolid over vancomycin as first-line treatment for MRSA because of its inhibition of bacterial exotoxin and better lung penetration. If the organism is not isolated from respiratory secretions or blood and/or the nasal or bronchoalveolar lavage PCR test for MRSA is negative and the patient is improving at 48 h, treatment may be de-escalated to a standard regimen.

If, however, the risk factors are recent hospitalization and antibiotic use within the previous 3 months, appropriate samples should be obtained for culture, and, in severe cases only, extended-spectrum treatment for MRSA or *P. aeruginosa* should be initiated. Depending on the severity of infection, local data on *P. aeruginosa* resistance, and antibiotic use within the previous 90 days, single- or double-drug coverage should be used such as antipseudomonal β-lactam plus ciprofloxacin, levofloxacin, or aminoglycoside.

If two antipseudomonal agents are started, the drugs should be from different classes. Whenever possible, assessment for possible de-escalation of therapy is urged. If the patient's illness is not severe, empirical extended treatment should be withheld until culture results are available.

Regardless of the site of care, CAP patients with proven influenza should be given anti-influenza treatment (e.g., oseltamivir) as well as appropriate antibacterial therapy. Physicians should be vigilant about possible superinfection with MRSA. If a viral pathogen such as influenza or SARS-CoV-2 is found and no bacterial pathogen is obvious, antibacterial treatment can be discontinued. However, in those with severe illness, the possibility of bacterial-viral coinfection should be considered.

Although hospitalized patients have traditionally received initial therapy by the IV route, some drugs, particularly the fluoroquinolones, are very well absorbed and may be given orally from the outset to select patients. For those initially treated with IV agents, a switch to oral treatment is appropriate when the patient can ingest and absorb the drugs, is hemodynamically stable, and is showing clinical improvement. A 5-day course of treatment is usually sufficient for uncomplicated CAP, but longer treatment may be required for patients who have not stabilized clinically and for those with bacteremia, metastatic infection, or infection with a more virulent pathogen such as *P. aeruginosa* or MRSA. There are some data to suggest that in select patients who are doing well and are clinically stable, treatment may be discontinued after 3 days.

ADJUNCTIVE MEASURES

In addition to appropriate antimicrobial therapy, certain adjunctive measures should be used. Adequate hydration, oxygen therapy for

hypoxemia, vasopressor treatment, and assisted ventilation when necessary are critical to successful treatment. Glucocorticoids may be beneficial in cases of severe CAP requiring invasive or noninvasive mechanical ventilation or with shock. Recent data show a mortality benefit for corticosteroid therapy in those with severe CAP (ventilated and nonventilated), especially if there is a high level of systemic inflammation (CRP >15 mg/dL); therapy is usually continued for 8–14 days and given either by intermittent or continuous infusion. Data support the use of dexamethasone plus a Janus kinase inhibitor or an interleukin 6 inhibitor in COVID-19 patients with rapidly increasing oxygen needs and systemic inflammation.

FAILURE TO IMPROVE

Patients slow to respond to therapy should be reevaluated at about day 3 (or sooner if their condition is worsening), with several scenarios considered. A number of noninfectious conditions mimic pneumonia, including pulmonary edema, pulmonary embolism, lung carcinoma, radiation and hypersensitivity pneumonitis, and connective tissue disease involving the lungs. If the patient truly has CAP and empirical treatment is aimed at the likely expected pathogens, lack of response may be explained in a number of ways. The pathogen may be resistant to the drug, or a sequestered focus (e.g., lung abscess or empyema) may prevent antibiotic access to the pathogen. The patient may be getting the wrong drug or the correct drug at the wrong dose or frequency of administration. Another possibility is that CAP has been diagnosed correctly but an unexpected pathogen (e.g., CA-MRSA, *M. tuberculosis*, or a fungus) is the cause. Nosocomial superinfections—both pulmonary and extrapulmonary—are other possible explanations for a hospitalized patient's failure to improve. In all cases of delayed response or worsening condition, the patient must be carefully reassessed and appropriate studies initiated, possibly including CT or bronchoscopy.

COMPLICATIONS

Complications of severe CAP include respiratory failure, shock and multiorgan failure, and exacerbation of comorbid illnesses. Three particularly noteworthy conditions are metastatic infection, lung abscess, and complicated pleural effusion. Metastatic infection (e.g., brain abscess or endocarditis) is unusual and requires a high degree of suspicion and a detailed workup for proper treatment. Lung abscess may occur in association with aspiration pneumonia or with infection caused by pathogens such as CA-MRSA, *P. aeruginosa*, or (rarely) *S. pneumoniae*. A significant pleural effusion should be tapped for diagnostic and therapeutic purposes. If the fluid has a pH <7.2, a glucose level of <2.2 mmol/L, and a lactate dehydrogenase concentration of >1000 U/L or if bacteria are seen or cultured, drainage is needed.

Cardiovascular events with pneumonia, particularly in the elderly and usually in association with pneumococcal pneumonia and influenza, are increasingly recognized. These events, which may be acute or whose occurrence may extend to at least 1 year, include congestive heart failure, arrhythmia, myocardial infarction, or stroke and may be caused by a variety of mechanisms, including increased myocardial load and/or destabilization of atherosclerotic plaques by inflammation.

FOLLOW-UP

Fever and leukocytosis usually resolve within 2–4 days in otherwise healthy CAP patients, but physical findings may persist longer. Chest radiographic abnormalities are slowest to resolve (4–12 weeks), with the speed of clearance depending on the patient's age and underlying lung disease, and the etiologic pathogen. Patients may be discharged from hospital once their clinical condition, including any comorbidity, is stable. The site of residence after discharge (nursing home, home with family, home alone) is an important consideration, particularly for elderly patients. For a hospitalized patient, we generally recommend a follow-up radiograph ~4–6 weeks later. If relapse or recurrence occurs, particularly in the same lung segment, the possibility of an underlying neoplasm or other local abnormalities (e.g., focal bronchiectasis) must be considered. For individuals managed as outpatients, routine follow-up chest radiography is not necessary if they are nonsmokers, if they are otherwise well, and if symptoms resolved within 5–7 days.

PROGNOSIS

The prognosis depends on the patient's age, comorbidities, and site of treatment (inpatient or outpatient). Young patients without comorbidity do well and usually recover fully after ~2 weeks. Older patients and those with comorbid conditions may take several weeks longer to recover fully. The overall mortality rate for the outpatient group is <5%. For patients requiring hospitalization, overall mortality ranges from 12% to 40%, depending on the patient category and the processes of care, particularly the timely administration of appropriate antibiotics. Recent data, especially in older patients, show that the 1-year mortality following CAP exceeds the 30-day mortality.

PREVENTION

The main preventive measure is vaccination. Recommendations of National Advisory Committees on Immunization Practices should be followed **(Chap. 129)**.

VENTILATOR-ASSOCIATED PNEUMONIA

Research on hospital-acquired pneumonia has focused on VAP (onset ≥48 h after mechanical ventilation). However, the same information and principles can also be applied to ventilated HAP and to non-ICU HAP. Approximately 70% of HAP cases are acquired outside the ICU and 30% in the ICU; the fact that 35% of all HAP patients need mechanical ventilation defines ventilated HAP as a distinct entity. In nonintubated patients with HAP, an expectorated sputum sample is used for microbiologic diagnosis, but results are confounded by frequent colonization by oral pathogens. Microbiologic information in VAP and ventilated HAP is obtained from direct access to deep lower respiratory tract samples, which provide reliable microbiologic data; however, these samples can also contain colonizing pathogens.

ETIOLOGY

Potential etiologic agents of VAP include both MDR and non-MDR bacterial pathogens **(Table 131-6)**. The non-MDR group of "core pathogens" is nearly identical to the pathogens found in severe CAP (Table 131-1); it is not surprising that such pathogens predominate if VAP develops in the first 5–7 days of the hospital stay. However, if patients have other risk factors (particularly prior antibiotic treatment), MDR pathogens are a consideration, even early in the hospital course. The relative frequency of individual MDR pathogens can vary significantly from hospital to hospital and even between different critical care units within the same institution. Most hospitals have problems with *P. aeruginosa* and MRSA, but other MDR pathogens are often institution-specific. Less commonly, fungal and viral pathogens cause VAP, usually affecting severely immunocompromised patients. Rarely,

TABLE 131-6 Microbiologic Causes of Ventilator-Associated Pneumonia

NON-MDR PATHOGENS (CORE PATHOGENS)	MDR PATHOGENS
Streptococcus pneumoniae	*Pseudomonas aeruginosa*
Other *Streptococcus* spp.	Methicillin-resistant *S. aureus*
Haemophilus influenzae	*Acinetobacter* spp.
Methicillin-sensitive *Staphylococcus aureus*	Antibiotic-resistant Enterobacteriaceae
Antibiotic-sensitive Enterobacteriaceae	ESBL-positive strains
Escherichia coli	Carbapenem-resistant strains
Klebsiella pneumoniae	*Legionella pneumophila*
Proteus spp.	*Burkholderia cepacia*
Enterobacter spp.	*Aspergillus* spp.
Serratia marcescens	

Abbreviations: ESBL, extended-spectrum β-lactamase; MDR, multidrug-resistant.

community-associated viruses cause mini-epidemics, usually when introduced by ill health care workers.

EPIDEMIOLOGY

Pneumonia is a common complication among patients requiring mechanical ventilation. Prevalence estimates vary between 6 and 52 cases per 100 patients, depending on the population studied. On any given day in the ICU, an average of 10% of patients will have pneumonia—VAP in the overwhelming majority of cases. Although in recent years the frequency of this infection was declining as a result of effective prevention strategies, with the advent of COVID-19, there has been an increase in its frequency. The frequency of VAP changes with the duration of mechanical ventilation, with the highest hazard ratio in the first 5 days and a plateau in additional cases (1% per day) after ~2 weeks. However, the cumulative rate among patients who remain ventilated for as long as 30 days is as high as 70%. These rates often do not reflect the recurrence of VAP in the same patient. Once a ventilated patient is transferred to a chronic-care facility or to home, the incidence of pneumonia drops significantly, especially in the absence of other risk factors for pneumonia. However, in chronic ventilator units, purulent tracheobronchitis becomes a significant issue, often interfering with efforts to wean patients off mechanical ventilation (Chap. 313).

Three factors are critical in the pathogenesis of VAP: colonization of the oropharynx with pathogenic microorganisms, aspiration of these organisms from the oropharynx into the lower respiratory tract, and compromise of normal host defense mechanisms. Most risk factors and their corresponding prevention strategies pertain to one of these three factors (Table 131-7).

The most important risk factor is the endotracheal tube, which bypasses the normal mechanical factors preventing aspiration. While the presence of an endotracheal tube may prevent large-volume aspiration, microaspiration is actually exacerbated by secretions pooling above the cuff. The endotracheal tube and the concomitant need for suctioning can damage the tracheal mucosa, thereby facilitating tracheal colonization. In addition, pathogenic bacteria can form a glycocalyx biofilm on the tube's surface that protects them from both antibiotics and host defenses. The bacteria can also be dislodged during suctioning (done preferably with a closed catheter system) and can reinoculate the trachea, or tiny fragments of a glycocalyx can embolize to distal airways, carrying bacteria with them. The ventilator circuit tubing can harbor pathogenic organisms that can wash back to the patient if manipulated too often; thus, circuits are changed only when soiled and with each new patient. Heat moisture exchangers are changed every 5–7 days or if visibly soiled or malfunctioning.

In a high percentage of critically ill patients, the normal oropharyngeal flora is replaced by pathogenic microorganisms. The most important risk factors are antibiotic selection pressure, cross-infection from other infected/colonized patients or contaminated equipment, severe systemic illness, and malnutrition. Of these factors, antibiotic exposure poses the greatest risk by far. Pathogens such as *P. aeruginosa* almost never cause infection in patients without prior exposure to antibiotics. The recent emphasis on hand hygiene has lowered the cross-infection rate.

Almost all intubated patients experience microaspiration and are at least transiently colonized with pathogenic bacteria. However, only around one-third of colonized patients develop VAP. Colony counts increase to high levels, sometimes days before the development of clinical pneumonia; these increases suggest that the final step in VAP development, independent of aspiration and oropharyngeal colonization, is the overwhelming of host defenses by a large bacterial inoculum. Severely ill patients with sepsis and trauma appear to enter a state of immunoparalysis several days after admission to the ICU—a time that corresponds to the greatest risk of developing VAP. The mechanism of this immunosuppression is not clear, although hyperglycemia and frequent transfusions adversely affect the immune response.

CLINICAL MANIFESTATIONS

The clinical manifestations of HAP and VAP are nonspecific: fever, leukocytosis, increased respiratory secretions, and pulmonary consolidation on physical examination, along with a new or changing radiographic infiltrate. The frequency of abnormal chest radiographs before the onset of pneumonia in intubated patients and the limitations of portable radiographic technique make interpretation of radiographs more difficult than in patients who are not intubated. Other clinical features may include tachypnea, tachycardia, worsening oxygenation, and increased minute ventilation. Serial changes in oxygenation may identify pneumonia earlier than other findings and may also be a means to monitor improvement with therapy.

TABLE 131-7 Pathogenic Mechanisms and Corresponding Prevention Strategies for Ventilator-Associated Pneumonia

PATHOGENIC MECHANISM	PREVENTION STRATEGY
Oropharyngeal colonization with pathogenic bacteria	
Elimination of normal flora, overgrowth by pathogenic bacteria	Avoidance of prolonged antibiotic courses; consider oral chlorhexidine[a]
Large-volume oropharyngeal aspiration around time of intubation	Short course of prophylactic antibiotics for comatose patients; short course of prophylactic inhaled aminoglycoside antibiotics[b]
Gastroesophageal reflux	Postpyloric enteral feeding with orally placed feeding tube[a]; avoidance of high gastric residuals, prokinetic agents
Bacterial overgrowth of stomach	Avoidance of prophylactic agents that raise gastric pH[a]; selective decontamination of digestive tract with nonabsorbable antibiotics[a]
Cross-infection from other colonized patients	Hand washing, especially with alcohol-based hand rub; intensive infection control education[b]; isolation; proper cleaning of reusable equipment
Large-volume aspiration Ventilator circuit humidification	Endotracheal intubation; rapid-sequence intubation technique; avoidance of sedation; decompression of small-bowel obstruction Change ventilator circuits only when soiled and with new patient; drain ventilator circuit condensate away from patient; replace heat moisture exchanger every 5–7 days or if soiled or malfunctioning[a]
Microaspiration around endotracheal tube	
Endotracheal intubation	Noninvasive ventilation[b]
Prolonged duration of ventilation	Daily awakening from sedation,[b] weaning protocols[b]
Abnormal swallowing function	Early percutaneous tracheostomy[b]
Secretions pooled above endotracheal tube	Head of bed elevated[b]; continuous aspiration of subglottic secretions with specialized endotracheal tube[b]; avoidance of reintubation; minimization of sedation and patient transport; prophylactic PEEP[c] of 5–8 cm
Altered lower respiratory host defenses	Tight glycemic control[a]; lowering of hemoglobin transfusion threshold

[a]Strategies with negative randomized trials or conflicting results. [b]Strategies demonstrated to be effective in at least one randomized controlled trial. [c]Positive end-expiratory pressure.

DIAGNOSIS

No single set of criteria is reliably diagnostic of pneumonia in a ventilated patient. The inability to accurately identify such patients compromises efforts to prevent and treat VAP and even calls into question estimates of the impact of VAP on mortality rates.

Application of clinical criteria typical for CAP consistently results in overdiagnosis of VAP, largely because of (1) frequent tracheal colonization with pathogenic bacteria in patients with endotracheal tubes, (2) multiple alternative causes of radiographic infiltrates in mechanically ventilated patients, and (3) the high frequency of other sources

of fever in critically ill patients. The differential diagnosis of VAP includes atypical pulmonary edema, pulmonary contusion, alveolar hemorrhage, hypersensitivity pneumonitis, acute respiratory distress syndrome, and pulmonary infarction. Findings of fever and/or leukocytosis may have alternative causes, including antibiotic-associated diarrhea, central line–associated infection, sinusitis, urinary tract infection, pancreatitis, and drug fever. Conditions mimicking pneumonia are often documented in patients in whom VAP has been ruled out by accurate diagnostic techniques. Most of these alternative diagnoses do not require antibiotic treatment; require antibiotics different from those used to treat VAP (fungal or viral pneumonia); or require some additional intervention, such as surgical drainage or catheter removal, for optimal management.

This diagnostic dilemma has led to debate and controversy about whether a quantitative-culture approach as a means of eliminating false-positive clinical diagnoses is superior to a clinical approach enhanced by principles learned from quantitative-culture studies. The most recent IDSA/ATS guidelines for HAP/VAP give a weak recommendation for a clinical approach based on semiquantitative cultures, with consideration of the availability of resources, cost, and the availability of expertise. The guidelines acknowledge that the use of a quantitative approach may result in less antibiotic use, which may be critical for antibiotic stewardship in the ICU. Therefore, the approach at each institution—or potentially for each patient—should be individualized and based on local colonization rates, local diagnostic expertise, and recent history of antibiotic therapy.

Quantitative-Culture Approach This method uses quantitative cultures of deep respiratory tract samples to distinguish colonization from true infection. The more distal in the respiratory tree the diagnostic sampling, the more specific are the results and therefore the lower the threshold of growth necessary to diagnose pneumonia and exclude colonization. For example, an endotracheal aspirate yields proximal samples, and the diagnostic threshold is 10^6 cfu/mL. The protected specimen brush method, in contrast, collects distal samples and has a threshold of 10^3 cfu/mL. Conversely, sensitivity declines as more distal secretions are obtained, especially when they are collected blindly (i.e., by a technique other than bronchoscopy). Additional tests that may increase the diagnostic yield include Gram staining, differential cell counts, staining for intracellular organisms, and detection of local protein levels elevated in response to infection.

If the quantitative approach is used, therapy decisions should be linked to culture results (no antibiotics if below the diagnostic threshold), with antibiotics withheld until results are available unless the patient is critically ill. Studies have documented less antibiotic use with this approach than with the clinical approach, but the results are less clear if antibiotic decisions are not directly linked to culture data. One common limitation of the quantitative approach is that the use of a new and effective antibiotic agent in the 24–48 h prior to sampling can lead to false-negative results. With antimicrobial-sensitive microorganisms, a single antibiotic dose can reduce colony counts below the diagnostic threshold. After 3 days, the operating characteristics of the tests improve to the point at which they are equivalent to results obtained when no prior antibiotic therapy has been given. Conversely, colony counts above the diagnostic threshold during antibiotic therapy suggest that the current antibiotics are ineffective. In addition, quantitative cultures may give results below the diagnostic threshold if samples are collected early in the course of infection or if sampling is delayed until after an effective host response has reduced bacterial counts. Ideally, a specimen should be obtained as soon as pneumonia is suspected and before antibiotic therapy is initiated or changed.

Clinical Approach The lack of specificity of a clinical diagnosis of VAP has hampered its utility, but this approach has been improved by the addition of microbiologic and other laboratory data. Tracheal aspirates generally yield at least twice as many potential pathogens as quantitative cultures, but the causative pathogen is almost always present. The absence of bacteria in Gram-stained endotracheal aspirates makes pneumonia an unlikely cause of fever or pulmonary infiltrates. These findings, coupled with a heightened awareness of the alternative diagnoses possible in patients with suspected VAP, can prevent inappropriate antibiotic overtreatment. Furthermore, the absence of an MDR pathogen in tracheal aspirate cultures eliminates the need for MDR coverage, allowing de-escalation of empirical antibiotic therapy. Similarly, with newer and more sensitive molecular diagnostic methods, a suspected MDR pathogen can be eliminated as a therapy target if test results are negative. A clinical approach that focuses on careful antimicrobial use and de-escalation of therapy after culture results become available may have an impact on the avoidance of antimicrobial overuse and the consideration of alternative sites of infection similar to that of a quantitative-culture approach.

TREATMENT

Ventilator-Associated Pneumonia

Many studies have demonstrated higher mortality rates with the delay of initially appropriate empirical antibiotic therapy. The key to appropriate antibiotic management of VAP is an appreciation of the resistance patterns of the most likely pathogens in a given patient and consideration of local microbiology.

ANTIBIOTIC RESISTANCE

Because of a higher risk of infection with MDR pathogens (Table 131-6), VAP is treated with antibiotics different from those used for severe CAP. Antibiotic selection pressure leads to the frequent involvement of MDR pathogens by selecting either for drug-resistant isolates of common pathogens (e.g., MRSA and Enterobacteriaceae producing ESBLs or carbapenemases) or for intrinsically resistant pathogens (e.g., *P. aeruginosa* and *Acinetobacter* species). Frequent use of β-lactam drugs, especially cephalosporins, appears to be the major risk factor for infection with MRSA and ESBL-positive strains.

P. aeruginosa can develop resistance to all routinely used antibiotics, and, even if initially sensitive, *P. aeruginosa* isolates may develop resistance during treatment. Either derepression of resistance genes or selection of resistant clones within the large bacterial inoculum associated with most pneumonias may be the cause. *Acinetobacter* species, *Stenotrophomonas maltophilia*, and *Burkholderia cepacia* are intrinsically resistant to many of the empirical antibiotic regimens employed (see below). VAP caused by these pathogens typically emerges during treatment of other infections, and resistance is always evident at initial diagnosis.

EMPIRICAL THERAPY

Recommended options for empirical therapy are listed in **Table 131-8**. Treatment should be started once diagnostic specimens have been obtained. The major factors in the selection of agents are the presence of risk factors for MDR pathogens and the predicted risk of death (≤15% is considered low risk). Choices among the various options listed depend on local patterns of resistance and—a very important factor—the patient's prior antibiotic exposure. Knowledge of the local hospital's—and even the specific ICU's—antibiogram and the local incidence of specific MDR pathogens (e.g., MRSA) is critical in selecting appropriate empirical therapy.

The majority of patients *without* risk factors for MDR infection can be treated with a single agent. In fact, mortality is lower with a single agent than with combination therapy for those with a low mortality risk. For these patients, monotherapy options listed in Table 131-8 are active against the core pathogens, as well as nonresistant *P. aeruginosa*. However, in selected settings, it may be possible to use a nonpseudomonal agent such as cefotaxime or moxifloxacin. Unfortunately, the proportion of patients with no MDR risk factors is <10% in some ICUs and is unknown for HAP patients. The major difference from CAP is the markedly lower incidence of atypical pathogens in VAP; the exception is *Legionella*, which can be a nosocomial pathogen, especially with local epidemics due to breakdowns in the treatment of potable water in the hospital. The standard recommendation for patients *with* risk factors for MDR infection and a high mortality risk is for three antibiotics:

TABLE 131-8 Empirical Antibiotic Treatment of Hospital-Acquired and Ventilator-Associated Pneumonia

NO RISK FACTORS FOR RESISTANT GRAM-NEGATIVE PATHOGEN	RISK FACTORS FOR RESISTANT GRAM-NEGATIVE PATHOGEN[a] *(CHOOSE ONE FROM EACH COLUMN)*	
Piperacillin-tazobactam (4.5 g IV q6h)	Piperacillin-tazobactam (4.5 g IV q6h)	Amikacin (15–20 mg/kg IV q24h)
Cefepime (2 g IV q8h)	Cefepime (2 g IV q8h)	Gentamicin (5–7 mg/kg IV q24h)
Levofloxacin (750 mg IV q24h)	Ceftazidime (2 g IV q8h)	Tobramycin (5–7 mg/kg IV q24h)
	Imipenem (500 mg IV q6h)	Ciprofloxacin (400 mg IV q8h)
	Meropenem (1 g IV q8h)	Levofloxacin (750 mg IV q24h)
	Consider newer agents[c]	Colistin (loading dose of 5 mg/kg IV followed by maintenance doses of 2.5 mg × [1.5 × CrCl + 30] IV q12h)
		Polymyxin B (2.5–3.0 mg/kg per day IV in 2 divided doses)
Risk Factors for MRSA[b] *(Add to above)*		
Linezolid (600 mg IV q12h) *or* Adjusted-dose vancomycin (trough level, 15–20 mg/dL)		

[a]Prior antibiotic therapy, prior hospitalization, local antibiogram. [b]Prior antibiotic therapy, prior hospitalization, known MRSA colonization, chronic hemodialysis, local documented MRSA pneumonia rate >10% (or local rate unknown). [c]Newer agents can have activity against resistant *P. aeruginosa* (ceftazidime-avibactam, ceftolozane-tazobactam, imipenem-relebactam, plazomicin), carbapenem-resistant *Enterobacteriaceae* (ceftazidime-avibactam, imipenem-relebactam, meropenem-vaborbactam), metallo-β-lactamase–producing *Enterobacteriaceae* (ceftazidime-avibactam, cefiderocol), *Stenotrophomona*s (cefiderocol), and *Acinetobacter* spp. (cefiderocol, sulbactam-durlobactam).

Abbreviations: CrCl, creatinine clearance rate; MRSA, methicillin-resistant *Staphylococcus aureus*.

two directed at *P. aeruginosa* and other resistant gram-negative organisms and one directed at MRSA. However, in the absence of septic shock, a single agent may be effective for these patients, provided there is a single agent that is likely to be effective against at least 90% of the gram-negative pathogens in that ICU. Empirical combination therapy enhances the likelihood of initially appropriate therapy over that with monotherapy. A β-lactam agent provides the greatest coverage, yet even the broadest-spectrum agent—a carbapenem—still constitutes inappropriate initial therapy in up to 10–15% of cases at some centers. The emergence of carbapenem resistance at some institutions requires the addition of polymyxins to the combination-therapy options. A number of emerging agents may modify our approach to therapy. New antipseudomonal agents include ceftazidime–avibactam, ceftolozane–tazobactam, imipenem–relebactam, and plazomicin. Therapy for carbapenem-resistant *Enterobacteriaceae* can consist of ceftazidime–avibactam, imipenem–relebactam, or meropenem–vaborbactam, while *Enterobacteriacea*e that produce metallo-β-lactamases can be treated with ceftazidime–avibactam or cefiderocol. *Acinetobacter* spp. can be treated with cefiderocol (as part of a combination regimen) or with sulbactam-durlobactam, and *Stenotrophomonas* can be treated with cefiderocol.

SPECIFIC TREATMENT

Once an etiologic diagnosis is made, broad-spectrum empirical therapy can be modified (de-escalated) to specifically address the known pathogen. For patients with MDR risk factors, antibiotic regimens can be reduced to a single agent in most cases. Only a minority of cases require a complete course with two or three drugs. A negative tracheal-aspirate culture or growth below the threshold for quantitative cultures of samples obtained before any antibiotic change strongly suggests that antibiotics should be discontinued or that an alternative diagnosis should be pursued. Identification of other confirmed or suspected sites of infection may require ongoing antibiotic therapy, but the spectrum of pathogens (and the corresponding antibiotic choices) may be different from those for VAP. A 7- or 8-day course of therapy is just as effective as a 2-week course and is associated with less frequent emergence of antibiotic-resistant strains. Exceptions include cases in which initial therapy is inappropriate or consists of second-line antibiotics and cases caused by some more resistant organisms, such as carbapenemase-producing *Acinetobacter* species. In these situations, serial measurements of procalcitonin may help guide duration of therapy.

A major controversy regarding specific therapy for VAP concerns the need for ongoing combination treatment of *Pseudomonas* pneumonia. No randomized controlled trials have demonstrated a benefit of combination therapy with a β-lactam and an aminoglycoside, nor have subgroup analyses in other trials found a survival benefit with such a regimen. Combination therapy may increase the likelihood of initially appropriate therapy and may have value in bacteremic infection with septic shock, but the benefit may last for only a few days. The unacceptably high rates of clinical failure and death despite combination therapy among patients with VAP caused by *P. aeruginosa* (see "Failure to Improve," below) indicate that better regimens are needed, perhaps including aerosolized antibiotics. In most cases of *Pseudomonas* pneumonia, current guidelines recommend against continuing combination therapy after the isolate's antimicrobial susceptibility is known.

FAILURE TO IMPROVE

Treatment failure is not uncommon in VAP, especially that caused by MDR pathogens. VAP caused by MRSA is associated with a 40% clinical failure rate when treated with standard-dose vancomycin. One proposed but unproven solution is the use of high-dose individualized treatment, although the risk of renal toxicity increases with this strategy. In addition, the MIC of MRSA to vancomycin has been increasing, and a high percentage of clinical failures occur when the MIC is in the upper range of sensitivity (i.e., 1.5–2 μg/mL). Linezolid appears to be 15% more efficacious than even adjusted-dose vancomycin and is preferred in patients with renal insufficiency and those infected with high-MIC isolates of MRSA. VAP due to *Pseudomonas* has a 40–50% failure rate, no matter what the regimen. Therapy-related causes of clinical failure include not using the recommended combination regimen (Table 131-8) and inadequate antibiotic dosing. However, the emergence of β-lactam resistance during therapy is an important problem, especially in infection with *Pseudomonas* and *Enterobacter* species. Recurrent VAP caused by the same pathogen is possible because the biofilm on endotracheal tubes allows persistence and reintroduction of the microorganism. Studies of VAP caused by *Pseudomonas* show that approximately half of recurrent cases are caused by a new strain. Some studies have suggested that treatment failure may be less common with optimized β-lactam dosing and use of either prolonged or continuous infusion therapy.

Possible causes of treatment failure can be difficult to determine early in the therapeutic course and can include superinfection, the presence of extrapulmonary infection, as well as patient factors such as severe comorbid illness and immunosuppression. Serial quantitative cultures may clarify the microbiologic response, and recent data in ICU patients have shown a role for biomarkers, such as procalcitonin, to guide duration of therapy in conjunction with the patient's initial response to treatment.

COMPLICATIONS

Apart from death, the major complication of VAP is prolongation of mechanical ventilation, with corresponding increases in the duration of ICU and hospital stay. In most studies, the need for additional mechanical ventilation resulting from VAP justifies aggressive efforts at prevention.

In rare cases, necrotizing pneumonia (e.g., due to *P. aeruginosa* or *S. aureus*) can cause significant pulmonary hemorrhage or empyema. More commonly, necrotizing infections result in the long-term complications of bronchiectasis and parenchymal scarring leading to recurrent pneumonia. Other long-term complications of

pneumonia can include need for prolonged oxygen therapy, a catabolic state in a patient already nutritionally at risk, the necessity for ongoing rehabilitation, and—in the elderly—an inability to return to independent function and the need for nursing home placement.

FOLLOW-UP

Clinical improvement, if it occurs, is usually evident within 48–72 h of the initiation of antimicrobial treatment, usually with an improvement in oxygenation. Because findings on chest radiography often worsen initially during treatment, they are less helpful than clinical criteria as an indicator of response to therapy.

PROGNOSIS

VAP is associated with crude mortality rates as high as 50–70%, but the real issue is attributable mortality. Many patients with VAP have underlying diseases that would result in death even if VAP did not occur. Attributable mortality exceeded 25% in one matched-cohort study, while more recent studies have suggested much lower rates (5–10%), although patients with VAP complicating COVID-19 have a higher attributable mortality than those with other forms of VAP. Some variability in VAP mortality rates is clearly related to the type of patient and ICU studied. VAP in trauma patients is not associated with attributable mortality, possibly because many of the patients were otherwise healthy before being injured. The causative pathogen also plays a major role. Generally, MDR pathogens are associated with significantly greater attributable mortality than non-MDR pathogens. Pneumonia caused by some pathogens (e.g., *S. maltophilia*) is simply a marker for a patient whose immune system is highly compromised and is therefore at high risk.

PREVENTION (TABLE 131-7)

Because endotracheal intubation is a risk factor for VAP, the most important preventive intervention is to avoid intubation or minimize its duration. Successful noninvasive ventilation avoids many of the problems associated with endotracheal tubes. Strategies that minimize the duration of ventilation through daily holding of sedation and formal weaning protocols have also been highly effective in preventing VAP.

Unfortunately, a tradeoff in risks is sometimes necessary. Aggressive attempts to extubate early may result in reintubation(s) and increase aspiration, posing a risk of VAP. Heavy continuous sedation increases VAP risk, but self-extubation because of insufficient sedation is also a risk. The tradeoffs also apply to antibiotic therapy. Short-course antibiotic prophylaxis can decrease the risk of early-onset VAP in comatose patients requiring intubation, and data suggest that antibiotics decrease VAP rates overall. Conversely, prolonged courses of antibiotics consistently increase the risk of MDR VAP; pseudomonal VAP is rare among patients who have not recently received antibiotics. In one recent randomized trial, 3 days of daily inhaled aminoglycoside prophylaxis reduced the occurrence of VAP for the next 28 days, with no impact on mortality or antibiotic use.

Minimizing microaspiration around the endotracheal tube cuff also can prevent VAP. Simply elevating the head of the bed (at least 30° above horizontal, but preferably 45°) and using specially modified endotracheal tubes that allow removal of the secretions pooled above the cuff can prevent microaspiration. The risk-to-benefit ratio of transporting the patient outside the ICU for diagnostic tests or procedures should be carefully considered since VAP rates are increased among transported patients.

The role played by overgrowth of the normal bowel flora in the stomach—in the presence of elevated gastric pH—in the pathogenesis of VAP is questionable. Therefore, avoidance of agents that raise gastric pH may be relevant only in certain populations, such as liver transplant recipients and patients who have undergone other major intraabdominal procedures or who have bowel obstruction. MRSA and nonfermenters such as *P. aeruginosa* and *Acinetobacter* species are not normally part of the bowel flora but reside primarily in the nose and on the skin, respectively.

In outbreaks of VAP due to specific pathogens, the possibility of a breakdown in infection control measures (particularly contamination of reusable equipment) should be investigated. Even high rates of pathogens that are already common in a particular ICU may result from cross-infection. Education and reminders of the need for consistent hand washing and other infection-control practices can minimize this risk.

HOSPITAL-ACQUIRED PNEUMONIA

While less well studied than VAP, HAP in nonintubated patients—both inside and outside the ICU—is similar to VAP. The main differences are the higher frequency of non-MDR pathogens and the generally better underlying host immunity in nonintubated patients. The lower frequency of MDR pathogens allows monotherapy in a larger proportion of cases of HAP than of VAP. However, the bacteriology and outcome of ventilated HAP patients may be very similar to those of patients with VAP.

The only pathogens that may be more common in the non-VAP population are anaerobes because of a greater risk of macroaspiration and the lower oxygen tensions in the lower respiratory tract of these patients. Anaerobes usually contribute only to polymicrobial pneumonias, and specific therapy targeting anaerobes probably is not needed since many of the recommended antibiotics are active against anaerobes.

Diagnosis is even more difficult for HAP in the nonintubated patient than for VAP. Lower respiratory tract samples appropriate for culture are considerably more difficult to obtain from nonintubated patients. Many of the underlying diseases that predispose a patient to HAP are also associated with an inability to cough adequately. Since blood cultures are infrequently positive (<15% of cases), the majority of patients with HAP do not have culture data on which antibiotic modifications can be based, and de-escalation is less likely. Despite these difficulties, the better host defenses in non-ICU patients result in lower mortality rates than are documented for VAP and for ventilated HAP. In addition, the risk of antibiotic failure is lower in HAP.

GLOBAL IMPACT

From the available data, it is virtually impossible to accurately assess the impact of pneumonia from a global perspective. Any differences in incidence, disease burden, and costs across different age, ethnic, and racial groups are compounded by differences among countries in terms of etiologic pathogens, resistance rates, access to health-care and diagnostic facilities, and vaccine availability and use.

A standard approach with clearly defined outcome measures is needed before the impact of pneumonia can be accurately evaluated. However, simple extrapolation from U.S. data for CAP and HAP/VAP shows that pneumonia has a significant impact on quality of life, morbidity, health costs, and mortality rates and that this impact has implications for patients and for society as a whole.

132 Lung Abscess

Rebecca M. Baron, Beverly W. Baron, Miriam Baron Barshak

Lung abscess represents necrosis and cavitation of the lung following microbial infection. Lung abscesses can be single or multiple but usually are marked by a single dominant cavity >2 cm in diameter.

ETIOLOGY

The low prevalence of lung abscesses makes them difficult to study in randomized controlled trials. Although the incidence of lung abscesses has decreased in the antibiotic era, they are still a source of significant morbidity and mortality.

Lung abscesses usually are characterized as either primary (~80% of cases) or secondary. *Primary* lung abscesses generally arise from aspiration, often are caused principally by anaerobic bacteria, and occur in the absence of an underlying pulmonary or systemic condition. *Secondary* lung abscesses arise in the setting of an underlying condition, such as a postobstructive process (e.g., bronchial foreign body, tumor) or a systemic process (e.g., HIV infection, another immunocompromising condition). Lung abscesses can also be characterized as acute (<4–6 weeks in duration) or chronic (~40% of cases).

EPIDEMIOLOGY

The majority of the existing epidemiologic information involves primary lung abscesses. In general, middle-aged men are more commonly affected than middle-aged women. The major risk factor for primary lung abscesses is aspiration. Patients at particular risk for aspiration, such as those with altered mental status, alcoholism, drug overdose, seizures, bulbar dysfunction, prior cerebrovascular or cardiovascular events, or neuromuscular disease, are most commonly affected. At additional risk are patients with esophageal dysmotility or esophageal lesions (strictures or tumors) and those with gastric distention and/or gastroesophageal reflux, especially those who spend substantial time in the recumbent position.

It is widely thought that colonization of the gingival crevices by anaerobic bacteria or microaerophilic streptococci (especially in patients with gingivitis and periodontal disease), combined with a risk of aspiration, is important in the development of lung abscesses. In fact, many physicians consider it extremely rare for lung abscesses to develop in the absence of teeth as a nidus for bacterial colonization.

The importance of these risk factors in the development of lung abscesses is highlighted by a significant reduction in abscess incidence in the late 1940s that coincided with a change in oral surgical technique: beginning at that time, these operations were no longer performed with the patient in the seated position without a cuffed endotracheal tube, and the frequency of perioperative aspiration events was thus decreased. In addition, the introduction of penicillin around the same time significantly reduced the incidence of and mortality rate from lung abscess.

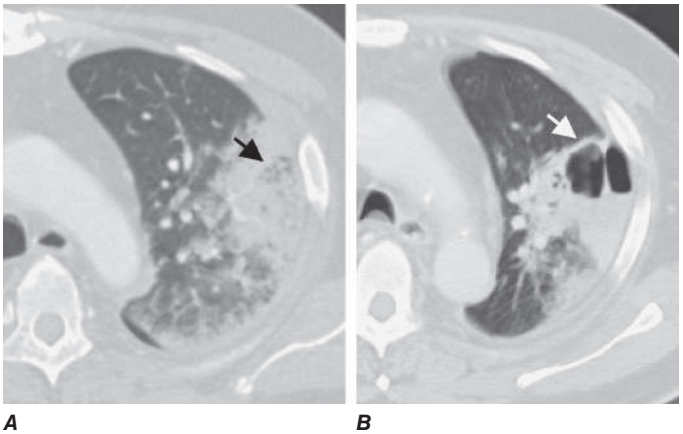

TABLE 132-1 Examples of Microbial Pathogens That Can Cause Lung Abscesses

CLINICAL CONDITION	PATHOGENS
Primary lung abscess (often with risk factors for aspiration)	Anaerobes (e.g., *Peptostreptococcus* spp., *Prevotella* spp., *Bacteroides* spp., milleri group streptococci), microaerophilic streptococci
Secondary lung abscess (often with underlying immunocompromise)	*Staphylococcus aureus*, gram-negative rods (e.g., *Pseudomonas aeruginosa*, Enterobacteriaceae), *Nocardia* spp., *Aspergillus* spp., Mucorales, *Cryptococcus* spp., *Legionella* spp., *Rhodococcus equi*, *Pneumocystis jirovecii*
Embolic lesions	*Staphylococcus aureus* (often from endocarditis), *Fusobacterium necrophorum* (Lemierre's syndrome; see text for details)
Endemic infections (with or without underlying immunocompromise)	*Mycobacterium tuberculosis* (as well as *Mycobacterium avium* and *Mycobacterium kansasii*), *Coccidioides* spp., *Histoplasma capsulatum*, *Blastomyces* spp., parasites (e.g., *Entamoeba histolytica*, *Paragonimus westermani*, *Strongyloides stercoralis*)
Miscellaneous conditions	Bacterial pathogen (often *S. aureus*) after influenza or another viral infection, *Actinomyces* spp.

PATHOGENESIS

Primary Lung Abscesses The development of primary lung abscesses is thought to originate when chiefly anaerobic bacteria (as well as microaerophilic streptococci) in the gingival crevices are aspirated into the lung parenchyma in a susceptible host (Table 132-1). Patients who develop primary lung abscesses usually carry an overwhelming burden of aspirated material or are unable to clear the bacterial load. Pneumonitis develops initially (exacerbated in part by tissue damage caused by gastric acid); then, over a period of 7–14 days, the bacteria produce parenchymal necrosis and cavitation whose extent depends on host–pathogen interaction (Fig. 132-1). Anaerobes are thought to produce more extensive tissue necrosis in polymicrobial infections in which virulence factors of the various bacteria can act synergistically to cause more significant tissue destruction.

Secondary Lung Abscesses The pathogenesis of secondary abscesses depends on the predisposing factor. For example, in cases of bronchial obstruction from malignancy or a foreign body, the

A *B*

FIGURE 132-1 Representative chest CT scans demonstrating development of lung abscesses. This patient was immunocompromised from underlying lymphoma and developed severe *Pseudomonas aeruginosa* pneumonia, as represented by a left lung infiltrate with concern for central regions of necrosis (*panel **A**, black arrow*). Two weeks later, areas of cavitation with air-fluid levels were visible in this region and were consistent with the development of lung abscesses (*panel **B**, white arrow*). *(Images provided by Dr. Ritu Gill, formerly of the Division of Chest Radiology, Brigham and Women's Hospital, Boston; with permission.)*

obstructing lesion prevents clearance of oropharyngeal secretions, leading to abscess development. With underlying systemic conditions (e.g., immunosuppression after bone marrow or solid organ transplantation), impaired host defense mechanisms lead to increased susceptibility to the development of lung abscesses caused by a broad range of pathogens, including opportunistic organisms (Table 132-1).

Lung abscesses also arise from septic emboli, either in tricuspid valve endocarditis (often involving *Staphylococcus aureus*) or in Lemierre's syndrome, in which an infection begins in the pharynx (classically involving *Fusobacterium necrophorum*) and then spreads to the neck and the carotid sheath (which contains the jugular vein) to cause septic thrombophlebitis.

PATHOLOGY AND MICROBIOLOGY

Primary Lung Abscesses The dependent segments (posterior upper lobes and superior lower lobes) are the most common locations of primary lung abscesses, given the predisposition of aspirated materials to be deposited in these areas. Generally, the right lung is affected more commonly than the left because the right mainstem bronchus is less angulated.

Primary lung abscesses often are polymicrobial, primarily including anaerobic organisms as well as microaerophilic streptococci (Table 132-1). The retrieval and culture of anaerobes can be complicated by the contamination of samples with microbes from the oral cavity, the need for expeditious transport of the cultures to the laboratory, the need for early plating with special culture techniques, the prolonged time required for culture growth, and the need for collection of specimens prior to administration of antibiotics. When attention is paid to these factors, rates of recovery of specific isolates are reportedly as high as 78%.

Because it is not clear that knowing the identity of the causative anaerobic isolate alters the approach to treatment of a primary lung abscess, practice has shifted away from the use of specialized techniques to obtain material for culture, such as transtracheal aspiration and bronchoalveolar lavage with protected brush specimens that allow recovery of culture material while avoiding contamination from the oral cavity. When no pathogen is isolated from a primary lung abscess (which occurs as often as 40% of the time), the abscess is termed a *nonspecific lung abscess*, and the presence of anaerobes is often presumed. A *putrid lung abscess* refers to cases with foul-smelling breath, sputum, or empyema; these manifestations are essentially diagnostic of an anaerobic lung abscess.

Secondary Lung Abscesses The location of secondary abscesses may vary with the underlying cause. The microbiology of secondary lung abscesses can encompass a broad bacterial spectrum, with infection by *Pseudomonas aeruginosa* and other gram-negative rods the most common. In addition, a broad array of pathogens can be identified in patients from certain endemic areas and in specific clinical scenarios (e.g., a significant incidence of fungal infections among immunosuppressed patients following bone marrow or solid organ transplantation). Because immunocompromised hosts and patients without the classic presentation of a primary lung abscess can be infected with a wide array of unusual organisms (Table 132-1), it is of special importance to obtain culture material to target therapy.

CLINICAL MANIFESTATIONS

Clinical manifestations initially may be similar to those of pneumonia, with fevers, cough, sputum production, and chest pain; a more chronic and indolent presentation that includes night sweats, fatigue, and anemia is often observed with anaerobic lung abscesses. A subset of patients with putrid lung abscesses may report discolored phlegm and foul-tasting or foul-smelling sputum. Patients with lung abscesses due to non-anaerobic organisms, such as *S. aureus*, may present with a more fulminant course characterized by high fevers and rapid progression.

Findings on physical examination may include fevers, poor dentition, and/or gingival disease as well as amphoric and/or cavernous breath sounds on lung auscultation. Additional findings may include digital clubbing and the absence of a gag reflex.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of lung abscesses is broad and includes other noninfectious processes that result in cavitary lung lesions, including lung infarction, malignancy, sequestration, cryptogenic organizing pneumonia, sarcoidosis, vasculitides and autoimmune diseases (e.g., granulomatosis with polyangiitis), lung cysts or bullae containing fluid, and septic emboli (e.g., from tricuspid valve endocarditis). Other less common entities can include pulmonary manifestations of diseases that usually present at locations other than the chest (e.g., inflammatory bowel disease, pyoderma gangrenosum).

DIAGNOSIS

Lung abscesses are documented by chest imaging. Although a chest radiograph usually detects a thick-walled cavity with an air-fluid level, CT permits better definition and may provide earlier evidence of cavitation. CT may also yield additional information regarding a possible underlying cause of lung abscess, such as malignancy, and may help distinguish a peripheral lung abscess from a pleural infection. This distinction has important implications for treatment because a pleural space infection, such as an empyema, may require urgent drainage.

As described earlier (see "Pathology and Microbiology," above), more invasive diagnostics (such as transtracheal aspiration) were traditionally undertaken for primary lung abscesses, whereas empirical therapy that includes drugs targeting anaerobic organisms currently is used more often. While sputum can be collected noninvasively for Gram's stain and culture, which may yield a pathogen, the infection is likely to be polymicrobial, and culture results may not reflect the presence of anaerobic organisms. Increasing use of molecular techniques for bacterial detection (e.g., 16S RNA gene amplification) may eventually yield more specific pathogen identification. As stated above, many physicians consider putrid-smelling sputum to be virtually diagnostic of an anaerobic infection.

When a secondary lung abscess is present or empirical therapy fails to elicit a response, sputum and blood cultures are advised in addition to serologic studies for opportunistic pathogens (e.g., viruses and fungi causing infections in immunocompromised hosts). Additional diagnostics, such as bronchoscopy with bronchoalveolar lavage or protected brush specimen collection and CT-guided percutaneous needle aspiration, can be undertaken. Risks posed by these more invasive diagnostics include spillage of abscess contents into the other lung (with bronchoscopy) and pneumothorax and bronchopleural fistula development (especially with CT-guided needle aspiration). However, early diagnostics in secondary abscesses, especially in immunocompromised hosts, are particularly important because the patients involved may be especially fragile, at risk for infection with a broad array of pathogens, and therefore less likely than other patients to respond to empirical therapy.

TREATMENT

Lung Abscess

The availability of antibiotics in the 1940s and 1950s established therapy with this drug class as the primary approach to the treatment of lung abscess. Previously, surgery had been relied upon much more frequently. For many decades, penicillin was the antibiotic of choice for primary lung abscesses in light of its anaerobic coverage; however, because oral anaerobes can produce β-lactamases, clindamycin has proved superior to penicillin in clinical trials. For primary lung abscesses, the recommended regimens are (1) clindamycin (600 mg IV three times daily; then, with the disappearance of fever and clinical improvement, 300 mg PO four times daily) or (2) an IV-administered β-lactam/β-lactamase combination, followed—once the patient's condition is stable—by orally administered amoxicillin-clavulanate. This therapy should be continued until imaging demonstrates that the lung abscess has cleared or regressed to a small scar. Treatment duration may range from 3–4 weeks to as long as 14 weeks, with some literature suggesting that a course of at least 6 weeks may be associated with better outcomes. One small

study suggested that moxifloxacin (400 mg/d PO) is as effective and well tolerated as ampicillin-sulbactam. Notably, metronidazole is not effective as a single agent: it covers anaerobic organisms but not the microaerophilic streptococci that are often components of the mixed flora of primary lung abscesses.

In secondary lung abscesses, antibiotic coverage should be directed at the identified pathogen, and a prolonged course (until resolution of the abscess is documented) is often required. Treatment regimens and courses vary widely, depending on the immune state of the host and the identified pathogen. Other interventions may be necessary as well, such as relief of an obstructing lesion or treatment directed at the underlying condition predisposing the patient to lung abscess. Similarly, if the condition of patients with presumed primary lung abscess fails to improve, additional studies to rule out an underlying predisposing cause for a secondary lung abscess are indicated.

Although it can take as long as 7 days for patients receiving appropriate therapy to defervesce, as many as 10–20% of patients may not respond at all, with continued fevers and progression of the abscess cavity on imaging. An abscess >6–8 cm in diameter is less likely to respond to antibiotic therapy without additional interventions. Options for patients who do not respond to antibiotics and whose additional diagnostic studies fail to identify a pathogen that can be treated include surgical resection and percutaneous drainage of the abscess, especially when the patient is a poor surgical candidate. Timing of surgical intervention can be challenging; the goal is to balance the morbidity/mortality risk of a procedure with the need for definitively clearing the abscess in the setting of persistent infection that is not responsive to nonsurgical approaches. Possible complications of percutaneous drainage include bacterial contamination of the pleural space as well as pneumothorax and hemothorax. Traversing normal lung parenchyma might represent a risk factor for major complications from percutaneous abscess drainage.

COMPLICATIONS

Larger cavity size on presentation may correlate with the development of persistent cystic changes (pneumatoceles) or bronchiectasis. Additional possible complications include recurrence of abscesses despite appropriate therapy, extension to the pleural space with development of empyema, life-threatening hemoptysis, and massive aspiration of lung abscess contents.

PROGNOSIS AND PREVENTION

Reported mortality rates for primary abscesses have been as low as 2%, while rates for secondary abscesses are generally higher—as high as 75% in some case series. Other poor prognostic factors include age >60, malignancy-related abscesses, the presence of aerobic bacteria, sepsis at presentation, symptom duration of >8 weeks, and abscess size >6 cm.

Mitigation of underlying risk factors may be the best approach to prevention of lung abscesses, with attention directed toward airway protection, oral hygiene, and minimized sedation with elevation of the head of the bed for patients at risk for aspiration. Prophylaxis against certain pathogens in at-risk patients (e.g., recipients of bone marrow or solid organ transplants or patients whose immune systems are significantly compromised by HIV infection) may be undertaken.

APPROACH TO THE PATIENT

Lung Abscess

For patients with a lung abscess and a low likelihood of malignancy (e.g., smokers <45 years old) and with risk factors for aspiration, it is reasonable to administer empirical treatment and then to pursue further evaluation if therapy does not elicit a response. However, some clinicians may opt for up-front cultures, even in primary lung abscesses. In patients with risk factors for malignancy or other underlying conditions (especially immunocompromised hosts) or with an atypical presentation, earlier diagnostics should be considered, such as bronchoscopy with biopsy or CT-guided needle aspiration. Bronchoscopy should be performed early in patients whose history, symptoms, or imaging findings are consistent with possible bronchial obstruction. In patients from areas endemic for tuberculosis or patients with other risk factors for tuberculosis (e.g., underlying HIV infection), induced sputum samples should be examined early in the workup to rule out this disease.

133 Infective Endocarditis

Sara E. Cosgrove, Michael T. Melia

The prototypic lesion of infective endocarditis (IE), the *vegetation* (Fig. 133-1), is a mass of platelets, fibrin, microorganisms, and scant inflammatory cells. Infection most commonly involves heart valves but may also occur on the low-pressure side of a ventricular septal defect, on mural endocardium damaged by aberrant jets of blood or foreign bodies, or on intracardiac devices. The analogous process involving arteriovenous shunts, arterio-arterial shunts (patent ductus arteriosus), or a coarctation of the aorta is called *infective endarteritis*.

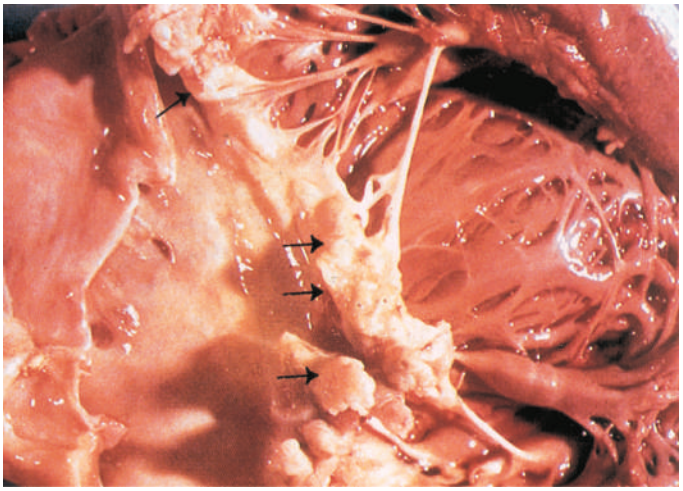

FIGURE 133-1 Vegetations (*arrows*) due to viridans streptococci endocarditis involving the mitral valve.

IE can be classified according to the temporal evolution of disease, the site of infection, the cause of infection, or the predisposing risk factor (e.g., injection drug use, health care–associated). *Acute IE* is a hectically febrile illness that rapidly damages cardiac structures, seeds extracardiac sites, and, if untreated, progresses to death within weeks. *Subacute IE* follows an indolent course; causes structural cardiac damage only slowly, if at all; rarely metastasizes; and is gradually progressive unless complicated by a major embolic event or a ruptured mycotic aneurysm.

In the United States and likely in other developed countries, the incidence of IE is estimated to be 15 cases per 100,000 population per year, with progressive increases during recent decades. While congenital heart diseases remain a constant predisposition, predisposing conditions in developed countries have shifted from chronic rheumatic heart disease (still common in developing countries) to injection drug use, degenerative valve disease, and intracardiac devices. Although the incidence of IE is increased among the elderly, recent data indicate age-adjusted mortality rates in people ≥55 years old have declined in the United States. Recently, however, there has been acceleration in mortality in people aged 25–44 years, likely associated with an increase in opioid use disorder (OUD) and injection drug use in this age group. In developed countries, 25–35% of cases of native-valve endocarditis (NVE) are health care–associated, and 16–30% of all cases are prosthetic-valve infections (PVE). The risk of PVE is greatest during the initial year after valve replacement; gradually declines to a low, stable rate thereafter; and is greater for bioprosthetic valves than mechanical valves. The incidence and rate of decline of transcatheter aortic valve replacement (TAVR)-PVE are similar to those for surgically implanted bioprosthetic aortic valves. IE involving cardiovascular implantable electronic devices (CIED-IE)—greater on implanted defibrillators and resynchronization devices than on permanent pacemakers—occurs in 0.5–1.14 cases per 1000 recipients.

ETIOLOGY

Although many species of bacteria and fungi cause sporadic episodes of IE, a few bacterial species cause the majority of cases **(Table 133-1)**. Recent large studies from developed areas identify *Staphylococcus aureus* as the most common bacterial species causing IE. The oral cavity, skin, and upper respiratory tract are the respective primary portals for viridans streptococci, staphylococci, and HACEK organisms (*Haemophilus* species, *Aggregatibacter* species, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*). *Streptococcus gallolyticus* subspecies *gallolyticus* (formerly *S. bovis* biotype 1) originates from the gastrointestinal tract and is associated with colonic polyps and tumors. Enterococci enter the bloodstream primarily from the genitourinary tract. Health care–associated IE, most commonly caused by *S. aureus*, coagulase-negative staphylococci (CoNS), and enterococci, may have either a nosocomial onset (55%) or a community onset (45%). IE complicates 8–25% of episodes of catheter-associated *S. aureus* bacteremia; the higher rates are detected in high-risk patients studied by transesophageal echocardiography (TEE) (see "Cardiac Imaging," below).

PVE arising within 2 months of valve surgery—i.e., early PVE—is generally nosocomial and is the result of intraoperative contamination of the prosthesis or a postoperative infection. This nosocomial origin is reflected in the microbial causes: *S. aureus*, CoNS, facultative gram-negative bacilli, diphtheroids, and fungi. The portals of entry and organisms causing PVE beginning >12 months after surgery—i.e., late PVE—are similar to those in community-acquired NVE. Regardless of the time of onset after surgery, the majority of CoNS strains that cause PVE are resistant to methicillin. The microbiology of TAVR-PVE, while generally similar to that of PVE, is notable for an increased frequency of enterococci. Risk factors associated with TAVR-PVE include male sex, diabetes, renal failure, and moderate postimplantation aortic valve regurgitation.

CIED-IE involves the device or the endothelium at points of device contact. Occasionally, there is concurrent valvular infection. One-third of cases of CIED-IE present within 3 months after device implantation or manipulation, one-third between 3 and 12 months, and one-third >1 year. *S. aureus* and CoNS cause the majority of cases.

IE in people who inject drugs (PWID), especially that involving the tricuspid valve, is commonly caused by *S. aureus*, which is often resistant to methicillin. Left-sided valve infections in PWID have a more varied etiology. In addition to the usual causes of IE, infection due to Enterobacterales, *Pseudomonas aeruginosa*, *Candida* species, and sporadically by unusual organisms (*Bacillus*, *Lactobacillus*, *Corynebacterium* species) is encountered.

About 5–15% of patients with IE have negative blood cultures; in one-third to one-half of these cases, cultures are negative because of prior antibiotic exposure. The remainder are infected by fastidious organisms, such as some streptococci; nutritionally variant bacteria now designated *Granulicatella, Gemella,* and *Abiotrophia* species; *Coxiella burnetii*; and *Bartonella* species. Some fastidious organisms

[a]Includes methicillin-susceptible and -resistant isolates. [b]Includes viridans streptococci; *Streptococcus gallolyticus*; other non–group A, groupable streptococci; and *Abiotrophia* and *Granulicatella* spp. (nutritionally variant, pyridoxal-requiring streptococci). [c]Primarily *E. faecalis* or nonspeciated isolates; occasionally *E. faecium* or other less likely species. [d]Methicillin resistance is common among these *S. aureus* strains. [e]Includes *Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

Abbreviations: CIED, cardiac implantable electronic device; TAVR, transcatheter aortic valve replacement.

Note: Data are compiled from multiple studies.

occur in characteristic geographic settings (e.g., *C. burnetii* and *Bartonella* species in Europe, *Brucella* species in the Middle East). *Tropheryma whipplei* causes an indolent, culture-negative form of IE. *C. burnetii* has a predilection for prosthetic valves. *Corynebacterium* species and *Cutibacterium acnes* may involve intracardiac devices and be slow to grow in blood cultures. *Mycobacterium chimaera,* which may be difficult to recover from blood cultures unless special media is used, has caused a global outbreak of PVE and disseminated infection as a result of aerosols from contaminated heater-cooler machines used during cardiopulmonary bypass. Lastly, atrial myxoma, marantic endocarditis, and the antiphospholipid antibody syndrome may mimic culture-negative IE.

PATHOGENESIS

The undamaged endothelium is resistant to infection by most bacteria. Endothelial injury (e.g., at the site of impact of high-velocity blood jets or on the low-pressure side of a cardiac structural lesion) allows either direct infection by virulent organisms or the development of a platelet–fibrin thrombus—a condition called *nonbacterial thrombotic endocarditis* (NBTE). This thrombus serves as a site of bacterial attachment during transient bacteremia. The cardiac conditions most commonly resulting in NBTE are mitral regurgitation, aortic stenosis, aortic regurgitation, ventricular septal defects, and complex congenital heart disease. NBTE also arises as a result of a hypercoagulable state; this phenomenon gives rise to *marantic endocarditis* (uninfected vegetations seen in patients with malignancy and chronic diseases) and to bland vegetations complicating systemic lupus erythematosus and antiphospholipid antibody syndrome.

Organisms that cause IE enter the bloodstream from colonized body surfaces or sites of infection. *S. aureus* adherence to intact endothelium may be mediated by local inflammation inducing von Willebrand factor on endothelial cell surfaces with resulting adherence of both platelets and *S. aureus*. Alternatively, *S. aureus* adherence to injured endothelium may be mediated by local deposition of fibrin and circulating von Willebrand factor on exposed subendothelial tissue to which in turn *S. aureus* adhere directly. Other microorganisms in the blood adhere to NBTE. The organisms that commonly cause IE have surface adhesin molecules, collectively called microbial surface components recognizing adhesin matrix molecules (MSCRAMMs) that mediate adherence to NBTE sites or injured endothelium. Adherence is facilitated by fibronectin-binding proteins present on many gram-positive bacteria; by clumping factor (a fibrinogen- and fibrin-binding surface protein) on *S. aureus*; by fibrinogen-binding surface proteins (Fss2), collagen-binding surface protein (Ace), and Ebp pili (the latter mediating platelet adherence) on *Enterococcus faecalis*; and by glucans or FimA (a member of the family of oral mucosal adhesins) on streptococci. Fibronectin-binding proteins are required for *S. aureus* invasion of intact endothelium; thus, these surface proteins may facilitate infection of previously normal valves. If resistant to the bactericidal activity of serum and the microbicidal peptides released locally by platelets, adherent organisms proliferate to form dense microcolonies. Microorganisms also induce platelet deposition and a localized procoagulant state by eliciting tissue factor from the endothelium and, in the case of *S. aureus,* from monocytes as well. Fibrin deposition combines with platelet aggregation and microorganism proliferation to generate an infected vegetation. Organisms deep in vegetations are metabolically inactive (nongrowing) and relatively resistant to killing by antimicrobial agents. Proliferating surface organisms are shed into the bloodstream continuously.

The clinical manifestations of IE—other than constitutional symptoms, which probably result from cytokine production—arise from damage to intracardiac structures; embolization of vegetation fragments leading to infection or infarction of remote tissues; hematogenous infection of sites during bacteremia; and tissue injury due to the deposition of circulating immune complexes or immune responses to deposited bacterial antigens.

CLINICAL MANIFESTATIONS

The highly variable clinical IE syndrome spans a continuum between acute and subacute presentations. Most forms of IE share clinical and laboratory manifestations (Table 133-2). The causative microorganism is primarily responsible for the temporal course of IE. β-Hemolytic streptococci, *S. aureus*, and pneumococci typically result in an acute course, and IE caused by *Staphylococcus lugdunensis* (a coagulase-negative species) or by enterococci may present acutely. Subacute IE is typically caused by viridans streptococci, enterococci, CoNS, and the HACEK group. IE caused by *Bartonella* species, *T. whipplei*, *C. burnetii*, or *M. chimaera* is exceptionally indolent.

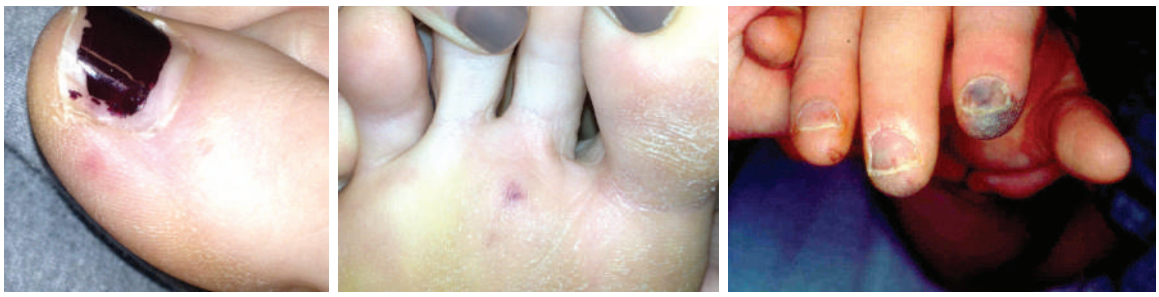

TABLE 133-2 Clinical and Laboratory Features of Infective Endocarditis

FEATURE	FREQUENCY, %
Fever	80–90
Chills and sweats	40–75
Anorexia, weight loss, malaise	25–50
Myalgias, arthralgias	15–30
Back pain	7–15
Heart murmur	80–85
New/worsened regurgitant murmur	20–50
Arterial emboli	20–50
Splenomegaly	15–50
Clubbing	10–20
Neurologic manifestations	20–40
Peripheral manifestations (Osler's nodes, subungual hemorrhages, Janeway lesions, Roth's spots)	2–15
Petechiae	10–40
Laboratory manifestations	
Anemia	70–90
Leukocytosis	20–30
Microscopic hematuria	30–50
Elevated erythrocyte sedimentation rate	60–90
Elevated C-reactive protein level	>90
Rheumatoid factor	50
Circulating immune complexes	65–100
Decreased serum complement	5–40

In patients with subacute presentations, fever is typically low-grade, rarely exceeding 39.4°C (103°F); in contrast, temperatures of 39.4°–40°C (103°–104°F) are often noted in acute IE. Fever may be blunted in patients who are elderly, are severely debilitated, or have renal failure.

Cardiac Manifestations Although heart murmurs are usually indicative of the predisposing cardiac pathology rather than of IE, valvular damage and ruptured chordae may result in new regurgitant murmurs. In acute IE involving a normal valve, murmurs may be absent initially but ultimately are detected in 85% of cases. Congestive heart failure (CHF) resulting from valve dysfunction or, occasionally, intracardiac fistulae develop in 30–40% of patients. Extension of leaflet infection into adjacent annular or myocardial tissue results in paravalvular abscesses, which in turn may cause intracardiac fistulae with new murmurs. Aortic paravalvular infection may burrow into the upper ventricular septum and interrupt the conduction system, leading to varying degrees of heart block. Mitral paravalvular abscesses are more distant from the conduction system and rarely cause conduction abnormalities. Coronary artery emboli occur in 2% of patients and may result in myocardial infarction.

Noncardiac Manifestations The classic nonsuppurative peripheral manifestations of subacute IE (e.g., Janeway lesions; Fig. 133-2*A*) are related to prolonged infection; with early diagnosis and treatment, these have become infrequent. In contrast, septic embolization mimicking some of these lesions (subungual hemorrhage, Osler's nodes) is common in patients with acute *S. aureus* IE (Fig. 133-2*B*). Musculoskeletal pain usually remits promptly with treatment but

A B

FIGURE 133-2 ***A.*** Janeway lesions on the toe (*left*) and plantar surface (*right*) of the foot in subacute *Neisseria mucosa* infective endocarditis (IE). *(Images courtesy of Rachel Baden, MD.)* ***B.*** Septic emboli with hemorrhage and infarction due to acute *Staphylococcus aureus* IE.

must be distinguished from focal metastatic infections (e.g., spondylodiscitis), which may complicate 10–15% of cases. Hematogenously seeded focal infection occurs most often in the skin, spleen, kidneys, skeletal system, and meninges. Arterial emboli, one-half of which precede the diagnosis of IE, are clinically apparent in up to 50% of patients. *S. aureus* IE, mobile vegetations >10 mm in diameter, and infection involving the mitral valve anterior leaflet are independently associated with an increased risk of embolization. Embolic arterial occlusion causes regional pain or ischemia-induced organ dysfunction (e.g., of the kidney, spleen, bowel, extremity). Cerebrovascular emboli presenting as strokes or occasionally as encephalopathy complicate 15–35% of cases; however, evidence of clinically asymptomatic emboli is found on magnetic resonance imaging (MRI) in 30–65% of patients with left-sided IE. The frequency of stroke is 8 per 1000 patient-days during the week prior to diagnosis and decreases to 4.8 and 1.7 per 1000 patient-days during the first and second weeks of effective antimicrobial therapy, respectively. Only 3% of strokes occur after 1 week of effective therapy. Emboli occurring late during or after effective therapy do not in themselves constitute evidence of failed antimicrobial treatment.

Other neurologic complications include aseptic or purulent meningitis, intracranial hemorrhage due to hemorrhagic infarcts or ruptured mycotic aneurysms, and seizures. *Mycotic aneurysms* are focal dilations of arteries occurring at points in the artery wall that have been weakened by infection in the vasa vasorum or where septic emboli have lodged. Microabscesses in the brain and meninges occur commonly in *S. aureus* IE; intracerebral abscesses requiring surgical drainage are infrequent.

Immune complex deposition on the glomerular basement membrane causes diffuse hypocomplementemic glomerulonephritis and renal dysfunction, which typically improve with effective antimicrobial therapy. Embolic renal infarcts cause flank pain and hematuria but rarely renal dysfunction. Splenic infarcts or abscess can manifest as left upper abdominal, pleuritic chest, or left shoulder pain.

Manifestations with Specific Predisposing Conditions Among PWID, 35–60% of IE is limited to the tricuspid valve and presents with fever with faint or no murmur and without peripheral manifestations. Septic pulmonary emboli, which are common with tricuspid IE, cause cough, pleuritic chest pain, nodular pulmonary infiltrates, and occasionally empyema or pyopneumothorax. Infection of the aortic or mitral valve presents with the typical clinical features of IE, including peripheral manifestations.

Health care–associated IE has typical manifestations unless associated with an intracardiac device or masked by the symptoms of concurrent illness. CIED-IE may be associated with obvious (especially within 6 months of device manipulation) or cryptic generator pocket infection or arise through bacteremic seeding without pocket infection. Fever, sepsis, minimal murmur, and occasionally pulmonary symptoms due to septic emboli are seen. Late-onset PVE and TAVR-PVE present with typical clinical features. In early PVE, symptoms may be masked by recent surgery. In both early and late PVE, paravalvular infection is common and often results in partial valve dehiscence, regurgitant murmurs, CHF, or disruption of the conduction system.

DIAGNOSIS

Careful clinical, microbiologic, and echocardiographic evaluations should be pursued when febrile patients have IE predispositions, cardiac or noncardiac (e.g., stroke or splenic infarct) features of IE, or blood cultures yielding an IE-associated organism.

Duke Criteria The diagnosis of IE is established with certainty only when vegetations are examined histologically and microbiologically. Nevertheless, a common clinical approach utilizes a diagnostic schema based on clinical, laboratory, and echocardiographic findings commonly encountered in patients with IE **(Table 133-3)**. Now known as the Duke–International Society for Cardiovascular Infectious Diseases (Duke-ISCVID) Criteria for IE, the criteria were updated in 2023 to encompass new epidemiologic data and microbiologic testing and imaging methodologies; these modifications have been validated in at least four bacteremia cohorts and show sensitivity in the 80–93% range. Clinical judgment must be exercised to use the criteria effectively. A clinical diagnosis of definite IE requires two major criteria, one major and three minor criteria, or five minor criteria. IE is rejected if an alternative diagnosis is established, if there is no recurrence despite therapy for <4 days, or if surgery or autopsy after <4 days of antimicrobial therapy yields no histologic evidence of IE. Cases not classified as definite or rejected are considered possible IE when either one major and one minor criterion or three minor criteria are fulfilled. Absent extenuating circumstances, patients with definite and possible IE are treated as having IE.

Blood Cultures The Duke-ISCVID Criteria reiterate that multiple blood cultures are the gold standard for diagnosing IE. Collection of three cultures from separate venipuncture sites is still recommended but is no longer required. Further, the bacterial species considered "typical" for causing IE are defined as those whose recovery from blood has been strongly associated with IE; the pathogen list has been expanded to include all streptococcal species except *S. pneumoniae* and *S. pyogenes*, *S. lugdunensis*, *E. faecalis* regardless of the primary source, and "streptococcus-like bacteria" (e.g., *Granulicatella* spp., *Abiotrophia* spp., and *Gemella* spp.). To fulfill a major criterion, a typical organism that causes IE (e.g., those listed previously plus *S. aureus* and HACEK organisms) must be recovered in two or more blood culture sets; other organisms, considered "nontypical" must grow in three or more blood culture sets and the clinical presentation must be unexplained by an extracardiac focus of infection. In patients with intracardiac prosthetic material, CoNS, *Corynebacterium striatum*, *Corynebacterium jeikeium*, *C. acnes*, *Serratia marcescens*, *Pseudomonas aeruginosa*, nontuberculous mycobacteria (e.g., *M. chimaerae*), and *Candida* species should be considered "typical." Otherwise these organisms must be found in three or more blood culture sets to satisfy a major criterion.

In patients with suspected NVE, PVE, TAVR-PVE, or CIED-IE who have not received antibiotics during the prior 2 weeks, three two-bottle blood culture sets containing the appropriate volume of blood (10 mL per bottle) should be obtained, ideally from different venipuncture sites. If the cultures remain negative after 48–72 h, two or three additional blood culture sets should be obtained, and the laboratory should be consulted for advice regarding optimal culture techniques.

TABLE 133-3 The Modified Duke Criteria for the Clinical Diagnosis of Infective Endocarditis (IE)[a]

Major Criteria

A. Microbiologic Criteria

1. Positive blood culture

   Microorganism that commonly cause IE in 2 or more separate blood culture sets (Typical—i.e., *S. aureus*, *S. lugdunensis*, *E. faecalis*, all streptococcal species except *S. pneumoniae* and *S. pyogenes*, *Granulicatella* spp., *Abiotrophia* spp., *Gemella* spp., HACEK group organisms AND in the setting of intracardiac prosthetic material, CoNS, *C. striatum*, *C. jeikeium*, *S. marcescens*, *P. aeruginosa*, *C. acnes*, nontuberculosis mycobacteria, *Candida* spp.)

   or

   Microorganisms that occasionally or rarely cause IE isolated from 3 or more separate blood culture sets (Nontypical)

2. Positive laboratory tests

   Positive polymerase chain reaction (PCR) for *Coxiella burnetti*, *Bartonella* spp., or *Tropheryma whipplei* from blood

   or

   Single blood culture growing *C. burnetti* or phase I IgG Ab titer ≥ 1:800

   or

   Indirect immunofluorescence assays (IFA) for IgM Ab and IgG Ab to *B. henselae* or *B. quintana* with IgG Ab titer ≥ 1:800

B. Imaging Criteria

1. Echocardiography or cardiac CT showing vegetation, valvular/leaflet perforation/aneurysm, abscess, pseudoaneurysm or intracardiac fistula

   or

   New valvular regurgitation (new/worsening murmur is NOT sufficient; requires echocardiographic evidence)

   or

   New prosthetic valve dehiscence/insufficiency

2. FDG-PET/CT with abnormal metabolic activity involving a native or prosthetic valve, ascending aortic graft, intracardiac device leads, or other prosthetic material

C. Surgical Criteria

Evidence of IE documented by direct inspection during heart surgery

Minor Criteria

A. Predisposition: previous history of IE, injection drug use, prosthetic valve, previous valve repair, congenital heart disease (e.g., bicuspid AV), CIED, more than mild regurgitation or stenosis, hypertrophic cardiomyopathy

B. Fever: T > 38.0°C (100.4°F)

C. Vascular phenomenon: arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhage, Janeway lesions, cerebral/splenic abscesses, purulent purpura

D. Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, positive rheumatoid factor

E. Microbiologic evidence: positive blood cultures (not meeting above criteria)

or

Positive culture, PCR, or other nucleic acid-based test for an organism consistent with IE from a non-endovascular site or single finding of a skin bacterium by PCR on a valve or wire without additional clinical or microbiological supporting evidence

F. Imaging criteria: abnormal metabolic activity on FDG-PET/CT within 3 months of implantation of a prosthetic valve, ascending aortic graft, intracardiac device lead

G. Physical exam criteria: New valvular regurgitation on auscultation

DIAGNOSIS

Definite IE: 1. Pathologic criteria (microorganisms or active endocarditis identified in a vegetation/intra-cardiac abscess from cardiac tissue, prosthetic material, arterial embolus) 2. Clinical criteria (2 major or 1 major + 3 minor or 5 minor)

Possible IE: 1 major + 1 minor or 3 minor

Rejected IE: does not meet above criteria or firm alternative dx or lack of recurrence with <4 days of antibiotics or no evidence on autopsy

Abbreviations: Ab, antibody; AV, aortic valve; CIED, cardiac implantable electronic device; CoNS, coagulase-negative staphylococci; CT, computed tomography; FDG, ^{18}F-fluorodeoxyglucose; HACEK, *Haemophilus* species, *Aggregatibacter* species, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*; PET, positron emission tomography.

Source: Reproduced with permission from VG Fowler Jr et al: The 2023 Duke-International Society for Cardiovascular Infectious Diseases criteria for infective endocarditis: Updating the modified Duke criteria. Clin Infect Dis. 77:518, 2023, Table 2.

Pending culture results, empirical antimicrobial therapy should be withheld initially from hemodynamically and clinically stable patients with suspected subacute IE, especially those who have received antibiotics within the preceding 2 weeks. The delay allows blood for additional cultures to be obtained without the confounding effect of empirical treatment. Patients with sepsis or deteriorating hemodynamics who may require urgent surgery should receive empirical treatment immediately after the initial three sets of blood cultures are obtained.

Non–Blood Culture Tests Non–blood culture laboratory criteria have been added to microbiologic major criteria in the Duke-ISCVID Criteria to implicate organisms that are difficult to recover by blood culture. These include polymerase chain reaction (PCR) or other nucleic acid–based techniques identifying *C. burnetii*, *Bartonella* spp., or *T. whipplei* from the blood and indirect immunofluorescence assays for IgM and IgG antibodies to *Bartonella henselae* or *B. quintana* with IgG titer ≥1:800. Next-generation (shotgun metagenomic) sequencing of pathogen DNA from serum has emerged as a novel nonculture technology capable of identifying a wide array of organisms in blood culture–negative IE. However, Duke-ISCVID Criteria recommend results from such testing that yield organisms other than *C. burnetii*, *Bartonella* spp., or *T. whipplei* be considered minor criteria at this time.

In vegetations recovered at surgery or by embolectomy, pathogens can be identified by culture and histopathologic examination with special stains. A sample of the vegetation should be collected using sterile technique and saved for molecular testing using PCR with organism-specific primers (e.g., *C. burnetii*, *Bartonella*, *T. whipplei*, *C. acnes*, *Mycoplasma hominis*) or broad-range PCR targeting 16S ribosomal RNA (or 28S rRNA, if fungi are suspected) followed by sequencing for organism identification. Histopathology may inform the selection of specific molecular tests. Molecular testing is a useful diagnostic technology when the histopathology of a vegetation is consistent with IE; however, it cannot be used to establish the viability of residual bacteria in vegetations. Additionally, molecular testing is only moderately sensitive, and thus, a negative test cannot exclude IE. When tissue is limited, molecular testing should be prioritized over culture.

Cardiac Imaging Echocardiography anatomically confirms and measures vegetations, detects intracardiac complications, and assesses cardiac function. Transthoracic echocardiography (TTE) is exceptionally specific; however, in 20% of patients, the images are inadequate. TTE fails to detect vegetations in 20–35% of patients with definite clinical IE, missing vegetations <2 mm in diameter. It is not optimal for evaluating prosthetic valves, especially TAVR with large stents, or detecting intracardiac complications. TEE detects vegetations in >90% of patients with definite IE; nevertheless, initial studies may yield false-negative results in 6–18% of IE patients, especially in TAVR-PVE. A negative TEE, when IE is likely, does not exclude the diagnosis but rather warrants repeating the study in 7–10 days. TEE is sometimes augmented by three-dimensional TEE, which can better visualize vegetations and perivalvular extension of infection.

Other imaging should be pursued when anatomic confirmation of IE is unclear, when TEE is not confirmatory or is contraindicated, and in suspected PVE. Electrocardiographic-gated multislice cardiac CT angiogram (CTA), which is less sensitive than TEE in detection of vegetations, valvular perforation, and paravalvular leakage but superior in defining pseudoaneurysm or abscess, may be definitive. Further, it can be used in lieu of preoperative cardiac catheterization to assess coronary artery patency in patients at low to intermediate risk of coronary disease. ^{18}F-Fluorodeoxyglucose positron emission tomography (FDG-PET)/CT is less sensitive than TEE or CTA in detecting intracardiac pathology in NVE or CIED-IE but provides increased sensitivity in assessing suspected PVE, including TAVR-PVE, infection of ascending aorta grafts, extracardiac complications, left ventricular assist device (LVAD) infection, and CIED pocket and lead infection. As a whole-body image, findings may modify therapy in 25% of NVE and PVE patients. However, FDG-PET/CT is costly, requires preprocedure patient preparation, can have false-positive results in patients with recent valve surgery (<3 months), and requires experienced radiographers for interpretation. Of note, findings indicative of IE on CTA and

FDG-PET/CT are major criteria and considered equivalent to echocardiography in the Duke-ISCVID schema.

In population-based studies and large series (using various diagnostic criteria), IE occurs frequently among patients who have monomicrobial bacteremia due to those gram-positive organisms that are commonly associated with IE. For example, 12–17% of patients with blood cultures growing *E. faecalis* have IE; 7% of patients with blood cultures growing non-β-hemolytic streptococci have IE; and 8–14% of patients with blood cultures growing *S. aureus* have IE. Among patients with one or more positive monomicrobial blood culture, IE risk-prediction scoring systems have been developed to identify patients who are at sufficient risk of IE to justify echocardiographic assessment **(Table 133-4)**. Because *S. aureus* bacteremia is associated with a high prevalence of IE and a resultant high risk for mortality, echocardiographic evaluation (high-quality TTE or preferably TEE) is recommended routinely. Prediction scores suggest that with *S. aureus* bacteremia, a patient with any of the features listed in Table 133-4 incurs at least a 6% risk of IE, with risk increasing when multiple features are present. Thus, when present, these findings are a strong indication for early TEE. In their absence, TTE should suffice unless other findings suggest IE. Among patients with either monomicrobial *E. faecalis* or non-β-hemolytic streptococcal bacteremia, any three of the respective listed features (Table 133-4) are associated with a significant frequency of IE. For these patients, the estimated number needed to test with TEE to detect IE is 2.4 and 3.6, respectively. While these predictive scoring systems need further evaluation and should be used with clinical judgment, they appear to have a high sensitivity and therefore a high negative predictive value, which allows identification of patients at low risk of IE where echocardiography, particularly TEE, can be omitted. An approach to echocardiographic evaluation of patients with suspected IE is illustrated in **Fig. 133-3**.

Other Studies Many studies that are not diagnostic—i.e., complete blood count, creatinine determination, liver function tests, chest radiography, and electrocardiography—are important in the management of patients with IE. The erythrocyte sedimentation rate, C-reactive protein level, rheumatoid factor, and circulating immune complex titer are commonly increased in IE (Table 133-2). Brain MRI/magnetic resonance angiography (MRA) should be obtained in patients with neurologic signs or symptoms, including unusual headache, to assess for emboli, hemorrhage, or mycotic aneurysms. The findings can support the IE diagnosis as well as provide evidence requiring changes in planned surgical treatment. Patients with recalcitrant back pain or focal spine tenderness should undergo spine MRI targeted to the appropriate level based on symptoms to assess for osteomyelitis and epidural abscess. Contrast-enhanced whole-body tomography to detect silent emboli in patients without localizing symptoms is not likely to enhance diagnostic accuracy and is associated with significant risk of kidney injury due to contrast media exposure; thus, it should not be performed routinely.

TABLE 133-4 Features Guiding the Need for Echocardiographic Assessment in Patients with Selected Monomicrobial Bacteremia

BLOOD CULTURE ISOLATE		
S. AUREUS[a]	*E. FAECALIS*[b]	NON-β-HEMOLYTIC STREPTOCOCCI[c]
Intracardiac device	Symptoms ≥7 days	Symptoms ≥7 days
Preexisting valve disease (including prior endocarditis or valve prosthesis)	Emboli	>2 positive cultures
Injection drug use	≥2 positive cultures	One species: *S. gallolyticus, S. sanguinis, S. mutans* (not *S. anginosus*)
Cerebral/peripheral emboli	Unknown origin (no focus)	Preexisting valve disease (including prior endocarditis or valve prosthesis)
Meningitis	Heart murmur	Heart murmur
Persistent bacteremia (≥72 h)	Preexisting valve disease (including prior endocarditis or valve prosthesis)	Community acquisition
Vertebral osteomyelitis		
Community acquisition		
Nonnosocomial health care associated (including hemodialysis)

TREATMENT

Infective Endocarditis

ANTIMICROBIAL THERAPY

To cure IE, all bacteria in the vegetation must be killed. This is difficult because local host defenses are deficient and because the bacteria are largely nongrowing and metabolically inactive and thus are less easily killed by antibiotics. Consequently, therapy must be prolonged. Antibiotics are generally given parenterally to achieve serum concentrations that, through passive diffusion, result in effective concentrations in the depths of the vegetation. The decision to initiate treatment empirically must balance the need to establish a microbiologic diagnosis against the potential disease progression or the need to control infection prior to urgent surgery (see "Blood Cultures," above). Infection at other sites (such as the meninges), allergies, end-organ dysfunction, interactions with concomitantly administered medications, and risks of adverse events must be considered in the selection of therapy.

The regimens recommended for the treatment of PVE (except that caused by staphylococci), although given for several weeks longer, are similar to those used to treat NVE **(Table 133-5)**. Recommended antibiotic dosing and duration of therapy, which is measured from the time blood cultures become negative, should be followed unless alterations are required by end-organ dysfunction or adverse events.

Organism-Specific Therapies • **Streptococci** The recommended therapies for streptococcal IE are based on the minimal inhibitory concentration (MIC) of penicillin for the causative isolate (Table 133-5). The 2-week penicillin/gentamicin and ceftriaxone/gentamicin regimens should not be used to treat NVE complicated by cardiac or extracardiac abscess or PVE. Caution should be exercised in considering aminoglycoside-containing regimens in patients at increased risk for aminoglycoside toxicity (renal or eighth cranial nerve). The regimens recommended for relatively penicillin-resistant streptococci are advocated for treatment of group B, C, or G streptococcal IE. *Granulicatella*, *Abiotrophia*, and *Gemella* species are treated with the regimens for moderately penicillin-resistant streptococci, as is PVE caused by these organisms or by streptococci with a penicillin MIC of >0.1 μg/mL (Table 133-5).

Enterococci Enterococci are resistant to oxacillin, nafcillin, and the cephalosporins and are only inhibited—not killed—by the cell wall–active agents penicillin, ampicillin, teicoplanin (not available in the United States), and vancomycin, with ampicillin and penicillin being preferred when susceptible. Enterococci are killed by the synergistic interaction of these cell wall–active antibiotics combined with gentamicin, unless the isolate exhibits high-level resistance to gentamicin, defined as growth of the isolate in the presence of gentamicin at ≥500 μg/mL. Bactericidal synergy with other aminoglycosides—tobramycin, netilmicin, kanamycin, and amikacin—is unpredictable even in the absence of high-level resistance; thus, they are not used to treat enterococcal IE.

Although the dose of gentamicin used to achieve bactericidal synergy in treating enterococcal IE is smaller than that used in standard therapy, nephrotoxicity is not uncommon during treatment

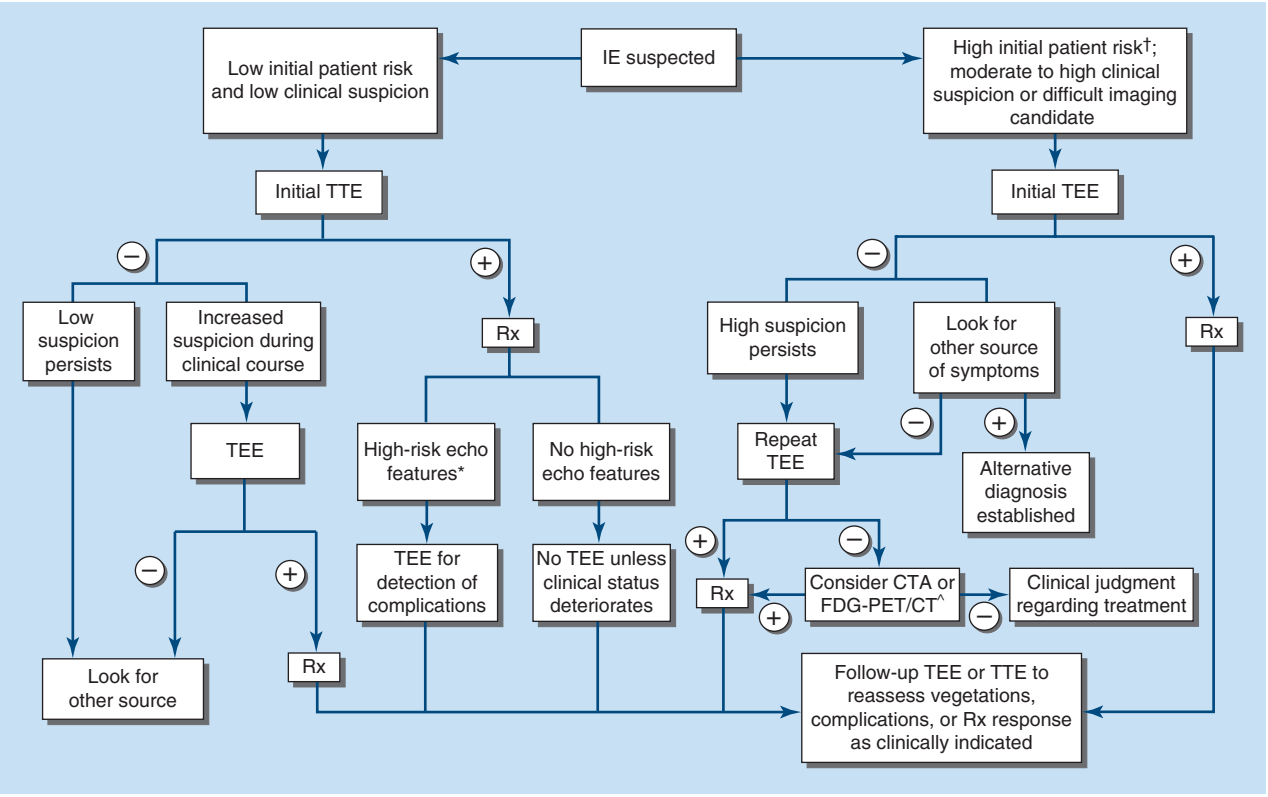

FIGURE 133-3 The diagnostic use of transesophageal and transthoracic echocardiography (TEE and TTE, respectively). †High initial patient risk for infective endocarditis (IE) or evidence of intracardiac complications (new regurgitant murmur, new electrocardiographic conduction changes, or congestive heart failure). *High-risk echocardiographic features include large vegetations, valve insufficiency, paravalvular infection, or ventricular dysfunction. Rx indicates initiation of antibiotic therapy. CTA, electrocardiogram-gated cardiac computed tomography (CT) angiogram; FDG-PET/CT, fluorodeoxyglucose-positron emission tomography CT. ^See text for discussion of these modalities. *(Reproduced with permission from AS Bayer: Diagnosis and management of infective endocarditis and its complications. Circulation 98:2936, 1998, Figure 1.)*

lasting 4–6 weeks. High concentrations of ampicillin plus ceftriaxone or cefotaxime, by expanded binding of penicillin-binding proteins, also kill *E. faecalis* in vitro and in animal models of IE. Nonrandomized comparative studies suggest that high-dose regimens using ampicillin-ceftriaxone appear comparable and less nephrotoxic than penicillin or ampicillin plus gentamicin for treatment of *E. faecalis* (but not *E. faecium*) IE and may also provide effective treatment when strains possess high-level gentamicin resistance. This regimen has been used increasingly to address not only high-level gentamicin-resistant strains but also to minimize nephrotoxicity. Alternatively, if there is a contraindication to an ampicillin-ceftriaxone regimen, shorter 2- to 3-week courses of synergistic gentamicin can be considered. The combinations of vancomycin (or teicoplanin) or gentamicin with ceftriaxone are not bactericidal for *E. faecalis* and are not recommended for treatment of enterococcal IE. If a combination regimen cannot be used due to resistance or toxicity, an 8- to 12-week course of a single cell wall–active agent can be considered, although the patient should be followed carefully for evidence of failure.

Treatment of IE caused by *E. faecium*, which is generally more antibiotic resistant than *E. faecalis* and may be vancomycin resistant, is not well established. Successful treatment of IE caused by vancomycin-resistant enterococci with high-dose daptomycin (10–12 mg/kg IV once daily), often in combination with ampicillin or other β-lactams, has been reported. If the isolate susceptibility allows treatment with penicillin or ampicillin plus gentamicin, this is preferred. These cases should be managed in conjunction with an infectious disease consultant.

Staphylococci Management of *S. aureus* bacteremia and IE in conjunction with infectious disease consultants has been associated with improved outcomes and is recommended. Treatment of staphylococcal IE (Table 133-5) is based on the presence of a prosthetic valve or foreign device, the native valve(s) involved (right vs left side), and the antibiotic susceptibility of the isolate. Penicillin resistance and, except in specific countries, methicillin resistance are widespread among staphylococci. Thus, empirical therapy for possible staphylococcal IE should use a regimen effective against methicillin-resistant organisms. Therapy should be revised to an antistaphylococcal penicillin if the isolate is susceptible to methicillin. Cefazolin is generally considered an alternative β-lactam agent for the treatment of methicillin-susceptible *S. aureus* (MSSA) IE. Ease of administration and reduced adverse events compared to treatment with an antistaphylococcal penicillin have prompted use of cefazolin as a primary agent in this setting. Concerns, however, have been raised about inactivation of cefazolin by type A and C staphylococcal β-lactamases (these do not hydrolyze antistaphylococcal penicillins), resulting in treatment failure in high-inoculum infections. Initiating treatment with an antistaphylococcal penicillin until there is source control and a reduced inoculum and then transitioning to cefazolin should be considered. The addition of gentamicin to a β-lactam antibiotic or vancomycin to enhance therapy for left-sided NVE has not improved survival rates and is associated with nephrotoxicity. Guidelines do not recommend the routine addition of gentamicin, fusidic acid, rifampin, or daptomycin to regimens for MSSA NVE.

For treatment of NVE due to methicillin-resistant *S. aureus* (MRSA), vancomycin, dosed to achieve trough concentrations of 15 μg/mL (or an area under the time-concentration curve/broth microdilution MIC ratio [AUC:MIC] >400 achieved with the assistance of a pharmacist), is recommended, with the caveat that high vancomycin trough concentrations may be associated with nephrotoxicity. Although resistance to vancomycin among staphylococci is rare, reduced vancomycin susceptibility among MRSA strains is increasingly encountered. Isolates with a vancomycin MIC of 4–8 μg/mL have intermediate susceptibility and are referred to as

TABLE 133-5 Antibiotic Treatment for Infective Endocarditis Caused by Common Organisms[a]

ORGANISM(S)	DRUG (DOSE, DURATION)	COMMENTS
Streptococci		**For PVE 6-week regimens are preferred.**
Penicillin-susceptible streptococci, *S. gallolyticus* (MIC ≤0.12 µg/mL)	• Penicillin G (2–3 mU IV q4h for 4 weeks)	Can use ampicillin or amoxicillin (2 g IV q4h) if penicillin is unavailable.
	• Ceftriaxone (2 g once daily for 4 weeks)	Can use ceftriaxone in patients with nonimmediate penicillin allergy.
	• Vancomycin[b] (15 mg/kg IV q12h for 4 weeks)	Use vancomycin for patients with immediate (urticarial) or severe penicillin allergy. Obtain allergy consultation for further evaluation including role of β-lactam desensitization.
	• Penicillin G (2–3 mU IV q4h) *or* ceftriaxone (2 g IV once daily) for 2 weeks *plus* Gentamicin[c] (3 mg/kg daily IV or IM, as a single dose[d] for 2 weeks)	Can use ampicillin or amoxicillin (2 g IV q4h) if penicillin is unavailable. Avoid 2-week regimen when risk of aminoglycoside toxicity is increased and in prosthetic-valve or complicated endocarditis. Penicillin G at a dose of 4 mU IV q4h or ceftriaxone 2 g once daily for 6 weeks both with or without gentamicin during the initial 2 weeks preferred for PVE caused by streptococci with penicillin MICs ≤0.12 µg/mL.
Relatively penicillin-resistant streptococci, *S. gallolyticus* (MIC >0.12 µg/mL and <0.5 µg/mL[e])	• Penicillin G (4 mU IV q4h) *or* ceftriaxone (2 g IV daily) for 4 weeks *plus* Gentamicin[c] (3 mg/kg daily IV or IM, as a single dose[d] for 2 weeks)	Can use ampicillin or amoxicillin (2 g IV q4h) if penicillin is unavailable. Penicillin G at a dose of 4 mU IV q4h or ceftriaxone 2 g once daily for 6 weeks both with gentamicin during the initial 2 weeks preferred for PVE caused by streptococci with penicillin MICs >0.12 µg/mL.
	• Vancomycin[b] as noted above for 4 weeks	Use vancomycin for patients with immediate (urticarial) or severe penicillin allergy. Obtain allergy consultation for further evaluation including role of β-lactam desensitization. Ceftriaxone alone or with gentamicin can be used in patients with nonimmediate β-lactam allergy.
Moderately penicillin-resistant streptococci (MIC, ≥0.5 µg/mL and <8 µg/mL); *Granulicatella*, *Abiotrophia*, or *Gemella* spp.	• Penicillin G (4–5 mU IV q4h) *or* ceftriaxone (2 g IV daily) for 6 weeks *plus* Gentamicin[c] (3 mg/kg daily IV or IM in 2–3 equally divided doses for 6 weeks)	Can use ampicillin or amoxicillin (2 g IV q4h) if penicillin is unavailable.
	• Vancomycin[b] as noted above for 6 weeks	Regimen is preferred by some.
Enterococci[e]		**For PVE, 6-week regimens are preferred.**
	• Ampicillin (2 g IV q4h) *plus* ceftriaxone (2 g IV q12h), both for 6 weeks	Use for *E. faecalis* isolates with or without high-level resistance to gentamicin or for patients at risk for aminoglycoside nephrotoxicity.
	• Penicillin G (4–5 mU IV q4h) for 4–6 weeks *plus* gentamicin[c] (3 mg/kg daily IV or 1 mg/kg IV q8h) for 2–6 weeks	Can treat NVE for 4 weeks if symptoms last <3 months. Treat NVE for 6 weeks if >3 months of symptoms. Can abbreviate gentamicin course in some patients (see text).
	• Ampicillin (2 g IV q4h) for 4–6 weeks *plus* gentamicin[c] (3 mg/kg daily IV or 1 mg/kg IV q8h) for 2–6 weeks	Can use IV amoxicillin in lieu of ampicillin (same dose). Can abbreviate gentamicin course in some patients (see text).
	• Vancomycin[b] (15 mg/kg IV q12h) for 6 weeks *plus* gentamicin[c] (3 mg/kg daily IV or 1 mg/kg IV q8h) for 2–6 weeks	Use vancomycin plus gentamicin only for penicillin-allergic patients (preferable to desensitize to penicillin if immediate [urticarial] allergy; consult allergy) and for isolates resistant to penicillin/ampicillin.
Staphylococci (*S. aureus* and coagulase-negative)		
MSSA infecting native valves (no foreign devices) including complicated right-sided and left-sided endocarditis.	• Nafcillin, oxacillin, *or* flucloxacillin (2 g IV q4h for 4–6 weeks)	Addition of gentamicin is not recommended. For uncomplicated right-sided endocarditis, a 2-week course may be effective (see text).
	• Cefazolin (2 g IV q8h for 4–6 weeks)	Can use cefazolin regimen for patients with nonimmediate penicillin allergy; see text regarding cefazolin vs antistaphylococcal penicillin as primary therapy. Addition of gentamicin not recommended.
	• Vancomycin[b] (15 mg/kg IV q12h for 4–6 weeks)	Only use vancomycin for patients with immediate (urticarial) or severe penicillin allergy until allergy consultation can be obtained for β-lactam desensitization evaluation; addition of gentamicin not recommended.
MRSA infecting native valves (no foreign devices)	• Vancomycin[b] (15 mg/kg IV q8–12h) or daptomycin (8–10 mg/kg daily) for 4–6 weeks	No role for routine use of rifampin (see text). For daptomycin treatment, see text.
MSSA infecting prosthetic valves	• Nafcillin, oxacillin, *or* flucloxacillin (2 g IV q4h for 6–8 weeks) *plus* Gentamicin[c] (1 mg/kg IM or IV q8h for 2 weeks) *plus* • Rifampin[f] (300 mg PO q8h for 6–8 weeks)	Use gentamicin during initial 2 weeks; determine gentamicin susceptibility and await blood culture clearance before initiating rifampin (see text); if patient is highly allergic to penicillin, use regimen for MRSA and obtain allergy consultation; if β-lactam allergy is of the minor nonimmediate type, cefazolin can be substituted for oxacillin, nafcillin, or flucloxacillin.
MRSA infecting prosthetic valves	• Vancomycin[b] (15 mg/kg IV q12h for 6–8 weeks) *plus* Gentamicin[c] (1 mg/kg IM or IV q8h for 2 weeks) *plus* • Rifampin[f] (300 mg PO q8h for 6–8 weeks)	Use gentamicin during initial 2 weeks; determine gentamicin susceptibility and await blood culture clearance before initiating rifampin (see text). Daptomycin (8–10 mg/kg daily) is an alternative to vancomycin.

(*Continued*)

TABLE 133-5 Antibiotic Treatment for Infective Endocarditis Caused by Common Organisms[a] (Continued)

ORGANISM(S)	DRUG (DOSE, DURATION)	COMMENTS
HACEK organisms		**For PVE, 6-week regimens are preferred.**
	• Ceftriaxone (2 g once daily IV for 4 weeks)	
	• Ampicillin/sulbactam (3 g IV q6h for 4 weeks)	Use ampicillin alone (2 g IV q4h) only if β-lactamase production can be excluded. If the isolate is susceptible, ciprofloxacin (500 mg by mouth q12h or 400 mg IV q12h) can be used.
Coxiella burnetii		
	• Doxycycline (100 mg PO q12h) *plus* hydroxychloroquine (200 mg PO q8h), both for at least 18 (native valve) or 24 (prosthetic valve) months	Follow serology to monitor response during treatment (antiphase I IgG and IgA decreased fourfold and IgM antiphase II negative) and thereafter for relapse.
***Bartonella* spp.**		
	• Doxycycline (100 mg q12h PO) for 6 weeks *plus* Gentamicin (1 mg/kg IV q8h for 2 weeks)	If doxycycline is not tolerated, use azithromycin (500 mg PO daily). Some experts recommend that doxycycline be continued for 3–6 months unless all infection is resected surgically.

[a]Regimens adapted from the guidelines of the American Heart Association and the European Society of Cardiology (ESC). Doses of gentamicin, vancomycin, and daptomycin must be adjusted for reduced renal function. Ideal body weight is used to calculate doses of gentamicin and daptomycin per kilogram (men = 50 kg + 2.3 kg per inch over 5 feet; women = 45.5 kg + 2.3 kg per inch over 5 feet). [b]Vancomycin dose is based on actual body weight. Adjust for trough level of 10–15 μg/mL for streptococcal and enterococcal infections and 15–20 μg/mL for staphylococcal infections (see text). [c]Target peak and trough serum concentrations of divided-dose gentamicin 1 h after a 20- to 30-min infusion or IM injection are ~3.5 μg/mL and ≤1 μg/mL, respectively. [d]Netilmicin (4 mg/kg qd, as a single dose) can be used in lieu of gentamicin for streptococcal infection only. [e]Antimicrobial susceptibility must be evaluated; see text. [f]Rifampin increases warfarin and dicumarol requirements for anticoagulation.

Abbreviations: HACEK, *H*aemophilus species, *A*ggregatibacter species, *C*ardiobacterium hominis, *E*ikenella corrodens, and *K*ingella kingae; MIC, minimal inhibitory concentration; MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-susceptible *S. aureus*; NVE, native-valve endocarditis; PVE, prosthetic-valve endocarditis.

vancomycin-intermediate S. aureus (VISA). Isolates with a vancomycin MIC of 2 μg/mL may harbor subpopulations with higher MICs. These isolates, called *heteroresistant VISA* (hVISA), are not detectable by routine susceptibility testing and yet may impair vancomycin effectiveness.

Daptomycin has provided effective alternative treatment for left-sided NVE caused by documented daptomycin-susceptible MRSA and is associated with less nephrotoxicity than vancomycin (although it is associated with myositis and, rarely, eosinophilic pneumonitis). Although it is U.S. Food and Drug Administration (FDA) approved only for right-sided IE at a dose of 6 mg/kg daily, most recommend doses of 8–10 mg/kg daily for treatment of left-sided IE. Because receipt of vancomycin has been associated with emergence of daptomycin nonsusceptibility, caution should be exercised when switching from vancomycin to daptomycin monotherapy in a patient who has received vancomycin without clearing blood cultures. Daptomycin activity against MRSA—even against some daptomycin-nonsusceptible isolates—is enhanced when given in combination with nafcillin or ceftaroline. Case series suggest that high-dose daptomycin combined with nafcillin or ceftaroline, ceftaroline combined with trimethoprim/sulfamethoxazole, or ceftaroline alone (600 mg IV q8h) may be effective salvage treatment for vancomycin-unresponsive MRSA IE and should be considered in patients with sepsis, in those with multifocal sites of infection, or when bacteremia persists for 4 or more days. Eradicable sources of bacteremia should always be addressed; failure of source control is a very common reason for persistent MRSA bacteremia.

MSSA IE that is uncomplicated and limited to the tricuspid or pulmonic valve can often be treated with 2 weeks of oxacillin or nafcillin (but not vancomycin). Prolonged fever (≥5 days) during therapy or multiple septic pulmonary emboli mandate standard-duration therapy. Right-sided MRSA IE is treated for at least 4 weeks with vancomycin or daptomycin (6 mg/kg daily); 2-week courses of therapy are suboptimal. Left-sided staphylococcal IE is treated with a minimum of 6 weeks of therapy.

Staphylococcal PVE is treated with a multidrug regimen for 6–8 weeks (Table 133-5). To achieve long-term bacterial eradication, rifampin, which kills staphylococci embedded in biofilm adherent to foreign material, is considered an essential component of this regimen. Rifampin resistance can emerge during therapy. To prevent emergence of resistance, administration of rifampin should be delayed until initial therapy with two agents (gentamicin plus an antistaphylococcal penicillin or vancomycin selected on the basis of susceptibility testing) has eradicated bacteremia (reduced the inoculum). The isolate's susceptibility to gentamicin or an alternative agent as well as to rifampin should be established before rifampin treatment is begun. The impact of adding rifampin and gentamicin on survival of patients with staphylococcal PVE has not been demonstrated convincingly; thus, it is reasonable to discontinue these agents if patients are experiencing toxicity or drug interactions.

Other Organisms In the absence of meningitis, IE caused by *Streptococcus pneumoniae* isolates with a penicillin MIC of ≤4 μg/mL can be treated with IV penicillin (4 million units IV every 4 h), ceftriaxone (2 g once daily), or vancomycin. Ceftriaxone or vancomycin is preferred for pneumococcal strains with a penicillin MIC of ≥2 μg/mL. If meningitis is suspected, treatment with vancomycin plus ceftriaxone—at the doses advised for meningitis—should be initiated until susceptibility results are known. Definitive therapy should then be selected on the basis of meningitis breakpoints (penicillin MIC, 0.06 μg/mL; ceftriaxone MIC, 0.5 μg/mL). Pneumococcal NVE is treated for 4 weeks and pneumococcal PVE for 6 weeks. *P. aeruginosa* IE is treated with an antipseudomonal cephalosporin and traditionally high doses of tobramycin, and IE caused by Enterobacterales is treated with a β-lactam antibiotic, also traditionally, plus an aminoglycoside, although data substantiating a need for combination therapy for these organisms are limited. Therapy for *Candida* IE consists of a lipid formulation of amphotericin B (5 mg/kg IV daily) with or without flucytosine (25 mg/kg PO q6h) (if using flucytosine, monitor renal function, flucytosine levels, and bone marrow function). Alternatively, a high-dose echinocandin regimen can be used. If there is valve dysfunction or PVE, early surgery is advised, as is long-term (if not indefinite) oral azole suppression. Absent valve dysfunction, medical treatment with long-term oral azole suppression may achieve results comparable to surgical treatment.

Empirical Therapy and Treatment for Culture-Negative IE In designing therapy to be administered before culture results are known or when cultures are truly negative, clinical clues to etiology (e.g., acute vs subacute presentation, NVE, early or late PVE, the patient's predispositions) as well as epidemiologic clues (e.g., region of residence, animal exposure) must be considered. Thus, empirical therapy for acute IE should cover MRSA and in a PWID or for health care–associated NVE potentially antibiotic-resistant

gram-negative bacilli. Treatment with vancomycin plus gentamicin or cefepime, initiated immediately after blood cultures are obtained, covers these organisms as well as many others. For empirical treatment of NVE with a subacute presentation, vancomycin plus ceftriaxone is reasonable. For blood culture–pending PVE, vancomycin, gentamicin, and cefepime should be used if the prosthetic valve has been in place for ≤1 year. Empirical therapy for late PVE (valve in place for >1 year) is similar to that for culture-negative NVE. Therapy is revised once a pathogen has been identified.

In the treatment of blood culture–negative episodes, marantic endocarditis and the antiphospholipid antibody syndrome must be considered. In the absence of prior antibiotic therapy, it is unlikely that infection due to *S. aureus*, CoNS, enterococci, or Enterobacterales will present with negative blood cultures; thus, recommended empirical therapy targets fastidious streptococci, *Abiotrophia*, *Gemella*, *Granulicatella*, the HACEK group, and *Bartonella* species. Pending the availability of diagnostic data, blood culture–negative subacute NVE is treated with vancomycin plus ampicillin-sulbactam (12 g every 24 h) or ceftriaxone; doxycycline (100 mg twice daily) is added for enhanced *Bartonella* coverage. If cultures are negative because of prior antibiotic administration, pathogens likely to be inhibited by the specific prior therapy should be considered.

TAVR-PVE The vast majority of these patients are treated medically with classic PVE antibiotic regimens for the given pathogen. Selection of empirical therapy pending blood culture results similarly parallels that for classic PVE but with recognition that enterococcal infection occurs with increased frequency.

CIED-IE Antimicrobial therapy for CIED-IE (as well as for generator pocket and lead infection) is adjunctive to complete removal of the device. The antimicrobial selected is based on the causative organism and should be used as recommended for NVE (Table 133-5). Bacteremic CIED infection may be complicated by coincident left-sided NVE, PVE, or remote-site infection (e.g., osteomyelitis), which may require modification of antimicrobial therapy. A 4- to 6-week course of IE-targeted therapy is recommended for patients with CIED-IE and for those with bacteremia that continues after device removal. Generator pocket infection without bacteremia is treated with a 10- to 14-day course, some of which can be given orally. In the absence of another source, *S. aureus* bacteremia (and persistent CoNS bacteremia) is likely indicative of CIED-IE or valvular IE and should be investigated and managed accordingly. However, not all bloodstream infections in these patients indicate IE. If evidence suggesting CIED-IE is lacking, bloodstream infection due to gram-negative bacilli, streptococci, and enterococci species may not indicate CIED-IE and can be treated with antimicrobial therapy for the alternative diagnosis. However, in these patients, relapse after antimicrobial therapy increases the likelihood of CIED-IE and warrants treatment as such. Attempted salvage of an infected CIED with antibiotics alone and long-term suppressive therapy is usually unsuccessful and should be reserved for patients whose devices cannot be removed or who decline removal. Careful follow-up is required.

Partial Oral Antibiotic Treatment of IE Recent studies have examined the use of oral antibiotics to complete therapy in patients who have received an initial course of intravenous treatment (with or without cardiac surgery). A noninferiority, multicenter, randomized study found mortality among patients with left-sided IE caused by streptococci, enterococci, and staphylococci who received partial oral treatment comparable to that of patients who were treated intravenously for the full course of therapy (6.5% and 7.5%, respectively). Four hundred clinically stable patients (20% of the population screened) who had received at least 10 days of parenteral therapy (or at least 7 days after surgery) were enrolled. IE was caused by streptococci (49%), enterococci (24%), and MSSA (22%); no patients had MRSA. Of note, the median duration of intravenous treatment before the switch to oral agents was 16 days (interquartile range, 13–23 days); thus, some patients may have been effectively cured by intravenous therapy with or without surgery prior to transition to oral therapy. The results in this highly selected and monitored cohort with relatively small numbers of patients with enterococcal and *S. aureus* IE may not be generalizable to most patients with IE. If oral therapy is considered in patients who meet the criteria in the studied population, the decision on agents and duration should be made in consultation with infectious diseases.

Use of Long-Acting Lipoglycopeptide Agents Dalbavancin, a lipoglycopeptide with a long half-life allowing for infrequent dosing, is FDA approved for treatment of skin and soft tissue infections. Only limited data are available supporting its use in the treatment of IE, particularly due to *S. aureus*, with most being case series of patients who received dalbavancin upon discharge from the hospital after having received several weeks of active intravenous therapy. Consideration can be given to using this agent in patients who are clinically stable with negative blood cultures and in patients with complicated IE who are not candidates to continue hospitalization or to transition to outpatient parenteral therapy, in consultation with infectious diseases.

Outpatient Parenteral Antimicrobial Therapy Fully compliant, clinically stable patients who are no longer bacteremic, are not febrile, and have no clinical or echocardiographic findings that suggest an impending complication may complete IV therapy as outpatients. Careful follow-up and a stable residential setting are necessary, as are predictable IV access and use of antimicrobial agents that are stable in solution and less frequently associated with severe adverse effects. Recommended regimens should not be compromised to accommodate outpatient therapy.

Monitoring Antimicrobial Therapy Antibiotic-related adverse events occur in 25–40% of IE patients and commonly arise after several weeks of therapy. Blood tests to detect renal, hepatic, and hematologic toxicity should be performed periodically. Serum concentrations of aminoglycosides and vancomycin should be monitored and doses adjusted to optimize treatment and minimize toxicity.

Control of peripheral sites of infection—source control—should be addressed promptly. Blood cultures should be repeated daily until sterile in patients with IE due to *S. aureus* or difficult-to-treat organisms and rechecked if there is recrudescent fever. Blood cultures become sterile after 2 days of appropriate therapy when infection is caused by viridans streptococci, *E. faecalis*, or HACEK organisms. In MSSA IE, β-lactam therapy results in sterile cultures in 3–5 days, whereas in MRSA IE, the duration of bacteremia is often longer with vancomycin or daptomycin treatment. MRSA bacteremia persisting despite an appropriate dosage of vancomycin or daptomycin may indicate emergence of reduced susceptibility in the infecting strain and point to a need for alternative therapy. When fever persists for 7 days despite appropriate antibiotic therapy, patients should be evaluated further for paravalvular abscess, extracardiac abscesses (spleen, kidney), or complications (embolic events). Recrudescent fever raises the possibility of these complications but also of drug reactions or complications of hospitalization. It is advisable to obtain follow-up echocardiography after the completion of therapy to assess valvular function. Of note, vegetations become smaller with effective therapy; however, 3 months after cure, 50% are unchanged, and 25% each are slightly larger or smaller.

Antithrombotic Therapy Because patients with IE are at risk for hemorrhagic transformation of embolic strokes and for intracerebral hemorrhage from septic arteritis or ruptured mycotic aneurysms, initiation of antithrombotic (anticoagulant or antiplatelet) therapy requires careful consideration of the risks and benefits. Antithrombotic therapy can render such bleeding catastrophic. Neither anticoagulant nor antiplatelet therapy reduces the risk of emboli in patients with NVE, and thus, such treatment is not

TABLE 133-6 Indications for Cardiac Surgical Treatment in Patients with Endocarditis

Surgery Required for Optimal Outcome
Native-valve or prosthetic-valve endocarditis
Moderate or severe congestive heart failure or shock due to valve dysfunction
Paravalvular extension of infection with abscess, fistula, or heart block
Persistent bacteremia without an extracardiac cause despite 7–10 days of optimal antimicrobial therapy
Lack of effective antimicrobial therapy (e.g., fungal [see text regarding *Candida* spp.], *Brucella*, multidrug-resistant gram-negative bacillary endocarditis)
Prosthetic-valve endocarditis
Partially dehisced unstable prosthetic valve
Surgery to Be Strongly Considered for Improved Outcome[a]
Prosthetic-valve endocarditis
S. aureus infection with intracardiac complications
Relapse after optimal antimicrobial therapy
Native-valve endocarditis
Large (>10-mm) hypermobile vegetation, particularly with prior systemic embolus and significant valve dysfunction[b]
Very large (>30-mm) vegetation
Persistent unexplained fever (≥10 days) in blood culture–negative endocarditis
Poorly responsive or relapsed endocarditis due to highly antibiotic-resistant enterococci or gram-negative bacilli

[a]Carefully consider surgery. Multiple findings are often combined to justify surgery.
[b]In the group with an estimated low cardiac-surgery mortality risk (see text).

indicated for that purpose. However, patients with IE may have coexisting conditions wherein anticoagulation is indicated. Thus, in the absence of a contraindication (i.e., no clinical or imaging evidence of a recent large embolic stroke, intracerebral hemorrhage, or mycotic aneurysm), anticoagulant therapy is given to patients who have a mechanical prosthetic valve, atrial fibrillation with either mitral stenosis or a CHA_2DS_2-VASc score ≥2, or deep-vein thrombophlebitis. Most experts use unfractionated or low-molecular-weight heparin for ease of reversal. Anticoagulant therapy should be reversed, at least temporarily, in most patients who have had an acute ischemic stroke or an intracerebral hemorrhage.

SURGICAL TREATMENT

The indications for cardiac surgical treatment of IE **(Table 133-6)** have been derived from observational studies and expert opinion. The strength of specific indications varies; thus, the risks and benefits as well as the timing of surgery must be individualized **(Table 133-7)**. These are best weighed by a team that includes cardiologists, cardiac surgeons, infectious disease physicians, and neurologists if there have been neurologic complications. Between 25% and 40% of patients with left-sided IE undergo cardiac surgery during active infection, with slightly higher surgery rates for PVE than NVE. The benefit of surgery has been assessed primarily in retrospective studies comparing populations of medically and surgically treated patients matched for the necessity of surgery, with adjustments for predictors of death (comorbidities) and the timing of surgical intervention (a correction for survival bias). Although study results vary, surgery for NVE based on current indications appears to convey a significant survival benefit (27–55%), which is greatest among those with the most pressing indications. The survival benefit becomes more apparent after ≥6 months. The effect of surgery for PVE is more nuanced, with survival benefits accruing largely to those with intracardiac complications. Of note, surgery itself carries mortality risks that may offset survival benefits in patients with lesser indications. Among patients with TAVR-PVE, 50–80% are reported to have an indication for surgical intervention—yet because of high pre-TAVR estimated operative mortality, <15% undergo surgery. Some patients with significant aortic regurgitation after medical cure of infection have undergone valve-in-valve redo-TAVR.

Indications • **Congestive Heart Failure** Moderate to severe refractory CHF caused by new or worsening valve dysfunction or intracardiac fistulae is the major indication for cardiac surgery. Surgery can relieve functional stenosis due to large vegetations or restore competence to damaged regurgitant valves by repair or replacement. At 6–12 months of follow-up of patients with left-sided NVE or PVE and moderate to severe CHF due to valve

TABLE 133-7 Timing of Cardiac Surgical Intervention in Patients with Endocarditis

	INDICATION FOR SURGICAL INTERVENTION	
TIMING	**STRONG SUPPORTING EVIDENCE**	**CONFLICTING EVIDENCE, BUT MAJORITY OF OPINIONS FAVOR SURGERY**
Emergent (same day)	Valve dysfunction with pulmonary edema or cardiogenic shock Acute aortic regurgitation plus preclosure of mitral valve Sinus of Valsalva abscess ruptured into right heart Rupture into pericardial sac	
Urgent (within 1–2 days)	Valve obstruction by vegetation Unstable (dehisced) prosthesis Acute aortic or mitral regurgitation with heart failure (New York Heart Association class III or IV) Septal perforation Paravalvular extension of infection with or without new electrocardiographic conduction system changes Lack of effective antibiotic therapy	Vegetation diameter >10 mm plus severe but not urgent aortic or mitral valve dysfunction[a] Major embolus plus persisting large vegetation (>10 mm) Mobile vegetation >30 mm
Elective (earlier usually preferred)	Progressive paravalvular prosthetic regurgitation Valve dysfunction plus persisting infection after ≥7–10 days of antimicrobial therapy Fungal (mold) endocarditis	Staphylococcal prosthetic-valve endocarditis with intracardiac complications Early prosthetic-valve endocarditis (≤2 months after valve surgery) *Candida* spp. endocarditis (see text) Antibiotic-resistant organisms

[a]Supported by a single-institution randomized trial showing benefit from early surgery. Implementation requires clinical judgment. If surgery is elected, it must be done early (see text).

Source: Reproduced with permission from L Olaison, G Pettersson: Current best practices and guidelines: Indications for surgical intervention in infective endocarditis. Infect Dis Clin North Am 16:453, 2002.

dysfunction, survival is significantly improved among those treated surgically compared with those treated medically. The survival benefit with surgery is inversely related to the severity of preoperative CHF; thus, surgery should not be delayed in the face of deteriorating hemodynamics.

Paravalvular Infection This complication, which is most common with aortic valve infection, occurs in 10–15% of patients with NVE and in 45–60% of those with PVE. It is suggested clinically by persistent unexplained fever during appropriate therapy, new electrocardiographic conduction disturbances, or pericarditis. TEE with color Doppler is the test of choice to detect paravalvular abscesses (sensitivity, ≥85%). Occasionally, three-dimensional TEE, ECG-gated CTA, or FDG-PET/CT demonstrates paravalvular infection not detected by TEE. For optimal outcome, paravalvular infection requires surgery, especially when fever persists, fistulae develop, prostheses are dehisced and unstable, or infection relapses after appropriate treatment. Cardiac rhythm must be monitored since high-grade heart block may require insertion of a pacemaker.

Uncontrolled Infection Continued positive blood cultures or otherwise unexplained persistent fevers despite optimal antibiotic therapy may reflect uncontrolled infection that warrants surgery. Surgical treatment is also advised for IE caused by organisms against which effective antimicrobial therapy is lacking (e.g., yeasts, molds, *P. aeruginosa*, other highly antibiotic-resistant bacteria, *Brucella* species).

S. *aureus* IE The mortality rate for *S. aureus* PVE exceeds 50% with medical treatment and may be reduced with surgical treatment. Nevertheless, surgery is not routinely advised for uncomplicated *S. aureus* PVE. Rather, survival benefits are most likely in those with paravalvular infection, dysfunctional valves, and CHF. Surgical treatment of *S. aureus* NVE should be guided by the standard indications. Isolated tricuspid-valve *S. aureus* IE, even with persistent fever, rarely requires surgery.

Prevention of Systemic Emboli Persisting morbidity and/or death may result from cerebral or coronary artery emboli. Antithrombotic therapy does not prevent systemic emboli in NVE. The frequency of embolization decreases rapidly with effective antimicrobial therapy. Thus, if emboli are to be prevented through surgical intervention, surgery must occur very early. Vegetation characteristics defined echocardiographically can identify patients at high risk of embolization but do not identify those patients in whom surgery to prevent emboli will increase survival. In a small randomized trial in patients who were at low risk of surgery-related mortality and had large vegetations (>10 mm) and significant valve dysfunction, emboli were prevented by early surgery (≤48 h after diagnosis), but there was no survival benefit. Rarely is prevention of emboli the sole indication for surgery; more often, this may be an additional benefit of early surgery for other indications. Valve repair, with the consequent avoidance of a prosthesis, improves the benefit-to-risk ratio of surgery performed to eliminate vegetations.

CIED-IE Removal of all hardware is recommended for patients with established CIED-IE as well as for pocket or intracardiac lead infection. Percutaneous lead extraction is preferred; if hardware remains after attempted percutaneous extraction, surgical removal should be considered. With lead vegetations >2 cm, there is a risk of a pulmonary embolism; nevertheless, the need for CIED removal surgically is unclear. Removal of the infected CIED during the initial hospitalization is associated with increased 30-day and 1-year survival rates over those attained with antibiotic therapy and device retention. The CIED, if needed, can be reimplanted at a new site after at least 10–14 days of effective antimicrobial therapy. CIEDs should be replaced when patients undergo surgery for IE.

Timing of Cardiac Surgery With life-threatening indications for surgery (valve dysfunction and severe CHF, perivalvular abscess, major prosthesis dehiscence), surgery during the initial days of therapy is associated with greater survival than later surgery. With less compelling indications, surgery may reasonably be delayed to allow further treatment as well as improvement in overall health (Table 133-7). Recrudescent IE on a newly implanted prosthetic valve follows surgery for active NVE and PVE in 2% and 6–15% of patients, respectively. These frequencies do not justify the increased mortality risk associated with delaying surgery in patients with severe heart failure, valve dysfunction, and uncontrolled infections. Delay is justified when infection and CHF are controlled with medical therapy.

Neurologic complications of IE may be exacerbated during cardiac surgery. The risk of neurologic deterioration is related to the type and severity of the preoperative neurologic complication and the interval between the complication and surgery. In a nonobtunded patient with an ischemic stroke and hemorrhage excluded by imaging, cardiac surgery, if urgent, should be performed early because risk of hemorrhagic conversion or other neurologic side effects is low. In patients with intracranial hemorrhage and need for urgent surgery, early surgery should be pursued as long as the patient is expected to have meaningful recovery. Similar rates of postoperative intracranial hemorrhage and no difference in mortality have been observed in patients with and without preoperative intracranial hemorrhage. Nonurgent cardiac surgery should be delayed for 2–3 weeks after a large nonhemorrhagic embolic infarction and for 4 weeks after a significant cerebral hemorrhage. A ruptured mycotic aneurysm should be treated before cardiac surgery.

Antibiotic Therapy after Cardiac Surgery Organisms have been detected on Gram stain—or their DNA has been detected by PCR—in excised valves from 45% of patients who have completed the recommended therapy for IE. However, organisms, most of which are unusual or antibiotic resistant, are rarely cultured from these valves. Detection of organisms or their DNA does not necessarily indicate antibiotic failure; in fact, relapse after surgery for active IE is uncommon. Thus, in uncomplicated NVE caused by susceptible organisms, the duration of preoperative plus postoperative treatment should equal the total duration of recommended therapy. For IE complicated by perivalvular abscess, partially treated PVE, or valves culture-positive for the original organism, a full course of therapy should be given postoperatively.

Treatment of IE in PWID PWID should be treated according to the standard guidelines for antibiotic selection and surgical intervention. Additionally, OUD must be recognized as an ongoing predisposition for IE and treated; this includes medication-assisted therapy that is initiated during hospitalization and continued without delay upon discharge. Addressing OUD significantly increases completion of antibiotic therapy, decreases resumption of injection drug use, and decreases recurrent IE and requirement for cardiac surgery.

Extracardiac Complications Splenic abscess develops in 3–5% of patients with IE. Effective therapy requires either image-guided percutaneous drainage or splenectomy. Mycotic aneurysms occur in 2–15% of IE patients; one-half of these cases involve the cerebral arteries and present as headaches, focal neurologic symptoms, or hemorrhage. Cerebral aneurysms should be monitored by angiography. Some will resolve with effective antimicrobial therapy, but those that have leaked or persist or enlarge should be treated surgically, if possible. Extracerebral aneurysms present as local pain, a mass, local ischemia, or bleeding; these are treated surgically.

OUTCOME

IE is a heterogeneous disease that occurs in extremely heterogeneous patient populations. Adverse outcomes are associated with older age, severe comorbid conditions and diabetes, delayed diagnosis, involvement of prosthetic valves or the aortic valve, an invasive (*S. aureus*) or antibiotic-resistant (*P. aeruginosa*, yeast) pathogen, intracardiac and major neurologic complications, and health care–associated infection.

TABLE 133-8 Antibiotic Regimens for Prophylaxis of Endocarditis in Adults with High-Risk Cardiac Lesions[a,b]

A. Standard oral regimen
Amoxicillin: 2 g PO 1 h before procedure
B. Inability to take oral medication
Ampicillin: 2 g IV or IM within 1 h before procedure
C. Penicillin allergy
1. Cephalexin[c]: 2 g PO 1 h before procedure
2. Clarithromycin or azithromycin: 500 mg PO 1 h before procedure
3. Doxycycline: 100 mg PO 1 h before procedure
D. Penicillin allergy, inability to take oral medication
Cefazolin[c] or ceftriaxone[c]: 1 g IV or IM 30 min before procedure

[a]Dosing for children: for amoxicillin, ampicillin, cephalexin, or cefadroxil, use 50 mg/kg PO; cefazolin, 25 mg/kg IV; clindamycin, 20 mg/kg PO or 25 mg/kg IV; clarithromycin, 15 mg/kg PO; and vancomycin, 20 mg/kg IV. [b]For high-risk lesions, see Table 133-9. Prophylaxis is not advised for other lesions. [c]Do not use cephalosporins in patients with immediate hypersensitivity (urticaria, angioedema, anaphylaxis) to penicillin.

Source: Table created using the guidelines published by the American Heart Association and the European Society of Cardiology (W Wilson et al: Circulation 116:1736, 2007; W Wilson et al: Circulation 143:e963, 2021; and G Habib et al: Eur Heart J 30:2369, 2009).

Death or poor outcome often is related not to failure of antibiotic therapy but rather to the interactions of comorbidities and IE-related end-organ complications. In developed countries, overall survival rates are 80–85%; however, rates vary considerably among subpopulations of IE patients. The outcome for a given patient depends on that individual's infection, the complexity of required therapy, and preexisting comorbidities. About 85–90% of patients with NVE caused by viridans streptococci, HACEK organisms, or enterococci (susceptible to synergistic therapy) survive. For *S. aureus* NVE in patients who do not inject drugs, survival rates are 55–70%; rates are 85–90% among PWID. However, 1-year mortality rises to 20–30% among PWID if substance use disorder is not successfully addressed. PVE beginning within 2 months after valve replacement results in mortality rates of 40–50%, whereas rates are only 10–20% in late-onset cases. In the elderly population with TAVR-PVE the in-hospital mortality is 35–50% and increases to 60–75% at 1 year. Crude survival rates after successful treatment of IE generally are 80–90% and 70–80% at 1 and 2 years, respectively.

PREVENTION

Prevention of IE has been a goal of clinical practice; however, the evidence establishing benefit from *antibiotic prophylaxis for IE* is insufficient to recommend it as a widespread standard of care. The American Heart Association and the European Society of Cardiology recommend limiting prophylactic antibiotics **(Table 133-8)** to only patients at highest risk for severe morbidity or death from IE **(Table 133-9)**.

TABLE 133-9 High-Risk Cardiac Lesions for Which Endocarditis Prophylaxis Is Advised Before Dental Procedures

Prosthetic heart valves or material
Left ventricular assist devices or implantable heart
Prior endocarditis
Unrepaired cyanotic congenital heart disease, including palliative shunts or conduits
Completely repaired congenital heart defects during the 6 months after repair
Repaired congenital heart disease with residual defects adjacent to prosthetic material
Surgical or transcatheter pulmonary artery valve or conduit placement
Valvulopathy developing after cardiac transplantation

Source: Table created using the guidelines published by the American Heart Association and the European Society of Cardiology (W Wilson et al: Circulation 116:1736, 2007; W Wilson et al: Circulation 143:e963, 2021; and G Habib et al: Eur Heart J 30:2369, 2009).

In at-risk patients, maintaining good dental hygiene is recommended, and antibiotic prophylaxis is recommended only when there is manipulation of gingival tissue or the periapical region of the teeth or perforation of the oral mucosa (including with respiratory tract surgery). Recent studies suggest that severe adverse events related to amoxicillin prophylaxis are exceedingly rare; however, clindamycin prophylaxis has been associated with low but significant rates of fatal and nonfatal adverse reactions with *Clostridioides difficile* infection. Consequently, the American Heart Association now recommends against the use of clindamycin for prophylaxis. Although prophylaxis is not advised for patients undergoing gastrointestinal or genitourinary tract procedures, genitourinary tract infections (or skin infection) should be treated before or when these sites undergo procedures.

In patients with aortic or mitral valve regurgitation or a prosthetic valve, treatment of acute Q fever for 12 months with doxycycline plus hydroxychloroquine (see Table 133-4) is highly effective in preventing *C. burnetii* IE.

134 Infections of the Skin, Muscles, and Soft Tissues

Dennis L. Stevens, Amy E. Bryant

Skin and soft tissue infections occur in all races, all ethnic groups, and all geographic locations, although some have unique geographic niches. In modern times, the frequency and severity of some skin and soft tissue infections have increased for several reasons. First, microbes are rapidly disseminated throughout the world via efficient air travel, acquiring genes for virulence factors and antibiotic resistance. Second, natural disasters, such as earthquakes, tsunamis, tornadoes, and hurricanes, appear to be increasing in frequency, and the injuries sustained during these events commonly cause major skin and soft tissue damage that predisposes to infection. Third, trauma and casualties resulting from combat and terrorist activities can markedly damage or destroy tissues and provide both endogenous and exogenous pathogens with ready access to deeper structures. Unfortunately, because the marvels of modern medicine may not be available during human-instigated and natural disasters, primary treatment may be delayed and the likelihood of severe infection and death increased.

ANATOMIC RELATIONSHIPS: CLUES TO THE DIAGNOSIS OF SOFT TISSUE INFECTIONS

Skin and soft tissue infections have been common human afflictions for centuries. However, between 2000 and 2004, hospital admissions for these infections rose by 27%, a remarkable increase that was attributable largely to the emergence of the USA300 clone of methicillin-resistant *Staphylococcus aureus* (MRSA). This chapter provides an anatomic approach to understanding the types of soft tissue infections and the diverse microbes responsible.

Protection against infection of the epidermis depends on the mechanical barrier afforded by the stratum corneum since the epidermis itself is devoid of blood vessels **(Fig. 134-1)**. Disruption of this layer by burns or bites, abrasions, foreign bodies, primary dermatologic disorders (e.g., herpes simplex, varicella, ecthyma gangrenosum), surgery, or vascular or pressure ulcers allows penetration of bacteria to the deeper structures. Similarly, the hair follicle can serve as a portal either for components of the normal flora (e.g., *Staphylococcus*) or for extrinsic bacteria (e.g., *Pseudomonas* in hot-tub folliculitis). Intracellular infection of the squamous epithelium with vesicle formation may arise from cutaneous inoculation, as in infection with herpes simplex virus (HSV) type 1; from the dermal capillary plexus, as in varicella and

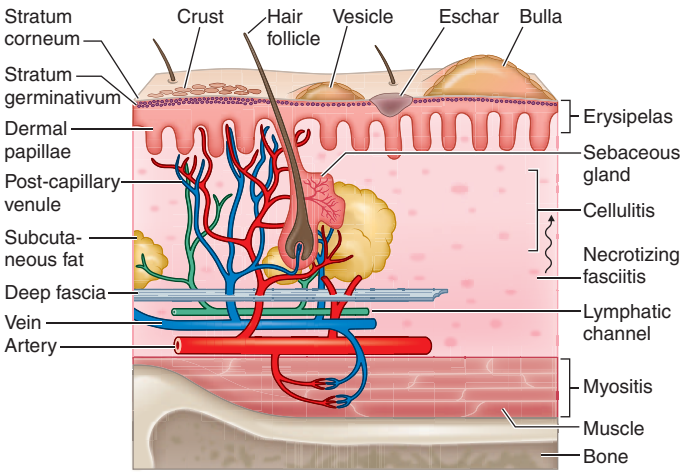

FIGURE 134-1 Structural components of the skin and soft tissues, superficial infections, and infections of the deeper structures. The rich capillary network beneath the dermal papillae plays a key role in the localization of infection and in the development of the acute inflammatory reaction.

infections due to other viruses associated with viremia; or from cutaneous nerve roots, as in herpes zoster. Bacteria infecting the epidermis, such as *Streptococcus pyogenes*, may be translocated laterally to deeper structures via lymphatics, an event that results in the rapid superficial spread of erysipelas. Later, engorgement or obstruction of lymphatics causes flaccid edema of the epidermis, another characteristic of erysipelas.

The rich plexus of capillaries beneath the dermal papillae provides nutrition to the stratum germinativum, and physiologic responses of this plexus produce important clinical signs and symptoms. For example, infective vasculitis of the plexus results in petechiae, Osler nodes, Janeway lesions, and palpable purpura, which, if present, are important clues to the existence of endocarditis **(Chap. 133)**. In addition, metastatic infection within this plexus can result in cutaneous manifestations of disseminated fungal infection **(Chap. 222)**, gonococcal infection **(Chap. 161)**, *Salmonella* infection **(Chap. 171)**, *Pseudomonas* infection (i.e., ecthyma gangrenosum; **Chap. 170**), meningococcemia **(Chap. 160)**, and staphylococcal infection **(Chap. 152)**. The plexus also provides bacteria with access to the circulation, thereby facilitating local spread or bacteremia. The postcapillary venules of this plexus are a prominent site of polymorphonuclear leukocyte sequestration, diapedesis, and chemotaxis to the site of cutaneous infection.

Amplification of these physiologic mechanisms by excessive levels of cytokines or bacterial toxins causes leukostasis, venous occlusion, and pitting edema. Edema with purple bullae, ecchymosis, and cutaneous anesthesia suggests loss of vascular integrity and necessitates exploration of the deeper structures for evidence of necrotizing fasciitis or myonecrosis. An early diagnosis requires a high level of suspicion in instances of unexplained fever and of pain and tenderness in the soft tissue, even in the absence of acute cutaneous inflammation.

Table 134-1 indicates the chapters in which the infections described below are discussed in greater detail. Many of these infections are illustrated in the chapters cited or in **Chap. A1**.

INFECTIONS ASSOCIATED WITH VESICLES

(Table 134-1) Vesicle formation due to infection is caused by viral proliferation within the epidermis. In varicella and variola, viremia precedes the onset of a diffuse centripetal rash that progresses from macules to vesicles, then to pustules, and finally to scabs over the course of 1–2 weeks. Vesicles of varicella have a "dewdrop" appearance and develop in crops randomly about the trunk, extremities, and face over 3–4 days. Herpes zoster occurs in a single dermatome; the appearance of vesicles is preceded by pain for several days. Zoster may occur in persons of any age but is most common among immunosuppressed individuals and elderly patients, whereas most cases of varicella occur in young children. Vesicles due to HSV are found on or around the lips (HSV-1) or genitals (HSV-2) but also may appear on the head and neck of young wrestlers (herpes gladiatorum) or on the digits of health care workers (herpetic whitlow). Recurrent herpes labialis (HSV-1) and herpes genitalis (HSV-2) commonly follow primary infection. Coxsackievirus A16 characteristically causes vesicles on the hands, feet, and mouth of children. Orf is caused by a DNA virus related to smallpox virus and infects the fingers of individuals who work around goats and sheep. Molluscum contagiosum virus induces flaccid vesicles on the skin of healthy and immunocompromised individuals. Although variola (smallpox) in nature was eradicated as of 1977, postmillennial terrorist events have renewed interest in this devastating infection **(Chap. S4)**. Viremia beginning after an incubation period of 12 days is followed by a diffuse maculopapular rash, with rapid evolution to vesicles, pustules, and then scabs. Secondary cases can occur among close contacts.

Rickettsialpox begins after mite-bite inoculation of *Rickettsia akari* into the skin. A papule with a central vesicle evolves to form a 1- to 2.5-cm painless crusted black eschar with an erythematous halo and proximal adenopathy. While more common in the northeastern United States and Ukraine in 1940–1950, rickettsialpox has recently been described in Ohio, Arizona, and Utah. Blistering dactylitis is a painful, vesicular, localized *S. aureus* or group A streptococcal infection of the pulps of the distal digits of the hands.

TABLE 134-1 Skin and Soft Tissue Infections

LESION, CLINICAL SYNDROME	INFECTIOUS AGENT(S)	SEE ALSO CHAP(S).
Vesicles		
Smallpox	Variola virus	S4
Chickenpox	Varicella-zoster virus	198
Shingles (herpes zoster)	Varicella-zoster virus	198
Cold sores, herpetic whitlow, herpes gladiatorum	Herpes simplex virus	197
Hand-foot-and-mouth disease	Coxsackievirus A16	210
Orf	Parapoxvirus	201
Molluscum contagiosum	Molluscum contagiosum poxvirus	201
Rickettsialpox	*Rickettsia akari*	192
Blistering distal dactylitis	*Staphylococcus aureus* or *Streptococcus pyogenes*	152, 153
Bullae		
Staphylococcal scalded-skin syndrome	*S. aureus*	152
Necrotizing fasciitis	*S. pyogenes*, *Clostridium* spp., mixed aerobes and anaerobes	153, 159, 182
Gas gangrene	*Clostridium* spp.	159
Halophilic *Vibrio*	*Vibrio vulnificus*	173
Crusted lesions		
Bullous impetigo/ecthyma	*S. aureus*	152
Impetigo contagiosa	*S. pyogenes*	153
Ringworm	Superficial dermatophyte fungi	225
Sporotrichosis	*Sporothrix schenckii*	225
Histoplasmosis	*Histoplasma capsulatum*	218
Coccidioidomycosis	*Coccidioides immitis*	219
Blastomycosis	*Blastomyces dermatitidis*	220
Cutaneous leishmaniasis	*Leishmania* spp.	233
Cutaneous tuberculosis	*Mycobacterium tuberculosis*	183
Nocardiosis	*Nocardia asteroides*	179
Folliculitis		
Furunculosis	*S. aureus*	152
Hot-tub folliculitis	*Pseudomonas aeruginosa*	170
Swimmer's itch	*Schistosoma* spp.	241
Acne vulgaris	*Propionibacterium acnes*	60
Papular and nodular lesions		
Fish-tank or swimming-pool granuloma	*Mycobacterium marinum*	185
Creeping eruption (cutaneous larva migrans)	*Ancylostoma braziliense*	238
Dracunculiasis	*Dracunculus medinensis*	240
Cercarial dermatitis	*Schistosoma mansoni*	241
Verruca vulgaris	Human papillomaviruses 1, 2, 4	203
Condylomata acuminata (anogenital warts)	Human papillomaviruses 6, 11, 16, 18	203
Onchocerciasis nodule	*Onchocerca volvulus*	240
Cutaneous myiasis	*Dermatobia hominis*	472
Verruca peruana	*Bartonella bacilliformis*	177
Cat-scratch disease	*Bartonella henselae*	177
Lepromatous leprosy	*Mycobacterium leprae*	184
Secondary syphilis (papulosquamous and nodular lesions, condylomata lata)	*Treponema pallidum*	187
Tertiary syphilis (nodular gummatous lesions)	*T. pallidum*	187
Ulcers with or without eschars		
Anthrax	*Bacillus anthracis*	S4
Ulceroglandular tularemia	*Francisella tularensis*	175, S4
Bubonic plague	*Yersinia pestis*	176, S4
Buruli ulcer	*Mycobacterium ulcerans*	185
Leprosy	*M. leprae*	184
Cutaneous tuberculosis	*M. tuberculosis*	183
Chancroid	*Haemophilus ducreyi*	162
Primary syphilis	*T. pallidum*	187
Erysipelas	*S. pyogenes*	153
Cellulitis	*Staphylococcus* spp., *Streptococcus* spp., various other bacteria	Various
Necrotizing fasciitis		
Streptococcal gangrene	*S. pyogenes*	153
Fournier gangrene	Mixed aerobic and anaerobic bacteria	182
Staphylococcal necrotizing fasciitis	Methicillin-resistant *S. aureus*	152
Myositis and myonecrosis		
Pyomyositis	*S. aureus*	152
Streptococcal necrotizing myositis	*S. pyogenes*	153
Gas gangrene	*Clostridium* spp.	159
Nonclostridial (crepitant) myositis	Mixed aerobic and anaerobic bacteria	182
Synergistic nonclostridial anaerobic myonecrosis	Mixed aerobic and anaerobic bacteria	182

The recent spike in mpox (formerly monkeypox virus; MPXV) **(Chap. 201)** cases has raised concerns due to its clinical resemblance to smallpox in terms of symptom onset, timing of rash occurrence, and rash distribution. MPXV infection is generally less severe than smallpox in terms of complication rate and levels of scarification. The case fatality rate (1–10%) is also less than that of smallpox. Though largely endemic in West and Central Africa, cases have recently emerged in at least 10 other African countries. In addition, cases have been reported in Israel, the United Kingdom, and in six midwestern states of the United States. Most non-African cases are associated with tourism to endemic African countries or with exposure to small mammals imported from such areas. However, human-to-human disease transmission was clearly documented in a British health care worker who attended a patient that had acquired the infection during a trip to Nigeria. Most patients are in lower age groups (<40 years) due to a lack cross-protective immunity, having been born after discontinuation of the smallpox eradication campaign in the 1980s. This finding heightens the concern for potential global disease spread.

INFECTIONS ASSOCIATED WITH BULLAE

(Table 134-1) Staphylococcal scalded-skin syndrome (SSSS) in neonates is caused by a toxin (exfoliatin) from phage group II *S. aureus*. SSSS must be distinguished from toxic epidermal necrolysis (TEN), which occurs primarily in adults, is drug-induced, and is associated with a higher mortality rate. Punch biopsy with frozen section is useful in making this distinction since the cleavage plane is the stratum corneum in SSSS and the stratum germinativum in TEN (Fig. 134-1). Treatment with intravenous immune globulin plus corticosteroids may reduce recovery time and improve prognosis in patients with TEN. Necrotizing fasciitis and gas gangrene also induce bulla formation (see "Necrotizing Fasciitis," below). Halophilic *Vibrio* infection can be as aggressive and fulminant as necrotizing fasciitis; a helpful clue in its diagnosis is a history of exposure to waters of the Gulf of Mexico or the Atlantic seaboard or (in a patient with cirrhosis) the ingestion of raw seafood. The etiologic organism (*Vibrio vulnificus*) is highly susceptible to tetracycline.

INFECTIONS ASSOCIATED WITH CRUSTED LESIONS

(Table 134-1) Impetigo contagiosa is caused by *S. pyogenes*, and bullous impetigo is due to *S. aureus*. Both skin lesions may have an early bullous stage but then appear as thick crusts with a golden-brown color. Epidemics of impetigo caused by MRSA have been reported. Streptococcal lesions are most common among children 2–5 years of age, and epidemics may occur in settings of poor hygiene, particularly among children in lower socioeconomic settings in tropical climates. It is important to recognize impetigo contagiosa because of its relationship to poststreptococcal glomerulonephritis. Rheumatic fever is not a complication of skin infection caused by *S. pyogenes*. Superficial dermatophyte infection (ringworm) can occur on any skin surface, and skin scrapings with KOH staining are diagnostic. Primary infections with dimorphic fungi such as *Blastomyces dermatitidis* and *Sporothrix schenckii* can initially present as crusted skin lesions resembling ringworm. Disseminated infection with *Coccidioides immitis* can also involve the skin, and biopsy and culture should be performed on crusted lesions when the patient is from an endemic area. Crusted nodular lesions caused by *Mycobacterium chelonae* have been described in HIV-seropositive patients.

FOLLICULITIS

(Table 134-1) Hair follicles serve as portals for a number of bacteria, although *S. aureus* is the most common cause of localized folliculitis. Sebaceous glands empty into hair follicles and ducts and, if these portals are blocked, form sebaceous cysts that may resemble staphylococcal abscesses or may become secondarily infected. Inflammation of sweat glands (hidradenitis suppurativa) also can mimic infection of hair follicles, particularly in the axillae, but new treatments with potent anti-inflammatory agents hold promise. Chronic folliculitis is uncommon except in acne vulgaris, where constituents of the normal flora (e.g., *Propionibacterium acnes*) may play a role.

Diffuse folliculitis occurs in two settings. *Hot-tub folliculitis* is caused by *Pseudomonas aeruginosa* in waters that are insufficiently chlorinated and maintained at temperatures of 37–40°C. Infection is usually self-limited, although bacteremia and shock have been reported. *Swimmer's itch* occurs when a skin surface is exposed to water infested with freshwater avian schistosomes. Warm water temperatures and alkaline pH are suitable for mollusks that serve as intermediate hosts between birds and humans. Free-swimming schistosomal cercariae readily penetrate human hair follicles or pores but quickly die and elicit a brisk allergic reaction, causing intense itching and erythema.

PAPULAR AND NODULAR LESIONS

(Table 134-1) Raised lesions of the skin occur in many different forms. *Mycobacterium marinum* infections of the skin may present as cellulitis or as raised erythematous nodules. Similar lesions caused by *Mycobacterium abscessus* and *M. chelonae* have been described among patients undergoing cosmetic laser surgery and tattooing, respectively. Erythematous papules are early manifestations of cat-scratch disease (with lesions developing at the primary site of inoculation of *Bartonella henselae*) and bacillary angiomatosis (also caused by *B. henselae*). Raised serpiginous or linear eruptions are characteristic of cutaneous larva migrans, which is caused by burrowing larvae of dog or cat hookworms (*Ancylostoma braziliense*) and which humans acquire through contact with soil that has been contaminated with dog or cat feces. Similar burrowing raised lesions are present in dracunculiasis caused by migration of the adult female nematode *Dracunculus medinensis*. Nodules caused by *Onchocerca volvulus* measure 1–10 cm in diameter and occur mostly in persons bitten by *Simulium* flies in Africa. The nodules contain the adult worm encased in fibrous tissue. Migration of microfilariae into the eyes may result in blindness. Verruga peruana is caused by *Bartonella bacilliformis*, which is transmitted to humans by the sandfly *Phlebotomus*. This condition can take the form of single gigantic lesions (several centimeters in diameter) or multiple small lesions (several millimeters in diameter). Numerous subcutaneous nodules may also be present in cysticercosis caused by larvae of *Taenia solium*. Multiple erythematous papules develop in schistosomiasis; each represents a cercarial invasion site. Skin nodules as well as thickened subcutaneous tissue are prominent features of lepromatous leprosy. Large nodules or gummas are features of tertiary syphilis, whereas flat papulosquamous lesions are characteristic of secondary syphilis. Human papillomavirus may cause singular warts (verruca vulgaris) or multiple warts in the anogenital area (condylomata acuminata). The latter are major problems in HIV-infected individuals and others with defects in cell-mediated immunity.

ULCERS WITH OR WITHOUT ESCHARS

(Table 134-1) Cutaneous anthrax begins as a pruritic papule, which develops within days into an ulcer with surrounding vesicles and edema and then into an enlarging ulcer with a black eschar. Cutaneous anthrax may cause chronic nonhealing ulcers with an overlying dirty-gray membrane, although lesions may also mimic psoriasis, eczema, or impetigo. Ulceroglandular tularemia may have associated ulcerated skin lesions with painful regional adenopathy. Although buboes are the major cutaneous manifestation of plague, ulcers with eschars, papules, or pustules also are present in 25% of cases.

Mycobacterium ulcerans typically causes chronic skin ulcers on the extremities of individuals living in the tropics. *Mycobacterium leprae* may be associated with cutaneous ulcerations in patients with lepromatous leprosy related to Lucio's phenomenon, in which immune-mediated destruction of tissue bearing high concentrations of *M. leprae* bacilli occurs, usually several months after initiation of effective therapy. *Mycobacterium tuberculosis* also may cause ulcerations, papules, or erythematous macular lesions of the skin in both immunocompetent and immunocompromised patients.

Decubitus ulcers are due to tissue hypoxemia secondary to pressure-induced vascular insufficiency and may become secondarily infected with components of the skin and gastrointestinal flora, including anaerobes. Ulcerative lesions on the anterior shins may be due to pyoderma gangrenosum, which must be distinguished from similar lesions

of infectious etiology by histologic evaluation of biopsy sites. Ulcerated lesions on the genitals may be either painful (chancroid) or painless (primary syphilis).

ERYSIPELAS

(Table 134-1) Erysipelas is due to *S. pyogenes* and is characterized by an abrupt onset of fiery-red swelling of the face or extremities. The distinctive features of erysipelas are well-defined indurated margins, particularly along the nasolabial fold; rapid progression; and intense pain. Flaccid bullae may develop during the second or third day of illness, but extension to deeper soft tissues is rare. Treatment with penicillin is effective; swelling may progress despite appropriate treatment, although fever, pain, and the intense red color diminish. Desquamation of the involved skin occurs 5–10 days into the illness. Infants and elderly adults are most commonly afflicted, and the severity of systemic toxicity varies.

CELLULITIS

(Table 134-1) Cellulitis is an acute inflammatory condition of the skin that is characterized by localized pain, erythema, swelling, and heat. It may be caused by indigenous flora colonizing the skin and appendages (e.g., *S. aureus* and *S. pyogenes*) or by a wide variety of exogenous bacteria. Because the exogenous bacteria involved in cellulitis occupy unique niches in nature, a thorough history (including epidemiologic data) offers important clues to etiology. When there is drainage, an open wound, or an obvious portal of entry, Gram stain and culture provide a definitive diagnosis. In the absence of these findings, the bacterial etiology of cellulitis is difficult to establish, and in some cases, staphylococcal and streptococcal cellulitis may have similar features. Even with needle aspiration of the leading edge or a punch biopsy of the cellulitis tissue itself, cultures are positive in only 20% of cases. This observation suggests that relatively low numbers of bacteria may cause cellulitis and that the expanding area of erythema within the skin may be a direct effect of extracellular toxins or of the soluble mediators of inflammation elicited by the host.

Bacteria may gain access to the epidermis through cracks in the skin, abrasions, cuts, burns, insect bites, surgical incisions, and IV catheters. Cellulitis caused by *S. aureus* spreads from a central localized infection, such as an abscess, folliculitis, or an infected foreign body (e.g., a splinter, a prosthetic device, an IV catheter). MRSA is rapidly replacing methicillin-sensitive *S. aureus* (MSSA) as a cause of cellulitis in both inpatient and outpatient settings. Cellulitis caused by MSSA or MRSA is usually associated with a focal infection, such as a furuncle, a carbuncle, a surgical wound, or an abscess; the U.S. Food and Drug Administration preferentially refers to these types of infection as *purulent cellulitis*. In contrast, cellulitis due to *S. pyogenes* is a more rapidly spreading, diffuse process that is frequently associated with lymphangitis and fever and should be referred to as *nonpurulent cellulitis*. Recurrent streptococcal cellulitis of the lower extremities may be caused by organisms of group A, C, or G in association with chronic venous stasis or with saphenous venectomy for coronary artery bypass surgery. Streptococci also cause recurrent cellulitis among patients with chronic lymphedema resulting from elephantiasis, lymph node dissection, or congenital disorders. Recurrent staphylococcal cutaneous infections are more common among individuals who have Job syndrome, the autosomal dominant hyper-IgE recurrent infection syndrome, and among nasal carriers of staphylococci. Cellulitis caused by *Streptococcus agalactiae* (group B *Streptococcus*) occurs primarily in elderly patients and those with diabetes mellitus or peripheral vascular disease. *Haemophilus influenzae* typically causes periorbital cellulitis in children in association with sinusitis, otitis media, or epiglottitis. It is unclear whether this form of cellulitis will (like meningitis) become less common as a result of the impressive efficacy of the *H. influenzae* type b vaccine.

Many other bacteria also cause cellulitis. It is fortunate that these organisms occur in such characteristic settings that a good history provides useful clues to the diagnosis. Cellulitis associated with cat bites and, to a lesser degree, with dog bites is commonly caused by *Pasteurella multocida*, although in the latter case *Staphylococcus intermedius* and *Capnocytophaga canimorsus* also must be considered. Sites of cellulitis and abscesses associated with dog bites and human bites also contain a variety of anaerobic organisms, including *Fusobacterium*, *Bacteroides*, aerobic and anaerobic streptococci, and *Eikenella corrodens*. *Pasteurella* is notoriously resistant to dicloxacillin and nafcillin but is sensitive to other β-lactam antimicrobial agents as well as to quinolones, tetracycline, and erythromycin. Amoxicillin-clavulanate, ampicillin-sulbactam, and cefoxitin are good choices for the treatment of animal or human bite infections. *Aeromonas hydrophila* causes aggressive cellulitis and occasionally necrotizing fasciitis in tissues surrounding lacerations sustained in freshwater (lakes, rivers, and streams). This organism remains sensitive to aminoglycosides, fluoroquinolones, chloramphenicol, trimethoprim-sulfamethoxazole, and third-generation cephalosporins; it is resistant to ampicillin, however. *P. aeruginosa* causes three types of soft tissue infection: ecthyma gangrenosum in neutropenic patients, hot-tub folliculitis, and cellulitis following penetrating injury. Most commonly, *P. aeruginosa* is introduced into the deep tissues following a significant penetrating injury, such as occurs when a person steps on a nail. Treatment includes surgical inspection and drainage, particularly if the injury also involves bone or joint capsule. Choices for empirical treatment (while antimicrobial susceptibility data are awaited) include an aminoglycoside, a third-generation cephalosporin (ceftazidime, cefoperazone), a semisynthetic penicillin (ticarcillin or piperacillin), or a fluoroquinolone **(Chap. 170)**.

Gram-negative bacillary cellulitis, including that due to *P. aeruginosa*, is most common among hospitalized, immunocompromised hosts. Cultures and sensitivity tests are critically important in this setting because of multidrug resistance **(Chap. 170)**.

The gram-positive aerobic rod *Erysipelothrix rhusiopathiae* is most often associated with fish and domestic swine and causes cellulitis primarily in bone renderers and fishmongers. *E. rhusiopathiae* remains susceptible to most β-lactam antibiotics (including penicillin), erythromycin, clindamycin, tetracycline, and cephalosporins but is resistant to sulfonamides, chloramphenicol, and vancomycin. Its resistance to vancomycin, which is unusual among gram-positive bacteria, is of potential clinical significance since this agent is sometimes used in empirical therapy for skin infection. Fish food containing the water flea *Daphnia* is sometimes contaminated with *M. marinum*, which can cause cellulitis or granulomas on skin surfaces exposed to the water in aquariums or injured in swimming pools **(Chap. 185)**. Ethambutol and either clarithromycin or azithromycin are the best therapies.

NECROTIZING FASCIITIS

(Table 134-1) Necrotizing fasciitis, formerly called *streptococcal gangrene*, may be associated with group A *Streptococcus* or mixed aerobic–anaerobic bacteria or may occur as a component of gas gangrene caused by *Clostridium perfringens*. Strains of MRSA that produce the Panton-Valentine leukocidin (PVL) toxin have been reported to cause necrotizing fasciitis. Early diagnosis may be difficult when pain or unexplained fever is the only presenting manifestation. Swelling then develops and is followed by brawny edema and tenderness. With progression, dark-red induration of the epidermis appears, along with bullae filled with blue or purple fluid. Later the skin becomes friable and takes on a bluish, maroon, or black color. By this stage, thrombosis of blood vessels in the dermal papillae (Fig. 134-1) is extensive. Extension of infection to the level of the deep fascia causes this tissue to take on a brownish-gray appearance. Rapid spread occurs along fascial planes, through venous channels and lymphatics. Patients in the later stages are toxic and frequently manifest shock and multiorgan failure.

Necrotizing fasciitis caused by mixed aerobic–anaerobic bacteria begins with a breach in the integrity of a mucous membrane barrier, such as the mucosa of the gastrointestinal or genitourinary tract. The portal can be a malignancy, a diverticulum, a hemorrhoid, an anal fissure, or a urethral tear. Other predisposing factors include peripheral vascular disease, diabetes mellitus, surgery, and penetrating injury to the abdomen. Leakage into the perineal area results in a syndrome called *Fournier gangrene*, characterized by massive swelling of the scrotum and penis with extension into the perineum or the abdominal wall and the legs.

Necrotizing fasciitis caused by *S. pyogenes* has increased in frequency and severity since 1985. There are two distinct clinical presentations: patients without, versus those with, a defined portal of bacterial entry. Infections in the first category often begin deep at the site of a nonpenetrating, relatively minor trauma, such as a bruise or a muscle strain. Seeding of the site via transient bacteremia is likely, although most patients deny antecedent streptococcal infection. Affected patients present with only severe pain and fever and are frequently misdiagnosed (e.g., thrombophlebitis), given pain-relieving drugs, and sent home. Later in the course, the classic signs of necrotizing fasciitis, such as purple (violaceous) bullae, skin sloughing, and progressive toxicity, develop. Mortality in this setting is high, and survivors often undergo repeated surgeries including amputations. In infections of the second type, *S. pyogenes* may reach the deep fascia from a site of cutaneous infection or penetrating trauma. These patients have early signs of superficial skin infection with progression to necrotizing fasciitis. In either setting, toxicity is severe, and renal impairment may precede the development of shock. In 20–40% of cases, myositis occurs concomitantly, and, as in gas gangrene (see below), serum creatine phosphokinase levels may be markedly elevated. Necrotizing fasciitis due to mixed aerobic–anaerobic bacteria may be associated with gas in deep tissue, but gas usually is not present when the cause is *S. pyogenes* or MRSA. Prompt surgical exploration down to the deep fascia and muscle is essential. Necrotic tissue must be surgically removed, and Gram staining and culture of excised tissue are useful in establishing whether group A streptococci, mixed aerobic–anaerobic bacteria, MRSA, or *Clostridium* species are present (see "Treatment," below).

MYOSITIS AND MYONECROSIS

(Table 134-1) Muscle involvement can occur with viral infection (e.g., influenza, dengue, or coxsackievirus B infection) or parasitic invasion (e.g., trichinellosis, cysticercosis, or toxoplasmosis). Although myalgia develops in most of these infections, severe muscle pain is the hallmark of pleurodynia (coxsackievirus B), trichinellosis, and bacterial infection. Acute rhabdomyolysis predictably occurs with clostridial and streptococcal myositis but may also be associated with influenza virus, echovirus, coxsackievirus, Epstein-Barr virus, and *Legionella* infections.

Pyomyositis is usually due to *S. aureus*, is common in tropical areas, and generally has no known portal of entry. Cases of pyomyositis caused by MRSA producing the PVL toxin have been described among children in the United States. Muscle infection begins at the exact site of blunt trauma or muscle strain. Infection remains localized, and shock does not develop unless organisms produce toxic shock syndrome toxin 1 or certain enterotoxins and the patient lacks antibodies to the toxin produced by the infecting organisms. In contrast, *S. pyogenes* may induce primary myositis (referred to as *streptococcal necrotizing myositis*) in association with severe systemic toxicity. Myonecrosis occurs concomitantly with necrotizing fasciitis in ~50% of cases. Both are part of the streptococcal toxic shock syndrome.

Gas gangrene usually follows severe penetrating injuries that result in interruption of the blood supply and introduction of soil into wounds. Such cases of traumatic gangrene are usually caused by the clostridial species *C. perfringens*, *C. septicum*, and *C. histolyticum*. Rarely, latent or recurrent gangrene can occur years after penetrating trauma; dormant spores that reside at the site of previous injury are most likely responsible. Spontaneous nontraumatic gangrene among patients with neutropenia, gastrointestinal malignancy, diverticulosis, or recent radiation therapy to the abdomen is caused by several clostridial species, of which *C. septicum* is the most commonly involved. The tolerance of this anaerobe to oxygen probably explains why it can initiate infection spontaneously in normal tissue anywhere in the body.

Gas gangrene of the uterus, especially that due to *Clostridium sordellii,* historically occurred as a consequence of illegal or self-induced abortion and nowadays also follows spontaneous abortion, vaginal delivery, and Caesarean section. *C. sordellii* has also been implicated in medically induced abortion. Postpartum *C. sordellii* infections in young, previously healthy women present with little or no fever, lack of a purulent discharge, refractory hypotension, extensive peripheral edema and effusions, hemoconcentration, and a markedly elevated white blood cell count. The infection is often fatal, with death ensuing rapidly. *C. sordellii* and *C. novyi* have also been associated with cutaneous injection of black tar heroin; mortality rates are lower among these individuals, probably because their injection-site infections are readily apparent and diagnosis is therefore prompt.

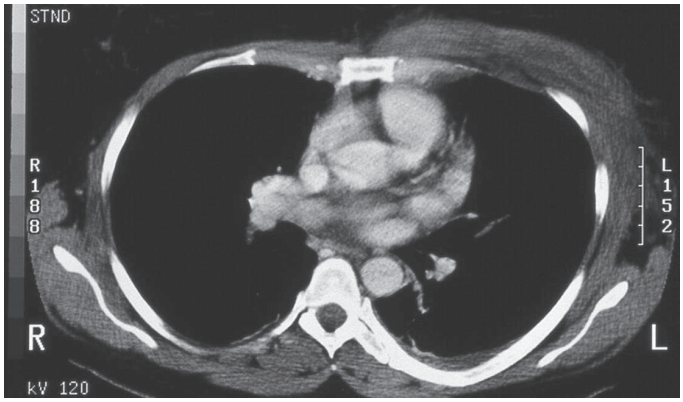

FIGURE 134-2 CT showing edema and inflammation of the left chest wall in a patient with necrotizing fasciitis and myonecrosis caused by group A *Streptococcus*.

Synergistic nonclostridial anaerobic myonecrosis, also known as *necrotizing cutaneous myositis* and *synergistic necrotizing cellulitis*, is a variant of necrotizing fasciitis caused by mixed aerobic and anaerobic bacteria with the exclusion of clostridial organisms (see "Necrotizing Fasciitis," above).

DIAGNOSIS

This chapter emphasizes the physical appearance and location of lesions within the soft tissues as important diagnostic clues. Other crucial considerations in narrowing the differential diagnosis are the temporal progression of the lesions as well as the patient's travel history, animal exposure or bite history, age, underlying disease status, and lifestyle. However, even the astute clinician may find it challenging to diagnose all infections of the soft tissues by history and inspection alone. Soft tissue radiography, computed tomography (CT) **(Fig. 134-2)**, and magnetic resonance imaging (MRI) may be useful in determining the depth of infection and should be performed when the patient has rapidly progressing lesions or evidence of a systemic inflammatory response syndrome. These tests are particularly valuable for defining a localized abscess or detecting gas in tissue. Unfortunately, they may reveal only soft tissue swelling and thus are not specific for fulminant infections such as necrotizing fasciitis or myonecrosis caused by group A *Streptococcus* (Fig. 134-2), where gas is not found in lesions.

Aspiration of the leading edge or punch biopsy with frozen section may be helpful if the results of imaging tests are positive, but negative results occur in ~80% of cases. There is some evidence that aspiration alone may be superior to injection and aspiration with normal saline. Frozen sections are especially useful in distinguishing SSSS from TEN and are quite valuable in cases of necrotizing fasciitis. Open surgical inspection, with debridement as indicated, is the best way to determine the extent and severity of infection and to obtain material for Gram staining and culture. Such an aggressive approach is important and may be lifesaving if undertaken early in the course of fulminant infections when there is evidence of systemic toxicity.

TREATMENT

Infections of the Skin, Muscles, and Soft Tissues

A full description of the treatment of all the clinical entities described herein is beyond the scope of this chapter. As a guide to the clinician in selecting appropriate treatment, the antimicrobial agents useful in the most common and the most fulminant cutaneous infections are listed in **Table 134-2**. Newer antibiotics approved

TABLE 134-2 Treatment of Common Infections of the Skin

DIAGNOSIS/CONDITION	PRIMARY TREATMENT	ALTERNATIVE TREATMENT	SEE ALSO CHAP(S).
Animal bite (prophylaxis or early infection)[a]	Amoxicillin–clavulanate (875/125 mg PO bid)	Doxycycline (100 mg PO bid)	146
Animal bite[a] (established infection)	Ampicillin–sulbactam (1.5–3 g IV q6h)	Clindamycin (600–900 mg IV q8h) *plus* Ciprofloxacin (400 mg IV q12h) *or* cefoxitin (2 g IV q6h)	146
Bacillary angiomatosis	Erythromycin (500 mg PO qid)	Doxycycline (100 mg PO bid)	177
Herpes simplex (primary genital)	Acyclovir (400 mg PO tid for 10 days)	Famciclovir (250 mg PO tid for 5–10 days) *or* valacyclovir (1000 mg PO bid for 10 days)	197
Herpes zoster (immunocompetent host >50 years of age)	Acyclovir (800 mg PO 5 times daily for 7–10 days)	Famciclovir (500 mg PO tid for 7–10 days) *or* valacyclovir (1000 mg PO tid for 7 days)	198
Cellulitis (staphylococcal or streptococcal[b,c])	Nafcillin or oxacillin (2 g IV q4–6h)	Cefazolin (1–2 g q8h) *or* ampicillin/sulbactam (1.5–3 g IV q6h) *or* erythromycin (0.5–1 g IV q6h) *or* clindamycin (600–900 mg IV q8h)	152, 153
MRSA skin infection[d]	Vancomycin (1 g IV q12h)	Linezolid (600 mg IV q12h)	152
Necrotizing fasciitis (group A streptococcal[b])	Clindamycin (600–900 mg IV q6–8h) *plus* penicillin G (4 million units IV q4h)	Clindamycin (600–900 mg IV q6–8h) *plus* a cephalosporin (first- or second-generation)	153
Necrotizing fasciitis (mixed aerobes and anaerobes)	Ampicillin (2 g IV q4h) *plus* clindamycin (600–900 mg IV q6–8h) *plus* ciprofloxacin (400 mg IV q6–8h)	Vancomycin (1 g IV q6h) *plus* metronidazole (500 mg IV q6h) *plus* ciprofloxacin (400 mg IV q6–8h)	182
Gas gangrene	Clindamycin (600–900 mg IV q6–8h) *plus* penicillin G (4 million units IV q4–6h)	Clindamycin (600–900 mg IV q6–8h) *plus* cefoxitin (2 g IV q6h)	159

[a] *Pasteurella multocida,* a species commonly associated with both dog and cat bites, is resistant to cephalexin, dicloxacillin, clindamycin, and erythromycin. *Eikenella corrodens,* a bacterium commonly associated with human bites, is resistant to clindamycin, penicillinase-resistant penicillins, and metronidazole but is sensitive to trimethoprim-sulfamethoxazole and fluoroquinolones. [b] The frequency of erythromycin resistance in group A *Streptococcus* is currently ~5% in the United States but has reached 70–100% in some other countries. Most, but not all, erythromycin-resistant group A streptococci are susceptible to clindamycin; clindamycin-resistant group A streptococci are susceptible to linezolid and to tedizolid. Approximately 90% of *Staphylococcus aureus* strains are sensitive to clindamycin, but resistance—both intrinsic and inducible—is increasing. [c] Severe hospital-acquired *S. aureus* infections or community-acquired *S. aureus* infections that are not responding to the β-lactam antibiotics recommended in this table may be caused by methicillin-resistant strains, requiring vancomycin, daptomycin, or linezolid or tedizolid. [d] Some strains of methicillin-resistant *S. aureus* (MRSA) remain sensitive to tetracycline and trimethoprim-sulfamethoxazole. Daptomycin (4 mg/kg IV q24h) or tigecycline (100-mg loading dose followed by 50 mg IV q12h) is an alternative treatment for MRSA.

by the U.S. Food and Drug Administration for uncomplicated skin and soft tissue infections including ceftaroline, dalbavancin, oritavancin, tedizolid, delafloxacin, and omadacycline.

Furuncles, carbuncles, and abscesses caused by MRSA and MSSA are common, and their treatment depends upon the size of the lesion. Furuncles <2.5 cm in diameter are usually treated with moist heat. Those that are larger (4.5 cm of erythema and induration) require surgical drainage, and the occurrence of these larger lesions when associated with fever, chills, or leukocytosis requires both drainage and antibiotic treatment. Previous studies in children demonstrated that surgical drainage of abscesses (mean diameter, 3.8 cm) was as effective when used alone as when combined with trimethoprim-sulfamethoxazole treatment. However, the rate of recurrence of new lesions was lower in the group undergoing both drainage and antibiotic treatment. A more recent study in patients with predominantly MRSA localized abscesses suggested that a 7- to 10-day course of treatment with trimethoprim-sulfamethoxazole or clindamycin was associated with higher cure rates and fewer recurrences.

Early and aggressive surgical exploration is essential in cases of suspected necrotizing fasciitis, myositis, or gangrene to (1) visualize the deep structures, (2) remove necrotic tissue, (3) reduce compartment pressure, and (4) obtain suitable material for Gram staining and for aerobic and anaerobic cultures and antimicrobial sensitivity testing. Appropriate empirical antibiotic treatment for mixed aerobic–anaerobic infections is reviewed in **Chap. 159**. Group A streptococcal and clostridial infection of the fascia and/or muscle carries a mortality rate of 20–50% with penicillin treatment. In experimental models of streptococcal and clostridial necrotizing fasciitis/myositis, clindamycin has exhibited markedly superior efficacy, but no comparative clinical trials have been performed. A retrospective study of children with invasive group A streptococcal infection demonstrated higher survival rates with clindamycin treatment than with β-lactam antibiotic therapy. Current guidelines recommend treatment with clindamycin (or linezolid) plus a β-lactam antibiotic. The emergence of macrolide resistance among group A streptococci has, however, created therapeutic dilemmas for patients allergic to penicillin and for those with life-threatening infections, such as necrotizing fasciitis/myonecrosis and streptococcal toxic shock syndrome, where clindamycin has been the treatment of choice. In such instances, linezolid or tedizolid could be used.

The use of intravenous immune globulin (IVIg) in patients with invasive group A streptococcal infections has been controversial, and early reports failed to demonstrate efficacy or were terminated early due to low enrollment. More recent prospective studies and one five-study meta-analysis demonstrated that administration of IVIg (often in combination with clindamycin) significantly reduced 30- and 90-day mortality. The combination of clindamycin and IVIg may help reduce production and activities of circulating toxins produced by group A *Streptococcus*. IVIg could be given early, and more than one dose should be used because different batches of IVIg have variable neutralizing activity against streptococcal exotoxins.

Hyperbaric oxygen (HBO) treatment has been suggested to be useful in gas gangrene due to clostridial species. However, no definitive comparative trials of HBO have been done for the treatment for invasive group A streptococcal infections, although some reports state that such treatment reduces mortality and the need for further debridements. The use of HBO should not delay, or be used in preference to, surgical debridement when the latter is indicated; such delays significantly contribute to mortality. Antibiotic treatment should be continued until all signs of systemic toxicity have resolved, all devitalized tissue has been removed, and granulation tissue has developed **(Chaps. 153, 159, and 182)**.

In summary, infections of the skin and soft tissues are diverse in presentation and severity and offer a great challenge to the clinician. This chapter provides an approach to diagnosis and understanding of the pathophysiologic mechanisms involved in these infections. More in-depth information is found in chapters on specific infections.

TABLE 135-1 Differential Diagnosis of Arthritis Syndromes

ACUTE MONARTICULAR ARTHRITIS	CHRONIC MONARTICULAR ARTHRITIS	POLYARTICULAR ARTHRITIS
Staphylococcus aureus	*Mycobacterium tuberculosis*	*Neisseria meningitidis*
Streptococcus pneumoniae	Nontuberculous mycobacteria	*N. gonorrhoeae*
β-Hemolytic streptococci	*Borrelia burgdorferi*	Nongonococcal bacterial arthritis
Gram-negative bacilli	*Treponema pallidum*	Bacterial endocarditis
Neisseria gonorrhoeae	*Candida* spp.	*Candida* spp.
Candida spp.	*Sporothrix schenckii*	Poncet's disease (tuberculous rheumatism)
Crystal-induced arthritis	*Coccidioides immitis*	Hepatitis B virus
Fracture	*Blastomyces dermatitidis*	Parvovirus B19
Hemarthrosis	*Aspergillus* spp.	HIV
Foreign body	*Cryptococcus neoformans*	Human T-lymphotropic virus type 1
Osteoarthritis	*Nocardia* spp.	Rubella virus
Ischemic necrosis	*Brucella* spp.	Arthropod-borne viruses
Monoarticular rheumatoid arthritis	Legg-Calvé-Perthes disease	Sickle cell disease flare
	Osteoarthritis	Reactive arthritis
		Serum sickness
		Acute rheumatic fever
		Inflammatory bowel disease
		Systemic lupus erythematosus
		Rheumatoid arthritis/ Still's disease
		Other vasculitides
		Sarcoidosis

135 Infectious Arthritis

Nongnooch Poowanawittayakom, Lawrence C. Madoff

Although *Staphylococcus aureus*, streptococci, and *Neisseria gonorrhoeae* are the most common causes of infectious arthritis, various mycobacteria, spirochetes, fungi, and viruses also infect joints **(Table 135-1)**. Since acute bacterial infection can destroy articular cartilage rapidly, all inflamed joints must be evaluated without delay to exclude noninfectious processes and determine appropriate antimicrobial therapy and drainage procedures. For more detailed information on infectious arthritis caused by specific organisms, the reader is referred to the chapters on those organisms.

Acute bacterial infection typically involves a single joint or a few joints. Subacute or chronic monoarthritis or oligoarthritis suggests mycobacterial or fungal infection; episodic inflammation is seen in syphilis, Lyme disease, and the reactive arthritis that follows enteric infections and chlamydial urethritis. Acute polyarticular inflammation occurs as an immunologic reaction during the course of endocarditis, rheumatic fever, disseminated neisserial infection, and acute viral hepatitis. Viruses often infect multiple joints; however, bacterial infections generally cause mono- or oligoarthritis except in persons with underlying diseases such as rheumatoid arthritis.

APPROACH TO THE PATIENT

Infectious Arthritis

Aspiration of synovial fluid or arthrocentesis—an essential element in the evaluation of potentially infected joints—can be performed without difficulty in most cases by the insertion of a large-bore needle into the site of maximal fluctuance or tenderness or by the route of easiest access. Ultrasonography or computed tomography (CT) may be used to guide aspiration of difficult-to-localize effusions of the hip and, occasionally, the shoulder and other joints. Normal synovial fluid contains <180 cells (predominantly mononuclear cells) per microliter. Synovial cell counts averaging 100,000/μL (range, 25,000–250,000/μL), with >90% neutrophils, are characteristic of acute bacterial infections. Crystal-induced, rheumatoid, and other noninfectious inflammatory arthritides usually are associated with <30,000–50,000 cells/μL; cell counts of 10,000–30,000/μL, with 50–70% neutrophils and the remainder lymphocytes, are common in mycobacterial and fungal infections. Definitive diagnosis of an infectious process relies on identification of the pathogen in stained smears of synovial fluid, isolation of the pathogen from cultures of synovial fluid and blood, or detection of microbial nucleic acids and proteins by nucleic acid amplification tests (NAATs) and immunologic techniques. Gram stain is positive in about 30–50% of cases, and synovial fluid culture is positive in >60% of nongonococcal bacterial arthritis cases. Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry is helpful in patients who have negative culture and high suspicion of infectious arthritis. Sonication of explanted prosthetic joints (placement of the material into liquid and then immersion in an ultrasound bath) increases the yield of organism detection, especially in the case of prior antibiotic use within 14 days.

ACUTE BACTERIAL ARTHRITIS

PATHOGENESIS

Bacteria enter the joint from the bloodstream; from a contiguous site of infection in bone or soft tissue; or by direct inoculation during surgery, injection, animal or human bite, or trauma. In hematogenous infection, bacteria escape from synovial capillaries, which have no limiting basement membrane, and within hours provoke neutrophilic infiltration

of the synovium. Neutrophils and bacteria enter the joint space; later, bacteria adhere to articular cartilage. Degradation of cartilage begins within 48 h as a result of increased intraarticular pressure, release of proteases and cytokines from chondrocytes and synovial macrophages, and invasion of the cartilage by bacteria and inflammatory cells. Histologic studies reveal bacteria lining the synovium and cartilage as well as abscesses extending into the synovium, cartilage, and—in severe cases—subchondral bone. Synovial proliferation results in the formation of a pannus over the cartilage, and thrombosis of inflamed synovial vessels develops. Bacterial factors that appear important in the pathogenesis of infective arthritis include various surface-associated adhesins in *S. aureus* that permit adherence to cartilage and endotoxins that promote chondrocyte-mediated breakdown of cartilage.

MICROBIOLOGY

The hematogenous route of infection is the most common route in all age groups, and nearly every bacterial pathogen is capable of causing septic arthritis. In infants, group B streptococci, gram-negative enteric bacilli, and *S. aureus* are the most common pathogens. Since the advent of the *Haemophilus influenzae* vaccine, the predominant causes among children <5 years of age have been *S. aureus*, *Streptococcus pyogenes* (group A *Streptococcus*), and (in some centers) *Kingella kingae*. Among young adults and adolescents, *N. gonorrhoeae* is the most commonly implicated organism. *S. aureus* (including methicillin-resistant *S. aureus* [MRSA]) accounts for most nongonococcal isolates in adults of all ages; gram-negative bacilli, pneumococci, and β-hemolytic streptococci—particularly groups A and B but also groups C, G, and F—are involved in up to one-third of cases in older adults, especially those with underlying comorbid illnesses. Gram-negative bacilli such as *Pseudomonas* may occur in immunocompromised patients or intravenous drug users.

Infections after surgical procedures or penetrating injuries are due most often to *S. aureus* and occasionally to other gram-positive bacteria or gram-negative bacilli. Infections with coagulase-negative staphylococci are unusual except after the implantation of prosthetic joints or arthroscopy. Anaerobic organisms, often in association with aerobic or facultative bacteria, are found after human bites and when decubitus ulcers or intraabdominal abscesses spread into adjacent joints. Polymicrobial infections complicate traumatic injuries with extensive contamination. Bites and scratches from cats and other animals may introduce *Pasteurella multocida* or *Bartonella henselae* into joints either directly or hematogenously, and bites from humans may introduce *Eikenella corrodens* or other components of the oral flora. Penetration of a sharp object through a shoe is associated with *Pseudomonas aeruginosa* arthritis in the foot.

NONGONOCOCCAL BACTERIAL ARTHRITIS

Epidemiology Although hematogenous infections with virulent organisms such as *S. aureus*, *H. influenzae*, and pyogenic streptococci occur in healthy persons, there is an underlying host predisposition in many cases of septic arthritis. Patients with rheumatoid arthritis have the highest incidence of infective arthritis (most often secondary to *S. aureus*) because of chronically inflamed joints; glucocorticoid therapy; and frequent breakdown of rheumatoid nodules, vasculitic ulcers, and skin overlying deformed joints. Diabetes mellitus, glucocorticoid therapy, hemodialysis, intravenous drug use, and malignancy all carry an increased risk of infection with *S. aureus* and gram-negative bacilli. Tumor necrosis factor inhibitors (e.g., etanercept, infliximab), which increasingly are used for the treatment of rheumatoid arthritis, predispose to mycobacterial infections and possibly to other pyogenic bacterial infections and could be associated with septic arthritis in this population. Pneumococcal infections complicate alcoholism, deficiencies of humoral immunity, and hemoglobinopathies. Pneumococci, *Salmonella* species, and *H. influenzae* cause septic arthritis in persons infected with HIV. Persons with primary immunoglobulin deficiency are at risk for mycoplasmal arthritis, which, while rare, results in permanent joint damage if tetracycline and replacement therapy with IV immunoglobulin are not administered promptly. IV drug users acquire staphylococcal and streptococcal infections from their own flora and acquire pseudomonal and other gram-negative infections from drugs and injection paraphernalia.

Clinical Manifestations Patients with acute septic arthritis usually present with joint pain often with limitation of passive and active joint movement, joint swelling, and/or erythema. Approximately 90% of patients present with involvement of a single joint—most commonly the knee; less frequently the hip; and still less often the shoulder, wrist, or elbow. Small joints of the hands and feet are more likely to be affected after direct inoculation or a bite. Among IV drug users, infections of the spine, sacroiliac joints, and sternoclavicular joints **(Fig. 135-1)** are more common than infections of the appendicular skeleton. Polyarticular infection is most common among patients with rheumatoid arthritis and may resemble a flare of the underlying disease.

The usual presentation consists of moderate to severe pain that is uniform around the joint, effusion, muscle spasm, and decreased range of motion. Fever in the range of 38.3–38.9°C (101–102°F) and sometimes higher is common but may not be present, especially in persons with rheumatoid arthritis, renal or hepatic insufficiency, or conditions requiring immunosuppressive therapy. The inflamed, swollen joint is usually evident on examination except in the case of a deeply situated joint such as the hip, shoulder, or sacroiliac joint. Cellulitis, bursitis, and acute osteomyelitis, which may produce a similar clinical picture, should be distinguished from septic arthritis by preservation of passive range of motion and less-than-circumferential swelling. A focus of extraarticular infection, such as a boil, pneumonia, or endocarditis, should be sought. Peripheral-blood leukocytosis with a left shift and elevation of the erythrocyte sedimentation rate or C-reactive protein level are common.

Plain radiographs show evidence of soft tissue swelling, joint space widening, and displacement of tissue planes by the distended capsule. Narrowing of the joint space and bony erosions indicate advanced infection and a poor prognosis. Ultrasound is useful for detecting effusions in the hip, and CT or MRI can demonstrate infections of the sacroiliac joint, the sternoclavicular joint, and the spine very well.

Laboratory Findings Specimens of peripheral blood and synovial fluid should be obtained before antibiotics are administered. Blood cultures are positive in up to 50–70% of *S. aureus* infections but are less frequently positive in infections due to other organisms. The synovial fluid is turbid, serosanguineous, or frankly purulent. Gram-stained smears confirm the presence of large numbers of neutrophils. Levels of total protein and lactate dehydrogenase in synovial fluid are elevated,

FIGURE 135-1 Acute septic arthritis of the sternoclavicular joint. A man in his forties with a history of cirrhosis presented with a new onset of fever and lower neck pain. He had no history of IV drug use or previous catheter placement. Jaundice and a painful swollen area over his left sternoclavicular joint were evident on physical examination. Cultures of blood drawn at admission grew group B *Streptococcus*. The patient recovered after treatment with IV penicillin. *(Courtesy of the late Francisco M. Marty, MD, Brigham and Women's Hospital, Boston; with permission.)*

and the glucose level is depressed; however, these findings are not specific for infection, and measurement of these levels is not necessary for diagnosis. The synovial fluid should be examined for crystals because gout and pseudogout can resemble septic arthritis clinically, and infection and crystal-induced disease occasionally occur together. Organisms are seen on synovial fluid smears in nearly three-quarters of infections with *S. aureus* and streptococci and in 30–50% of infections due to gram-negative and other bacteria. Cultures of synovial fluid are positive in >90% of cases. Inoculation of synovial fluid into bottles containing liquid media for blood cultures increases the yield of a culture, especially if the pathogen is a fastidious organism or the patient is taking an antibiotic, but should be interpreted in the context of the Gram's stain result. Pathogen nucleic acid amplification based assays (NAAT) or MALDI-TOF mass spectrometry, when available, can be useful for the diagnosis of partially treated or culture-negative arthritis. Inflammatory markers such as erythrocyte sedimentation rate and C-reactive protein tend to be elevated in septic arthritis but are nonspecific. Serum procalcitonin elevation is only ~50% sensitive and should not be used to rule out infectious arthritis. Synovial fluid procalcitonin might be useful, although data are limited.

TREATMENT

Nongonococcal Bacterial Arthritis

Prompt administration of systemic antibiotics and drainage of the involved joint can prevent destruction of cartilage, postinfectious degenerative arthritis, joint instability, or deformity. Once samples of blood and synovial fluid have been obtained for culture, empirical antibiotics should be directed against the bacteria visualized on smears or the pathogens that are likely in light of the patient's age and risk factors. Initial therapy should consist of IV-administered bactericidal agents; direct instillation of antibiotics into the joint is not necessary to achieve adequate levels in synovial fluid and tissue. If there are gram-positive cocci on the smear, IV vancomycin (15–20 mg/kg/dose) every 8–12 h should be started empirically. If methicillin-resistant *S. aureus* is an unlikely pathogen (e.g., when it is not widespread in the community), cefazolin (2 g every 8 h), oxacillin (2 g every 4 h), or nafcillin (2 g every 4 h) should be given.

If initial Gram's stain shows gram-negative bacilli, the risk for *P. aeruginosa* infection should be evaluated. If the patient does not have risk factors for *P. aeruginosa* infection, an IV third-generation cephalosporin such as cefotaxime (2 g every 8 h) or ceftriaxone (2 g every 24 h) provides adequate empirical coverage for most community-acquired infections. In addition, if the patient has a higher risk for *P. aeruginosa* infection, then anti-pseudomonal coverage such as cefepime (2 g every 8–12 h) or ceftazidime (2 g every 8 h) should be given. Double coverage of *Pseudomonas* with cephalosporin and ciprofloxacin or aminoglycoside can be considered empirically in severely ill patients or in the setting of highly resistant *Pseudomonas* infection incidence.

Definitive therapy is based on the identity and antibiotic susceptibility of the bacteria isolated in culture. Infections due to staphylococci are treated with cefazolin, oxacillin, nafcillin, or vancomycin for 4 weeks. In patients without evidence of endocarditis, IV antibiotics can be used for 7–14 days of treatment followed by oral antibiotics to complete the treatment course. Pneumococcal and streptococcal infections due to penicillin-susceptible organisms respond to 2 weeks of therapy with penicillin G (2 million units IV every 4 h); infections caused by *H. influenzae* and by strains of *Streptococcus pneumoniae* that are resistant to penicillin are treated with cefotaxime or ceftriaxone for 2 weeks. Most enteric gram-negative infections can be cured in 3–4 weeks by a second- or third-generation cephalosporin given IV or by a fluoroquinolone such as levofloxacin (500 mg IV or PO every 24 h). *P. aeruginosa* infection should be treated for at least 2 weeks with antipseudomonal cephalosporin such as ceftazidime (2 g IV every 8 h), cefepime (2 g every 8–12 h). If tolerated, this regimen is continued for an additional 2 weeks; alternatively, a fluoroquinolone such as ciprofloxacin (750 mg PO twice daily) may be given.

Timely drainage of pus and necrotic debris from the infected joint is required for a favorable outcome. Needle aspiration of readily accessible joints such as the knee may be adequate if loculations or particulate matter in the joint does not prevent its thorough decompression. Arthroscopic drainage and lavage may be employed initially or within several days if repeated needle aspiration fails to relieve symptoms, decrease the volume of the effusion and the synovial white cell count, and clear bacteria from smears and cultures. In some cases, arthrotomy is necessary to remove loculations and debride infected synovium, cartilage, or bone. Septic arthritis of the hip is best managed with arthrotomy, particularly in young children, in whom infection threatens the viability of the femoral head. Septic joints do not require immobilization except for pain control before symptoms are alleviated by treatment. Weight bearing should be avoided until signs of inflammation have subsided, but frequent passive motion of the joint is indicated to maintain full mobility. Although some clinical studies suggest that adjunctive use of glucocorticoids showed some benefit in children with septic arthritis, they are not widely used in clinical practice.

GONOCOCCAL ARTHRITIS

Epidemiology In the past, gonococcal arthritis **(Chap. 161)** accounted for up to 70% of episodes of infectious arthritis in persons <40 years of age in the United States. As the rates of mucosal gonorrhea have fallen in the United States, it is likely that the proportion of septic arthritis caused by *N. gonorrhoeae* also has fallen considerably. Arthritis due to *N. gonorrhoeae* is a consequence of bacteremia arising from gonococcal infection or, more frequently, from asymptomatic gonococcal mucosal colonization of the urethra, cervix, or pharynx. Women are at greatest risk during menses and during pregnancy and overall are two to three times more likely than men to develop disseminated gonococcal infection (DGI) and arthritis. Persons with complement deficiencies, especially of the terminal components, are prone to recurrent episodes of gonococcemia. Eculizumab, which is a long-acting monoclonal antibody targeting the C5 complement component and used mainly for the treatment of paroxysmal nocturnal hemoglobinuria, also has been reported to be associated with disseminated gonococcal infection.

Clinical Manifestations and Laboratory Findings The most common manifestation of DGI is a syndrome of arthritis-dermatitis. Patients present with fever, chills, rash, tenosynovitis, and articular symptoms. Small numbers of papules that progress to hemorrhagic pustules develop on the trunk and the extensor surfaces of the distal extremities. Migratory arthritis and tenosynovitis of the knees, hands, wrists, feet, and ankles are prominent. The cutaneous lesions and articular findings are believed to be the consequence of an immune reaction to circulating gonococci and immune-complex deposition in tissues. Thus, cultures of synovial fluid are consistently negative, and blood cultures are positive in <45% of patients. Synovial fluid may be difficult to obtain from inflamed joints and usually contains only 10,000–20,000 leukocytes/μL.

True gonococcal septic arthritis is less common than the DGI syndrome and always follows DGI, which is unrecognized in one-third of patients. A single joint such as the hip, knee, ankle, or wrist is usually involved. Synovial fluid, which contains >50,000 leukocytes/μL, can be obtained with ease; the gonococcus is evident only occasionally in Gram-stained smears, and cultures of synovial fluid are positive in <40% of cases. Blood cultures are almost always negative.

Because it is difficult to isolate gonococci from synovial fluid and blood, specimens for culture should be obtained from potentially infected mucosal sites. NAAT-based urine tests also may be positive. Culture requires endocervical (in female patients) or urethral (in male patients) swab specimens. Culture is available for detection of rectal, oropharyngeal, and conjunctival gonococcal infection. Cultures and Gram-stained smears of skin lesions are occasionally positive.

All specimens for culture should be plated onto Thayer-Martin agar directly or in special transport media at the bedside and transferred promptly to the microbiology laboratory in an atmosphere of 5% CO_2. NAAT assays are extremely sensitive in detecting gonococcal DNA in synovial fluid, but they are not FDA approved for this purpose. A dramatic alleviation of symptoms within 12–24 h after the initiation of appropriate antibiotic therapy supports a clinical diagnosis of the DGI syndrome if cultures are negative.

TREATMENT

Gonococcal Arthritis

Initial treatment consists of ceftriaxone (1 g IV or IM every 24 h) to cover possible penicillin-resistant organisms. Once local and systemic signs are clearly resolving, a 7-day course of antibiotics may be completed with daily IM ceftriaxone given at 500 mg daily (or 1g for those weighing over 150 kg). An oral fluoroquinolone such as ciprofloxacin (500 mg twice daily) may be used if the organism is known to be susceptible. If penicillin-susceptible organisms are isolated, amoxicillin (500 mg four times daily) may be used. Suppurative arthritis usually responds to needle aspiration of involved joints and 7–14 days of antibiotic treatment. Arthroscopic lavage or arthrotomy is rarely required. The Centers for Disease Control recommends that when chlamydial infection has not been excluded, treatment with PO doxycycline 100 mg twice daily for 7 days should be given. Sexual partners should be offered testing and presumptive treatment for gonorrhea and chlamydial infection. It is noteworthy that arthritis symptoms similar to those seen in DGI occur in meningococcemia. A dermatitis–arthritis syndrome, purulent monoarthritis, and reactive polyarthritis have been described. All respond to treatment with appropriate antibiotics.

SPIROCHETAL ARTHRITIS

LYME DISEASE

Lyme disease **(Chap. 191)** due to infection with the spirochete *Borrelia burgdorferi* causes arthritis in up to 60% of persons who are not treated. Intermittent arthralgias and myalgias—but not arthritis—occur within days or weeks of inoculation of the spirochete by the *Ixodes* tick. Later, there are three patterns of joint disease: (1) Fifty percent of untreated persons experience intermittent episodes of monoarthritis or oligoarthritis involving the knee and/or other large joints. The symptoms wax and wane without treatment over months, and each year, 10–20% of patients report loss of joint symptoms. (2) Twenty percent of untreated persons develop a pattern of waxing and waning arthralgias. (3) Ten percent of untreated patients develop chronic inflammatory synovitis that results in erosive lesions and destruction of the joint. Serologic tests for IgG antibodies to *B. burgdorferi* are positive in >90% of persons with Lyme arthritis, and a NAAT detects *Borrelia* DNA in synovial fluid in 85% of patients.

TREATMENT

Lyme Arthritis

Lyme arthritis generally responds well to therapy. A regimen of oral doxycycline (100 mg twice daily for 28 days), oral amoxicillin (500 mg three times daily for 28 days), or parenteral ceftriaxone (2 g/d for 2–4 weeks) is recommended. Patients who do not respond to a total of 2 months of oral therapy or 1 month of parenteral therapy are unlikely to benefit from additional antibiotic therapy and are treated with anti-inflammatory agents or synovectomy. Failure of therapy is associated with host features such as the human leukocyte antigen DR4 (HLA-DR4) genotype, persistent reactivity to OspA (outer-surface protein A), and the presence of hLFA-1 (human leukocyte function–associated antigen 1), which cross-reacts with OspA.

SYPHILITIC ARTHRITIS

Articular manifestations occur in different stages of syphilis **(Chap. 187)**. In early congenital syphilis, periarticular swelling and immobilization of the involved limbs (*Parrot's pseudoparalysis*) complicate osteochondritis of long bones. *Clutton's joint*, a late manifestation of congenital syphilis that typically develops between ages 8 and 15 years, is caused by chronic painless synovitis with effusions of large joints, particularly the knees and elbows. Secondary syphilis may be associated with arthralgias, with symmetric arthritis of the knees and ankles and occasionally of the shoulders and wrists, and with sacroiliitis. The arthritis follows a subacute to chronic course with a mixed mononuclear and neutrophilic synovial-fluid pleocytosis (typical cell counts, 5000–15,000/μL). Immunologic mechanisms may contribute to the arthritis, and symptoms usually improve rapidly with penicillin therapy. In tertiary syphilis, Charcot joint results from sensory loss due to tabes dorsalis. Penicillin is not helpful in this setting.

MYCOBACTERIAL ARTHRITIS

Tuberculous arthritis **(Chap. 183)** accounts for ~1% of all cases of tuberculosis and 10% of extrapulmonary cases. The most common presentation is chronic granulomatous monoarthritis. An unusual syndrome, *Poncet's disease*, is a reactive symmetric form of polyarthritis that affects persons with visceral or disseminated tuberculosis. No mycobacteria are found in the joints, and symptoms resolve with antituberculous therapy.

Unlike tuberculous osteomyelitis (*Pott's disease*) **(Chap. 136)**, which typically involves the thoracic and lumbar spine (50% of cases), tuberculous arthritis primarily involves the large weight-bearing joints, in particular the hips, knees, and ankles, and only occasionally involves smaller non-weight-bearing joints. Progressive monoarticular swelling and pain develop over months or years, and systemic symptoms are seen in only half of all cases. Tuberculous arthritis occurs as part of a disseminated primary infection or through late reactivation, often in persons with HIV infection or other immunocompromised hosts. Coexistent active pulmonary tuberculosis is unusual.

Aspiration of the involved joint yields fluid with an average cell count of 20,000/μL, with ~50% neutrophils. Acid-fast staining of the fluid yields positive results in fewer than one-third of cases, and cultures are positive in 80%. Culture of synovial tissue taken at biopsy is positive in ~90% of cases and shows granulomatous inflammation in most. NAAT can shorten the time to diagnosis to 1 or 2 days. Radiographs reveal peripheral erosions at the points of synovial attachment, periarticular osteopenia, and eventually joint-space narrowing. Therapy for tuberculous arthritis is the same as that for tuberculous pulmonary disease, requiring the administration of multiple agents for 6–9 months. Therapy is more prolonged in immunosuppressed individuals, such as those infected with HIV.

Various atypical mycobacteria **(Chap. 185)** found in water and soil may cause chronic indolent arthritis. Such disease results from trauma and direct inoculation associated with farming, gardening, or aquatic activities. Smaller joints, such as the digits, wrists, and knees, are usually involved. Involvement of tendon sheaths and bursae is typical. The mycobacterial species involved include *Mycobacterium marinum*, *M. avium complex*, *M. terrae*, *M. kansasii*, *M. fortuitum*, and *M. chelonae*. In persons who have HIV infection or are receiving immunosuppressive therapy, hematogenous spread to the joints has been reported for *M. kansasii*, *M. avium* complex, and *M. haemophilum*. Diagnosis usually requires biopsy and culture, and therapy is based on antimicrobial susceptibility patterns.

FUNGAL ARTHRITIS

Fungi are an unusual cause of chronic monoarticular arthritis. Granulomatous articular infection with the endemic dimorphic fungi *Coccidioides immitis*, *Blastomyces dermatitidis*, and (less commonly) *Histoplasma capsulatum* **(Fig. 135-2)** results from hematogenous seeding or direct extension from bony lesions in persons with disseminated disease. Joint involvement is an unusual complication of sporotrichosis (infection with *Sporothrix schenckii*) among gardeners and other persons who work with soil or sphagnum moss. Articular sporotrichosis

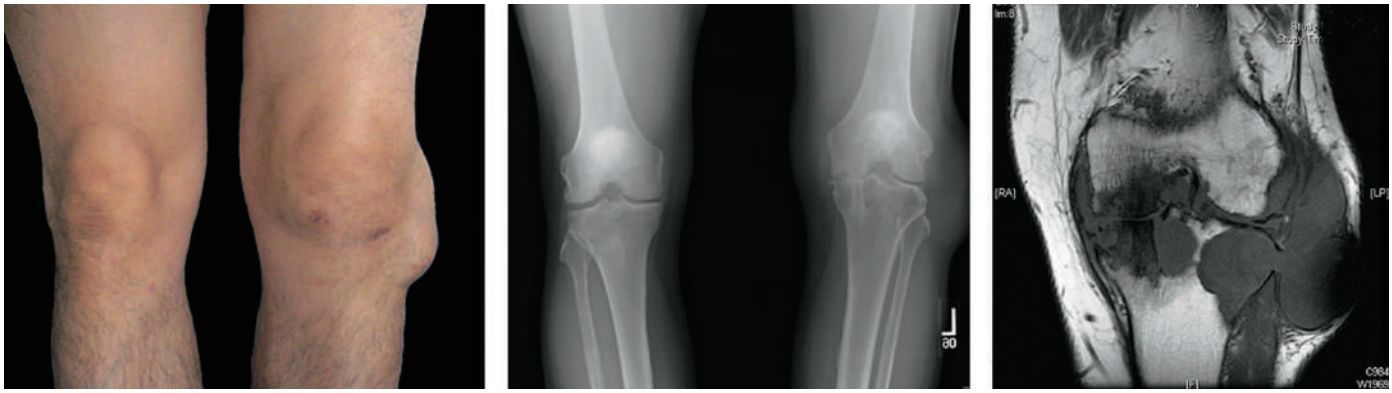

FIGURE 135-2 Chronic arthritis caused by *Histoplasma capsulatum* in the left knee. ***A.*** A man in his sixties from El Salvador presented with a history of progressive knee pain and difficulty walking for several years. He had undergone arthroscopy for a meniscal tear 7 years before presentation (without relief) and had received several intraarticular glucocorticoid injections. The patient developed significant deformity of the knee over time, including a large effusion in the lateral aspect. ***B.*** An x-ray of the knee showed multiple abnormalities, including severe medial femorotibial joint-space narrowing, several large subchondral cysts within the tibia and the patellofemoral compartment, a large suprapatellar joint effusion, and a large soft tissue mass projecting laterally over the knee. ***C.*** MRI further defined these abnormalities and demonstrated the cystic nature of the lateral knee abnormality. Synovial biopsies demonstrated chronic inflammation with giant cells, and cultures grew *H. capsulatum* after 3 weeks of incubation. All clinical cystic lesions and the effusion resolved after 1 year of treatment with itraconazole. The patient underwent a left total-knee replacement for definitive treatment. *(Courtesy of the late Francisco M. Marty, MD, Brigham and Women's Hospital, Boston; with permission.)*

is six times more common among men than among women, and alcoholics and other debilitated hosts are at risk for polyarticular infection.

Candida infection involving a single joint—usually the knee, hip, or shoulder—results from surgical procedures, intraarticular injections, or (among critically ill patients with debilitating illnesses such as diabetes mellitus or hepatic or renal insufficiency and patients receiving immunosuppressive therapy) hematogenous spread. *Candida* infections in IV drug users typically involve the spine, sacroiliac joints, or other fibrocartilaginous joints. Unusual cases of arthritis due to *Aspergillus* species, *Cryptococcus neoformans*, *Pseudallescheria boydii*, and the dematiaceous fungi also have resulted from direct inoculation or disseminated hematogenous infection in immunocompromised persons. In the United States, a 2012 national outbreak of fungal arthritis (and meningitis) caused by *Exserohilum rostratum* was linked to intraspinal and intraarticular injection of a contaminated preparation of methylprednisolone acetate.

The synovial fluid in fungal arthritis usually contains 10,000–40,000 cells/μL, with ~70% neutrophils. Stained specimens and cultures of synovial tissue often confirm the diagnosis of fungal arthritis when studies of synovial fluid give negative results. Treatment consists of drainage and lavage of the joint and systemic administration of an antifungal agent directed at a specific pathogen. The doses and duration of therapy are the same as for disseminated disease **(see Part 5, Section 16)**. In fungal prosthetic joint infection, the removal of all prosthetic joint material is highly recommended.

VIRAL ARTHRITIS

Viruses produce arthritis by infecting synovial tissue during systemic infection or by provoking an immunologic reaction that involves joints. As many as 50% of women report persistent arthralgias and 10% report frank arthritis within 3 days of the rash that follows natural infection with rubella virus and within 2–6 weeks after receipt of live-virus vaccine. Episodes of symmetric inflammation of fingers, wrists, and knees uncommonly recur for >1 year, but a syndrome of chronic fatigue, low-grade fever, headaches, and myalgias can persist for months or years. IV immunoglobulin has been helpful in selected cases. Self-limited monoarticular or migratory polyarthritis may develop within 2 weeks of the parotitis of mumps; this sequela is more common among men than women. Approximately 10% of children and 60% of women develop polyarthritis or polyarthralgia in small joints after infection with parvovirus B19. In adults, arthropathy sometimes occurs without fever or rash. Pain and stiffness, with less prominent swelling (primarily of the hands but also of the knees, wrists, and ankles), usually resolve within weeks, although a small proportion of patients develop chronic arthropathy.

About 2 weeks before the onset of jaundice, up to 10% of persons with acute hepatitis B develop an immune complex–mediated, serum sickness–like reaction with maculopapular rash, urticaria, fever, and arthralgias. Less common developments include symmetric arthritis involving the hands, wrists, elbows, or ankles and morning stiffness that resembles a flare of rheumatoid arthritis. Symptoms resolve at the time jaundice develops. Many persons with chronic hepatitis C infection report persistent arthralgia or arthritis, both in the presence and in the absence of cryoglobulinemia.

Painful arthritis often accompanies the fever and rash of several arthropod-borne viral infections, including those caused by Zika, chikungunya, O'nyong-nyong, Ross River, Mayaro, and Barmah Forest viruses **(Chap. 215)**. Symmetric arthritis involving the hands and wrists may occur during the convalescent phase of infection with lymphocytic choriomeningitis virus. Patients infected with an enterovirus frequently report arthralgias, and echovirus has been isolated from patients with acute polyarthritis.

Several arthritis syndromes are associated with HIV infection. An incomplete form of reactive arthritis with painful lower-extremity oligoarthritis may follow an episode of urethritis in HIV-infected persons. HIV-associated reactive arthritis appears to be extremely common among persons with the HLA-B27 haplotype, but sacroiliac joint disease is unusual and is seen mostly in the absence of HLA-B27. Up to one-third of HIV-infected persons with psoriasis develop psoriatic arthritis. Painless monoarthropathy and persistent symmetric polyarthropathy occasionally complicate HIV infection. Chronic persistent oligoarthritis of the shoulders, wrists, hands, and knees occurs in women infected with human T-lymphotropic virus type 1. Synovial thickening, destruction of articular cartilage, and leukemic-appearing atypical lymphocytes in synovial fluid are characteristic, but progression to T cell leukemia is unusual.

PARASITIC ARTHRITIS

Arthritis due to parasitic infection is rare. The guinea worm *Dracunculus medinensis* may cause destructive joint lesions in the lower extremities as migrating gravid female worms invade joints or cause ulcers in adjacent soft tissues that become secondarily infected. Hydatid cysts infect bones in 1–2% of cases of infection with *Echinococcus granulosus*. The expanding destructive cystic lesions may spread to and destroy adjacent joints, particularly the hip and pelvis. In rare cases, chronic synovitis has been associated with the presence of schistosomal eggs in synovial biopsies. Monoarticular arthritis in children with lymphatic filariasis appears to respond to therapy with diethylcarbamazine even in the absence of microfilariae in synovial fluid. Reactive arthritis has been attributed to hookworm,

Strongyloides, *Cryptosporidium*, and *Giardia* infection in case reports, but confirmation is required.

POSTINFECTIOUS OR REACTIVE ARTHRITIS

Reactive polyarthritis develops several weeks after ~1% of cases of nongonococcal urethritis and 2% of enteric infections, particularly those due to *Yersinia enterocolitica*, *Shigella flexneri*, *Campylobacter jejuni*, *Clostridioides difficile*, and *Salmonella* species. Only a minority of these patients have the other findings of classic reactive arthritis, including urethritis, conjunctivitis, uveitis, oral ulcers, and rash. Studies have identified microbial DNA or antigen in synovial fluid or blood, but the pathogenesis of this condition is poorly understood. The arthritis may occur several days or weeks after the infection and can be associated with dactylitis, enthesitis, or extraarticular involvement such as conjunctivitis.

Reactive arthritis is most common among young men (except after *Yersinia* infection) and has been linked to the HLA-B27 locus as a potential genetic predisposing factor. Patients report painful, asymmetric oligoarthritis that affects mainly the knees, ankles, and feet. Low back pain is common, and radiographic evidence of sacroiliitis is found in patients with long-standing disease. Most patients recover within 6 months, but prolonged recurrent disease is more common in cases that follow chlamydial urethritis. Anti-inflammatory agents help relieve symptoms, but the role of prolonged antibiotic therapy in eliminating microbial antigen from the synovium is controversial.

Migratory polyarthritis and fever constitute the usual presentation of acute rheumatic fever in adults **(Chap. 371)**. This presentation is distinct from that of poststreptococcal reactive arthritis, which also follows infections with group A *Streptococcus* but is not migratory, lasts beyond the typical 3-week maximum of acute rheumatic fever, and responds poorly to aspirin.

INFECTIONS IN PROSTHETIC JOINTS

Infection complicates 0.5–2% of total joint replacements. Prosthetic joint infection occurs more often in knee arthroplasty compared with hip arthroplasty. The majority of infections are acquired intraoperatively or immediately postoperatively as a result of wound breakdown or infection; less commonly, these joint infections develop later after joint replacement and are the result of hematogenous spread or direct inoculation. The presentation may be acute, with fever, pain, and local signs of inflammation, especially in infections due to *S. aureus*, pyogenic streptococci, and gram-negative bacilli. Alternatively, infection may persist for months or years without causing constitutional symptoms when less virulent organisms—such as coagulase-negative staphylococci, *Cutibacterium* (formerly *Propionibacterium*) species, enterococci, or diphtheroids—are involved. Such indolent infections usually are acquired during joint implantation and are discovered during evaluation of chronic unexplained pain or after a radiograph shows loosening of the prosthesis; the erythrocyte sedimentation rate and C-reactive protein level are usually elevated in such cases.

The diagnosis is best made by needle aspiration of the joint; accidental introduction of organisms during aspiration must be avoided meticulously. Synovial fluid pleocytosis with a predominance of polymorphonuclear leukocytes is highly suggestive of infection, since other inflammatory processes uncommonly affect prosthetic joints. Culture and Gram's stain usually yield the responsible pathogen. Sonication of explanted prosthetic material can improve the yield of culture, presumably by breaking up bacterial biofilms on the surfaces of prostheses. Semiquantitative culture should be obtained since a low number of organisms can represent contaminants. Molecular diagnostic testing of synovial fluid, sonicate fluid, or periprosthetic tissue also may improve the yield when routine culture is negative; however, it is not always available in microbiology laboratories. Use of special media for unusual pathogens such as fungi, atypical mycobacteria, and *Mycoplasma* may be necessary if routine and anaerobic cultures are negative. Molecular diagnostic results should be interpreted cautiously since they may represent colonization rather than a true pathogen. Testing of synovial fluid for alpha-defensin, C-reactive protein, leukocyte esterase, and calprotectin can be considered in challenging cases. These tests must be interpreted in the context of the synovial fluid leukocyte count and neutrophil percentage.

TREATMENT

Prosthetic Joint Infections

Treatment includes surgery and high doses of parenteral antibiotics, which are given for 4–6 weeks because bone is usually involved. In most cases, the prosthesis must be removed and replaced to cure the infection. Implantation of a new prosthesis is best delayed for several weeks or months because relapses of infection occur most commonly within this time frame. In some cases, reimplantation is not possible, and the patient must manage without a joint, with a fused joint, or even with amputation. Cure of infection without removal of the prosthesis is occasionally possible in cases that are due to streptococci or pneumococci and that lack radiologic evidence of loosening of the prosthesis. In these cases, antibiotic therapy must be initiated within several days of the onset of infection, and the joint should be drained vigorously by open arthrotomy or arthroscopically, preferably with polyethylene liner exchange, to have a more successful outcome. In selected patients who prefer to avoid the high morbidity rate associated with joint removal and reimplantation, lifelong suppression of the infection with antibiotics may be a reasonable goal. A high cure rate with retention of the prosthesis has been reported when the combination of oral rifampin and another antibiotic (e.g., a quinolone, an antistaphylococcal penicillin, or vancomycin) is given for 3–6 months to persons with staphylococcal prosthetic joint infection of short duration. This approach is based on the ability of rifampin to kill organisms adherent to foreign material and in the stationary growth phase.

PREVENTION

To avoid the disastrous consequences of infection, candidates for joint replacement should be selected with care. All modifiable risk factors should be identified and minimized preoperatively to improve the surgical outcome and prevent surgical site infection. Preoperative screening for *S. aureus* with decolonization should be considered. Rates of infection are particularly high among patients with rheumatoid arthritis, persons who have undergone previous surgery on the joint, and persons with medical conditions requiring immunosuppressive therapy. Perioperative antibiotic prophylaxis, usually with cefazolin, and measures to decrease intraoperative contamination, such as laminar flow, have lowered the rates of perioperative infection to <1% in many centers. After implantation, measures should be taken to prevent or rapidly treat extraarticular infections that might give rise to hematogenous spread to the prosthesis. The effectiveness of prophylactic antibiotics for the prevention of hematogenous infection after dental procedures has not been demonstrated; in fact, viridans streptococci and other components of the oral flora are extremely unusual causes of prosthetic joint infection. Accordingly, the American Dental Association and the American Academy of Orthopaedic Surgeons do not recommend antibiotic prophylaxis for most dental patients with total joint replacements and have stated that there is no convincing evidence to support its use. Similarly, guidelines issued by the American Urological Association and the American Academy of Orthopaedic Surgeons do not recommend the use of prophylactic antibiotics for most patients with prosthetic joints who are undergoing urologic procedures but state that prophylaxis should be considered in certain situations—e.g., for patients (especially immunocompromised patients) who are undergoing a procedure posing a relatively high risk of bacteremia (e.g., lithotripsy or surgery involving bowel segments).

136 Osteomyelitis

Werner Zimmerli

Osteomyelitis, an infection of bone, can be caused by various microorganisms that arrive at bone through different routes. Spontaneous hematogenous osteomyelitis may occur in otherwise healthy individuals, whereas local microbial spread mainly affects either individuals who have underlying disease (e.g., vascular insufficiency) or patients who have compromised skin or other tissue barriers, with consequent exposure of bone. The latter situation typically follows surgery involving bone, such as sternotomy or orthopedic repair.

The manifestations of osteomyelitis are different in children and adults. In children, circulating microorganisms seed mainly long bones, whereas in adults, the vertebral column is the most commonly affected site.

Management of osteomyelitis differs greatly depending on whether an implant is involved. The most important aim of the management of either type of osteomyelitis is to prevent progression to chronic osteomyelitis by rapid diagnosis and prompt treatment. Therefore, unambiguous case definitions are required. Device-related bone and joint infection necessitates a multidisciplinary approach requiring antibiotic therapy and, in many cases, surgical removal of the device. For most types of osteomyelitis, the optimal duration and route of antibiotic treatment have not been established in clinical trials. Therefore, the recommendations for therapy in this chapter reflect mainly expert opinions.

CLASSIFICATION

There is no generally accepted, comprehensive system for classification of osteomyelitis, primarily because of the multifaceted presentation of this infection. Different specialists are confronted with different facets of bone disease. Most often, however, general practitioners or internists are the first to encounter patients with the initial signs and symptoms of osteomyelitis. These primary care physicians should be able to recognize this disease in any of its forms. Osteomyelitis cases can be classified by various criteria, including pathogenesis, duration of infection, location of infection, and presence or absence of foreign material. The widely used Cierny-Mader staging system is useful mainly for trauma surgeons. It classifies osteomyelitis according to anatomic site, comorbidity, and radiographic findings, with stratification of long-bone osteomyelitis to optimize surgical management; this system encompasses both systemic and local factors affecting immune status, metabolism, and local vascularity.

Any of three mechanisms can underlie osteomyelitis: (1) hematogenous spread; (2) spread from a contiguous site following surgery; and (3) secondary infection in the setting of vascular insufficiency or concomitant neuropathy. Hematogenous osteomyelitis in adults typically involves the vertebral column. In only about half of patients a primary focus can be detected. The most common primary foci of infection are the urinary tract, skin/soft tissue, intravascular catheterization sites, and the endocardium. Spread from a contiguous source follows either bone trauma or surgical intervention. Wound infection leading to osteomyelitis typically occurs after cardiovascular intervention involving the sternum, orthopedic repair after open fracture, or prosthetic joint insertion. Osteomyelitis secondary to vascular insufficiency or peripheral neuropathy most often follows chronic, progressively deep skin and soft tissue infection of the foot. The most common underlying condition is diabetes. In diabetes that is poorly controlled, the *diabetic foot syndrome* is caused by skin, soft tissue, and bone ischemia combined with motor, sensory, and autonomic neuropathy.

Classification of osteomyelitis according to the duration of infection, although ill defined, is useful because the management of acute and chronic osteomyelitis differs. However, not a defined duration of infection, but the presence or absence of bone necrosis (sequesters) is crucial. Acute osteomyelitis without bone necrosis can generally be treated with antibiotics alone. In contrast, for chronic osteomyelitis antibiotic treatment should be combined with debridement surgery. Acute hematogenous or contiguous osteomyelitis evolves over a short period—i.e., a few days or weeks. In contrast, subacute or chronic osteomyelitis lasts for weeks or months before treatment is started. Typical examples of a subacute course are vertebral osteomyelitis due to tuberculosis or brucellosis and delayed implant-associated infections caused mainly by low-virulence microorganisms (coagulase-negative staphylococci, *Cutibacterium acnes*). A special form of osteomyelitis is Brodie's abscess, mainly occurring in young males. Chronic osteomyelitis develops when insufficient therapy leads to persistence or recurrence, most often after sternal, mandibular, or foot infection.

Classification by location distinguishes among cases in the long bones, the vertebral column, and the periarticular bones. Long bones are generally involved after hematogenous seeding in children or contiguous spread following trauma or surgery. The risk of vertebral osteomyelitis in adults increases with age. Periarticular osteomyelitis, which complicates septic arthritis that has not been adequately treated, is especially common in periprosthetic joint infection.

Osteomyelitis involving a foreign device requires surgical management for cure. Even acute implant-associated infection calls for prolonged antimicrobial therapy. Therefore, identification of this type of disease is of practical importance.

VERTEBRAL OSTEOMYELITIS

PATHOGENESIS

Vertebral osteomyelitis, also referred to as *disk-space infection*, *septic diskitis*, *spondylodiskitis*, or *spinal osteomyelitis*, is the most common manifestation of hematogenous bone infection in adults. This designation reflects a pathogenic process leading to involvement of the adjacent vertebrae and the corresponding intervertebral disk. In adults, the disk is avascular. Microorganisms invade via the segmental arterial circulation in adjacent endplates and then spread into the disk. Alternative routes of infection are retrograde seeding through the prevertebral venous plexus and direct inoculation during spinal surgery, epidural

infiltration, or trauma. In the setting of implant surgery, microorganisms are inoculated either during the procedure or, if wound healing is impaired, in the early postoperative period.

EPIDEMIOLOGY

Vertebral osteomyelitis occurs more often in male than in female patients (ratio, 1.5:1). Between 1995 and 2008, the incidence rate increased from 2.2 to 5.8 cases/100,000 person-years. There is a clear age-dependent increase. Men age ≥70 years have a sixfold higher incidence rate than those <70 years. The observed increase in reported cases over time may reflect improvements in diagnosis resulting from the broad availability of MRI technology. In addition, the fraction of cases of vertebral osteomyelitis acquired in association with health care is increasing as a consequence of comorbidity and the rising number of invasive interventions.

MICROBIOLOGY

Vertebral osteomyelitis is typically classified as pyogenic or nonpyogenic. However, this distinction is arbitrary: in "nonpyogenic" cases (tuberculous, brucellar), macroscopic pus formation (caseous necrosis, abscess) is quite common. A more accurate scheme is to classify cases as acute or subacute/chronic. Whereas the microbiologic spectrum of acute cases is similar in different parts of the world, the spectrum of subacute/chronic cases varies according to the geographic region. The great majority of cases are monomicrobial in etiology. Of episodes of acute vertebral osteomyelitis, 40–50% are caused by *Staphylococcus aureus*, 12% by streptococci, and 20% by gram-negative bacilli—mainly *Escherichia coli* (9%) and *Pseudomonas aeruginosa* (6%). Subacute vertebral osteomyelitis is typically caused by *Mycobacterium tuberculosis* or *Brucella* species in regions where these microorganisms are endemic. Osteomyelitis due to viridans streptococci also has a subacute presentation; these infections most often occur as secondary foci in patients with endocarditis. In vertebral osteomyelitis due to *Candida* species, the diagnosis is often delayed by several weeks; this etiology should be suspected in IV drug users who do not use sterile paraphernalia. In implant-associated spinal osteomyelitis, coagulase-negative staphylococci and *C. acnes*—which, in the absence of an implant, are generally considered contaminants—typically cause low-grade (chronic) infections. As an exception, coagulase-negative staphylococci can cause native spinal osteomyelitis in cases of prolonged bacteremia (e.g., in patients with infected pacemaker electrodes or implanted vascular catheters that are not promptly removed).

CLINICAL MANIFESTATIONS

The signs and symptoms of vertebral osteomyelitis are nonspecific. Only about half of patients develop fever >38°C (>100.4°F), perhaps because patients frequently use analgesic drugs. Back pain is the leading initial symptom (>85% of cases). The location of the pain corresponds to the site of infection: the cervical spine in ~10% of cases, the thoracic spine in 30%, and the lumbar spine in 60%. One exception is involvement at the thoracic level in two-thirds of cases of tuberculous osteomyelitis and at the lumbar level in only one-third. This difference is due to direct mycobacterial spread via pleural or mediastinal lymph nodes in pulmonary tuberculosis.

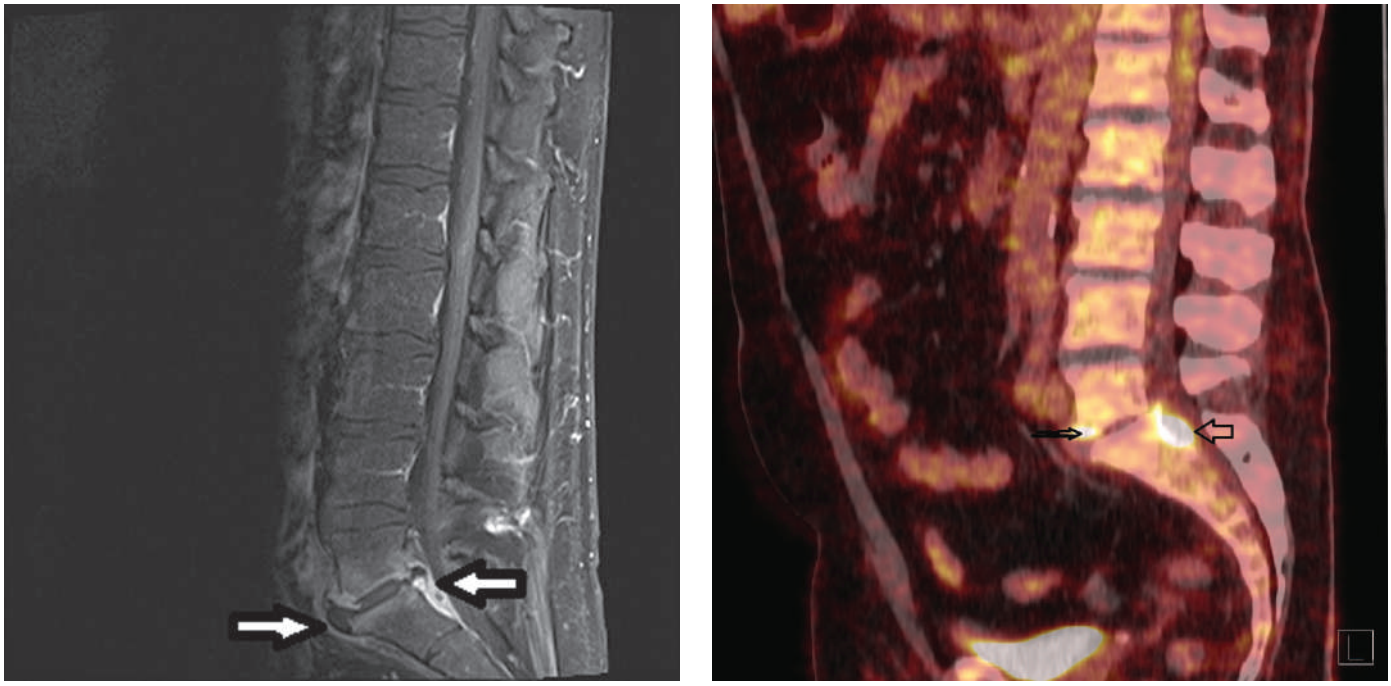
Neurologic deficits, such as radiculopathy, weakness, or sensory loss, are observed in about one-third of cases of vertebral osteomyelitis. Neurologic signs and symptoms are caused mostly by spinal epidural abscess. This complication starts with severe localized back pain and progresses to radicular pain, reflex changes, sensory abnormalities, motor weakness, bowel and bladder dysfunction, and paralysis.

A primary focus should always be sought but is found in only half of cases. Overall, endocarditis is identified in ~10% of patients. In osteomyelitis caused by viridans streptococci, endocarditis is the source in about half of patients.

Implant-associated spinal osteomyelitis can present as either early- or late-onset infection. Early-onset infection is diagnosed within 30 days after implant placement. *S. aureus* is the most common pathogen. Wound healing impairment and fever are the leading findings. Late-onset infection is diagnosed beyond 30 days after surgery, with low-virulence organisms such as coagulase-negative staphylococci or *C. acnes* as typical infecting agents. Fever is rare. One-quarter of patients have a sinus tract. Because of the delayed course and the lack of classic signs of infection, rapid diagnosis requires a high degree of suspicion.

DIAGNOSIS

Leukocytosis and neutrophilia have low levels of diagnostic sensitivity (only 65% and 40%, respectively). In contrast, an increased erythrocyte sedimentation rate or C-reactive protein (CRP) level has been reported in 98% and 100% of cases, respectively; thus, these tests are helpful in excluding vertebral osteomyelitis. The fraction of blood cultures that yield positive results depends heavily on whether the patient has been pretreated with antibiotics; across studies, the range is 30–78%. In view of this low rate of positive blood culture after antibiotic treatment, such therapy should be withheld until microbial growth is proven unless the patient has sepsis syndrome. In patients with negative blood cultures, CT-guided or open biopsy is needed. Whether a CT-guided biopsy with a negative result is repeated or followed by open biopsy depends on the experience of personnel at the specific center. Bone samples should be cultured for aerobic, anaerobic, and fungal agents, with a portion of the sample sent for histopathologic study. In cases with a subacute/chronic presentation, a suggestive history, or a granuloma detected during histopathologic analysis, mycobacteria and brucellae also should be sought. When blood and tissue cultures are negative despite suggestive histopathology, nonculture techniques (eubacterial or multiplex polymerase chain reaction analysis, metagenomics) of biopsy specimens or aspirated pus should be considered. These techniques allow detection of unusual pathogens such as *Helicobacter* spp. or *Tropheryma whipplei*.



Given that signs and symptoms of osteomyelitis are nonspecific, the clinical differential diagnosis of febrile back pain is broad, including pyelonephritis, pancreatitis, and viral syndromes. In addition, multiple noninfectious pathologies of the vertebral column, such as osteoporotic fracture, seronegative spondylitis (ankylosing spondylitis, psoriasis, reactive arthritis, enteropathic arthritis), and spinal stenosis must be considered.

Imaging procedures are the most important tools not only for the diagnosis of vertebral osteomyelitis but also for the detection of pyogenic complications and alternative conditions (e.g., bone metastases or osteoporotic fractures). Plain radiography is a reasonable first step in evaluating patients without neurologic symptoms and may reveal an alternative diagnosis. Because of its low sensitivity, plain radiography generally is not helpful in acute osteomyelitis, but it can be useful in subacute or chronic cases. The gold standard is MRI, which should be performed expeditiously in patients with neurologic impairment in order to rule out a herniated disk or to detect pyogenic complications in a timely manner **(Fig. 136-1, *left*)**. Even if the pathologic findings on MRI suggest vertebral osteomyelitis, alternative diagnoses should be considered, especially when blood cultures are negative. The most common alternative diagnosis is erosive osteochondrosis. Septic bone necrosis, gouty spondylodiskitis, and erosive diskovertebral lesions (Andersson lesions) in ankylosing spondylitis may likewise mimic vertebral osteomyelitis. CT is less sensitive than MRI but may be helpful in guiding a percutaneous biopsy. Positron emission tomography (PET) with ^{18}F-fluorodeoxyglucose, which has a high degree of diagnostic accuracy, is an alternative imaging procedure when MRI is contraindicated **(Fig. 136-1, *right*)**. ^{18}F-fluorodeoxyglucose PET should be considered for patients with implants and patients in whom several foci are suspected.

TREATMENT

Vertebral Osteomyelitis

The aims of therapy for vertebral osteomyelitis are (1) elimination of the pathogen(s), (2) protection from further bone loss, (3) relief of back pain, (4) prevention of complications, and (5) stabilization, if needed.

A B

FIGURE 136-1 Left: MRI from a 53-year-old man suffering from prosthetic aortic valve endocarditis (*Aggregatibacter actinomycetemcomitans*). In addition, he experienced lumbar pain for 7 weeks. MRI sagittal sequence shows on T1 fat-saturated post-gadolinium image enhancement in the intervertebral disk space (*ventral arrow*) and a small epidural abscess (*dorsal arrow*). **Right:** PET/CT from the same patient 4 weeks earlier. PET/CT fusion shows fluorodeoxyglucose uptake at L5 ventral (*small arrow*) and dorsal of S1 (*large arrow*: epidural abscess). *(Figures courtesy of Damien Toia, MD, Kantonsspital Baselland; with permission.)*

Table 136-1 summarizes suggested antimicrobial regimens for infections attributable to the most common etiologic agents. For optimal antimicrobial therapy, identification of the infecting agent is required. Therefore, in patients without sepsis syndrome, antibiotics should not be administered until the pathogen is identified in a blood culture, a bone biopsy, or an aspirated pus collection. Traditionally, bone infections are at least initially treated by the IV route. However, the preference for the IV route is not evidence based. There are no good arguments for the assumption that IV therapy is superior to oral administration if the following requirements are met: (1) optimal antibiotic spectrum, (2) excellent bioavailability of the oral drug, (3) clinical studies confirming efficacy of the oral drug, (4) normal intestinal function, and (5) no vomiting. Indeed, in a controlled trial in patients with bone and joint infections, including vertebral osteomyelitis, oral antibiotic therapy was noninferior to intravenous therapy when used during the first 6 weeks. Nevertheless, a short initial course of parenteral therapy with a β-lactam antibiotic may lower the risk of emergence of fluoroquinolone resistance, especially if *P. aeruginosa* infection is treated with ciprofloxacin or staphylococcal infection with the combination of a fluoroquinolone plus rifampin. These suggestions are based on observational studies and expert opinion. A randomized, controlled trial showed that 6 weeks of antibiotic treatment is not inferior to a 12-week course in patients with pyogenic vertebral osteomyelitis. The cure rate was 90.9% in both groups 1 year after therapy. Thus, prolonged antibiotic therapy is required only for patients with undrained abscesses and for patients with spinal implants. Treatment efficacy should be regularly monitored through inquiries about signs and symptoms (fever, pain) and assessment for signs of inflammation (elevated CRP concentrations). Follow-up MRI is appropriate only for patients with pyogenic complications since the correlation between clinical healing and improvement on MRI is very poor.

Surgical treatment generally is not needed in acute hematogenous vertebral osteomyelitis. However, it is always necessary in implant-associated spinal infection. Early infections (those occurring up to 30 days after internal stabilization) can be cured with debridement, implant retention, and a 3-month course of antibiotics (Table 136-2). In contrast, in late infection with a duration of >30 days, implant removal and a 6-week course of antibiotics (Table 136-1) are required for complete elimination of the infection. If implants cannot be removed, oral suppressive long-term treatment should follow the initial course of IV antibiotics. The optimal duration of suppressive therapy is unknown. However, if antibiotic therapy is discontinued after, for example, 1 year, close clinical and laboratory (CRP) follow-up is needed.

COMPLICATIONS

Complications should be suspected when there is persistent pain, a persistently increased CRP level, and new-onset or persistent neurologic impairment. In cases of persistent pain with or without signs of inflammation, paravertebral, epidural, or psoas abscesses must be sought. Epidural abscesses occur in 15–20% of cases. This complication is more common in the cervical column (30%) than in the lumbar spine (12%). Risk factors for severe neurologic deficit were epidural abscess, cervical and/or thoracic involvement, and *S. aureus* vertebral osteomyelitis. Persistent pain despite normalization of CRP values indicates mechanical complications such as severe osteonecrosis or spinal instability. These patients require a consult with an experienced orthopedic surgeon.

GLOBAL CONSIDERATIONS

The incidence rate of acute vertebral osteomyelitis is similar in different regions of the world. In contrast, subacute/chronic vertebral osteomyelitis predominates in defined regions. Cases attributable to brucellosis predominate in endemic areas such as the Middle East, Africa, Central and South America, and the Indian subcontinent. Tuberculosis is an especially frequent cause in Africa and Asia (India, Indonesia, China), where more than two-thirds of the global tuberculosis burden is reported. Thus, specific diagnostic tests are needed in patients either living in or having traveled to these regions.

OSTEOMYELITIS IN LONG BONES

PATHOGENESIS

Osteomyelitis in long bones is a consequence of hematogenous seeding, exogenous contamination during trauma (open fracture), or

TABLE 136-1 Antibiotic Therapy for Osteomyelitis in Adults without Implants[a]

MICROORGANISM	ANTIMICROBIAL AGENT (DOSE,[b] ROUTE)
Staphylococcus spp.	
Methicillin-susceptible	Nafcillin or oxacillin[c] (2 g IV q6h) ***followed by*** Rifampin (300–450 mg PO q12h) plus levofloxacin (750 mg PO q24h or 500 mg PO q12h)
Methicillin-resistant	Vancomycin[d] (15 mg/kg IV q12h) or daptomycin (8–10 mg/kg IV q24h) ***followed by*** Rifampin (300–450 mg PO q12h) ***plus*** Levofloxacin (750 mg PO q24h or 500 mg PO q12h) or TMP-SMX[e] (1 double-strength tablet PO q8h) or fusidic acid (500 mg PO q8h)
Streptococcus spp.	Penicillin G[c] (5 million units IV q6h) or ceftriaxone (2 g IV q24h)
Enterobacteriaceae	
Quinolone-susceptible	Ciprofloxacin (750 mg PO q24h)
Quinolone-resistant[f]	Imipenem (500 mg IV q6h) or meropenem (1–2g IV q8h)
Pseudomonas aeruginosa	Cefepime or ceftazidime (2 g IV q8h) *plus* an aminoglycoside[g] ***or*** Piperacillin-tazobactam (4.5 g IV q8h) plus an aminoglycoside[g] for 2–4 weeks ***followed by*** Ciprofloxacin[h] (750 mg PO q12h)
Anaerobes	Clindamycin (600 mg IV q6–8h) for 2–4 weeks ***followed by*** Clindamycin[i] (300 mg PO q6h)

[a]Unless otherwise indicated, the total duration of antimicrobial treatment is generally 6 weeks. [b]All dosages are for adults with normal renal function. [c]When the patient has delayed-type penicillin hypersensitivity, cefuroxime (1.5 g IV q6–8h) can be administered. When the patient has immediate-type penicillin hypersensitivity, the penicillin should be replaced by vancomycin (1 g IV q12h). [d]Target vancomycin trough level: 15–20 μg/mL. [e]Trimethoprim-sulfamethoxazole. A double-strength tablet contains 160 mg of trimethoprim and 800 mg of sulfamethoxazole. [f]Including isolates producing extended-spectrum β-lactamase. [g]The need for addition of an aminoglycoside has not yet been proven. However, this addition may decrease the risk of emergence of resistance to the β-lactam. [h]The rationale for starting ciprofloxacin treatment only after pretreatment with a β-lactam is the increased risk of emergence of quinolone resistance in the presence of a heavy bacterial load. [i]Alternatively, penicillin G (5 million units IV q6h) or ceftriaxone (2 g IV q24h) can be used against gram-positive anaerobes (e.g., *Cutibacterium acnes*), and metronidazole (500 mg IV/PO q8h) can be used against gram-negative anaerobes (e.g., *Bacteroides* spp.).

perioperative contamination during surgery involving bone. Hematogenous infection in long bones typically occurs in children. In adults, the leading pathogenic source is exogenous fracture-related infection, mainly associated with internal fixation devices. For classification, the presence of a sequestrum and the status of the surrounding soft tissue are crucial for the decision as to whether a surgical intervention is required. Chronic osteomyelitis can be reactivated after a symptom-free interval of >70 years. Such recurrences are most common among elderly patients who developed *S. aureus* osteomyelitis in the preantibiotic era.

EPIDEMIOLOGY

In adults, most cases of long-bone osteomyelitis are posttraumatic or postsurgical; less frequently, late recurrence arises from hematogenous infections during childhood. For postoperative or postsurgical osteomyelitis, the term "facture-related infection" was generated. The risk of infection depends on the type of fracture. After closed fracture, implant-associated infection occurs in fewer than 1% of patients. In contrast, after open fracture, the risk of osteomyelitis ranges from ~2% up to 30%, with the precise figure depending on the degree of tissue damage during trauma and the time between injury and admission to a specialized center.

MICROBIOLOGY

The spectrum of microorganisms causing hematogenous long-bone osteomyelitis does not differ from that in vertebral osteomyelitis. *S. aureus* is most commonly isolated in each type of osteomyelitis. In rare cases, mycobacteria or fungal agents such as *Cryptococcus* species, *Sporothrix schenckii*, *Blastomyces dermatitidis*, or *Coccidioides* species are found in patients who live or have traveled in endemic regions. Impaired cellular immunity (e.g., in HIV infection or after transplantation) predisposes to these etiologies. Coagulase-negative staphylococci are the second most common etiologic agents (after *S. aureus*) in implant-associated osteomyelitis. After open fracture, contiguous long-bone osteomyelitis is typically caused by gram-negative bacilli or a polymicrobial mixture of organisms.

CLINICAL MANIFESTATIONS

The leading symptoms in adults with primary or recurrent hematogenous long-bone osteomyelitis are pain and low-grade fever. Infection occasionally manifests as clinical sepsis and local signs of inflammation (erythema and swelling). After internal fixation, osteomyelitis can be classified as early (acute; <3 weeks), delayed (3–10 weeks), or late (chronic) infection. Early/acute long-bone osteomyelitis manifests as signs of surgical site infection, such as erythema and impaired wound healing. Acute implant-associated infection may also follow hematogenous seeding at any time after implantation of a device. Typical symptoms are new-onset pain and signs of sepsis. Delayed or late (chronic) infections are usually caused by low-virulence microorganisms or occur after ineffective treatment of early-onset infection. Patients may present with persisting pain, subtle local signs of inflammation, intermittent discharge of pus, or fluctuating erythema over the scar **(Fig. 136-2)**. A special form of subacute osteomyelitis is Brodie's abscess, which is characterized by pain (98%) and swelling (53%), mainly in the tibia or the femur. Fever and inflammatory markers are typical. The median delay from symptoms to diagnosis is 3 months. Thus, a young patient with unclear localized pain in the tibia or femur should be worked-up with an imaging modality (plain x-ray, MRI, or CT).

DIAGNOSIS

The diagnostic workup for acute hematogenous long-bone osteomyelitis is similar to that for vertebral osteomyelitis. Bone remodeling and thus marker uptake are increased for at least 1 year after surgery. Therefore, the three-phase bone scan is not useful during this interval. However, in late recurrences it allows rapid diagnosis at low cost. If the results are positive, CT is required to estimate the extent of inflamed tissue and detect bone necrosis (sequesters). Implant-associated infection should be suspected if CRP values do not return to the normal range or rise after an initial decrease. Clinical and laboratory suspicion should prompt surgical exploration and sampling.

In osteomyelitis of >1 year's duration, single-photon emission CT plus conventional CT (SPECT/CT) is a good option, either with ^{99m}Tc methylene diphosphonate (^{99m}Tc-MDP)–labeled leukocytes or with labeled monoclonal antibodies to granulocytes. Surgical debridement is needed for diagnostic (biopsy culture, histology) and therapeutic reasons.

TREATMENT

Osteomyelitis in Long Bones

Treatment for acute hematogenous infection in long bones is identical to that for acute vertebral osteomyelitis (Table 136-1). The suggested duration of antibiotic therapy is 4–6 weeks. In patients with good soft tissue condition and no sequestra or implants, generally no surgical intervention is required. According to a controlled trial, oral treatment can be given, provided that a regimen with excellent oral biocompatibility is available. An initial IV course can be as short as a few days, if the microorganism and

TABLE 136-2 Antibiotic Therapy for Osteomyelitis Associated with Orthopedic Devices

MICROORGANISM	ANTIMICROBIAL AGENT[a] (DOSE, ROUTE)
Staphylococcus spp.	*Recommendation for initial treatment phase (2 weeks with implant)*

	plus
	Nafcillin or oxacillin[c] (2 g IV q6h)
Methicillin-resistant	Rifampin (450 mg PO/IV q12h[b])
	plus
	Vancomycin (15 mg/kg IV q12h) or daptomycin (8–10 mg/kg IV q24h)
Staphylococcus spp.	*Recommendation after completion of initial treatment phase*
	Rifampin (450 mg PO q12h[b])
	plus
	Levofloxacin (750 mg PO q24h or 500 mg PO q12h) or ciprofloxacin (750 mg PO q12h) or fusidic acid (500 mg PO q8h) or TMP-SMX[d] (1 double-strength tablet PO q8h) or minocycline (100 mg PO q12h) or linezolid (600 mg PO q12h) or clindamycin (1200–1350 mg/d PO in 3 or 4 divided doses)
Streptococcus spp.[e]	Penicillin G[c] (18–24 million units/d IV in 6 divided doses) or ceftriaxone (2 g IV q24h) for 4 weeks
	followed by
	Amoxicillin (750–1000 mg PO q6–8h) or clindamycin (1200–1350 mg/d PO in 3 or 4 divided doses)
Enterococcus spp.[f]	
Penicillin-susceptible	Penicillin G[c] (24 million units/d IV in 6 divided doses) *or* ampicillin or amoxicillin[g] (2 g IV q4–6h)
Penicillin-resistant	Vancomycin (15 mg/kg IV q12h) or daptomycin (6–10 mg/kg IV q24h) or linezolid (600 mg IV/PO q12h)
Enterobacteriaceae	A β-lactam selected in light of in vitro susceptibility profile for 2 weeks[h]
	followed by
	Ciprofloxacin (750 mg PO q12h)
Enterobacter spp.[i] and nonfermenters[i] (e.g., *Pseudomonas aeruginosa*)	Cefepime or ceftazidime (2 g IV q8h) *or* meropenem (1–2 g IV q8h[k]) for 2–4 weeks
	followed by
	Ciprofloxacin (750 mg PO q12h)
Cutibacterium spp.	Penicillin G[c] (18–24 million units/d IV in 6 divided doses) or clindamycin (600–900 mg IV q8h) for 2–4 weeks
	followed by
	Amoxicillin (750–1000 mg PO q6–8h) or clindamycin (1200–1350 mg/d PO in 3 or 4 divided doses)
Gram-negative anaerobes (e.g., *Bacteroides* spp.)	Metronidazole (500 mg IV/PO q8h)
Mixed bacteria (without methicillin-resistant staphylococci)	Ampicillin-sulbactam (3 g IV q6h) or amoxicillin-clavulanate[l] (2.2 g IV q6h) or piperacillin-tazobactam (4.5 g IV q8h) or imipenem (500 mg IV q6h) or meropenem (1–2 g IV q8h[k]) for 2–4 weeks
	followed by
	Individualized oral regimens chosen in light of antimicrobial susceptibility

[a]Antimicrobial agents should be chosen in light of the isolate's in vitro susceptibility, the patient's drug allergies and intolerances, potential drug interactions, and contraindications to specific drugs. All dosages recommended are for adults with normal renal and hepatic function. See text for total durations of antibiotic treatment. [b]Other dosages and intervals of administration with equivalent success rates have been reported. [c]When the patient has delayed-type penicillin hypersensitivity, cefazolin (2 g IV q8h) can be administered. When the patient has immediate-type penicillin hypersensitivity, the penicillin should be replaced by vancomycin (1 g IV q12h). [d]Trimethoprim-sulfamethoxazole. A double-strength tablet contains 160 mg of trimethoprim and 800 mg of sulfamethoxazole. [e]Determination of the minimal inhibitory concentration (MIC) of penicillin is advisable. [f]Combination therapy with an aminoglycoside is optional since its superiority to monotherapy for prosthetic joint infection is unproved. When using combination therapy, monitor for signs of aminoglycoside ototoxicity and nephrotoxicity; the latter is potentiated by other nephrotoxic agents (e.g., vancomycin). [g]For patients with hypersensitivity to penicillin, see treatment options for penicillin-resistant enterococci. [h]Ciprofloxacin (PO or IV) can be administered to patients with hypersensitivity to β-lactams. [i]Ceftriaxone and ceftazidime should not be administered for treatment targeting *Enterobacter* species, even strains that test susceptible in the laboratory, but can be used against nonfermenters. Strains producing extended-spectrum β-lactamases should not be treated with any cephalosporin, including cefepime. *Enterobacter* infections can also be treated with ertapenem (1 g IV q24h); however, ertapenem is not effective against *Pseudomonas* spp. and other nonfermenters. [j]Addition of an aminoglycoside is optional. Use of two active drugs can be considered in light of the patient's clinical condition. [k]The recommended dosage is in line with the guidelines of the Infectious Diseases Society of America. In Europe, 2 g IV q8h is suggested for *P. aeruginosa* infections. [l]Not available as an IV formulation in the United States.

its antibiotic susceptibility is known. In recurrences of chronic osteomyelitis as well as in each type of exogenous osteomyelitis (acute, chronic, with or without an implant), a combination of surgical debridement, obliteration of dead space, and long-term antibiotic therapy is required. The length of therapy depends on the completeness of the surgical intervention (removal of sequestra, implants, and necrotic tissue).

The therapeutic aims in patients whose infections are associated with internal fixation devices are consolidation of the fracture and prevention of chronic osteomyelitis. Stable implants can be maintained except in patients with uncontrolled sepsis. In a systematic review reporting the outcome of 276 patients, the success rate with retention of the implant was 86–100% in early, 82–89% in delayed, and only 67% in late fracture-related infection. Appropriate antimicrobial therapies are listed in Table 136-2. The cure rate for early staphylococcal implant-associated infections treated with a fluoroquinolone plus rifampin is >90%. Rifampin is efficacious against staphylococcal biofilms of ≤3 weeks' duration. Similarly, fluoroquinolones are active against biofilms formed by gram-negative bacilli. In these cases, a short initial course of IV therapy with a β-lactam antibiotic is suggested to minimize the risk of emergence of resistance to the oral drugs. The total duration of treatment is 3 months, and the device can be retained even after antibiotics have been discontinued. In contrast, in cases caused by rifampin-resistant staphylococci or fluoroquinolone-resistant gram-negative bacilli, all hardware should be removed after consolidation of the fracture and before discontinuation of antibiotics. These patients are treated with an oral antibiotic (suppressive therapy) as long as the hardware is retained.

FIGURE 136-2 A 42-year-old man who had sustained a malleolar fracture 6 weeks previously had persistent pain and slight inflammation after orthopedic repair. His infection was treated with oral antibiotics without debridement surgery. This insufficient management of an implant-associated *Staphylococcus aureus* infection was complicated by a sinus tract.

FIGURE 136-3 Acute postoperative periprosthetic joint infection of the left hip caused by group B streptococci in a 68-year-old woman.

COMPLICATIONS

The main complication of long-bone osteomyelitis is the persistence of infection with progression to chronic osteomyelitis. This risk is especially high after internal fixation of an open fracture and among patients with implant-associated osteomyelitis that is treated without surgical debridement. In longstanding osteomyelitis, recurrent sinus tracts result in severe damage to skin and soft tissue (Fig. 136-2). Patients who have chronic open wounds need a therapeutic approach combining orthopedic repair and plastic reconstructive surgery.

GLOBAL CONSIDERATIONS

In North American and Western European countries, tuberculous osteomyelitis is extremely rare, occurring mainly in very old people, HIV-infected patients, and immigrants from endemic countries. In contrast, in countries where the prevalence of tuberculosis is high (India, Indonesia, China), tuberculous osteomyelitis must routinely be considered.

PERIPROSTHETIC JOINT INFECTION

PATHOGENESIS

Implanted foreign material is highly susceptible to local infection due to local immunodeficiency around the device. Infection occurs by either the exogenous or the hematogenous route. More rarely, contiguous spread from adjacent sites of osteomyelitis or deep soft-tissue infection may cause periprosthetic joint infection (PJI). The fact that foreign devices are covered with host proteins such as fibronectin favors the adherence of staphylococci and the formation of a biofilm that resists phagocytosis.

EPIDEMIOLOGY

The risk of infection manifesting during the first 2 postoperative years varies according to the joint. It is lowest after hip and knee arthroplasty (0.3–1.5%) and highest after ankle and elbow replacement (4–10%). The risk of hematogenous PJI is highest in the early postoperative period. However, hematogenous seeding occurs throughout life, and most cases therefore develop >2 years after implantation. The rate of risk for secondary PJI during *S. aureus* bacteremia is 30–40%.

MICROBIOLOGY

About 50–70% of cases of PJI are caused by staphylococci (*S. aureus* and coagulase-negative staphylococci), 6–10% by streptococci, 4–10% by gram-negative bacilli, and the rest by various other microorganisms. In patients with hematogenous PJI, the fraction of streptococci and gram-negative bacilli is higher and the fraction of coagulase-negative staphylococci is much lower. All microorganisms can cause PJI, including fungi and mycobacteria. *C. acnes* causes up to one-third of episodes of periprosthetic shoulder infection.

CLASSIFICATION AND CLINICAL MANIFESTATIONS

PJI is traditionally classified as early (<3 months after implantation), delayed (3–24 months after surgery), or late (>2 years after implantation). For therapeutic decision-making (see below), it is more useful to classify PJI as (1) acute hematogenous PJI with <3 weeks of symptoms, (2) early postinterventional PJI manifesting within 1 month after surgery, or (3) chronic PJI with symptom duration of >3 weeks.

Acute exogenous PJI typically presents with local signs of infection **(Fig. 136-3)**. In contrast, acute hematogenous PJI is most often caused by *S. aureus* and is characterized by new-onset pain. Local inflammatory signs are rare in hip PJI but frequent in knee PJI. Fever is rare after the initial phase of bacteremia. Key findings in chronic PJI are joint effusion, local pain, implant loosening, and occasionally a sinus tract. Chronic PJI is most commonly caused by low-virulence microorganisms such as coagulase-negative staphylococci or *C. acnes*. These infections are characterized by nonspecific symptoms, such as chronic pain caused by low-grade inflammation or early loosening.

DIAGNOSIS

Blood tests such as the measurement of CRP (elevated levels, ≥10 mg/L) and erythrocyte sedimentation rate (elevated rates, ≥30 mm/h) are sensitive (91–97%) but not specific (70–78%). Synovial fluid cell counts are ~90% sensitive and specific, with threshold values of 1700 leukocytes/μL in periprosthetic knee infection and 4200 leukocytes/μL in periprosthetic hip infection. A biomarker, α-defensin, can be tested in synovial fluid; this biomarker is highly specific and therefore useful in confirming PJI. However, this test is expensive and its sensitivity is limited; therefore, it should not be used for screening. During debridement surgery, at least three but optimally six tissue samples should be obtained for culture and histopathology. If implant material (modular parts, screws, or the prosthesis) is removed, sonication of this material followed by culture and/or use of molecular methods to examine the sonicate fluid allows the detection of microorganisms in biofilms.

The three-phase bone scan is very sensitive for detecting PJI but is not specific. As mentioned above, this test does not differentiate bone remodeling from infection and therefore is not useful during at least the first year after implantation. CT and MRI detect soft tissue infection, prosthetic loosening, and bone erosion, but imaging artifacts caused by metal implants limit their use. ^{18}F-fluorodeoxyglucose PET (^{18F}-FD-PET) is an alternative method with good sensitivity but low specificity for the detection of PJI. Therefore, ^{18}F-FDG-PET/CT is useful only in excluding but not confirming PJI.

TREATMENT

Periprosthetic Joint Infection

The outcome following treatment of PJI is better when managed using a multidisciplinary approach involving an experienced orthopedic surgeon, an infectious disease specialist, a plastic reconstructive surgeon, and a microbiologist. Therefore, most patients are referred to a specialized center. In general, the goal of treatment is cure—i.e., a pain-free functional joint with complete eradication of the infecting pathogen(s). However, for patients with severe comorbidity, lifelong suppressive antimicrobial therapy may be preferred. As a rule, antimicrobial therapy without surgical intervention is not curative but merely suppressive. There are four curative surgical options: debridement and implant retention, one-stage implant exchange, two-stage implant exchange, and implant removal without replacement. The least invasive treatment option should be selected for each patient without compromising the cure rate. The choice can be guided following a treatment algorithm. However, the different surgical options have not been tested in a randomized controlled trial. Implant retention offers a good chance of infection-free survival (>80%) only if the following conditions are fulfilled: (1) acute infection, (2) stable implant, (3) pathogen susceptible to a biofilm-active antimicrobial agent (see below), and (4) skin and soft tissue in good condition.

Table 136-2 summarizes pathogen-specific antimicrobial therapy for PJI. Initial IV therapy is followed by long-term oral antibiotics. Efficacious treatment is best defined in staphylococcal implant-associated infections. Rifampin exhibits excellent activity against biofilms composed of susceptible staphylococci. Because of the risk of rapid emergence of resistance, rifampin must always be combined with another effective antibiotic. If gram-negative infections are treated with implant retention, fluoroquinolones should be used because of their activity against gram-negative biofilms.

PREVENTION OF HEMATOGENOUS INFECTION

As mentioned above, hematogenous seeding may occur throughout life. This risk is highest during *S. aureus* bacteremia from a distant focus. Therefore, documented bacterial infections should be promptly treated in patients with prosthetic joints. However, according to a prospective case-control study, the risk of prosthetic hip or knee infection is not increased following dental procedures. Therefore, antibiotic prophylaxis is not needed during dental work.

GLOBAL CONSIDERATIONS

Rifampin and fluoroquinolones are still the only antimicrobial agents with good activity against staphylococcal and gram-negative biofilms, respectively. Thus, in countries with high rates of rifampin resistance in staphylococci and/or high rates of fluoroquinolone resistance in gram-negative bacilli, debridement with implant retention generally does not yield a good cure rate.

STERNAL OSTEOMYELITIS

PATHOGENESIS

Sternal osteomyelitis occurs primarily after sternal surgery (with the entry of exogenous organisms) and more rarely by hematogenous seeding or contiguous extension from adjacent sites of sternocostal arthritis. Exogenous sternal osteomyelitis after open sternal surgery is also called *deep sternal-wound infection.* Exogenous infection may follow minor sternal trauma, sternal fracture, and manubriosternal septic arthritis. Tuberculous sternal osteomyelitis typically manifests during hematogenous seeding in children or as reactivated infection in adults. Reactivation is sometimes preceded by blunt trauma. In rare cases, tuberculous sternal osteomyelitis is caused by continuous infection from an infected internal mammary lymph node.

EPIDEMIOLOGY

The incidence of poststernotomy wound infection varies from 0.5% to 2%, but figures are even higher among patients with risk factors such as diabetes, obesity, chronic renal failure, emergency surgery, use of bilateral internal mammary artery grafts, and re-exploration for bleeding. Rapid diagnosis and correct management of superficial sternal wound infection prevent its progression to sternal osteomyelitis. Primary (hematogenous) sternal osteomyelitis accounts for only 0.3% of all cases of osteomyelitis. Risk factors are IV drug use, HIV infection, radiotherapy, blunt trauma, cardiopulmonary resuscitation, alcohol abuse, liver cirrhosis, and hemoglobinopathy.

MICROBIOLOGY

Poststernotomy osteomyelitis is generally caused by *S. aureus* (10–20% of cases), coagulase-negative staphylococci (40–60%), gram-negative bacilli (5-15%), or *C. acnes* (2–10%). The spectrum of microorganisms greatly varies in different populations (as represented in different publications); this is perhaps due to local epidemiologic conditions, such as antimicrobial stewardship and the incidence of chronic infections. Polymicrobial cases are rare in acute infection and indicate exogenous superinfection during therapy. Hematogenous sternal osteomyelitis is caused most commonly by *S. aureus*. Other microorganisms play a role in special populations—e.g., *P. aeruginosa* in IV drug users, *Salmonella* species in individuals with sickle cell anemia, and *M. tuberculosis* in patients from endemic areas who have previously had tuberculosis.

CLINICAL MANIFESTATIONS

Exogenous sternal osteomyelitis manifests as fever, increased local pain, erythema, wound discharge, and sternal instability **(Fig. 136-4)**. Contiguous mediastinitis is a feared complication, occurring in ~10–30% of patients with sternal osteomyelitis. Hematogenous sternal osteomyelitis is characterized by sternal pain, swelling, and erythema. In addition, most patients have systemic signs and symptoms of sepsis.

The differential diagnosis of hematogenous sternal osteomyelitis includes immunologic processes typically presenting as systemic or multifocal inflammation of the sternum or of the sternoclavicular or sternocostal joints (e.g., SAPHO [synovitis, acne, pustulosis, hyperostosis, osteitis], vasculitis, chronic multifocal relapsing osteomyelitis).

DIAGNOSIS

In primary sternal osteomyelitis, the diagnostic workup does not differ from that in other types of hematogenous osteomyelitis (see above). When a patient has grown up in regions where tuberculosis is endemic, a specific workup for mycobacterial infection should be performed, especially if osteomyelitis had its onset after a blunt sternal trauma. In secondary sternal osteomyelitis, leukocyte counts may be normal, but the CRP level is >100 mg/L in most cases. Tissue sampling for microbiologic studies is crucial. In osteomyelitis associated with sternal wires, low-virulence microorganisms, such as coagulase-negative staphylococci, play an important role. In order to differentiate between colonization and infection, samples from at least three deep biopsies should be subjected to microbiologic examination. Superficial swab cultures are not diagnostic and may be misleading. No studies have

FIGURE 136-4 Sternal osteomyelitis caused by *Staphylococcus epidermidis* 5 weeks after sternotomy for aortocoronary bypass in a 72-year-old man.

compared the value of the various imaging modalities in suspected primary sternal osteomyelitis. However, MRI is the current gold standard for detection of each type of osteomyelitis.

TREATMENT

Sternal Osteomyelitis

In cases of deep sternal-wound infection, a combined approach using both surgery and antibiotic treatment is required. Antimicrobial therapy should be started immediately after samples have been obtained for microbiologic analyses in order to control clinical sepsis. To protect a newly inserted heart valve, initial treatment should be directed against staphylococci, with consideration of the local susceptibility pattern. In centers with a high prevalence of methicillin-resistant *S. aureus*, vancomycin or daptomycin should be added to a broad-spectrum β-lactam drug. As soon as cultures of blood and/or deep wound biopsies have confirmed the pathogen's identity and susceptibility pattern, treatment should be optimized and narrowed accordingly. Tables 136-1 and 136-2 show appropriate therapeutic choices for the most frequently identified microorganisms causing sternal osteomyelitis in the absence and presence, respectively, of an implanted device. In a recent observational study of patients with staphylococcal deep sternal-wound infection, the use of a rifampin-containing regimen was predictive of success. The optimal duration of antibiotic therapy has not been established. In acute sternal osteomyelitis without hardware, a 6-week course is the rule. In patients with remaining sternal wires, treatment duration is generally prolonged to 3 months (Table 136-2). Like other types of tuberculous bone infection, tuberculous sternal osteomyelitis is treated for 6–12 months.

Primary sternal osteomyelitis can generally be treated without surgery. In contrast, in secondary sternal osteomyelitis, debridement is always required. This procedure should be performed by a team of experienced surgeons, since mediastinitis, bone infection, and skin and soft tissue damage may need to be treated during the same intervention.

PROGNOSIS

Primary sternal osteomyelitis poses a minimal mortality risk. In contrast, the mortality rates from secondary sternal osteomyelitis during the first year after diagnosis are 6–20%.

GLOBAL CONSIDERATIONS

In endemic areas, microorganisms such as *M. tuberculosis*, *Salmonella* species, and *Brucella* species should be considered during sampling for microbiologic diagnosis.

FOOT OSTEOMYELITIS

PATHOGENESIS

Osteomyelitis of the foot is a feared complication in patients with diabetic foot ulcers. It also usually occurs in patients with peripheral arterial insufficiency, or peripheral neuropathy and after foot surgery. These entities are often linked to each other, especially in diabetic patients with late complications. However, foot osteomyelitis is also seen in patients with isolated peripheral neuropathy and can manifest as implant-associated osteomyelitis in patients without comorbidity due to a deep wound infection after foot surgery (hallux valgus surgery, arthrodesis, total ankle arthroplasty). Foot osteomyelitis is acquired almost exclusively by the exogenous route. It is a complication of deep pressure ulcers and of impaired wound healing after surgery.

EPIDEMIOLOGY

About 34% of people with diabetes develop a foot ulcer during their lifetime. Among patients with foot ulcer, the annual incidence of progression to foot osteomyelitis is 5%. The condition starts with skin and soft tissue lesions and progresses to osteomyelitis, especially in patients with risk factors. Diabetic foot osteomyelitis increases the risk of amputation. With adequate management of the early stage of diabetic foot infections, the rate of amputation can be lowered.

FIGURE 136-5 Neuropathic joint disease (Charcot foot) complicated by chronic foot osteomyelitis in a 78-year-old woman with diabetes mellitus complicated by severe neuropathy.

RISK FACTORS

Risk factors for diabetic foot infection are (1) peripheral motor, sensory, and autonomic neuropathy; (2) neuro-osteoarthropathic deformities (Charcot foot; **Fig. 136-5**); (3) arterial insufficiency; (4) uncontrolled hyperglycemia; (5) disabilities such as reduced vision; and (6) maladaptive behavior.

MICROBIOLOGY

The correlation between cultures from bone biopsy and those from wound swabs or even deep soft-tissue punctures is poor. In a study of 31 patients with simultaneous sampling, the correlation between needle biopsy and bone biopsy cultures was only 24%. The correlation is better when *S. aureus* is isolated (40–50%) than when anaerobes (20–35%), gram-negative bacilli (20–30%), or coagulase-negative staphylococci (0–20%) are identified. When only bone-biopsy samples are considered, the leading pathogens are *S. aureus* (25–40%), anaerobes (5–20%), and various gram-negative bacilli (18–40%). The precise distribution depends on whether the patient has already been treated with antibiotics. Anaerobes are especially prevalent in chronic wounds. Pretreatment typically selects for *P. aeruginosa*, methicillin-resistant *S. aureus*, or enterococci.

DIAGNOSIS

In many cases, foot osteomyelitis can be diagnosed clinically, without imaging procedures. Most clinicians rely on the "probe-to-bone" test, which has a positive predictive value of ~90% in populations with a high pretest probability. Thus, in a patient with diabetes who is hospitalized for a chronic deep foot ulcer, the diagnosis of foot osteomyelitis is highly probable if bone can be directly touched with a metal instrument. In a patient with a lower pretest probability, MRI should be performed because of its high sensitivity (80–100%) and specificity (80–90%). Plain x-rays have typical features characterizing diabetic foot osteomyelitis. However, their sensitivity is only 30–90% and the specificity varies between 50% and 90%; thus, it is mainly useful for follow-up of patients with confirmed diabetic foot osteomyelitis.

TREATMENT

Foot Osteomyelitis

As mentioned above, correlation between cultures of bone and those of wound swabs or wound punctures is poor. Antibiotic treatment should be based on bone culture. If no bone biopsy is

performed, empirical therapy chosen in light of the most common infecting agents and the type of clinical syndrome should be given. In a controlled therapeutic trial of diabetic patients in whom no infected bone needed to be resected, the outcome of a 6-week course of antibiotics was not different from a 12-week course. In patients undergoing surgical debridement, a 3-week course of systemic antibiotics was noninferior to a 6-week course in a prospective, randomized pilot trial. Wound debridement combined with antibiotics renders amputation unnecessary in about two-thirds of patients. For the diagnosis and treatment of diabetic foot infections, the following management strategies should be considered. If a foot ulcer is clinically infected, prompt empirical antimicrobial therapy may prevent progression to osteomyelitis. When the risk of methicillin-resistant *S. aureus* is considered high, an agent active against these strains (e.g., vancomycin) should be chosen. If the patient has not recently received antibiotics, the spectrum of the selected antibiotic must include gram-positive cocci (e.g., clindamycin, ampicillin-sulbactam). If the patient has received antibiotics within the past month, the spectrum of empirical antibiotics should include gram-negative bacilli (e.g., clindamycin plus a fluoroquinolone). If the patient has risk factors for *Pseudomonas* infection (previous colonization, residence in a warm climate, frequent exposure of the foot to water), an empirical antipseudomonal agent (e.g., piperacillin-tazobactam, cefepime) is indicated. If osteomyelitis is suspected either on clinical grounds (probe to bone) or on the basis of imaging procedures (MRI), bone biopsy should be performed. If infected bone is not entirely removed by surgery, the patient should be treated for 4–6 weeks in line with the identified pathogen(s) and their susceptibility. Treatment should initially be given by the IV route. Whether therapy can later be administered by the oral route depends on the bioavailability of oral drugs that cover the infecting agents. In the future, phage therapy may be a valuable additive therapeutic option.

GLOBAL CONSIDERATIONS

The number of multiresistant microorganisms causing diabetic foot infection is increasing. The prevalence of methicillin-resistant *S. aureus* is 5–43% in various countries. Gram-negative pathogens are more common than gram-positive bacteria in Asia. In a study of 102 patients with diabetic foot infection from India, 69% of aerobic gram-negative bacilli produced extended-spectrum β-lactamase and 43% of *S. aureus* isolates were methicillin resistant. Risk factors for multidrug-resistant microorganisms are poor glycemic control, prolonged duration of infection, and large ulcer size.

137 Intraabdominal Infections and Abscesses

Miriam Baron Barshak

Intraperitoneal infections generally arise because a normal anatomic barrier is disrupted. This disruption may result from a variety of causes—e.g., when the appendix, a diverticulum, or an ulcer ruptures; when the bowel wall is weakened by ischemia, tumor, or inflammation (e.g., in inflammatory bowel disease); or with adjacent inflammatory processes, such as pancreatitis or pelvic inflammatory disease, in which enzymes (in the former case) or organisms (in the latter) may leak into the peritoneal cavity. Whatever the inciting event, once inflammation develops and organisms usually contained within the bowel or another organ enter the normally sterile peritoneal space, a knowable series of events takes place. Intraabdominal infections occur in two stages: peritonitis and—if the patient survives this stage and goes untreated—abscess formation. The types of microorganisms predominating in each stage of infection are responsible for the pathogenesis of disease.

PERITONITIS

Peritonitis is a life-threatening event that is often accompanied by bacteremia and sepsis syndrome (Chap. 315). The peritoneal cavity is large but is divided into compartments. The upper and lower peritoneal cavities are divided by the transverse mesocolon; the greater omentum extends from the transverse mesocolon and from the lower pole of the stomach to line the lower peritoneal cavity. The pancreas, duodenum, and ascending and descending colon are located in the anterior retroperitoneal space; the kidneys, ureters, and adrenals are found in the posterior retroperitoneal space. The other organs, including the liver, stomach, gallbladder, spleen, jejunum, ileum, transverse and sigmoid colon, cecum, and appendix, are within the peritoneal cavity. The cavity is lined with a serous membrane that can serve as a conduit for fluids—a property exploited in peritoneal dialysis (Fig. 137-1). A small amount of serous fluid is normally present in the

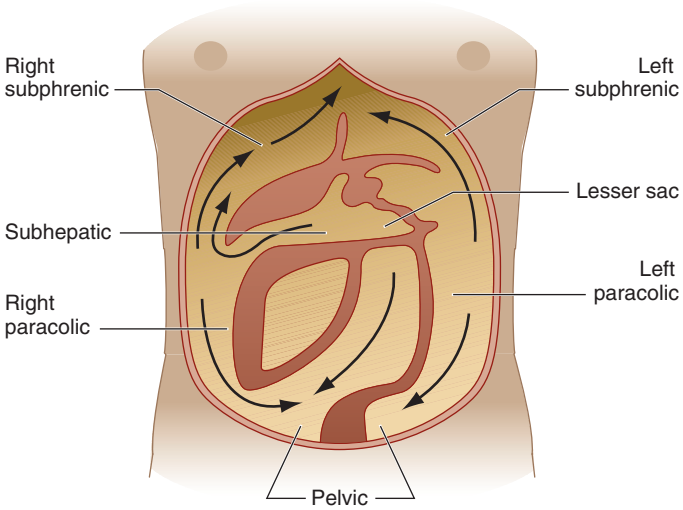

FIGURE 137-1 Diagram of the intraperitoneal spaces, showing the circulation of fluid and potential areas for abscess formation. Some compartments collect fluid or pus more often than others. These compartments include the pelvis (the lowest portion), the subphrenic spaces on the right and left sides, and Morrison's pouch, which is a posterosuperior extension of the subhepatic spaces and is the lowest part of the paravertebral groove when a patient is recumbent. The falciform ligament separating the right and left subphrenic spaces appears to act as a barrier to the spread of infection; consequently, it is unusual to find bilateral subphrenic collections. *(Reproduced with permission from B Lorber [ed]: Atlas of Infectious Diseases, vol VII: Intra-abdominal infections, hepatitis, and gastroenteritis. Springer; 1996.)*

peritoneal space, with a protein content (consisting mainly of albumin) of <30 g/L and <300 white blood cells (WBCs, generally mononuclear cells) per microliter. In bacterial infections, leukocyte recruitment into the infected peritoneal cavity consists of an early influx of polymorphonuclear leukocytes (PMNs) and a prolonged subsequent phase of mononuclear cell migration. The phenotype of the infiltrating leukocytes during the course of inflammation is regulated primarily by resident-cell chemokine synthesis.

PRIMARY (SPONTANEOUS) BACTERIAL PERITONITIS

Peritonitis is either primary (without an apparent source of contamination) or secondary. The types of organisms found and the clinical presentations of these two processes are different. In adults, primary bacterial peritonitis (PBP) occurs most commonly in conjunction with cirrhosis of the liver (frequently the result of alcoholism). However, the disease has been reported in adults with metastatic malignant disease, postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, systemic lupus erythematosus, and lymphedema as well as in patients with no underlying disease. Although PBP virtually always develops in patients with preexisting ascites, it is, in general, an uncommon event, occurring in ≤10% of cirrhotic patients. The cause of PBP has not been established definitively but is believed to involve hematogenous spread of organisms in a patient in whom a diseased liver and altered portal circulation result in a defect in the usual filtration function. Organisms multiply in ascites, a good medium for growth. Proteins of the complement cascade are found in peritoneal fluid, with lower levels in cirrhotic patients than in patients with ascites of other etiologies. The opsonic and phagocytic properties of PMNs are diminished in patients with advanced liver disease. Cirrhosis is associated with alterations in the gut microbiota, including an increased prevalence of potentially pathogenic bacteria such as Enterobacteriaceae. Small-intestinal bacterial overgrowth is frequently present in advanced stages of liver cirrhosis and has been linked with pathologic bacterial translocation and PBP. Factors promoting these changes in cirrhosis may include deficiencies in Paneth cell defensins, reduced intestinal motility, decreased pancreatobiliary secretions, and portal-hypertensive enteropathy.

The presentation of PBP differs from that of secondary peritonitis. The most common manifestation is fever, which is reported in up to 80% of patients. Ascites is found but virtually always predates infection. Abdominal pain, an acute onset of symptoms, and peritoneal irritation during physical examination can be helpful diagnostically, but the absence of any of these findings does not exclude this often-subtle diagnosis. Nonlocalizing symptoms (such as malaise, fatigue, or encephalopathy) or jaundice or acute kidney injury without another clear etiology also should prompt consideration of PBP in a susceptible patient. It is vital to sample the peritoneal fluid of any cirrhotic patient with ascites and fever. The finding of >250 PMNs/μL is diagnostic for PBP. This criterion does not apply to secondary peritonitis (see below). The microbiology of PBP also is distinctive. While enteric gram-negative bacilli such as *Escherichia coli* are commonly encountered, gram-positive organisms such as streptococci, enterococci, or even pneumococci are sometimes found. In an important development, widespread use of quinolones to prevent PBP in high-risk subgroups of patients, frequent hospitalizations, and exposure to broad-spectrum antibiotics have led to a change in the etiology of infections in patients with cirrhosis, with more gram-positive bacteria and extended-spectrum β-lactamase (ESBL)–producing Enterobacteriaceae in recent years. Risk factors for multidrug-resistant infections include nosocomial origin of infection, long-term norfloxacin prophylaxis, recent infection with multiresistant bacteria, and recent use of β-lactam antibiotics. In PBP, a single organism is typically isolated; anaerobes are found less frequently in PBP than in secondary peritonitis, in which a mixed flora including anaerobes is the rule. In fact, if PBP is suspected and multiple organisms including anaerobes are recovered from the peritoneal fluid, the diagnosis must be reconsidered and a source of secondary peritonitis sought.

The diagnosis of PBP is not easy. It depends on the exclusion of a primary intraabdominal source of infection. Contrast-enhanced CT is useful in identifying an intraabdominal source for infection. It may be difficult to recover organisms from cultures of peritoneal fluid, presumably because the burden of organisms is low. However, the yield can be improved if 10 mL of peritoneal fluid is placed directly into a blood culture bottle. Because bacteremia frequently accompanies PBP, blood should be cultured simultaneously. To maximize the yield, culture samples should be collected prior to administration of antibiotics. There is interest in identifying biomarkers in ascites that may be associated with PBP. No specific radiographic studies are helpful in the diagnosis of PBP. A plain film of the abdomen would be expected to show ascites. Chest and abdominal radiography should be performed when patients have abdominal pain to exclude free air, which signals a perforation **(Fig. 137-2)**.

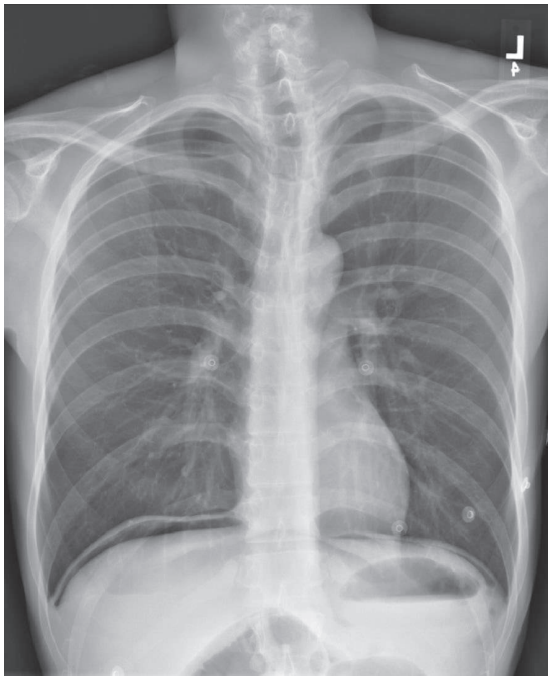

FIGURE 137-2 Pneumoperitoneum. Free air under the diaphragm on an upright chest film suggests the presence of a bowel perforation and associated peritonitis. *(Image courtesy of Dr. John Braver; with permission.)*

TREATMENT

Primary Bacterial Peritonitis

Treatment for PBP is directed at the isolate from blood or peritoneal fluid. Gram's staining of peritoneal fluid often gives negative results in PBP. Delays in antibiotic treatment of PBP are associated with increased mortality. Therefore, until culture results become available, prompt therapy should cover gram-negative aerobic bacilli and gram-positive cocci. Third-generation cephalosporins such as cefotaxime (2 g q8h, administered IV) provide reasonable initial coverage in moderately ill patients if the local prevalence of multidrug resistant organisms is low. Broad-spectrum antibiotics, such as β-lactam/β-lactamase inhibitor combinations (e.g., piperacillin/tazobactam, 3.375 g q6h IV for adults with normal renal function) or ceftriaxone (2 g q24h IV), also are options, with vancomycin for patients who have had prior infection or colonization with methicillin-resistant *Staphylococcus aureus*. Broader empirical coverage aimed at resistant hospital-acquired gram-negative bacteria (e.g., carbapenem or newer agents, such as ceftolozane-tazobactam or ceftazidime-avibactam) and vancomycin-resistant *Enterococcus* (e.g., daptomycin) may be appropriate for nosocomially acquired PBP or in patients with prior antibiotic-resistant infections or critical illness until culture results become available. Empirical coverage for anaerobes is not necessary. A mortality benefit from albumin (1.5 g/kg of body weight within 6 h of detection and 1.0 g/kg on day 3) has been demonstrated for patients with PBP, with greatest

benefit among those who present with serum creatinine levels ≥1 mg/dL, blood urea nitrogen levels ≥30 mg/dL, or total bilirubin levels ≥5 mg/dL. After the infecting organism is identified, therapy should be narrowed to target the specific pathogen. Patients with PBP usually respond within 72 h to appropriate antibiotic therapy. Antimicrobial treatment can be administered for as little as 5 days if rapid improvement occurs and blood cultures are negative, but a course of up to 2 weeks may be required for patients with bacteremia and for those whose improvement is slow. Persistence of WBCs in the ascitic fluid after therapy should prompt a search for additional diagnoses.

Prognosis: PBP is associated with significant morbidity and mortality, perhaps reflecting the fact that PBP risk is highest among patients with advanced liver disease. In a 2018 study of hospitalized patients with PBP in the United States, in-hospital mortality was 17.6%. Another study in 2019 found that among patients at a U.S. tertiary academic center, mortality following PBP was 23% at 30 days and 37% at 90 days. The morbidity and mortality associated with PBP has led to interest in strategies for PBP prevention.

Prevention • **PRIMARY PREVENTION** Several observational studies and a meta-analysis raise the concern that gastric acid suppression may increase the risk of PBP. No prospective studies have yet addressed whether avoidance of such therapy may prevent PBP. A 2021 guideline from the American Association for the Study of Liver Diseases recommends chronic antibiotic prophylaxis be considered, after discussing risks and benefits, with a regimen described in the next section for patients who are at highest risk for PBP—that is, those with an ascitic-fluid total protein level <1.5 g/dL along with impaired renal function (creatinine, ≥1.2 mg/dL; blood urea nitrogen, ≥25 mg/dL; or serum sodium, ≤130 mEq/L) and/or liver failure (Child-Turcotte-Pugh score, ≥9; and bilirubin, ≥3 mg/dL). A course of antibiotic prophylaxis is recommended for patients with cirrhosis and gastrointestinal bleeding until bleeding has resolved and vasoactive drugs are stopped.

SECONDARY PREVENTION PBP has a high rate of recurrence. Up to 70% of patients experience a recurrence within 1 year. Antibiotic prophylaxis has been recommended for patients with a history of PBP to reduce this rate and improve short-term survival rates. Prophylactic regimens for adults with normal renal function include fluoroquinolones (ciprofloxacin, 500 mg weekly; or norfloxacin [not available in the United States], 400 mg/d) or trimethoprim-sulfamethoxazole (one double-strength tablet daily). However, these recommendations are being reconsidered in recent years as the risks and benefits evolve. Long-term administration of broad-spectrum antibiotics in this setting has been shown to increase the risk of severe staphylococcal infections and of infections with multidrug-resistant organisms (MDRO). Additionally, quinolone prophylaxis is less effective in patients who are colonized with MDRO. There is increased interest in using rifaximin, a broad-spectrum antibiotic that is used already for hepatic encephalopathy and is not absorbed, for PBP prophylaxis (1200 mg daily).

SECONDARY PERITONITIS

Secondary peritonitis develops when bacteria contaminate the peritoneum as a result of spillage from an intraabdominal viscus. The organisms found almost always constitute a mixed flora in which facultative gram-negative bacilli and anaerobes predominate, especially when the contaminating source is colonic. Early in the course of infection, when the host response is directed toward containment, exudate containing fibrin and PMNs is found. Early death in this setting is attributable to gram-negative bacillary sepsis and to potent endotoxins circulating in the bloodstream **(Chap. 315)**. Gram-negative bacilli, particularly *E. coli*, are common bloodstream isolates, but *Bacteroides fragilis* bacteremia also occurs. The severity of abdominal pain and the clinical course depend on the inciting process. The organisms isolated from the peritoneum also vary with the source of the initial process and the normal flora at that site. Secondary peritonitis can result primarily from chemical irritation and/or bacterial contamination. For example, as long as the patient is not achlorhydric, a ruptured gastric ulcer will release low-pH gastric contents that will serve as a chemical irritant. The normal flora of the stomach comprises the same organisms found in the oropharynx but in lower numbers. Thus, the bacterial burden in a ruptured ulcer is negligible compared with that in a ruptured appendix. The normal flora of the colon below the ligament of Treitz contains ~10^{11} anaerobic organisms/g of feces but only 10^8 aerobes/g; therefore, anaerobic species account for 99.9% of the bacteria **(Chap. 484)**. Leakage of colonic contents (pH 7–8) does not cause significant chemical peritonitis, but infection is intense because of the heavy bacterial load.

Depending on the inciting event, local symptoms may occur in secondary peritonitis—for example, epigastric pain from a ruptured gastric ulcer. In appendicitis **(Chap. 342)**, the initial presenting symptoms are often vague, with periumbilical discomfort and nausea followed in a number of hours by pain more localized to the right lower quadrant. Unusual locations of the appendix (including a retrocecal position) can complicate this presentation further. Once infection has spread to the peritoneal cavity, pain increases, particularly with infection involving the parietal peritoneum, which is innervated extensively. Patients usually lie motionless, often with knees drawn up to avoid stretching the nerve fibers of the peritoneal cavity. Coughing and sneezing, which increase pressure within the peritoneal cavity, are associated with sharp pain. There may or may not be pain localized to the infected or diseased organ from which secondary peritonitis has arisen. Patients with secondary peritonitis generally have abnormal findings on abdominal examination, with marked voluntary and involuntary guarding of the anterior abdominal musculature. Later findings include tenderness, especially rebound tenderness. In addition, there may be localized findings in the area of the inciting event. In general, patients are febrile, with marked leukocytosis and a left shift of the WBCs to band forms.

While recovery of organisms from peritoneal fluid is easier in secondary than in primary peritonitis, a tap of the abdomen is rarely the procedure of choice in secondary peritonitis. An exception is in cases involving trauma, where the possibility of a hemoperitoneum may need to be excluded early. Emergent studies (such as abdominal CT) to find the source of peritoneal contamination should be undertaken if the patient is hemodynamically stable; unstable patients may require surgical intervention without prior imaging. Results of cultures from chronic drain sites are not reliable for defining the etiology of infections.

TREATMENT

Secondary Peritonitis

Treatment for secondary peritonitis includes early administration of antibiotics aimed particularly at aerobic gram-negative bacilli and anaerobes (see below). The most appropriate regimen depends on the anticipated flora and the degree of illness. Community-acquired infections associated with mild to moderate disease can be treated with many drugs covering these organisms, including broad-spectrum β-lactam/β-lactamase inhibitor combinations (e.g., ticarcillin/clavulanate, 3.1 g q4–6h IV; or piperacillin/tazobactam, 3.375 g q6h IV) or a combination of either a fluoroquinolone (e.g., levofloxacin, 750 mg q24h IV) or a third-generation cephalosporin (e.g., ceftriaxone, 2 g q24h IV) plus metronidazole (500 mg q8h IV). Eravacycline is a newer antibiotic in the tetracycline class that has been approved by the U.S. Food and Drug Administration for treatment of complicated intraabdominal infections (1 mg/kg q12h IV). Patients in intensive care units and/or those with health care–associated infections should receive antibiotics targeting more resistant gram-negative organisms such as *Pseudomonas aeruginosa*—e.g., imipenem (500 mg q6h IV), meropenem (1 g q8h IV), higher-dose piperacillin/tazobactam (4.5 g IV q6h), or drug combinations such as cefepime (2 g IV q8h) or ceftazidime (2 g IV q8h) plus metronidazole. The role of enterococci and *Candida* species in mixed infections is controversial; however, because cephalosporin-based regimens lack activity against enterococci, ampicillin or vancomycin can be added to these regimens for enterococcal coverage in very ill patients until culture results are

available. For patients known to be colonized with ampicillin-resistant, vancomycin-resistant enterococci (VRE), a VRE-active agent, such as linezolid or daptomycin, should be included. Antifungal coverage is warranted if there is growth of *Candida* species from a sterile site. Patients who are known to be colonized with highly resistant gram-negative organisms may require treatment with a newer agent such as ceftazidime/avibactam or ceftolozane/tazobactam. Secondary peritonitis usually requires both surgical intervention to address the inciting process and antibiotics to treat early bacteremia, to decrease the incidence of abscess formation and wound infection, and to prevent distant spread of infection. Although surgery is rarely indicated in PBP in adults, it may be life-saving in secondary peritonitis. In a recent study, the urgency and success of source control impacted the odds of survival, while the choice of empiric antibiotics did not. Recombinant human activated protein C (APC) was considered at one time for treatment of severe sepsis from causes including secondary peritonitis but was withdrawn from the market in 2011 after it was determined that the drug was associated with an increased risk of bleeding and that evidence for its beneficial effects was inadequate. Thus APC should not be used for sepsis or septic shock outside randomized clinical trials.

Peritonitis may develop as a complication of abdominal surgeries. These infections may be accompanied by localizing pain and/or nonlocalizing signs or symptoms such as fever, malaise, anorexia, and toxicity. As a nosocomial infection, postoperative peritonitis may be associated with organisms such as staphylococci, components of the gram-negative hospital microflora, and the microbes that cause PBP and secondary peritonitis, as described above.

PERITONITIS IN PATIENTS UNDERGOING CONTINUOUS AMBULATORY PERITONEAL DIALYSIS

A third type of peritonitis arises in patients who are undergoing continuous ambulatory peritoneal dialysis (CAPD). Unlike PBP and secondary peritonitis, which are caused by endogenous bacteria, CAPD-associated peritonitis usually involves skin organisms. The pathogenesis of infection is similar to that of intravascular device–related infection, in which skin organisms migrate along the catheter, which both serves as an entry point and exerts the effects of a foreign body. Exit-site or tunnel infection may or may not accompany CAPD-associated peritonitis. Like PBP, CAPD-associated peritonitis is usually caused by a single organism. Peritonitis is, in fact, the most common reason for discontinuation of CAPD. Improvements in equipment design, especially the Y-set connector, have resulted in a decrease from one case of peritonitis per 9 months of CAPD to one case per 24 months. Diabetes was reported to be a risk factor for CAPD-associated peritonitis in a study from Taiwan.

The clinical presentation of CAPD peritonitis resembles that of secondary peritonitis in that diffuse pain and peritoneal signs are common. The dialysate is usually cloudy and contains >100 WBCs/μL, >50% of which are neutrophils. However, the number of cells depends in part on dwell time. According to a guideline from the International Society for Peritoneal Dialysis (2016), for patients undergoing automated peritoneal dialysis who present during their nighttime treatment and whose dwell time is much shorter than with CAPD, the clinician should use the percentage of PMNs rather than the absolute number of WBCs to diagnose peritonitis. As the normal peritoneum has very few PMNs, a proportion above 50% is strong evidence of peritonitis even if the absolute WBC count does not reach 100/μL. Meanwhile, patients undergoing automated peritoneal dialysis without a daytime exchange who present with abdominal pain may have no fluid to withdraw, in which case 1 L of dialysate should be infused and permitted to dwell a minimum of 1–2 h, then drained, examined for turbidity, and sent for cell count with differential and culture. The differential (with a shortened dwell time) may be more useful than the absolute WBC count. In equivocal cases or in patients with systemic or abdominal symptoms in whom the effluent appears clear, a second exchange is performed, with a dwell time of at least 2 h. Clinical judgment should guide initiation of therapy.

The most common organisms are *Staphylococcus* species, which accounted for ~45% of cases in one series. Historically, coagulase-negative staphylococcal species were identified most commonly in these infections, but these isolates have more recently been decreasing in frequency. *Staphylococcus aureus* is more often involved among patients who are nasal carriers of the organism than among those who are not, and this organism is the most common pathogen in overt exit-site infections. Gram-negative bacilli and fungi such as *Candida* species also are found. Vancomycin-resistant enterococci and vancomycin-intermediate *S. aureus* have been reported to produce peritonitis in CAPD patients. The finding of more than one organism in dialysate culture should prompt evaluation for secondary peritonitis. As with PBP, culture of dialysate fluid in blood culture bottles improves the yield. To facilitate diagnosis, several hundred milliliters of removed dialysis fluid should be concentrated by centrifugation before culture.

TREATMENT

CAPD Peritonitis

Empirical therapy for CAPD peritonitis should be directed at *S. aureus*, coagulase-negative *Staphylococcus*, and gram-negative bacilli until the results of cultures become available. Guidelines suggest that agents should be chosen on the basis of local experience with resistant organisms. In some centers, a first-generation cephalosporin such as cefazolin (for gram-positive bacteria) and a fluoroquinolone or a third-generation cephalosporin such as ceftazidime (for gram-negative bacteria) may be reasonable; in areas with high rates of infection with methicillin-resistant *S. aureus*, vancomycin should be used instead of cefazolin, and gram-negative coverage may need to be broadened—e.g., with an aminoglycoside, ceftazidime, cefepime, or a carbapenem. Broad coverage including vancomycin should be particularly considered for patients with septic physiology or exit-site infections. Vancomycin should also be included in the regimen if the patient has a history of colonization or infection with methicillin-resistant *S. aureus* or has a history of severe allergy to penicillins and cephalosporins. Loading doses are administered intraperitoneally; doses depend on the dialysis method and the patient's renal function. Intraperitoneal antibiotics are given either continuously (i.e., with each exchange) or intermittently (i.e., once daily, with the dose allowed to remain in the peritoneal cavity for at least 6 h). If the patient is severely ill, IV antibiotics should be added at doses appropriate for the patient's degree of renal failure. The clinical response to an empirical treatment regimen should be rapid; if the patient has not responded after 48–96 h of treatment, new samples should be collected for cell counts and cultures, and catheter removal should be considered. For patients who lack exit-site or tunnel infection, the typical duration of antibiotic treatment is 14 days. For patients with exit-site or tunnel infection, catheter removal should be considered, and a longer duration of antibiotic therapy (up to 21 days) may be appropriate. In fungal infections, the catheter should be removed immediately.

TUBERCULOUS PERITONITIS

See Chap. 183.

INTRAABDOMINAL ABSCESSES

INTRAPERITONEAL ABSCESSES

Abscess formation is common in untreated peritonitis if overt gram-negative sepsis either does not develop or develops but is not fatal. In experimental models of abscess formation, mixed aerobic and anaerobic organisms have been implanted intraperitoneally. Without therapy directed at anaerobes, animals develop intraabdominal abscesses. As in humans, these experimental abscesses may stud the peritoneal cavity, lie within the omentum or mesentery, or even develop on the surface of or within viscera such as the liver.

Pathogenesis and Immunity There is often disagreement about whether an abscess represents a disease state or a host response. In a

sense, it represents both: while an abscess is an infection in which viable infecting organisms and PMNs are contained in a fibrous capsule, it is also a process by which the host confines microbes to a limited space, thereby preventing further spread of infection. In any event, abscesses do cause significant symptoms, and patients with abscesses can be quite ill. Experimental work has helped to define both the host cells and the bacterial virulence factors responsible—most notably in the case of *B. fragilis*. This organism, although accounting for only 0.5% of the normal colonic flora, is the anaerobe most frequently isolated from intraabdominal infections, is especially prominent in abscesses, and is the most common anaerobic bloodstream isolate. On clinical grounds, therefore, *B. fragilis* appears to be uniquely virulent. Moreover, *B. fragilis* acts alone to cause abscesses in animal models of intraabdominal infection, whereas most other *Bacteroides* species must act synergistically with a facultative organism to induce abscess formation.

Of the several virulence factors identified in *B. fragilis*, one is critical: the capsular polysaccharide complex found on the bacterial surface. This complex comprises at least eight distinct surface polysaccharides. Structural analysis of these polysaccharides has shown an unusual motif of oppositely charged sugars. Polysaccharides having these *zwitterionic* characteristics, such as polysaccharide A, evoke a host response in the peritoneal cavity that localizes bacteria into abscesses. *B. fragilis* and polysaccharide A have been found to adhere to primary mesothelial cells in vitro; this adherence, in turn, stimulates the production of tumor necrosis factor α and intercellular adhesion molecule 1 by peritoneal macrophages. Although abscesses characteristically contain PMNs, the process of abscess induction depends on the stimulation of T lymphocytes by these unique zwitterionic polysaccharides. The stimulated CD4+ T lymphocytes secrete leukoattractant cytokines and chemokines. The alternative pathways of complement and fibrinogen also participate in abscess formation.

While antibodies to the capsular polysaccharide complex enhance bloodstream clearance of *B. fragilis*, CD4+ T cells are critical in immunity to abscesses. When administered experimentally, *B. fragilis* polysaccharide A has immunomodulatory characteristics and stimulates CD4+ T regulatory cells via an interleukin 2–dependent mechanism to produce interleukin 10. Interleukin 10 downregulates the inflammatory response, thereby preventing abscess formation.

Clinical Presentation Of all intraabdominal abscesses, 74% are intraperitoneal or retroperitoneal and are not visceral. Most intraperitoneal abscesses result from fecal spillage from a colonic source, such as an inflamed appendix. Abscesses can also arise from other processes. They usually form within weeks of the development of peritonitis and may be found in a variety of locations from omentum to mesentery, pelvis to psoas muscles, and subphrenic space to a visceral organ such as the liver, where they may develop either on the surface of the organ or within it. Periappendiceal and diverticular abscesses occur commonly. Diverticular abscesses are least likely to rupture. Infections of the female genital tract and pancreatitis also are among the more common causative events. When abscesses occur in the female genital tract—either as a primary infection (e.g., tuboovarian abscess) or as an infection extending into the pelvic cavity or peritoneum—*B. fragilis* figures prominently among the organisms isolated. *B. fragilis* is not found in large numbers in the normal vaginal flora. For example, it is encountered less commonly in pelvic inflammatory disease and endometritis without an associated abscess. In pancreatitis with leakage of damaging pancreatic enzymes, inflammation is prominent. Therefore, clinical findings such as fever, leukocytosis, and even abdominal pain do not distinguish pancreatitis itself from complications such as pancreatic pseudocyst, pancreatic abscess **(Chap. 359)**, or intraabdominal collections of pus. Especially in cases of necrotizing pancreatitis, in which the incidence of local pancreatic infection may be as high as 30%, needle aspiration under CT guidance is performed to sample fluid for culture. Traditionally, many centers have prescribed preemptive antibiotics for patients with necrotizing pancreatitis. Imipenem is frequently used for this purpose because it reaches high tissue levels in the pancreas (although it is not unique in this regard). Randomized controlled studies have not demonstrated a benefit from this practice, and guidelines no longer recommend preemptive antibiotics for patients with acute pancreatitis. If needle aspiration yields infected fluid in the setting of acute necrotizing pancreatitis, antibiotic treatment is appropriate in conjunction with surgical and/or percutaneous drainage of infected material. Infected pseudocysts that occur remotely from acute pancreatitis are unlikely to be associated with significant amounts of necrotic tissue and may be treated with either surgical or percutaneous catheter drainage in conjunction with appropriate antibiotic therapy.

Diagnosis Scanning procedures have considerably facilitated the diagnosis of intraabdominal abscesses. Abdominal CT probably has the highest yield, although ultrasonography is particularly useful for the right upper quadrant, kidneys, and pelvis. Both indium-labeled WBCs and gallium tend to localize in abscesses and may be useful in finding a collection. Because gallium is taken up in the bowel, indium-labeled WBCs may have a slightly greater yield for abscesses near the bowel. Neither indium-labeled WBC scans nor gallium scans serve as a basis for a definitive diagnosis, however; both need to be followed by other, more specific studies, such as CT, if an area of possible abnormality is identified. PET scanning should also be considered due to its ready availability and because it provides more resolution. Abscesses contiguous with or contained within diverticula are particularly difficult to diagnose with scanning procedures. Although barium should not be injected if a perforation is suspected, a barium enema occasionally may detect a diverticular abscess not diagnosed by other procedures. If one study is negative, a second study sometimes reveals a collection. Although exploratory laparotomy has been less commonly used since the advent of CT, this procedure still must be undertaken on occasion if an abscess is strongly suspected on clinical grounds.

TREATMENT

Intraperitoneal Abscesses

An algorithm for the management of patients with intraabdominal (including intraperitoneal) abscesses by percutaneous drainage is presented in **Fig. 137-3**. Treatment of intraabdominal infections involves determination of the initial focus of infection, administration of broad-spectrum antibiotics targeting the organisms involved, and performance of a drainage procedure if one or more definitive abscesses have formed. Antimicrobial therapy, in general, is adjunctive to drainage and/or surgical correction of an underlying lesion or process in intraabdominal abscesses. Results of cultures from drain sites are not reliable for defining the etiology of infections. Unlike the intraabdominal abscesses resulting from most causes, for which drainage of some kind is generally required,

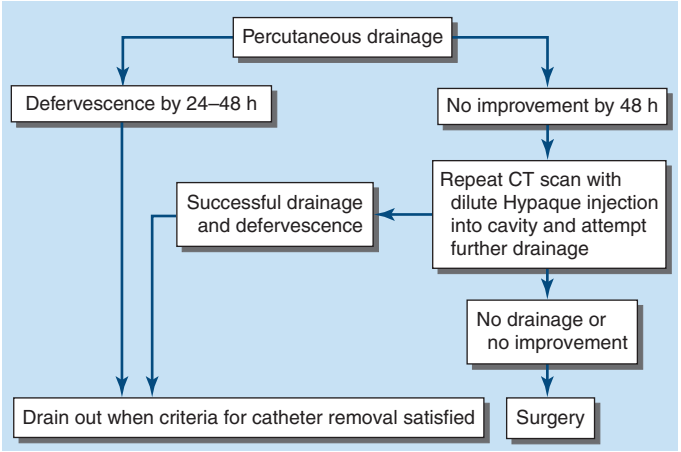

FIGURE 137-3 Algorithm for the management of patients with intraabdominal abscesses by percutaneous drainage. Antimicrobial therapy should be administered concomitantly. *(Reproduced with permission from B Lorber [ed]: Atlas of Infectious Diseases, vol VII: Intra-abdominal infections, hepatitis, and gastroenteritis. Philadelphia, Current Medicine, 1996, p 1.30, as adapted from OD Rotstein, RL Simmons, in SL Gorbach et al [eds]: Infectious Diseases. Philadelphia, Saunders; 1992.)*

abscesses associated with diverticulitis usually wall off locally after rupture of a diverticulum, so that surgical intervention is not routinely required.

A number of agents exhibit excellent activity against aerobic gram-negative bacilli. Because death in intraabdominal sepsis is linked to gram-negative bacteremia, empirical therapy for intraabdominal infection always needs to include adequate coverage of gram-negative aerobic, facultative, and anaerobic organisms. Even if anaerobes are not cultured from clinical specimens, they still must be covered by the therapeutic regimen. Empirical antibiotic therapy should be the same as that discussed above for secondary peritonitis. Most clinical treatment failures are due to failure to drain the abscess and thereby achieve source control. The appropriate duration of antibiotic treatment for abdominal abscesses depends on whether the presumptive source of the intraabdominal infection has been controlled. With adequate source control, antibiotic treatment may be limited to 4 or 5 days.

VISCERAL ABSCESSES

Liver Abscesses The liver is the organ most subject to the development of abscesses. In one study of 540 intraabdominal abscesses, 26% were visceral. Liver abscesses made up 13% of the total number, or 48% of all visceral abscesses. Liver abscesses may be solitary or multiple; they may arise from hematogenous spread of bacteria or from local spread from contiguous sites of infection within the peritoneal cavity. In the past, appendicitis with rupture and subsequent spread of infection was the most common source for a liver abscess. Currently, associated disease of the biliary tract is most common. Pylephlebitis (suppurative thrombosis of the portal vein), usually arising from infection in the pelvis but sometimes from infection elsewhere in the peritoneal cavity, is another common source for bacterial seeding of the liver.

Fever is the most common presenting sign of liver abscess. Some patients, particularly those with associated disease of the biliary tract, have symptoms and signs localized to the right upper quadrant, including pain, guarding, punch tenderness, and even rebound tenderness. Nonspecific symptoms, such as chills, anorexia, weight loss, nausea, and vomiting, also may develop. Only 50% of patients with liver abscesses, however, have hepatomegaly, right-upper-quadrant tenderness, or jaundice; thus, one-half of patients have no symptoms or signs to direct attention to the liver. Fever of unknown origin may be the only manifestation of liver abscess, especially in the elderly. Diagnostic studies of the abdomen, especially the right upper quadrant, should be a part of any workup for fever of unknown origin. The single most reliable laboratory finding is an elevated serum concentration of alkaline phosphatase, which is documented in 70% of patients with liver abscesses. Other tests of liver function may yield normal results, but 50% of patients have elevated serum levels of bilirubin, and 48% have elevated concentrations of aspartate aminotransferase. Other laboratory findings include leukocytosis in 77% of patients, anemia (usually normochromic, normocytic) in 50%, and hypoalbuminemia in 33%. Concomitant bacteremia is found in one-third to one-half of patients. A liver abscess is sometimes suggested by chest radiography, especially if a new elevation of the right hemidiaphragm is seen; other suggestive findings include a right basilar infiltrate and a right pleural effusion.

Imaging studies are the most reliable methods for diagnosing liver abscesses. These studies include ultrasonography, CT **(Fig. 137-4)**, indium-labeled WBC or gallium scan, and MRI. More than one such study may be required.

Organisms recovered from liver abscesses vary with the source. In liver infection arising from the biliary tree, enteric gram-negative aerobic bacilli and enterococci are common isolates. *Klebsiella pneumoniae* liver abscess has been well described in Southeast Asia for more than 20 years and has become an emerging syndrome in North America and elsewhere. These community-acquired infections have been linked to a virulent hypermucoviscous *K. pneumoniae* phenotype and to a specific genotype. The typical syndrome includes liver abscess, bacteremia, and metastatic infection in the eye(s) and lung(s). Ampicillin/amoxicillin therapy started within the previous 30 days has been associated with increased risk for this syndrome, presumably because of selection for the causative strain. Unless previous surgery has been performed, anaerobes are not generally involved in liver abscesses arising from biliary infections. In contrast, in liver abscesses arising from pelvic and other intraperitoneal sources, a mixed flora including both aerobic and anaerobic species is common; *B. fragilis* is the species most frequently isolated. With hematogenous spread of infection, usually only a single organism is encountered; this species may be *S. aureus* or a streptococcal species such as one in the *Streptococcus milleri* group. Liver abscesses may also be caused by *Candida* species; such abscesses usually follow fungemia in patients receiving chemotherapy for cancer and often present when PMNs return after a period of neutropenia. Amebic liver abscesses are not an uncommon problem **(Chap. 230)**. Amebic serologic testing gives positive results in >95% of cases. In addition, polymerase chain reaction (PCR) testing has been used in recent years. Negative results from these studies help to exclude this diagnosis.

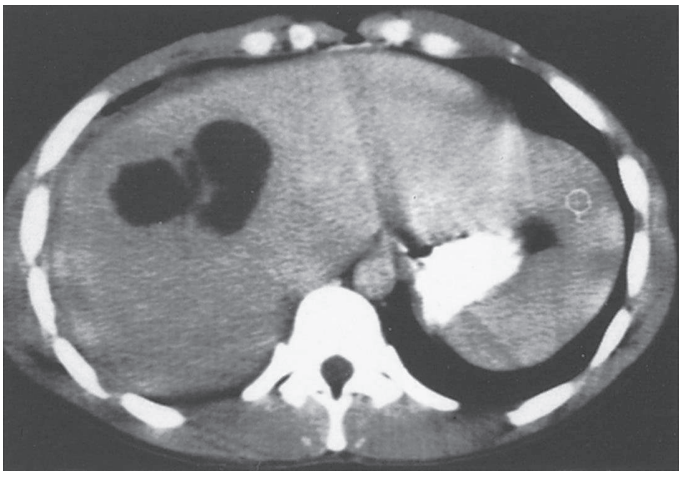

FIGURE 137-4 Multilocular liver abscess on CT scan. Multiple or multilocular abscesses are more common than solitary abscesses. *(Reprinted with permission from B Lorber [ed]: Atlas of Infectious Diseases, vol VII: Intra-abdominal Infections, Hepatitis, and Gastroenteritis. Philadelphia, Current Medicine, 1996, Fig. 1.22.)*

TREATMENT

Liver Abscesses

(Fig. 137-3) Drainage is the mainstay of therapy for intraabdominal abscesses, including liver abscesses; the approach can be either percutaneous (with a pigtail catheter kept in place or possibly with a device that can perform pulse lavage to fragment and evacuate the semisolid contents of a liver abscess), transluminal (with endoscopic ultrasound guidance), or surgical. However, there is growing interest in medical management alone for pyogenic liver abscesses. The drugs used for empirical therapy include the same ones used in intraabdominal sepsis and secondary bacterial peritonitis. Usually, blood cultures and a diagnostic aspirate of abscess contents should be obtained before the initiation of empirical therapy, with antibiotic choices adjusted when the results of Gram's staining and culture become available. Cases treated without definitive drainage generally require longer courses of antibiotic therapy. When percutaneous drainage was compared with open surgical drainage, the average length of hospital stay for the former was almost twice that for the latter, although both the time required for fever to resolve and the mortality rate were the same for the two procedures. The mortality rate was appreciable despite treatment, averaging 15%. Several factors predict the failure of percutaneous drainage and therefore may favor primary surgical intervention. These factors include the presence of multiple, sizable abscesses; viscous abscess contents that tend to plug the catheter; associated disease (e.g., disease of the biliary tract) requiring surgery; the presence of yeast; communication with an untreated obstructed biliary tree; or the lack of a clinical response to percutaneous drainage in 4–7 days.

Treatment of candidal liver abscesses often entails initial administration of liposomal amphotericin B (3–5 mg/kg IV daily) or an echinocandin, with subsequent fluconazole therapy **(Chap. 222)**. In some cases, therapy with fluconazole alone (6 mg/kg daily) may be used—e.g., in clinically stable patients whose infecting isolate is susceptible to this drug.

Splenic Abscesses Splenic abscesses are much less common than liver abscesses. The incidence of splenic abscesses has ranged from 0.14 to 0.7% in various autopsy series. The clinical setting and the organisms isolated usually differ from those for liver abscesses. The degree of clinical suspicion for splenic abscess needs to be high because this condition is frequently fatal if left untreated. Even in the most recently published series, diagnosis was made only at autopsy in 37% of cases. Although splenic abscesses may arise occasionally from contiguous spread of infection or from direct trauma to the spleen, hematogenous spread of infection is more common. Bacterial endocarditis is the most common associated infection **(Chap. 133)**. Splenic abscesses can develop in patients who have received extensive immunosuppressive therapy (particularly those with malignancy involving the spleen) and in patients with hemoglobinopathies or other hematologic disorders (especially sickle cell anemia).

Although ~50% of patients with splenic abscesses have abdominal pain, the pain is localized to the left upper quadrant in only one-half of these cases. Splenomegaly is found in ~50% of cases. Fever and leukocytosis are generally present; the development of fever preceded diagnosis by an average of 20 days in one series. Left-sided chest findings may include abnormalities to auscultation, and chest radiographic findings may include an infiltrate or a left-sided pleural effusion. CT scan of the abdomen has been the most sensitive diagnostic tool. Ultrasonography can yield the diagnosis but is less sensitive. Liver–spleen scan or gallium scan also may be useful. Streptococcal species are the most common bacterial isolates from splenic abscesses, followed by *S. aureus*—presumably reflecting the associated endocarditis. An increase in the prevalence of gram-negative aerobic isolates from splenic abscesses has been reported; these organisms often derive from a urinary tract focus, with associated bacteremia, or from another intraabdominal source. *Salmonella* species are seen fairly commonly, especially in patients with sickle cell hemoglobinopathy. Anaerobic species accounted for only 5% of isolates in the largest collected series, but the reporting of a number of "sterile abscesses" may indicate that optimal techniques for the isolation of anaerobes were not used.

TREATMENT

Splenic Abscesses

Because of the high mortality figures reported for splenic abscesses, splenectomy with adjunctive antibiotics has traditionally been considered standard treatment and remains the best approach for complex, multilocular abscesses or multiple abscesses. However, percutaneous drainage has worked well for single, small (<3-cm) abscesses in some studies and may also be useful for patients with high surgical risk. Patients undergoing splenectomy should be vaccinated against encapsulated organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*). The most important factor in successful treatment of splenic abscesses is early diagnosis.

Perinephric and Renal Abscesses Perinephric and renal abscesses are not common. The former accounted for only ~0.02% of hospital admissions and the latter for ~0.2% in Altemeier's series of 540 intraabdominal abscesses. Before antibiotics became available, most renal and perinephric abscesses were hematogenous in origin, usually complicating prolonged bacteremia, with *S. aureus* most commonly recovered. Now, in contrast, >75% of perinephric and renal abscesses arise from a urinary tract infection. Infection ascends from the bladder to the kidney, with pyelonephritis preceding abscess development. Bacteria may directly invade the renal parenchyma from medulla to cortex. Local vascular channels within the kidney may facilitate the transport of organisms. Areas of abscess developing within the parenchyma may rupture into the perinephric space. The kidneys and adrenal glands are surrounded by a layer of perirenal fat that, in turn, is surrounded by Gerota's fascia, which extends superiorly to the diaphragm and inferiorly to the pelvic fat. Abscesses extending into the perinephric space may track through Gerota's fascia into the psoas or transversalis muscles, into the anterior peritoneal cavity, superiorly to the subdiaphragmatic space, or inferiorly to the pelvis. Of the risk factors that have been associated with the development of perinephric abscesses, the most important is concomitant nephrolithiasis obstructing urinary flow. Of patients with perinephric abscess, 20–60% have renal stones. Other structural abnormalities of the urinary tract, prior urologic surgery, trauma, and diabetes mellitus also have been identified as risk factors.

The organisms most frequently encountered in perinephric and renal abscesses are *E. coli*, *Proteus* species, and *Klebsiella* species. *E. coli*, the aerobic species most commonly found in the colonic flora, seems to have unique virulence properties in the urinary tract, including factors promoting adherence to uroepithelial cells. The urease of *Proteus* species splits urea, thereby creating a more alkaline and more hospitable environment for bacterial proliferation. *Proteus* species are frequently found in association with large struvite stones caused by the precipitation of magnesium ammonium sulfate in an alkaline environment. These stones serve as a nidus for recurrent urinary tract infection. Although a single bacterial species is usually recovered from a perinephric or renal abscess, multiple species may be found. If a urine culture is not contaminated with periurethral flora and is found to contain more than one organism, a perinephric or renal abscess should be considered in the differential diagnosis. Urine cultures may also be polymicrobial in cases of bladder diverticulum.

Candida species can cause renal abscesses. Fungi of this genus may spread to the kidney hematogenously or by ascension from the bladder. The hallmark of the latter route of infection is ureteral obstruction with large fungal balls.

The presentation of perinephric and renal abscesses is quite nonspecific. Flank pain and abdominal pain are common. At least 50% of patients are febrile. Pain may be referred to the groin or leg, particularly with extension of infection. The diagnosis of perinephric abscess, like that of splenic abscess, is frequently delayed, and the mortality rate in some series is appreciable, although lower than in the past. Perinephric or renal abscess should be most seriously considered when a patient presents with symptoms and signs of pyelonephritis and remains febrile after 4 or 5 days of treatment. Moreover, when a urine culture yields a polymicrobial flora, when a patient is known to have renal stones, or when fever and pyuria coexist with a sterile urine culture, these diagnoses should be entertained.

Renal ultrasonography and abdominal CT are the most useful diagnostic modalities. If a renal or perinephric abscess is diagnosed, nephrolithiasis should be excluded, especially when a high urinary pH suggests the presence of a urea-splitting organism.

TREATMENT

Perinephric and Renal Abscesses

Treatment for perinephric and renal abscesses, like that for other intraabdominal abscesses, includes drainage of pus and antibiotic therapy directed at the organism(s) recovered. For perinephric abscesses, percutaneous drainage is usually successful.

Psoas Abscesses The psoas muscle is another location in which abscesses are encountered. Psoas abscesses may arise from a hematogenous source, by contiguous spread from an intraabdominal or pelvic process, or by contiguous spread from nearby bony structures (e.g., vertebral bodies). Associated osteomyelitis due to spread from bone to muscle or from muscle to bone is common in psoas abscesses. When Pott's disease was common, *Mycobacterium tuberculosis* was a frequent cause of psoas abscess. Currently, either *S. aureus* or a mixture

of enteric organisms including aerobic and anaerobic gram-negative bacilli is usually isolated from psoas abscesses in the United States. *S. aureus* is most likely to be isolated when a psoas abscess arises from hematogenous spread or a contiguous focus of osteomyelitis; a mixed enteric flora is the most likely etiology when the abscess has an intraabdominal or pelvic source. Patients with psoas abscesses frequently present with fever, lower abdominal or back pain, or pain referred to the hip or knee. CT is the most useful diagnostic technique.

TREATMENT

Psoas Abscesses

Treatment includes surgical drainage and the administration of an antibiotic regimen directed at the inciting organism(s).

Pancreatic Abscesses See Chap. 359.

138 Acute Infectious Diarrheal Diseases and Bacterial Food Poisoning

Ana A. Weil, Regina C. LaRocque

Diarrheal disease mortality has decreased substantially in the past three decades. Nevertheless, acute diarrheal disease is still a leading cause of illness globally and is associated with an estimated 1.57 million deaths per year. Across low-income and middle-income countries, one in ten deaths among children <5 years of age is attributable to diarrhea, with substantial variation in incidence and mortality between countries. The morbidity from diarrhea also is significant. Recurrent intestinal infections are associated with physical and mental stunting, wasting, micronutrient deficiencies, and malnutrition. In short, diarrheal disease is a driving factor in global morbidity and mortality.

The wide range of clinical manifestations of acute gastrointestinal illnesses is matched by the wide variety of infectious agents involved, including viruses, bacteria, and parasites **(Table 138-1)**. This chapter discusses factors that enable gastrointestinal pathogens to cause disease, reviews host defense mechanisms, and delineates an approach to the evaluation and treatment of patients presenting with acute diarrhea. Individual organisms causing acute gastrointestinal illnesses are discussed in detail in subsequent chapters.

PATHOGENIC MECHANISMS

Enteric pathogens have developed a variety of tactics to overcome host defenses. Understanding the virulence factors employed by these organisms is important in the diagnosis and treatment of clinical disease.

INOCULUM SIZE

The number of microorganisms that must be ingested to cause disease varies considerably from species to species. For *Shigella*, enterohemorrhagic *Escherichia coli*, *Giardia lamblia*, or *Entamoeba*, as few as 10–100 bacteria or cysts can produce infection, while 10^5–10^8 *Vibrio cholerae* organisms must be ingested to cause disease. The infective dose of *Salmonella* varies widely, depending on the species, host, and food vehicle. The ability of organisms to overcome host defenses has important implications for transmission; *Shigella*, enterohemorrhagic *E. coli*, *Entamoeba*, and *Giardia* can spread by person-to-person contact, whereas under some circumstances, *Salmonella* may need to grow in food for several hours before reaching an effective infectious dose.

ADHERENCE

Many organisms must adhere to the gastrointestinal mucosa as an initial step in the pathogenic process; thus, organisms that can compete with the normal bowel flora and colonize the mucosa have an important advantage in causing disease. Specific cell-surface proteins involved in attachment of bacteria to intestinal cells are important virulence determinants. *V. cholerae*, for example, adheres to the brush border of small-intestinal enterocytes via specific surface adhesins, including the toxin-coregulated pilus and other accessory colonization factors. Enterotoxigenic *E. coli*, which causes watery diarrhea, produces an adherence protein called *colonization factor antigen* that is necessary for colonization of the upper small intestine by the organism prior to the production of enterotoxin. Enteropathogenic *E. coli*, an agent of diarrhea in young children, and enterohemorrhagic *E. coli*, which causes hemorrhagic colitis and the hemolytic-uremic syndrome, produce virulence determinants that allow these organisms to attach to and efface the brush border of the intestinal epithelium.

TOXIN PRODUCTION

The production of one or more exotoxins is important in the pathogenesis of numerous enteric organisms. Such toxins include *enterotoxins*, which cause watery diarrhea by acting directly on secretory mechanisms in the intestinal mucosa; *cytotoxins*, which cause destruction of mucosal cells and associated inflammatory diarrhea; and *neurotoxins*, which act directly on the central or peripheral nervous system.

The prototypical enterotoxin is cholera toxin, a heterodimeric protein composed of one A and five B subunits. The A subunit contains the enzymatic activity of the toxin, while the B subunit pentamer binds holotoxin to the enterocyte surface receptor, the ganglioside G_{M1}. After the binding of holotoxin, a fragment of the A subunit is translocated across the eukaryotic cell membrane into the cytoplasm, where it catalyzes the adenosine diphosphate ribosylation of a guanosine triphosphate (GTP)–binding protein and causes persistent activation of adenylate cyclase. The result is an increase of cyclic adenosine monophosphate in the intestinal cell, which increases Cl^- secretion and decreases Na^+ absorption, leading to a loss of fluid and the production of diarrhea.

Enterotoxigenic strains of *E. coli* may produce a protein called *heat-labile enterotoxin* (LT) that is like cholera toxin and causes secretory diarrhea by the same mechanism. Alternatively, enterotoxigenic strains of *E. coli* may produce *heat-stable enterotoxin* (ST), one form of which causes diarrhea by activation of guanylate cyclase and elevation of intracellular cyclic guanosine monophosphate. Some enterotoxigenic strains of *E. coli* produce both LT and ST.

Bacterial cytotoxins, in contrast, destroy intestinal mucosal cells and produce the syndrome of dysentery, with bloody stools containing

TABLE 138-1 Gastrointestinal Pathogens Causing Acute Diarrhea

MECHANISM	LOCATION	ILLNESS	STOOL FINDINGS	EXAMPLES OF PATHOGENS INVOLVED
Noninflammatory (enterotoxin)	Proximal small bowel	Watery diarrhea	No fecal leukocytes; mild or no increase in fecal lactoferrin	*Vibrio cholerae*, enterotoxigenic *Escherichia coli* (LT and/or ST), enteroaggregative *E. coli, Clostridium perfringens, Bacillus cereus, Staphylococcus aureus, Aeromonas hydrophila, Plesiomonas shigelloides*, rotavirus, norovirus, enteric adenoviruses, *Giardia lamblia, Cryptosporidium* spp., *Cyclospora* spp., microsporidia
Inflammatory (invasion or cytotoxin)	Colon or distal small bowel	Dysentery or inflammatory diarrhea	Fecal polymorphonuclear leukocytes; substantial increase in fecal lactoferrin	*Shigella* spp., *Salmonella* spp., *Campylobacter jejuni*, enterohemorrhagic *E. coli*, enteroinvasive *E. coli, Yersinia enterocolitica, Listeria monocytogenes, Vibrio parahaemolyticus, Clostridium difficile, A. hydrophila, P. shigelloides, Entamoeba histolytica, Klebsiella oxytoca*
Penetrating	Distal small bowel	Enteric fever	Fecal mononuclear leukocytes	*Salmonella* Typhi, *Y. enterocolitica*

Abbreviations: LT, heat-labile enterotoxin; ST, heat-stable enterotoxin.

inflammatory cells. Enteric pathogens that produce such cytotoxins include *Shigella dysenteriae* type 1, *Vibrio parahaemolyticus*, and *Clostridioides difficile*. *S. dysenteriae* type 1 and Shiga toxin–producing strains of *E. coli* produce potent cytotoxins and have been associated with outbreaks of hemorrhagic colitis and hemolytic-uremic syndrome.

Neurotoxins are usually produced by bacteria outside the host and therefore cause symptoms soon after ingestion. Included are the staphylococcal and *Bacillus cereus* toxins, which act on the central nervous system to produce vomiting.

INVASION

Dysentery may result not only from the production of cytotoxins but also from bacterial invasion and destruction of intestinal mucosal cells. Infections due to *Shigella* and enteroinvasive *E. coli* are characterized by the organisms' invasion of mucosal epithelial cells, intraepithelial multiplication, and subsequent spread to adjacent cells. *Salmonella* causes inflammatory diarrhea by invading the bowel mucosa but generally is not associated with the destruction of enterocytes or the full clinical syndrome of dysentery. *Salmonella enterica* serovar Typhi and *Yersinia enterocolitica* can penetrate intact intestinal mucosa, multiply intracellularly in Peyer patches and intestinal lymph nodes, and then disseminate through the bloodstream to cause enteric fever—a syndrome characterized by fever, headache, relative bradycardia, abdominal pain, splenomegaly, and leukopenia.

HOST DEFENSES

Given the enormous number of microorganisms ingested with every meal, the normal host must combat a constant influx of potential enteric pathogens. Studies of infections in patients with alterations in defense mechanisms have led to a greater understanding of the variety of ways in which the normal host can protect itself against disease.

INTESTINAL MICROBIOTA

The large numbers of bacteria that normally inhabit the intestine (*the intestinal microbiota*) act as an important host defense mechanism, preventing colonization by potential enteric pathogens. Mechanisms of colonization resistance are not fully understood but include geographic and nutritional exclusion at the mucosal surface. Persons with fewer intestinal bacteria, such as infants who have not yet developed normal enteric colonization or patients receiving antibiotics, are at greater risk of developing infections with enteric pathogens. The bacterial community composition of the intestinal microbiota is as important as abundance of organisms present. More than 99% of the normal colonic microbiota is made up of anaerobic bacteria, and the acidic pH and volatile fatty acids produced by these organisms appear to be critical elements in resistance to colonization.

GASTRIC ACID

The acidic pH of the stomach is an important barrier to enteric pathogens, and an increased frequency of infections due to *Salmonella*, *G. lamblia*, and a variety of helminths has been reported among patients who have undergone gastric surgery or are achlorhydric for some other reason. Neutralization of gastric acid with antacids, proton pump inhibitors, or H_2 blockers—a common practice in the management of hospitalized patients—similarly increases the risk of enteric colonization. In addition, some microorganisms can survive the extreme acidity of the gastric environment; rotavirus and *Shigella,* for example, are highly stable to acidity.

INTESTINAL MOTILITY

Peristalsis is the major mechanism for clearance of bacteria from the proximal small intestine. When intestinal motility is impaired (e.g., by treatment with opioids or other antimotility drugs, anatomic abnormalities, or hypomotility states), the frequency of bacterial overgrowth and infection of the small bowel with enteric pathogens is increased. Some patients whose treatment for *Shigella* infection consists of diphenoxylate hydrochloride with atropine (Lomotil) experience prolonged fever and shedding of organisms, while patients treated with opioids for mild *Salmonella* gastroenteritis have a higher frequency of bacteremia than those not treated with opioids.

INTESTINAL MUCIN

A complex layer of mucus, produced by specialized secretory cells, covers the stomach, small intestine, and large intestine, and separates the lumenal commensal microbiota from the epithelium. The thickness and constituents of this mucus barrier vary throughout the gastrointestinal tract. The mucus barrier turns over rapidly and comprises glycoproteins and a range of antimicrobial molecules and secreted immunoglobulins directed against specific microbial antigens. Enteric pathogens have evolved a wide range of strategies to overcome this barrier and thus to reach the underlying epithelium and cause disease. For example, pathogens can penetrate the mucus layer by secreting enzymes to degrade the mucus or through flagella-mediated motility. Some organisms, such as *Shigella*, secrete toxins that can diffuse through the mucus layer and disrupt the underlying epithelium. The resulting reduction of mucus production allows the pathogen to reach the cell surface.

IMMUNITY

Both cellular immune responses and antibody production play important roles in protection from enteric infections. Humoral immunity to enteric pathogens consists of systemic IgG and IgM as well as secretory IgA. The mucosal immune system may be the first line of defense against many gastrointestinal pathogens. The binding of bacterial antigens to the lumenal surface of M cells in the distal small bowel and the subsequent presentation of antigens to subepithelial lymphoid tissue leads to the proliferation of sensitized and specialized lymphocytes. These lymphocytes circulate and populate all of the mucosal tissues of the body as IgA-secreting plasma cells.

GENETIC DETERMINANTS

Host genetic variation influences susceptibility to diarrheal diseases. People with blood group O show increased susceptibility to disease due to *V. cholerae*, *Shigella*, *E. coli* O157, and norovirus. Polymorphisms in genes encoding inflammatory mediators have been associated with the outcome of infection with enteroaggregative *E. coli*, enterotoxin-producing *E. coli*, *Salmonella*, *C. difficile*, and *V. cholerae*.

APPROACH TO THE PATIENT

Infectious Diarrhea or Bacterial Food Poisoning

The approach to the patient with possible infectious diarrhea or bacterial food poisoning is shown in **Fig. 138-1**.

HISTORY

Diarrhea is defined as the passage of loose or watery stools that conform to the shape of a container three or more times in a 24-h period. The answers to questions with high discriminating value can quickly narrow the range of potential causes of diarrhea and help determine whether treatment is needed. Important elements of the narrative history are detailed in Fig. 138-1.

PHYSICAL EXAMINATION

The examination of patients for signs of dehydration provides essential information about the severity of the diarrheal illness and the need for rapid therapy. Mild dehydration is indicated by thirst, dry mouth, decreased axillary sweat, decreased urine output, and slight weight loss. Signs of moderate dehydration include an orthostatic fall in blood pressure, skin tenting, and sunken eyes (or, in infants, a sunken fontanelle). Signs of severe dehydration include lethargy, obtundation, feeble pulse, hypotension, and shock.

DIAGNOSTIC APPROACH

After assessing severity of illness, the clinician must distinguish between *inflammatory* and *noninflammatory* disease. Using the

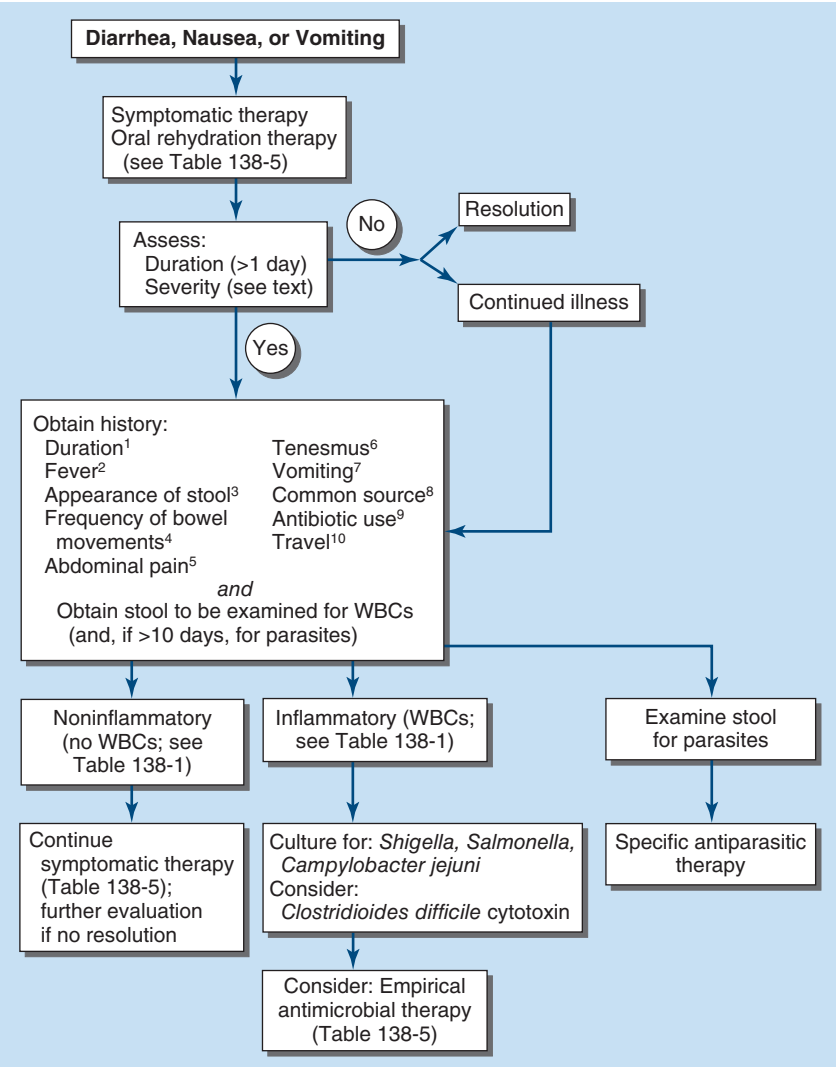

FIGURE 138-1 Clinical algorithm for the approach to patients with community-acquired infectious diarrhea or bacterial food poisoning. Key to superscripts: 1. Diarrhea lasting >2 weeks is generally defined as chronic; in such cases, many of the causes of acute diarrhea are much less likely, and a new spectrum of causes needs to be considered. 2. Fever often implies invasive disease, although fever and diarrhea may also result from infection outside the gastrointestinal tract, as in malaria. 3. Stools that contain blood or mucus indicate ulceration of the large bowel. Bloody stools without fecal leukocytes should alert the laboratory to the possibility of infection with Shiga toxin–producing enterohemorrhagic *Escherichia coli*. Bulky white/gray stools suggest a small-intestinal process that is causing malabsorption. An acute illness with profuse "rice-water" stools, with an appearance of water after rice has been cooked, suggests cholera or a similar toxigenic process. 4. Frequent stools over a given period can provide the first warning of impending dehydration. 5. Abdominal pain may be most severe in inflammatory processes like those due to *Shigella, Campylobacter*, and necrotizing toxins. Painful abdominal muscle cramps, caused by electrolyte loss, can develop in severe cases of cholera. Bloating is common in giardiasis. An appendicitis-like syndrome should prompt a culture for *Yersinia enterocolitica* with cold enrichment. 6. Tenesmus (painful rectal spasms with a strong urge to defecate but little passage of stool) may be a feature of cases with proctitis, as in shigellosis or amebiasis. 7. Vomiting implies an acute infection (e.g., a toxin-mediated illness or food poisoning) but can also be prominent in a variety of systemic illnesses (e.g., malaria) and in intestinal obstruction. 8. Asking patients whether anyone they know is sick is a more efficient means of identifying a common source than is constructing a list of recently eaten foods. If a common source seems likely, specific foods can be investigated. See text for a discussion of bacterial food poisoning. 9. Current antibiotic therapy or a recent history of treatment suggests *Clostridioides difficile* diarrhea (**Chap. 139**). Stop antibiotic treatment if possible and consider tests for *C. difficile* toxins. Antibiotic use may increase the risk of chronic intestinal carriage following salmonellosis. 10. See text (and **Chap. 130**) for a discussion of traveler's diarrhea. *(From The New England Journal of Medicine. Bacterial and Protozoal Gastroenteritis. RL Guerrant, DA Bobak 325:327-340. Copyright @1991 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

history and epidemiologic features of the case, the clinician can then rapidly evaluate the need for further efforts to define a specific etiology and for therapeutic intervention. Examination of a stool sample may supplement the narrative history. Grossly bloody or mucoid stool suggests an inflammatory process. A test for fecal leukocytes (preparation of a thin smear of stool on a glass slide, addition of a drop of methylene blue, and examination of the wet mount) can suggest inflammatory disease in patients with diarrhea, although the predictive value of this test is still debated. A test for fecal lactoferrin, which is a marker of fecal leukocytes, is more sensitive and is available in latex agglutination and enzyme-linked immunosorbent assay formats. Stool culture or molecular testing is useful for diagnosing a causative organism, particularly in patients with severe illness or high-risk comorbidities. Causes of acute infectious diarrhea, categorized as inflammatory and noninflammatory, are listed in Table 138-1.

POST DIARRHEA COMPLICATIONS

Short- or long-term complications may follow the resolution of an acute diarrheal episode. The clinician should inquire about prior diarrheal illness if the conditions listed in **Table 138-2** are observed.

EPIDEMIOLOGY

TRAVEL HISTORY

Of the several million people who travel from temperate industrialized countries to tropical regions of Asia, Africa, and Central and South America each year, 20–50% experience a sudden onset of abdominal cramps, anorexia, and watery diarrhea; thus, *traveler's diarrhea* is the most common travel-related infectious illness **(Chap. 130)**. The time of onset is usually 3 days to 2 weeks after the traveler's arrival in a resource-poor area; most cases begin within the first 3–5 days. The illness is generally self-limited, lasting 1–5 days. The high rate of diarrhea among travelers is related to the ingestion of contaminated food or water.

The pathogens that cause traveler's diarrhea vary considerably with location **(Table 138-3)**, as does the pattern of antimicrobial resistance. In all areas, enterotoxigenic and enteroaggregative *E. coli* are the most common pathogens among persons with the classic secretory traveler's diarrhea syndrome. Infection with *Campylobacter jejuni* is especially common in areas of Asia.

LOCATION

Closed and semi-closed communities, including day-care centers, schools, residential facilities, and cruise ships, are important settings for outbreaks of enteric infections. Norovirus, which is highly contagious and robust in surviving on surfaces, is the most common etiologic agent associated with outbreaks of acute gastroenteritis. Other common organisms, often spread by fecal–oral contact in such communities, are *Shigella*, *C. jejuni*, and *Cryptosporidium*. Rotavirus is rarely a cause of pediatric diarrheal outbreaks in the United States since rotavirus vaccination was broadly recommended in 2006. Similarly, hospitals are sites in which enteric infections are concentrated. Diarrhea is one of the most common manifestations of nosocomial infections. *C. difficile* is the predominant cause of nosocomial diarrhea among adults in the United States, and outbreaks of norovirus infection are common in health care settings. *Klebsiella oxytoca* has been identified as a cause of antibiotic-associated hemorrhagic colitis. Enteropathogenic *E. coli* has been associated with outbreaks of diarrhea in nurseries for newborns. One-third of elderly patients in chronic-care institutions develop a significant diarrheal illness each year; more than one-half of these cases are caused by cytotoxin-producing *C. difficile*. Antimicrobial therapy can predispose to pseudomembranous colitis by altering the normal colonic microbiota, which then permits the multiplication of *C. difficile* **(Chap. 139)**.

AGE

Globally, most morbidity and mortality from enteric pathogens involve children <5 years of age. Breast-fed infants are protected from pathogens in contaminated food and water and derive some protection from maternal antibodies, but their risk of infection rises dramatically when they begin to eat solid foods. Exposure to rotavirus is universal, with most children experiencing their first infection in the first or second year of life if not vaccinated. Older children and adults are more commonly infected with norovirus. Other organisms with higher attack rates among children than among adults include enterotoxigenic, enteropathogenic, and enterohemorrhagic *E. coli*; *Shigella*; *C. jejuni*; and *G. lamblia*.

TABLE 138-2 Postdiarrhea Complications of Acute Infectious Diarrheal Illness

COMPLICATION	COMMENTS
Chronic diarrhea (diarrhea lasting >4 weeks) • Lactase deficiency • Small-bowel bacterial overgrowth • Malabsorption syndromes (tropical and celiac sprue)	Occurs in ~1% of travelers with acute diarrhea Protozoa account for approximately one-third of cases
Initial presentation or exacerbation of inflammatory bowel disease	May be precipitated by traveler's diarrhea
Irritable bowel syndrome	Occurs in ~10% of travelers with traveler's diarrhea
Reactive arthritis	Particularly likely after infection with invasive organisms (*Shigella, Salmonella, Campylobacter, Yersinia*)
Hemolytic-uremic syndrome (hemolytic anemia, thrombocytopenia, and renal failure)	Follows infection with Shiga toxin–producing bacteria (*Shigella dysenteriae* type 1 and enterohemorrhagic *Escherichia coli*)
Guillain-Barré syndrome	Particularly likely after *Campylobacter* infection

TABLE 138-3 Causes of Traveler's Diarrhea

ETIOLOGIC AGENT	APPROXIMATE PERCENTAGE OF CASES	COMMENTS
Bacteria	**50–75**	
Enterotoxigenic *Escherichia coli*	10–45	Single most important agent
Enteroaggregative *E. coli*	5–35	Emerging enteric pathogen with worldwide distribution
Campylobacter jejuni	5–25	More common in Asia
Shigella	0–15	Major cause of dysentery
Salmonella	0–15	—
Others	0–5	Including *Aeromonas, Plesiomonas,* and *Vibrio cholerae*
Viruses	**0–20**	
Norovirus	0–10	Associated with cruise ships
Rotavirus	0–5	Particularly common among children
Parasites	**0–10**	
Giardia lamblia	0–5	Affects hikers and campers who drink from freshwater streams
Cryptosporidium	0–5	Resistant to chlorine treatment of water sources
Entamoeba histolytica	<1	—
Cyclospora	<1	—
Other	**0–10**	
Acute food poisoning[a]	0–5	—
No pathogen identified	10–50	—

[a]For etiologic agents, see Table 138-4.

HOST IMMUNE STATUS

Immunocompromised hosts are at elevated risk of acute and chronic infectious diarrhea. Individuals with defects in cell-mediated immunity (including those with AIDS) are at particularly high risk of invasive enteropathies, including salmonellosis, listeriosis, and cryptosporidiosis. Individuals with hypogammaglobulinemia are at particular risk of *C. difficile* colitis and giardiasis and can develop chronic infections with viral pathogens such as norovirus. Patients with cancer are more likely to develop *C. difficile* infection due to chemotherapy-associated antibiotic exposure and frequent hospitalizations. Infectious diarrhea can be life-threatening in immunocompromised hosts, with complications including persistent infection, bacteremia, and metastatic seeding of infection. Furthermore, dehydration may compromise renal function and increase the toxicity of immunosuppressive drugs.

BACTERIAL FOOD POISONING

If the history and the stool examination indicate a noninflammatory etiology of diarrhea and there is evidence of a common-source outbreak, questions concerning the ingestion of specific foods and the time of onset of diarrhea after a meal can provide clues to the bacterial cause of the illness. Potential causes of bacterial food poisoning are shown in **Table 138-4**.

Bacterial disease caused by an enterotoxin elaborated outside the host, such as that due to *Staphylococcus aureus* or *B. cereus*, has the shortest incubation period (1–6 h) and generally lasts <12 h. Most cases of staphylococcal food poisoning are caused by contamination from *Staphylococcus*-infected human carriers. Staphylococci can multiply at a wide range of temperatures; thus, if food is left to cool slowly and remains at room temperature after cooking, the organisms will have the opportunity to form enterotoxin. Outbreaks following picnics where potato salad, mayonnaise, and cream pastries have been served offer classic examples of staphylococcal food poisoning. Diarrhea, nausea, vomiting, and abdominal cramping are common, while fever is rare.

B. cereus can produce either a syndrome with a short incubation period—the *emetic* form, mediated by a staphylococcal type of enterotoxin—or one with a longer incubation period (8–16 h)—the *diarrheal* form, caused by an enterotoxin resembling *E. coli* LT, in which diarrhea and abdominal cramps are characteristic but vomiting is uncommon. The emetic form of *B. cereus* food poisoning is associated with contaminated fried rice; the organism is common in uncooked rice, and its heat-resistant spores survive boiling. If cooked rice is not refrigerated, the spores can germinate and produce toxin. Frying before serving may not destroy the preformed, heat-stable toxin.

Food poisoning due to *Clostridium perfringens* also has a slightly longer incubation period (8–14 h) and results from the survival of heat-resistant spores in inadequately cooked meat, poultry, or legumes. After ingestion, toxin is produced in the intestinal tract, causing moderately severe abdominal cramps and diarrhea; vomiting is rare, as is fever. The illness is self-limited, rarely lasting >24 h.

Not all food poisoning has a bacterial cause. Nonbacterial agents of short-incubation food poisoning include capsaicin, which is found in hot peppers, and a variety of toxins found in fish and shellfish **(Chap. 471)**.

TABLE 138-4 Bacterial Food Poisoning

INCUBATION PERIOD, ORGANISM	SYMPTOMS	COMMON FOOD SOURCES
1–6 h		
Staphylococcus aureus	Nausea, vomiting, diarrhea	Ham, poultry, potato or egg salad, mayonnaise, cream pastries
Bacillus cereus	Nausea, vomiting, diarrhea	Fried rice
8–16 h		
Clostridium perfringens	Abdominal cramps, diarrhea (vomiting rare)	Beef, poultry, legumes, gravies
B. cereus	Abdominal cramps, diarrhea (vomiting rare)	Meats, vegetables, dried beans, cereals
>16 h		
Vibrio cholerae	Watery diarrhea	Shellfish, water
Enterotoxigenic *Escherichia coli*	Watery diarrhea	Salads, cheese, meats, water
Enterohemorrhagic *E. coli*	Bloody diarrhea	Ground beef, roast beef, salami, raw milk, raw vegetables, apple juice
Salmonella spp.	Inflammatory diarrhea	Beef, poultry, eggs, dairy products
Campylobacter jejuni	Inflammatory diarrhea	Poultry, raw milk
Shigella spp.	Dysentery	Potato or egg salad, lettuce, raw vegetables
Vibrio parahaemolyticus	Dysentery	Mollusks, crustaceans

LABORATORY EVALUATION

Many cases of noninflammatory diarrhea are self-limited or can be treated empirically, and in these instances, the clinician may not need to determine a specific etiology. Potentially pathogenic *E. coli* cannot be distinguished from normal fecal flora by routine culture, and tests to detect enterotoxins are not available in most clinical laboratories. In situations in which cholera is a concern, stool should be cultured on selective media such as thiosulfate–citrate–bile salts–sucrose (TCBS) or tellurite–taurocholate–gelatin (TTG) agar; rapid diagnostic tests are also available. A latex agglutination test has made the rapid detection of rotavirus in stool practical for many laboratories, while reverse-transcriptase polymerase chain reaction (PCR) and specific antigen enzyme immunoassays have been developed for the identification of norovirus. Stool specimens should be examined by immunofluorescence-based rapid assays, PCR, or (less sensitive) standard microscopy for *Giardia* cysts or *Cryptosporidium* if the level of clinical suspicion regarding the involvement of these organisms is high.

All patients with fever and evidence of inflammatory diarrhea acquired outside the hospital should be evaluated for *Salmonella*, *Shigella*, and *Campylobacter*. *Salmonella* and *Shigella* can be selected on MacConkey agar as non-lactose-fermenting (colorless) colonies or can be grown on *Salmonella–Shigella* agar or in selenite enrichment broth, both of which inhibit most organisms except these pathogens. Evaluation of nosocomial diarrhea should initially focus on *C. difficile*; stool culture for other pathogens in the hospital setting is extremely low yield and is not cost-effective. Toxins A and B produced by pathogenic strains of *C. difficile* can be detected by rapid enzyme immunoassays, latex agglutination tests, or PCR **(Chap. 139)**. Isolation of *C. jejuni* requires inoculation of fresh stool onto selective growth medium and incubation at 42°C in a microaerophilic atmosphere. In many laboratories in the United States, *E. coli* O157:H7 is among the most common pathogens isolated from visibly bloody stools. Shiga-toxin containing strains of this enterohemorrhagic serotype can be identified by PCR or in specialized laboratories by serotyping, but also can be identified presumptively as lactose-fermenting, indole-positive colonies of sorbitol nonfermenters (white colonies) on sorbitol MacConkey plates. If the clinical presentation suggests the possibility of intestinal amebiasis, stool should be examined by a rapid antigen detection assay or by (less sensitive and less specific) microscopy. Multiplex nucleic acid amplification methods for detection of many stool pathogens (viral, bacterial, and parasitic) are increasingly being used in clinical microbiology laboratories to decrease the time to detection of a pathogen. These tests are more sensitive and rapid than standard culture methods and may detect multiple pathogens, which may lead to challenges in interpretation. For bacterial enteric infections, the lack of a microbial isolate prevents determination of antimicrobial susceptibility and typing of strains by public health authorities in order to detect and respond to common-source outbreaks. For this reason, the Centers for Disease Control and Prevention suggests that diagnosis of an enteric bacterial infection by a nucleic acid amplification method should be followed by attempted isolation of the pathogen by culture.

TREATMENT

Infectious Diarrhea or Bacterial Food Poisoning

In many cases, a specific diagnosis is not necessary or not available to guide treatment. The clinician can proceed with the information obtained from the history, stool examination, and evaluation of dehydration severity. Empirical regimens for the treatment of traveler's diarrhea are listed in **Table 138-5**.

The mainstay of treatment is adequate rehydration. The treatment of cholera and other dehydrating diarrheal diseases was revolutionized by the development and promotion of oral rehydration solution (ORS), the efficacy of which depends on the fact that glucose-facilitated absorption of sodium and water in the small intestine remains intact in the presence of cholera toxin. The use of ORS has reduced cholera mortality rates from >50% (in untreated cases) to <1%. Several ORS formulas have been developed and tested. Initial preparations were based on the treatment of patients with cholera and included a solution containing 3.5 g of sodium chloride, 2.5 g of sodium bicarbonate (or 2.9 g of sodium citrate), 1.5 g of potassium chloride, and 20 g of glucose (or 40 g of sucrose) per liter of water. Such a preparation can still be used for the treatment of severe cholera. Many causes of secretory diarrhea, however, are associated with less electrolyte loss than occurs in cholera. Beginning in 2002, the World Health Organization recommended a reduced-osmolarity/reduced-salt ORS that is better tolerated and more effective than classic ORS. This preparation contains 2.6 g of sodium chloride, 2.9 g of trisodium citrate, 1.5 g of potassium chloride, and 13.5 g of glucose (or 27 g of sucrose) per liter of water. ORS formulations containing rice or cereal as the carbohydrate source may be even more effective than glucose-based solutions. Patients who are severely dehydrated, are unable to drink, or in whom vomiting precludes oral therapy should receive IV solutions such as Ringer's lactate in addition to ORS when the patient can ingest it safely.

Most cases of traveler's diarrhea (usually due to enterotoxigenic or enteroaggregative *E. coli* or to *Campylobacter*) can be treated effectively with rehydration, bismuth subsalicylate, or antiperistaltic agents. Antimicrobial agents can shorten the duration of illness from 3–4 days to 24–36 h but may be associated with the acquisition of multidrug-resistant organisms; their use should therefore be reserved for severe cases. Changes in diet have not been shown to have an impact on the duration of illness, and the efficacy of probiotics to hasten recovery continues to be debated. Most individuals who present with dysentery (bloody diarrhea and fever) should be treated empirically with an antimicrobial agent (e.g., a fluoroquinolone or a macrolide, depending on local antimicrobial susceptibility patterns) pending diagnostic testing. Individuals with shigellosis should receive a 3- to 7-day course. Patients with severe or prolonged *Campylobacter* infection often benefit from antimicrobial treatment. Because of widespread resistance of *Campylobacter* to fluoroquinolones, especially in parts of Asia, a macrolide antibiotic such as erythromycin or azithromycin is preferred for this infection.

Treatment of salmonellosis must be tailored to the individual patient. Since administration of antimicrobial agents often prolongs intestinal colonization with *Salmonella*, these drugs are usually reserved for individuals at high risk of complications from disseminated salmonellosis, such as infants, patients with prosthetic devices, patients over age 50, and immunocompromised persons. Antimicrobial agents should not be administered to individuals (especially children) in whom enterohemorrhagic *E. coli* infection is suspected. Laboratory studies of enterohemorrhagic *E. coli* strains have demonstrated that many antibiotics induce replication of Shiga toxin–producing lambdoid bacteriophages, thereby significantly increasing toxin production by these strains. Clinical studies have supported these laboratory results, and antibiotics may increase by 20-fold the risk of hemolytic-uremic syndrome and renal failure during enterohemorrhagic *E. coli* infection. A clinical clue in the diagnosis of the latter infection is bloody diarrhea in a patient with a low-grade fever or who is afebrile.

TABLE 138-5 Treatment of Traveler's Diarrhea on the Basis of Clinical Features[a]

CLINICAL SYNDROME	SUGGESTED THERAPY
Watery diarrhea (no blood in stool, no fever), 1 or 2 unformed stools per day without distressing enteric symptoms	Oral fluids (oral rehydration solution, Pedialyte, Lytren, or flavored mineral water) and saltine crackers
Watery diarrhea (no blood in stool, no fever), 1 or 2 unformed stools per day with distressing enteric symptoms	Bismuth subsalicylate (for adults): 30 mL or 2 tablets (262 mg/tablet) every 30 min for 8 doses; or loperamide[b]: 4 mg initially followed by 2 mg after passage of each unformed stool, not to exceed 8 tablets (16 mg) per day (prescription dose) or 4 caplets (8 mg) per day (over-the-counter dose); drugs can be taken for 2 days. Antibacterial drug[c] can be considered in selected circumstances.
Dysentery (passage of bloody stools) or fever (>37.8°C)	Antibacterial drug[c]
Vomiting, minimal diarrhea	Bismuth subsalicylate (for adults; see dose above)
Diarrhea in infants (<2 years old)	Fluids and electrolytes (oral rehydration solution, Pedialyte, Lytren); continue feeding, especially with breast milk; seek medical attention for moderate dehydration, fever lasting >24 h, bloody stools, or diarrhea lasting more than several days

[a]All patients should take oral fluids (Pedialyte, Lytren, or flavored mineral water) plus saltine crackers. If diarrhea becomes moderate or severe, if fever persists, or if bloody stools or dehydration develops, the patient should seek medical attention. [b]Loperamide should not be used by patients with fever or dysentery; its use may prolong diarrhea in patients with infection due to *Shigella* or other invasive organisms. [c]The recommended antibacterial drugs are as follows:

If the level of suspicion is low for fluoroquinolone-resistant *Campylobacter*:

Adults: (1) A fluoroquinolone such as ciprofloxacin, 750 mg as a single dose or 500 mg bid for 3 days; levofloxacin, 500 mg as a single dose or 500 mg qd for 3 days; or norfloxacin, 800 mg as a single dose or 400 mg bid for 3 days. (2) Azithromycin, 1000 mg as a single dose or 500 mg qd for 3 days. (3) Rifaximin, 200 mg tid or 400 mg bid for 3 days (not recommended for use in dysentery).

Children: Azithromycin, 10 mg/kg on day 1, 5 mg/kg on days 2 and 3 if diarrhea persists.

If fluoroquinolone-resistant *Campylobacter* is suspected (for example, following travel to Southeast Asia):

Adults: Azithromycin (at above dose for adults). *Children:* Same as for children traveling to other areas (see above).

Source: After DR Hill et al: The practice of travel medicine: Guidelines by the Infectious Diseases Society of America. Clin Infect Dis 43:1499, 2006.

PROPHYLAXIS

Improvements in safe water infrastructure to limit fecal–oral spread of enteric pathogens will be necessary if the prevalence of diarrheal diseases is to be significantly reduced in resource-poor countries. Travelers can reduce their risk of diarrhea by eating only hot, freshly cooked food; by avoiding raw vegetables, salads, and unpeeled fruit; and by drinking only boiled or treated water and avoiding ice. Historically, few travelers to tourist destinations adhere to these dietary restrictions, even after pretravel counseling. Bismuth subsalicylate is an inexpensive agent for the prophylaxis of traveler's diarrhea; it is taken at a dosage of 2 tablets (525 mg) four times a day. Treatment appears to be effective and safe for up to 3 weeks, but adverse events such as temporary darkening of the tongue, constipation, and tinnitus can occur. A meta-analysis suggests that probiotics may lessen the likelihood of traveler's diarrhea by ~15%, but further studies are needed. Prophylactic antimicrobial agents, although effective, are not generally recommended for the prevention of traveler's diarrhea except when travelers are immunosuppressed or have underlying illness that places them at high risk for morbidity from gastrointestinal infection. If prophylaxis is indicated, the nonabsorbed antibiotic rifaximin can be considered.

The possibility of exerting a major impact on the worldwide morbidity and mortality associated with diarrheal diseases has led to intensive efforts to develop effective vaccines against common bacterial and

viral enteric pathogens. An effective rotavirus vaccine is available. Vaccines against *V. cholerae* are available and recommended in areas where active transmission is ongoing, although the protection they offer is incomplete and short lived. A typhoid conjugate vaccine is now recommended by the World Health Organization for use in countries where typhoid is endemic. At present, there are no effective commercially available vaccines against pathogenic *E. coli*, *Shigella*, *Campylobacter*, nontyphoidal *Salmonella*, norovirus, or intestinal parasites.

139 *Clostridioides difficile* Infection, Including Pseudomembranous Colitis

Dale N. Gerding, Stuart Johnson

DEFINITION

Clostridioides difficile infection (CDI) is a unique colonic disease that is acquired most commonly in association with antimicrobial use and the consequent disruption of the normal colonic microbiota. The most commonly diagnosed diarrheal illness acquired in the hospital, CDI results from the ingestion of spores of *C. difficile* that vegetate, multiply, and secrete toxins, causing diarrhea and, in the most severe cases, pseudomembranous colitis (PMC).

ETIOLOGY AND EPIDEMIOLOGY

C. difficile is an obligately anaerobic, gram-positive, spore-forming bacillus whose spores are found widely in nature, particularly in the environment of hospitals and chronic-care facilities. CDI occurs frequently in hospitals and nursing homes (or shortly after discharge from these facilities) where the level of antimicrobial use is high and the environment is contaminated by *C. difficile* spores.

Clindamycin, ampicillin, and cephalosporins were the first antibiotics associated with CDI. The second- and third-generation cephalosporins, particularly cefotaxime, ceftriaxone, cefuroxime, and ceftazidime, are agents frequently responsible for this condition, and the fluoroquinolones (ciprofloxacin, levofloxacin, and moxifloxacin) are the most recent drug class to be implicated in hospital outbreaks. Penicillin/β-lactamase-inhibitor combinations such as ticarcillin/clavulanate and piperacillin/tazobactam pose significantly less risk. However, all antibiotics, including vancomycin (the agent most commonly used to treat CDI), have been found to carry a risk of subsequent CDI. A minority of cases, especially in the community, are reported in patients without documentation of prior antibiotic exposure.

C. difficile is acquired exogenously—most often in the hospital or nursing home, but also in the outpatient setting—and is carried in the stool of both symptomatic and asymptomatic patients. The rate of fecal colonization increases in proportion to length of hospital stay and is often ≥20% among adult patients hospitalized for >2 weeks; in contrast, the rate is 1–3% among community residents. CDI is the most common health care–associated infection in the United States, with an estimated 462,100 cases in 2017. Between 2011 and 2017, the total burden of CDI in the United States decreased by 24%, which was due primarily to decreases in health care–associated CDI. The estimated burden of community-associated CDI was unchanged, but it now approximates the health care–associated rate in the United States.

Asymptomatic fecal carriage of *C. difficile* in healthy neonates is very common, with repeated colonization by multiple strains in infants <1–2 years of age, but associated disease in these infants is extremely rare if it occurs at all. Spores of *C. difficile* are found on environmental surfaces (where the organism can persist for months) and on the hands of hospital personnel who fail to practice good hand hygiene. Hospital epidemics of CDI have been attributed to a single *C. difficile* strain and to multiple different strains, introduced by patients on admission, that are present simultaneously. Other identified risk factors for CDI include older age, greater severity of underlying illness, gastrointestinal surgery, use of electronic rectal thermometers, enteral tube feeding, and antacid treatment. Use of proton pump inhibitors may be a risk factor, but this risk is probably modest, and no firm data have implicated these agents in patients who are not already receiving antibiotics.

PATHOLOGY AND PATHOGENESIS

Spores of toxigenic *C. difficile* are ingested, survive gastric acidity, germinate in the small bowel, and, in the presence of a disrupted microbiota, colonize the lower intestinal tract, where they elaborate two large toxins: toxin A (an enterotoxin) and toxin B (a cytotoxin). These toxins initiate processes resulting in the disruption of epithelial-cell barrier function, diarrhea, and pseudomembrane formation. Toxin A is a potent neutrophil chemoattractant, and both toxins glucosylate the GTP-binding proteins of the Rho subfamily that regulate the actin cell cytoskeleton. Data from studies using molecular disruption of toxin genes in isogenic mutants suggest that toxin B may be the more important virulence factor, which is consistent with the well-documented occurrence of clinical disease caused by toxin A–negative strains but not by toxin B–negative strains. Disruption of the cytoskeleton results in loss of cell shape, adherence, and tight junctions, with consequent fluid leakage. A third toxin, binary toxin CDT, was previously found in only ~6% of strains but is present in all isolates of the widely recognized epidemic NAP1/BI/027 strain (see "Global Considerations," below); this toxin is related to *C. perfringens* iota toxin. Its role in the pathogenesis of CDI has not yet been defined.

The pseudomembranes of PMC are confined to the colonic mucosa and initially appear as 1- to 2-mm whitish-yellow plaques. The intervening mucosa appears unremarkable, but, as the disease progresses,

FIGURE 139-1 Autopsy specimen showing confluent pseudomembranes covering the cecum of a patient with pseudomembranous colitis. Note the sparing of the terminal ileum (*arrow*).

the pseudomembranes coalesce to form larger plaques and become confluent over the entire colon wall (Fig. 139-1). The whole colon is usually involved, but 10% of patients have rectal sparing. Viewed microscopically, the pseudomembranes have a mucosal attachment point and contain necrotic leukocytes, fibrin, mucus, and cellular debris. The epithelium is eroded and necrotic in focal areas, with neutrophil infiltration of the mucosa.

Patients colonized with *C. difficile* were initially thought to be at high risk for CDI. However, four prospective studies have shown that colonized patients who have not previously had CDI actually have a decreased risk of CDI, possibly because many of these patients are colonized by nontoxigenic strains. At least three events are proposed as essential for the development of CDI (Fig. 139-2). Exposure to antimicrobial agents is the first event and establishes susceptibility to CDI, most likely through disruption of the normal gastrointestinal microbiota. The second event is exposure to toxigenic *C. difficile*. Given that the majority of patients do not develop CDI after the first two events, a third event is clearly essential for its occurrence. Candidate third events include exposure to a *C. difficile* strain of particular virulence, exposure to antimicrobial agents especially likely to cause CDI, and an inadequate host immune response. The host anamnestic immune response as has been shown for serum IgG antibody response to toxin A of *C. difficile* is likely one factor in the third event that determines which patients develop diarrhea and which patients remain asymptomatic. The majority of humans probably first develop antibody to *C. difficile* toxins when colonized asymptomatically during the first year of life or after CDI in childhood. Infants are thought not to develop symptomatic CDI because they lack suitable mucosal toxin receptors that develop later in life. In adulthood, there is evidence that serum antibodies to both toxin A and B protect against recurrent CDI. Two large clinical trials in which intravenous monoclonal antibodies to toxin A and toxin B were used together and as single agents in addition to standard antibiotic therapy showed that rates of recurrent CDI were significantly lower with the combination of antibodies and with the toxin B antibody alone than with placebo plus standard therapy. Antibody to toxin A alone was ineffective.

GLOBAL CONSIDERATIONS

Rates and severity of CDI in the United States, Canada, and Europe increased markedly in the early 2000s. Rates in U.S. hospitals tripled between 2000 and 2005. Hospitals in Montreal, Quebec, reported rates in 2005 that were four times higher than the 1997 baseline, with directly attributable mortality of 6.9% (increased from 1.5%). An epidemic strain, variously known as toxinotype III, REA type BI, PCR ribotype 027, and pulsed-field type NAP1 (collectively designated NAP1/BI/027), likely accounted for much of the increase in incidence. Two clones of NAP1/BI/027 originated in the United States and Canada and spread to the United Kingdom, Europe, and Asia. This epidemic strain was characterized by (1) an ability to produce 16–23 times as much toxin A and toxin B as control strains in vitro, (2) the presence of binary toxin CDT, and (3) high-level resistance to all fluoroquinolones. National control policies instituted in England in 2006 resulted in a marked decline in CDI cases, and restriction of fluoroquinolones, in particular, was correlated with near elimination of fluoroquinolone-resistant strains of *C. difficile* (i.e., NAP1/BI/027) there by 2013. This epidemic strain has likewise decreased in the United States, with data from the Centers for Disease Control and Prevention showing a decrease among health care–associated isolates from 31% to 15% (and from 19% to 6% in community-associated isolates) between 2011 and 2017. New strains have been and will probably continue to be implicated in outbreaks, including a strain commonly found in food animals that also carries binary toxin and has been associated with high mortality rates in human infections (toxinotype V, ribotype 078). Currently, the most frequently isolated community-associated strain in the United States is ribotype 106 (REA group DH), which was previously found to be epidemic in the United Kingdom.

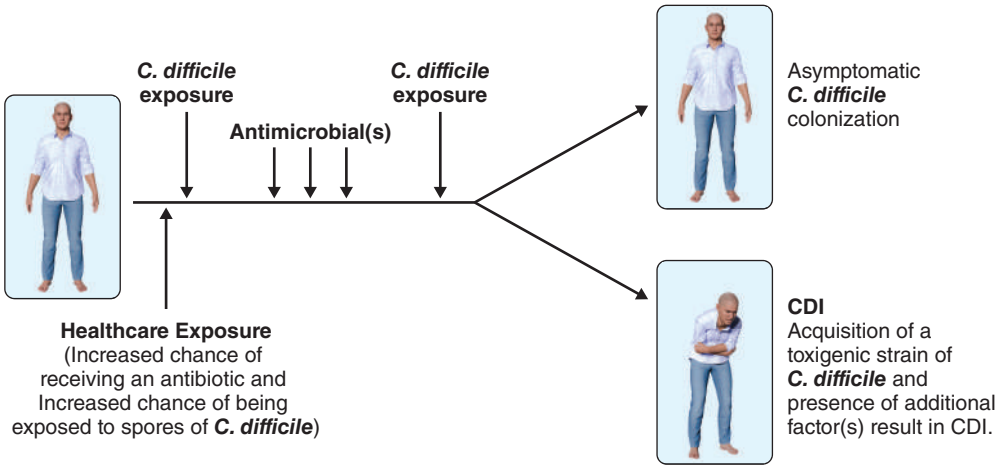

FIGURE 139-2 Pathogenesis model for *Clostridioides difficile* infection (CDI). At least three events are integral to *C. difficile* pathogenesis. Exposure to antibiotics establishes susceptibility to *C. difficile* infection. If susceptible, the patient may ingest nontoxigenic (nonpathogenic) or toxigenic strains of *C. difficile* as a second event. Acquisition of toxigenic *C. difficile* may be followed by asymptomatic colonization or CDI, depending on one or more additional factors, including the strain of *C. difficile* and an inadequate host anamnestic antibody response to *C. difficile* toxins.

CLINICAL MANIFESTATIONS

Diarrhea is the most common manifestation caused by *C. difficile*. Stools are almost never grossly bloody and range from soft and unformed to watery or mucoid in consistency, with a characteristic odor. Clinical and laboratory findings include fever in 28% of cases, abdominal pain in 22%, and leukocytosis in 50%. When adynamic ileus (which is seen on x-ray in ~20% of cases) results in cessation of stool passage, the diagnosis of CDI is frequently overlooked. A clue to the presence of unsuspected CDI in these patients is unexplained leukocytosis, with ≥15,000 white blood cells (WBCs)/μL. Such patients are at high risk for complications of CDI, particularly toxic megacolon and sepsis.

C. difficile diarrhea recurs after treatment in ~15–30% of cases and remains one of the most challenging treatment dilemmas. Recurrences may represent either relapses due to the same strain or reinfections with a new strain. Susceptibility to recurrence of clinical CDI is likely a result of continued disruption of the normal fecal microbiota caused by the antibiotic used to treat CDI.

DIAGNOSIS

The diagnosis of CDI is based on a combination of clinical criteria: (1) diarrhea (≥3 unformed stools per 24 h for ≥2 days) with no other recognized cause plus (2) detection of toxin A or B in the stool, detection of toxin-producing *C. difficile* in the stool by nucleic acid amplification testing (NAAT; e.g., polymerase chain reaction [PCR]) or by culture, or visualization of pseudomembranes in the colon. PMC is a more advanced form of CDI and is visualized at endoscopy in only ~50% of patients with diarrhea who have a positive stool culture and toxin assay for *C. difficile* (Table 139-1). Endoscopy is a rapid diagnostic tool in seriously ill patients with suspected PMC and an acute abdomen, but a negative result in this examination does not rule out CDI.

Despite the array of tests available for *C. difficile* and its toxins (Table 139-1), no single test has high sensitivity, high specificity, and rapid turnaround. Most laboratory tests for toxins, including enzyme immunoassays (EIAs), lack sensitivity. NAATs (including PCR) are widely used diagnostically and are both rapid and sensitive; however, concern has been raised that PCR may detect colonization with toxigenic *C. difficile* in patients who have diarrhea for a reason other than CDI. Confirmation of the presence of toxin in the stool in addition to NAAT or glutamate dehydrogenase (GDH) positivity is recommended in the European CDI guidelines for diagnosis of CDI, and inclusion of a stool toxin test is recommended in the U.S. guidelines when there are no prior criteria for stool submission. Test algorithms that include NAAT followed by toxin EIA for NAAT+ results, and GDH plus toxin EIA arbitrated by NAAT when the two initial test results do not agree, have become widely used; however, when results of individual algorithm tests are discrepant (NAAT+ or GDH+/toxin EIA–), most patients are nonetheless treated for CDI. Empirical treatment is appropriate if stool testing is delayed. Testing of asymptomatic patients is not recommended except for epidemiologic study purposes. In particular, so-called tests of cure following treatment are not recommended because >50% of patients continue to harbor the organism and its toxin after diarrhea has ceased and test results are not predictive of recurrence of CDI. The results of such tests should not be used to restrict placement of patients in long-term care or nursing home facilities.

TREATMENT

Clostridioides difficile Infection

PRIMARY CDI

When possible, discontinuation of any ongoing antimicrobial administration is recommended as the first step in treatment of CDI. Earlier studies indicated that 15–23% of patients respond to this simple measure. However, with the advent of the NAP1/BI/027 epidemic strain and the associated rapid clinical deterioration of some patients, prompt initiation of specific CDI treatment has become the standard. General treatment guidelines include hydration and the avoidance of antiperistaltic agents and opiates, which may mask symptoms and possibly worsen disease. Nevertheless, antiperistaltic agents have been used safely with vancomycin or metronidazole treatment for mild to moderate CDI.

Oral administration of fidaxomicin was suggested as first-line treatment for CDI in the 2021 Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA) focused update guidelines on management of CDI in adults. However, because of resource availability issues, oral vancomycin remains an acceptable alternative. Oral metronidazole is recommended only for mild or moderate CDI when fidaxomicin or vancomycin is not available. IV vancomycin is ineffective for CDI. Fidaxomicin is available only for oral administration. Two large clinical trials comparing vancomycin and fidaxomicin indicated comparable clinical resolution of diarrhea in ~90% of patients, and the rate of recurrent CDI was significantly lower with fidaxomicin. The largest randomized controlled trial of vancomycin versus metronidazole showed that the vancomycin cure rate was superior to the metronidazole cure rate (81% vs 73%; $p = .034$) for all patients with CDI, regardless of severity. Although the mean time to resolution of diarrhea is 2–4 days, the response to metronidazole may be much slower. Treatment should not be deemed a failure until a drug has been given for at least 6 days. On the basis of data for shorter courses of vancomycin and the results of four large clinical trials, it is recommended that vancomycin or fidaxomicin be given for at least 10 days. Metronidazole was never approved for CDI by the

TABLE 139-1 Relative Sensitivity and Specificity of Diagnostic Tests for *Clostridioides difficile* Infection (CDI)

TYPE OF TEST	RELATIVE SENSITIVITY[a]	RELATIVE SPECIFICITY[a]	COMMENT
Stool culture for *C. difficile*	++++	+++	Most sensitive test; specificity of ++++ if the *C. difficile* isolate tests positive for toxin; turnaround time too slow for practical use
Cell culture cytotoxin test on stool	+++	++++	With clinical data, is diagnostic of CDI; highly specific but not as sensitive as stool culture; slow turnaround time
Enzyme immunoassay for toxins A and B in stool	++ to +++	+++	With clinical data, is diagnostic of CDI; rapid results, but not as sensitive as stool culture or cell culture cytotoxin test
Enzyme immunoassay for *C. difficile* common antigen in stool	+++ to ++++	+++	Detects glutamate dehydrogenase found in toxigenic and nontoxigenic strains of *C. difficile* and other stool organisms; more sensitive and less specific than enzyme immunoassay for toxins; requires confirmation with a toxin test; rapid results
Nucleic acid amplification tests for *C. difficile* toxin A or B gene in stool	++++	+++	Detects toxigenic *C. difficile* in stool; widely used in United States for clinical testing; more sensitive than enzyme immunoassay toxin testing; marked increase in CDI diagnoses when implemented
Colonoscopy or sigmoidoscopy	+	++++	Highly specific if pseudomembranes are seen; insensitive compared with other tests

[a]According to both clinical and test-based criteria.

Note: ++++, >90%; +++, 71–90%; ++, 51–70%; +, ~50%.

TABLE 139-2 Recommendations for the Treatment of *Clostridioides difficile* Infection (CDI)

CLINICAL SETTING	TREATMENT(S)	COMMENTS
Initial episode, mild to moderate	Fidaxomicin (200 mg bid × 10 d) ***or alternatively*** Oral vancomycin (125 mg qid × 10 d)	Oral metronidazole is less effective than the other options and may necessitate a longer treatment course for response. Metronidazole (500 mg tid × 10–14 d) is recommended only if vancomycin or fidaxomicin is not readily accessible and for mild to moderate disease only.
Initial episode, severe	Oral vancomycin (125 mg qid × 10 d) ***or alternatively*** Fidaxomicin (200 mg bid × 10 d)	Indicators of severe disease may include leukocytosis (≥15,000 white blood cells/μL) and a creatinine level ≥1.5 mg/dL.
Initial episode, fulminant	Vancomycin (500 mg PO or via nasogastric tube) plus metronidazole (500 mg IV q8h) ***plus consider*** Rectal instillation of vancomycin (500 mg in 100 mL of normal saline as a retention enema q6–8h)	Fulminant CDI is defined as severe CDI with the addition of hypotension, shock, ileus, or toxic megacolon. The duration of treatment may need to be >2 weeks and is dictated by response.
First recurrence	Fidaxomicin (200 mg bid × 10 d) ***or*** Oral vancomycin (125 mg qid × 10 d) ***or*** Oral vancomycin followed by a taper-and-pulse regimen[a]	Treatment for the initial episode may be considered when choosing treatment for the first recurrence.
Multiple recurrences	Oral vancomycin treatment followed by a taper-and-pulse regimen ***or*** Fidaxomicin (200 mg bid × 10 d or 200 mg bid × 5 d followed by every other day × 20 d) ***or*** Vancomycin (125 mg qid × 10 d), then stop vancomycin and start rifaximin (400 mg bid × 2 weeks) ***or*** Fecal microbiota replacement therapy (FMRT)	It is recommended that FMRT by fecal microbiota (Rebyota, live-jslm) given by enema or fecal microbiota spores (Vowst, live-brpk) given orally be considered only after appropriate antibiotic treatment for recurrent CDI.
Patients at high risk of recurrent CDI who are receiving vancomycin, fidaxomicin, or metronidazole	Bezlotoxumab 10 mg/kg given IV	Bezlotoxumab is adjuvant therapy (in addition to and during antibiotic treatment) for patients at high risk for recurrent CDI. Risk factors include age >65 years, immunocompromised host, severe CDI on presentation, and prior episode of CDI in the past 6 months.

[a]A typical taper-and-pulse vancomycin regimen following a 10-day treatment course includes: 125 mg bid × 1 week, then daily × 1 week, then q2–3d for 2–8 weeks.

U.S. Food and Drug Administration (FDA), and its use for CDI treatment declined markedly after publication of the 2017 IDSA/SHEA CDI guidelines. It is important to initiate treatment with oral vancomycin or fidaxomicin for patients who appear seriously ill, particularly if they have a high WBC count (>15,000/μL) or creatinine level (≥1.5 mg/dL) **(Table 139-2)**. Small randomized trials of nitazoxanide, bacitracin, rifaximin, and fusidic acid for treatment of CDI have been conducted. These drugs have not been extensively studied, shown to be superior, or approved by the FDA for CDI, but they provide potential alternatives to vancomycin and fidaxomicin.

RECURRENT CDI

Overall, ~15–30% of successfully treated patients experience recurrences of CDI following treatment. CDI recurrence is significantly lower in patients treated with fidaxomicin than in those treated with vancomycin. Vancomycin and metronidazole have comparable recurrence rates, and metronidazole is not recommended for treatment of recurrent CDI. Patients who have a first recurrence of CDI have an even higher rate of second recurrence. Fidaxomicin is superior to vancomycin in reducing further recurrences in patients who have had one CDI recurrence (Table 139-2). Recurrent disease, once thought to be relatively mild, has now been documented to pose a significant (11%) risk of serious complications (shock, megacolon, perforation, colectomy, or death within 30 days). There is no standard treatment for multiple recurrences, but the use of vancomycin in a tapering and pulsed dosing regimen every other day for 2–8 weeks has been used for years as a practical approach to treating these patients, and recent data suggest it is still effective. Other recommended treatment options for patients with multiple CDI recurrences include fidaxomicin in standard or extended/pulsed dosing regimens, vancomycin followed by rifaximin, or fecal microbiota transplantation (FMT) via nasoduodenal tube, colonoscope, enema, or oral capsules (Table 139-2). FMT has been widely used over the past decade, and the availability of stool banks and oral capsule formulations made this approach more practical. Recently, the FDA has approved two microbiota replacement therapies and discontinued enforcement discretion for centralized donor stool banks. A fecal microbiota suspension (Rebyota, live-jslm) and a suspension of live fecal microbiota spores for oral delivery (Vowst, live-brpk) are now approved for patients with recurrent CDI to prevent further recurrence. Both of these products are adjunctive treatments that are indicated for patients who have completed antibiotic treatment for CDI.

In addition to antibacterial therapies, another adjunctive treatment is now available for patients who are receiving standard-of-care antibacterial agents and who are at high risk for recurrent CDI (rCDI). Bezlotoxumab, a monoclonal antibody directed against *C. difficile* toxin B, has been shown to reduce the risk of rCDI by an absolute rate of ~10% when administered to patients currently receiving vancomycin, fidaxomicin, or metronidazole. Risk factors for rCDI in the clinical trials included age >65 years, immunocompromise, severe CDI on presentation, and prior episode of CDI in the past 6 months.

SEVERE COMPLICATED OR FULMINANT CDI

Fulminant (rapidly progressive and severe) CDI presents the most difficult treatment challenge. Patients with fulminant disease often do not have diarrhea, and their illness mimics an acute surgical abdomen. Sepsis (hypotension, fever, tachycardia, leukocytosis) may result from fulminant CDI. An acute abdomen (with or without toxic megacolon) may include signs of obstruction, ileus, colon-wall thickening and ascites on abdominal CT, and peripheral-blood leukocytosis (≥20,000 WBCs/μL). With or without diarrhea, the differential diagnosis of an acute abdomen, sepsis, or toxic megacolon should include CDI if the patient has received antibiotics in the past 2 months. Cautious sigmoidoscopy or colonoscopy to visualize PMC and an abdominal CT examination are the best diagnostic tests in patients without diarrhea.

Medical management of fulminant CDI is suboptimal because of the difficulty of delivering oral fidaxomicin, metronidazole, or vancomycin to the colon in the presence of ileus (Table 139-2). The combination of vancomycin (given orally or via nasogastric tube and by retention enema) plus IV metronidazole has been used with some success in uncontrolled studies, as has IV tigecycline in small-scale uncontrolled studies. Surgical colectomy may be life-saving if there is no response to medical management. If possible,

colectomy should be performed before the serum lactate level reaches 5 mmol/L. However, mortality and morbidity associated with colectomy may be reduced by performing instead a laparoscopic ileostomy followed by colon lavage with polyethylene glycol and vancomycin infusion into the colon via the ileostomy.

PROGNOSIS

The mortality rate attributed to CDI, previously found to be 0.6–3.5%, has reached 6.9% in recent outbreaks and is progressively higher with increasing age. Most patients recover, but recurrences are common.

PREVENTION AND CONTROL

Strategies for the prevention of CDI are of two types: those aimed at preventing transmission of the organism to the patient and those aimed at reducing the risk of CDI if the organism is transmitted. Transmission of *C. difficile* in clinical practice has been prevented by gloving of personnel, elimination of the use of contaminated electronic thermometers, and use of hypochlorite (bleach) solution for environmental decontamination of patients' rooms. Hand hygiene is critical; hand washing is recommended in CDI outbreaks because alcohol hand gels are not sporicidal. CDI outbreaks have been best controlled by restricting the use of specific antibiotics, such as clindamycin, second- and third-generation cephalosporins, and fluoroquinolones. Outbreaks of CDI due to antibiotic-resistant strains have resolved promptly when specific antibiotic use is restricted. Future primary prevention strategies include use of monoclonal antibodies, as well as biotherapeutics with live organisms to prevent colonization. Vaccines have to date been unsuccessful.

140 Urinary Tract Infections: Cystitis, Prostatitis, and Pyelonephritis

Barbara W. Trautner, Prathit A. Kulkarni, Nicolás W. Cortés-Penfield, Kalpana Gupta

In the preantibiotic era, urinary tract infection (UTI) caused significant morbidity. Hippocrates described acute cystitis as sometimes lasting for a year before either resolving or worsening to involve the kidneys. Early twentieth-century chemotherapeutics for UTI were ineffective, and persistent infection was common. Nitrofurantoin, which became available during the 1950s, was the first tolerable and effective agent for UTI treatment. Today, UTI remains common, being one of the leading reasons for which antibiotics are used within and outside the hospital. Patients typically favorably and quickly to appropriately chosen modern antimicrobials.

Since the most common manifestation of UTI is acute cystitis, which is far more prevalent among women than among men, most clinical research on UTI has involved healthy young adult women recruited from college campuses or large U.S. health maintenance organizations. Therefore, clinicians must understand that UTI remains relatively understudied in other patient populations, and they must use expert judgment to decide when and to what extent UTI clinical trial data and treatment guidelines can be generalized to other groups of patients.

DEFINITIONS

The term *urinary tract infection* refers to an infection somewhere along the urinary tract that produces clinical symptoms. Infection can be caused either by bladder invasion by a new urinary pathogen or by a shift in the existing urinary bacteria's dynamic equilibrium with the host; both causes result in local tissue injury and inflammation. Thus, while UTI encompasses a broad range of clinical presentations, from acute simple cystitis to bacteremic emphysematous pyelonephritis, importantly, the presence alone of bacteria in the urinary tract in a patient *without* related symptoms does *not* constitute UTI. The presence of bacteria in the urine without associated symptoms is instead termed *asymptomatic bacteriuria* (ASB).

This distinction between UTI and ASB has major clinical implications. Both UTI and ASB connote the presence of bacteria in the urinary tract and are usually accompanied by white blood cells in the urine (termed *pyuria*). However, while antibiotic treatment of UTI is almost always indicated to relieve the symptoms attributable to urinary bacterial infection and to prevent progression of the infection, ASB typically poses no threat for most patients and usually does not require treatment. Limited data suggest inappropriate treatment of ASB might in fact *increase* risk for future UTI, perhaps by facilitating bladder colonization with more virulent and potentially more resistant pathogens. Two exceptions to the general rule that ASB should not be treated are patients who are pregnant or who are about to undergo certain urologic procedures. In pregnant patients, untreated ASB is associated with pyelonephritis, preterm delivery, and low birth weight, which justifies use of routine ASB screening and treatment. In patients undergoing procedures that cause urologic mucosal injury (e.g., lithotripsy or transurethral resection of the prostate), bacterial translocation from urine to blood can occur; therefore, screening for, and periprocedural treatment of, ASB is recommended in this setting.

In this chapter, the term *urinary tract infection* denotes symptomatic disease; *cystitis*, symptomatic infection of the bladder; *prostatitis*, symptomatic infection of the prostate; and *pyelonephritis*, symptomatic infection of the kidneys. *Uncomplicated urinary tract infection* refers to an infection confined to the bladder in a woman or man without a urinary catheter, whereas *complicated urinary tract infection* refers to infection that extends beyond the bladder (e.g., prostatitis, pyelonephritis, bacteremia, or UTI in the setting of intermittent or indwelling

urinary catheterization, termed *catheter-associated UTI* [CAUTI]). *Recurrent urinary tract infection* is not necessarily complicated; individual episodes can be uncomplicated and treated as such. This approach to UTI categorization differs from the classic approach, in which UTI in men and other populations perceived to be at higher risk for poor outcome (e.g., patients with diabetes, anatomic abnormalities of the urinary tract, or immunocompromise) was automatically considered complicated. The new updated approach more closely reflects actual clinical practice. For the frontline clinician, the key considerations in diagnostic workup and therapy for UTI include whether the patient is stable for outpatient management, whether a source of recalcitrant and/or recurrent infection (e.g., obstructing renal calculi) needs to be identified, and whether the prescribed antimicrobial agents must achieve adequate levels in the blood and renal tissue in addition to the urine.

Prostatitis, usually categorized as either acute bacterial prostatitis (ABP) or chronic bacterial prostatitis (CBP), can complicate cystitis or arise hematogenously (e.g., as a metastatic focus of *Staphylococcus aureus* bacteremia) in men and transgender women. While prostatitis is certainly an infection of the genitourinary tract, it is largely unrepresented in UTI clinical trial data, and earlier ABP literature suggests that prolonged therapy with antimicrobials penetrating the prostate might be required. Therefore, clinical practice guidelines for complicated UTI cannot be assumed to be generalizable to patients with prostatitis. *Urethritis* is occasionally caused by *Escherichia coli* and other urinary pathogens but is predominantly due to *Neisseria gonorrhea*, *Chlamydia trachomatis*, and *Mycoplasma genitalium*. Hence, symptoms such as urethral pain, pruritus, or discharge should prompt evaluation for sexually transmitted infections (STIs), which are covered in **Chap. 141**.

EPIDEMIOLOGY AND RISK FACTORS

During the neonatal period, the incidence of UTI is slightly higher among males than among females because male infants more commonly have congenital urinary tract anomalies. After 50 years of age, obstruction from prostatic hypertrophy becomes common in men, and incidence of UTI is almost as high among men as among women. Between 1 year and ~50 years of age, however, UTI and recurrent UTI are predominantly conditions of females, with most true male UTI occurring in the context of urinary catheterization or anatomic abnormalities. The prevalence of ASB is ~5% among women between ages 20 and 40 and might be as high as 40–50% among elderly women and men. Up to 80% of women develop at least one UTI during their lifetime, predominantly acute simple cystitis. The lifetime prevalence of UTI in men in the United States is estimated to be 14%.

About 20–30% of women who have had one episode of UTI will have recurrent episodes. Early recurrence (within 2 weeks) is usually regarded as relapse rather than reinfection and might indicate the need to evaluate the patient for a sequestered focus of ongoing infection. The rate of UTI recurrence ranges from 0.3 to 7.6 infections per patient per year, with an average of 2.6 reinfections per year. It is not uncommon for multiple recurrences to follow an initial infection, resulting in clustering of episodes. Clustering may be related to the presence of a new risk factor, sloughing of the protective outer bladder epithelial layer in response to bacterial attachment during acute cystitis, or possibly antibiotic-related alteration of the normal bacterial flora. The likelihood of recurrence decreases with increasing time since the last infection. Risk factors for recurrent UTI include frequent sexual intercourse, use of spermicide, a new sexual partner, first UTI before 15 years of age, and maternal history of UTI; of these, frequent sexual intercourse and spermicide use are the most consistently documented risk factors.

Some component of UTI susceptibility is likely hereditary, as family and maternal history of UTI has been identified as a risk factor for cystitis, pyelonephritis, and recurrent UTI. In addition, colonization with specific bacterial strains predisposed to cause infection might also be an important factor, as suggested by studies indicating that new sexual partners are a risk factor for UTI in women and that uropathogenic *E. coli* are shared between partners via vaginal and oral sex. Beyond this, risk factors for UTI can be grouped broadly into three categories: (1) factors that impede the normal outflow of urine, (2) factors that introduce new bacteria into the genitourinary tract or serve as a nidus of infection, and (3) factors that disrupt or impair local mucosal defenses.

The flushing action of normal urination is a key mechanism by which the host controls urinary bacterial populations and mitigates bacterial ascent from the urethra to the bladder and kidneys. Anatomic factors that result in urinary obstruction or retention have been associated with cystitis, pyelonephritis, and recurrent UTI. These risk factors include congenital urinary tract abnormalities, cystoceles, pelvic-organ prolapse, bladder dysfunction leading to overflow urinary incontinence, and benign prostatic hypertrophy. Importantly, not all men with UTI have detectable urinary tract abnormalities; this point is particularly relevant for men ≤45 years of age.

Factors that promote bacterial entry into the urinary tract predispose to UTI. Sexual activity is likely the most common among these and is temporally associated with cystitis, with an increased relative risk in one study ranging from 1.4 with weekly intercourse to 4.8 with intercourse five times weekly. For men, insertive rectal intercourse and lack of circumcision are associated with increased UTI risk, the latter likely because *E. coli* is tends to colonize the glans and prepuce and subsequently migrate into the urinary tract. For men and women, urinary instrumentation (e.g., intermittent or chronic catheterization or existence of a draining nephrostomy tube) dramatically increases bacterial entry into the urinary tract and risk of UTI. In addition, foreign bodies in the urinary tract (e.g., stents and kidney stones) also can become colonized with bacteria and serve as niduses for recurrent UTI.

Factors that disrupt or impair local mucosal defenses, usually either by irritating the urogenital mucosa or by disrupting the normal female urogenital microbiome (i.e., symbiotic lactobacilli), predispose to UTI. Such factors include recent use of diaphragms or spermicide and menopause. Women with diabetes have two- to threefold higher rates of ASB and UTI than women without diabetes, and this risk increases further with a longer duration of having had diabetes and with the need for insulin rather than oral medications. The specific mechanisms for this risk are not clear, although impaired cytokine secretion or diabetes complications leading to bladder dysfunction likely contribute. Whether glycosuria is major contributor to UTI risk remains controversial. The U.S. Food and Drug Administration has issued a drug-safety warning for the observed association between use sodium–glucose cotransporter 2 (SGLT-2) inhibitors for treatment of diabetes and UTI. The postulated mechanism is that these drugs increase excretion of glucose in the urine.

ETIOLOGY

E. coli is the predominant pathogen across the spectra of UTI clinical syndromes and patient populations. In cases of acute cystitis in the United States, *E. coli* accounts for 75–90% of isolates, *Staphylococcus saprophyticus* for 5–15% (with more frequent isolation from younger women), and other Enterobacterales species (i.e., *Klebsiella*, *Proteus*, *Enterobacter*, and *Citrobacter*) for the majority of the remainder. The microbiology of pyelonephritis is similar to that of acute cystitis, as would be expected since pyelonephritis usually develops as ascending infection from the bladder. The microbiology of CAUTI is more diverse, but *E. coli* remains the predominant organism. Other important pathogens in CAUTI are *Pseudomonas aeruginosa*, enterococci, *Staphylococcus aureus*, and *Candida*. Genetic sequencing of the bladder microbiome has consistently demonstrated that more bacterial species are present than can be identified by routine culture methods, in both symptomatic and asymptomatic states. The clinical significance of these noncultivable organisms is unknown, but such work demonstrates that the healthy bladder is often not a sterile site.

Antimicrobial resistance among Enterobacterales species that cause UTI is increasing. One recent surveillance study of isolates from the United States demonstrated resistance rates of >20% to trimethoprim-sulfamethoxazole (TMP-SMX), fluroquinolones, and nitrofurantoin among ambulatory patients in many regions of the country. In addition, approximately 6% of isolates were resistant to three or more antibiotic classes, and approximately 9% of isolates had production of extended-spectrum β-lactamase. Surveillance studies conducted in South America and Europe have yielded similar findings. The increased

prevalence of multidrug-resistant uropathogens has left few oral options for therapy in some cases and no single agent or agents that can confidently be recommended for empirical ambulatory treatment of UTI without regard to geographic region. Since resistance rates vary in different areas, local antibiogram data can help inform which drugs should be used as preferred empirical therapy in UTI, with the caveat that organisms are identified only in cases in which urine is sent for culture—typically, when complicated or recurrent UTI is suspected—and so may overestimate antimicrobial resistance in healthy ambulatory patients with a primary episode of UTI.

PATHOGENESIS

The urinary tract can be viewed as an anatomic unit linked by a continuous column of urine extending from the kidneys to the urethra. In the majority of UTIs, bacteria establish infection by ascending from the urethra to the bladder. Continuing ascent up the ureter to the kidney is the pathway for most renal parenchymal infections. The other main route of entry into the genitourinary tract is hematogenous in cases where bacteremia precedes UTI. Importantly, introduction of bacteria into the bladder does not inevitably lead to sustained and symptomatic infection. The interplay of host, pathogen, and environmental factors determines whether tissue invasion and symptomatic infection will ensue (**Fig. 140-1**). For example, bacteria often enter the bladder after sexual intercourse, but normal voiding and innate host defense mechanisms in the bladder eliminate these organisms. Any foreign body in the urinary tract, such as a urinary catheter or stone, provides an inert surface for bacterial colonization. Additionally, abnormal micturition and/or significant residual urine volume promotes infection. In the simplest terms, anything that increases the likelihood of bacteria entering the bladder and staying there increases risk of developing UTI. Intracellular bacterial communities of infecting organisms within the bladder epithelium have been demonstrated in animal models of UTI and in exfoliated human urothelial cells, but the clinical impact of this phenomenon in humans is not yet clear.

Bacteria can also gain access to the urinary tract through the bloodstream. However, hematogenous spread only accounts for less than 2% of documented UTIs and usually results from bacteremia caused by relatively virulent organisms, such as *S. aureus* and *Salmonella*. The isolation of either of these pathogens from a urine culture warrants consideration of concomitant bacteremia. Hematogenous infections can also produce focal renal abscesses or pyelonephritis.

The pathogenesis of candiduria in particular is distinct because the hematogenous route is more common in that situation. The presence of *Candida* in the urine of a non-instrumented immunocompetent patient implies either genital contamination or potentially widespread visceral dissemination. By contrast, candiduria is common in catheterized patients, particularly following antimicrobial therapy for CAUTI or inappropriate treatment of ASB.

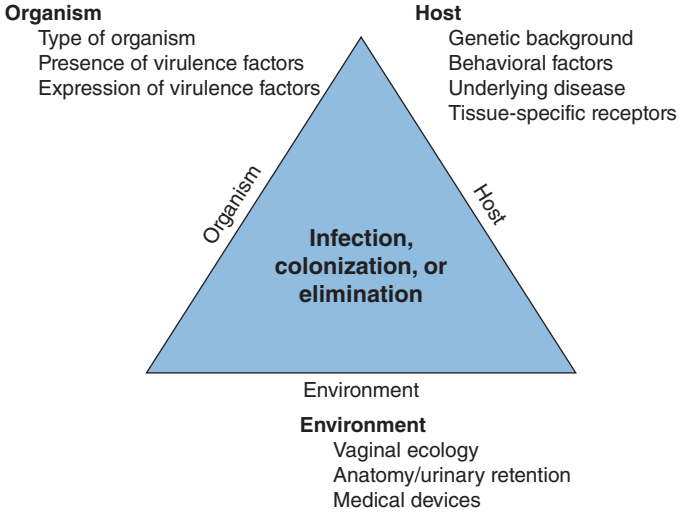

FIGURE 140-1 Pathogenesis of urinary tract infection. The relationship among specific host, pathogen, and environmental factors determines the clinical outcome.

Environmental Factors • **VAGINAL ECOLOGY** Vaginal ecology is an important environmental factor affecting risk of UTI in women. Colonization of the vaginal introitus and periurethral area with organisms from the intestinal flora (usually *E. coli*) is the critical initial step in the pathogenesis of UTI. Sexual intercourse is associated with an increased risk of vaginal colonization with *E. coli* and thereby increases risk of UTI. Nonoxynol-9 in spermicide is toxic to normal vaginal lactobacilli and thus is likewise associated with an increased risk of vaginal colonization and bacteriuria due to *E. coli*. In postmenopausal women, the previously predominant vaginal lactobacilli are replaced with colonizing Gram-negative bacteria because of vaginal atrophy. Topical estrogens have been demonstrated to reduce frequency of recurrent UTIs in postmenopausal women without altering systemic hormone levels. Given the side effects of systemic hormone replacement, oral estrogens should not be used to prevent UTI.

ANATOMIC AND FUNCTIONAL ABNORMALITIES Any condition that permits urinary stasis or obstruction predisposes the patient to development of UTI. Foreign bodies such as stones or urinary catheters provide an inert surface for bacterial colonization and formation of a persistent biofilm. Thus, vesicoureteral reflux, ureteral obstruction secondary to prostatic hypertrophy, neurogenic bladder, and urinary-diversion surgery all create an environment that can lead to UTI. Inhibition of ureteral peristalsis and decreased ureteral tone leading to vesicoureteral reflux are important in the pathogenesis of pyelonephritis in pregnant patients. Anatomic factors—in particular, the length of the urethra—are considered to be the primary reason why UTI is predominantly an illness of young women rather than of young men.

Host Factors The genetic background of the host influences the individual's susceptibility to recurrent UTI. In women, familial disposition to UTI is well documented. Additionally, women with recurrent UTI are more likely to have had their first UTI before the age of 15 years and to have a maternal history of UTI. A component of the underlying pathogenesis of this familial predisposition to recurrent UTI might be persistent vaginal colonization with *E. coli*, even during asymptomatic periods. Vaginal and periurethral mucosal cells from women with recurrent UTI bind uropathogenic bacteria threefold more than do mucosal cells from women without recurrent infection. This difference appears to be at least partly mediated by not expressing certain blood group antigens, facilitating adherence of *E. coli* to the urothelium. Mutations in host innate immune response genes (e.g., those coding for Toll-like receptors and the interleukin 8 receptor) also have been linked to recurrent UTI and pyelonephritis.

Microbial Factors Strains of *E. coli* that cause invasive symptomatic infection of the urinary tract in otherwise normal hosts often possess and express genetic virulence factors, including bacterial-surface adhesins that mediate microbial binding to specific receptors on the surface of uroepithelial cells. The best-studied adhesins are the P fimbriae, hairlike protein structures that interact with a specific receptor on renal epithelial cells. (The letter *P* denotes the ability of these fimbriae to bind to blood-group antigen P, which contains a D-galactose-D-galactose residue.) P fimbriae are important in the pathogenesis of pyelonephritis and subsequent bloodstream invasion from the kidney. Another adhesin is the type 1 pilus (fimbria), which all *E. coli* strains possess but which is not always expressed. Type 1 pili are thought to play a key role in initiating *E. coli* bladder infection; they mediate binding to mannose on the luminal surface of bladder uroepithelial cells. Toxins, metal (iron)-acquisition systems, biofilm formation, and bacterial capsules also can contribute to the ability of pathogenic *E. coli* to thrive in the bladder.

APPROACH TO THE PATIENT

Clinical Syndromes and Diagnostic Approaches

The key questions to be addressed when UTI is suspected are:

- Does the patient actually have UTI (rather than ASB or urinary symptoms not related to infection)?

- If the patient does have UTI, is it confined to the bladder (cystitis), or is there evidence that infection might be present beyond the bladder?
- If the diagnosis is uncertain, would it be safe to delay empirical antimicrobial therapy while attempting to achieve more diagnostic certainty?

The answers to these immediate clinical questions will shape the diagnostic and therapeutic approach.

ASYMPTOMATIC BACTERIURIA

A diagnosis of ASB should be strongly suspected when a patient with a positive urine culture does not have either localizing urinary symptoms or systemic symptoms that are unexplained. The clinical presentation is typically bacteriuria that is detected incidentally when a patient undergoes a screening urine culture. Accordingly, diagnostic stewardship (i.e., not sending urine cultures in patients who lack clinical signs and symptoms that suggest UTI except when screening patients who are pregnant or about to undergo urologic procedures) is the key intervention in reducing misdiagnosis of UTI and inappropriate treatment of ASB.

In the setting of pyuria (presence of white blood cells in the urine) and bacteriuria in a patient without symptoms localizing to the urinary tract, systemic symptoms and signs such as fever, altered mental status, and leukocytosis could be features of UTI but do not on their own merit a diagnosis of UTI unless other potential etiologic causes for such findings have been adequately explored and ruled out. Critically, the degree of pyuria in an asymptomatic patient should not influence the diagnosis of ASB versus true UTI. Very high levels of pyuria are common in urinary stasis, such as in patients with end-stage renal disease or obstructed urinary catheters.

In practice, one of the most challenging clinical scenarios to differentiate ASB from true UTI occurs when an older patient presents with isolated altered mentation, often superimposed on chronic cognitive deficits and potentially with little prior documentation. Accurately diagnosing the cause of such a patient's acute encephalopathy is challenging both because the patient might not be able to reliably report localizing urinary symptoms and because true UTI is an important diagnostic consideration on a long list of possible causes of the patient's symptoms. In such a patient, the treating clinician should first establish whether there is evidence of sepsis. If not, the next consideration is whether empirical therapy for potentially serious bacterial infection can be safely withheld while the diagnostic process is ongoing and symptomatic treatment for other noninfectious causes of delirium is given. The clinician should seek out collateral history, such as by calling the patient's caregivers if none are present at the bedside, to elicit information about what occurred prior to the patient's development of acute encephalopathy. A history of prior recurrent UTIs is might not be accurate and instead reflects a history of persistent ASB. The clinician must be vigilant to avoid premature diagnostic closure. Specifically, the clinician should rule out other potential causes of delirium, particularly those whose treatment is time-sensitive or that may worsen with if the diagnosis is not considered and addressed.

CYSTITIS

The typical symptoms of cystitis are dysuria, urinary frequency, and urinary urgency. Other common symptoms include suprapubic discomfort or tenderness and new nocturia, hesitancy, or gross hematuria. Fever, rigors, and unilateral back or flank pain are all inconsistent with uncomplicated cystitis and should provoke investigation for infection beyond the bladder (i.e., involving the kidneys, prostate, or bloodstream).

Cystitis in women can be treated on the basis of history alone. However, if the symptoms are not specific or if a reliable history cannot be obtained, then a urine dipstick (or, if rapidly available, urine microscopy) should be performed. In the scenario of a woman with symptoms potentially suggestive of cystitis, a negative dipstick result does not fully rule out UTI, and appropriate next steps would include formal urine microscopy with reflex to culture, possibly a pelvic examination or STI testing, and close clinical follow-up. In pregnant patients, in patients suspected to have a resistant organism, or in cases of recurrent UTI, a urine culture is specifically warranted to guide appropriate therapy. Urine dipstick and/or urine microscopy alone are not sufficient.

The signs and symptoms of cystitis in men are similar to those in women, but this diagnosis should be approached cautiously, as cystitis in men is less common, except in the setting of urinary catheterization/instrumentation or obstructive uropathy due to prostatic hypertrophy. Urine cultures should be obtained for all cases of male UTI, as the documentation of bacteriuria can differentiate the less common syndromes of acute and chronic bacterial prostatitis from the more common entity of chronic pelvic pain syndrome, which is not associated with bacteriuria and not improved by antibiotics.

PROSTATITIS

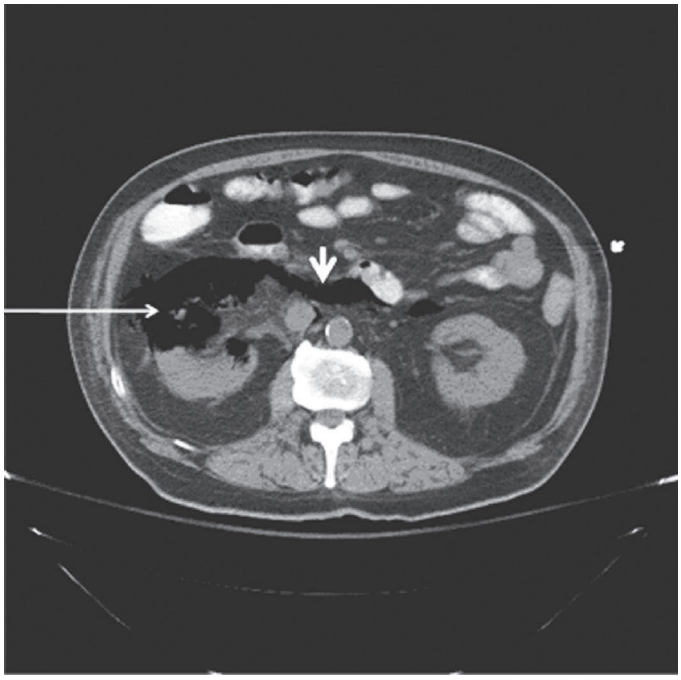
Prostatitis includes both infectious and noninfectious abnormalities of the prostate gland. Infections can be acute or chronic, are almost always bacterial in nature, and are far less common than the noninfectious entity *chronic pelvic pain syndrome* (formerly known as chronic prostatitis). ABP presents as dysuria, frequency, and pain in the prostatic pelvic or perineal area. It is typically a severe illness that can be accompanied by fever, rigors, and/or bladder outlet obstruction. CBP presents more insidiously as recurrent episodes of cystitis, sometimes with associated pelvic and perineal pain. Systemic signs of infection are typically absent, and many patients are evaluated for CBP in the ambulatory setting. Males with recurrent cystitis should be evaluated for a prostatic focus as well as for urinary retention.

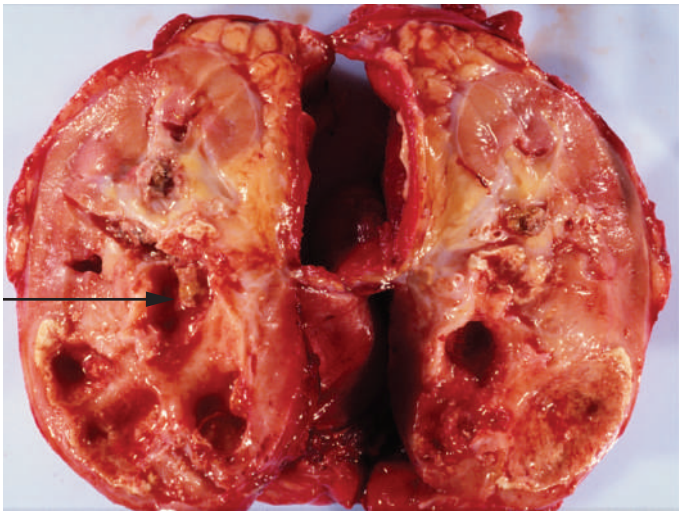
Men with febrile UTI can have an elevated serum level of prostate-specific antigen and an enlarged prostate and enlarged seminal vesicles on ultrasound—findings suggestive of prostate involvement. In a study of 85 men with febrile UTI, symptoms of urinary retention, early recurrence of UTI, hematuria at follow-up, and voiding difficulties were predictive of surgically correctable disorders. Men with none of these symptoms had normal upper and lower urinary tracts on urologic workup. In general, men with febrile UTI, including at the first episode, should have imaging performed (CT or ultrasound) if it has not been performed previously. The purpose of such investigation is specifically to evaluate for urinary tract abnormalities or obstruction. If the diagnosis of UTI is unclear or if UTI is recurrent, referral for urologic consultation is appropriate.

PYELONEPHRITIS

Fever is one of the main features distinguishing cystitis from pyelonephritis, and while "febrile UTI" is sometimes used as a diagnostic category in UTI research, practically speaking, many of these patients have pyelonephritis or other infection that has extended beyond the bladder (hence the inclusion of fever as a criterion for complicated UTI).

Mild pyelonephritis can present with low-grade fever with or without lower back or costovertebral angle pain, whereas severe pyelonephritis often manifests with high fever, rigors, nausea, vomiting, and flank pain. Symptoms are generally acute in onset and may or may not be preceded by symptomatic cystitis. Obstructive uropathy related to acute papillary necrosis (i.e., when the sloughed papillae obstruct the ureter) can complicate pyelonephritis. Acute papillary necrosis can also occur in sickle cell disease and analgesic nephropathy. In the rare cases of bilateral papillary necrosis, a rapid rise in the serum creatinine level might be the first indication of the condition. *Emphysematous pyelonephritis* is a particularly severe form of pyelonephritis associated with production of gas in the renal and perinephric tissues. It occurs almost exclusively in patients with poorly controlled diabetes **(Fig. 140-2)**. *Xanthogranulomatous pyelonephritis* occurs when chronic urinary obstruction (often by staghorn calculi), together with chronic infection, leads to suppurative destruction of renal tissue **(Fig. 140-3)**. On pathologic





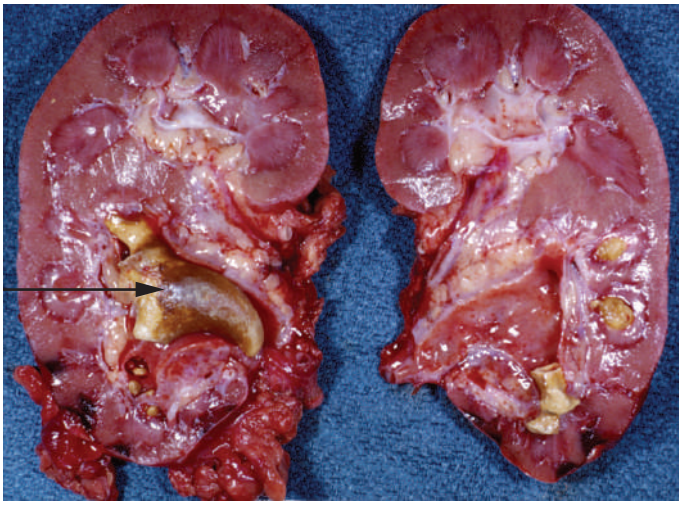


FIGURE 140-2 Emphysematous pyelonephritis. Infection of the right kidney of a diabetic man by *Escherichia coli*, a gas-forming, facultative anaerobic uropathogen, has led to destruction of the renal parenchyma (*arrow*) and tracking of gas through the retroperitoneal space (*arrowhead*).

A

B

FIGURE 140-3 Xanthogranulomatous pyelonephritis. ***A.*** This photograph shows extensive destruction of renal parenchyma due to long-standing suppurative inflammation. The precipitating factor was obstruction by a staghorn calculus, which has been removed, leaving a depression (*arrow*). The mass effect of xanthogranulomatous pyelonephritis can mimic renal malignancy. ***B.*** A large staghorn calculus (*arrow*) is seen obstructing the renal pelvis and calyceal system. The lower pole of the kidney shows areas of hemorrhage and necrosis with collapse of cortical areas. *(Images courtesy of Dharam M. Ramnani, MD, Virginia Urology Pathology Laboratory, Richmond, VA.)*

examination, the residual renal tissue frequently has a yellow coloration, with infiltration by lipid-laden macrophages (hence the term *xanthogranulomatous*). Pyelonephritis can also be complicated by intraparenchymal abscess formation; this development should be suspected when a patient has continued fever and/or bacteremia despite antibacterial therapy.

CATHETER-ASSOCIATED URINARY TRACT INFECTION (CAUTI)

Clinically, CAUTI can be defined by the presence of symptoms along with presence of bacteriuria and pyuria. CAUTI may cause localizing urinary symptoms or otherwise unexplained systemic manifestations, such as fever. The accepted threshold for bacteriuria to meet the definition of CAUTI is $\geq 10^3$ colony-forming units per milliliter of urine.

The central diagnostic difficulty of CAUTI is that, because catheters provide a conduit for bacteria to enter the bladder, bacteriuria is inevitable with urinary catheterization. The typical signs and symptoms of UTI, including pain, urgency, dysuria, fever, and peripheral leukocytosis, also have less predictive value for diagnosis of UTI in catheterized patients. Since bacteriuria and pyuria are expected in this population, the diagnostic evaluation of a febrile patient with a urinary catheter should not end with an abnormal urinalysis. To make a diagnosis of CAUTI, first, signs and symptoms of UTI (localizing and/or systemic) should be present along with pyuria and bacteriuria. Additionally, other infectious and noninfectious causes of the patient's symptoms should be systematically ruled out before settling on the diagnosis of CAUTI.

DIAGNOSTIC TOOLS

History The diagnosis of any of the UTI syndromes or ASB begins with a detailed history **(Fig. 140-4)**. Patient-reported symptoms have high positive predictive value in uncomplicated cystitis, at least among adult women; data are lacking for other populations. Self-diagnoses among women with recurrent UTI are particularly accurate and account for the success of patient-initiated treatment for recurrent cystitis. A meta-analysis of the diagnostic utility of history and physical findings for UTI concluded that, in women presenting with at least one localizing urinary symptom (dysuria, frequency, hematuria, or back pain) and no complicating factors, the probability of acute cystitis or pyelonephritis is 50%. If vaginal discharge and complicating factors are absent and risk factors for UTI are present, then the probability of UTI is close to 90%. Further laboratory evaluation with dipstick testing or urine culture prior to antimicrobial treatment is not necessary in such patients unless there is concern for resistant pathogens (e.g., in patients presenting with recurrent UTI, prior treatment failure, known colonization with extensively resistant pathogens, or high local prevalence of resistance to the empirical antibiotic being given).

In applying the patient's history as a diagnostic tool, one significant concern is that STIs—caused by *C. trachomatis* in particular—might be inappropriately treated as UTI. Importantly, women with multiple sexual partners and inconsistent use of condoms are at increased risk for both UTI and STIs, and symptoms alone do not always distinguish between these conditions. Dysuria might instead be due to cervicitis (*C. trachomatis*, *N. gonorrhoeae*), vaginitis (*Candida albicans*, *Trichomonas vaginalis*), herpetic urethritis, interstitial cystitis, or noninfectious vaginal or vulvar irritation. Vaginal discharge in particular should prompt consideration of STI. In this particular patient population, consideration should

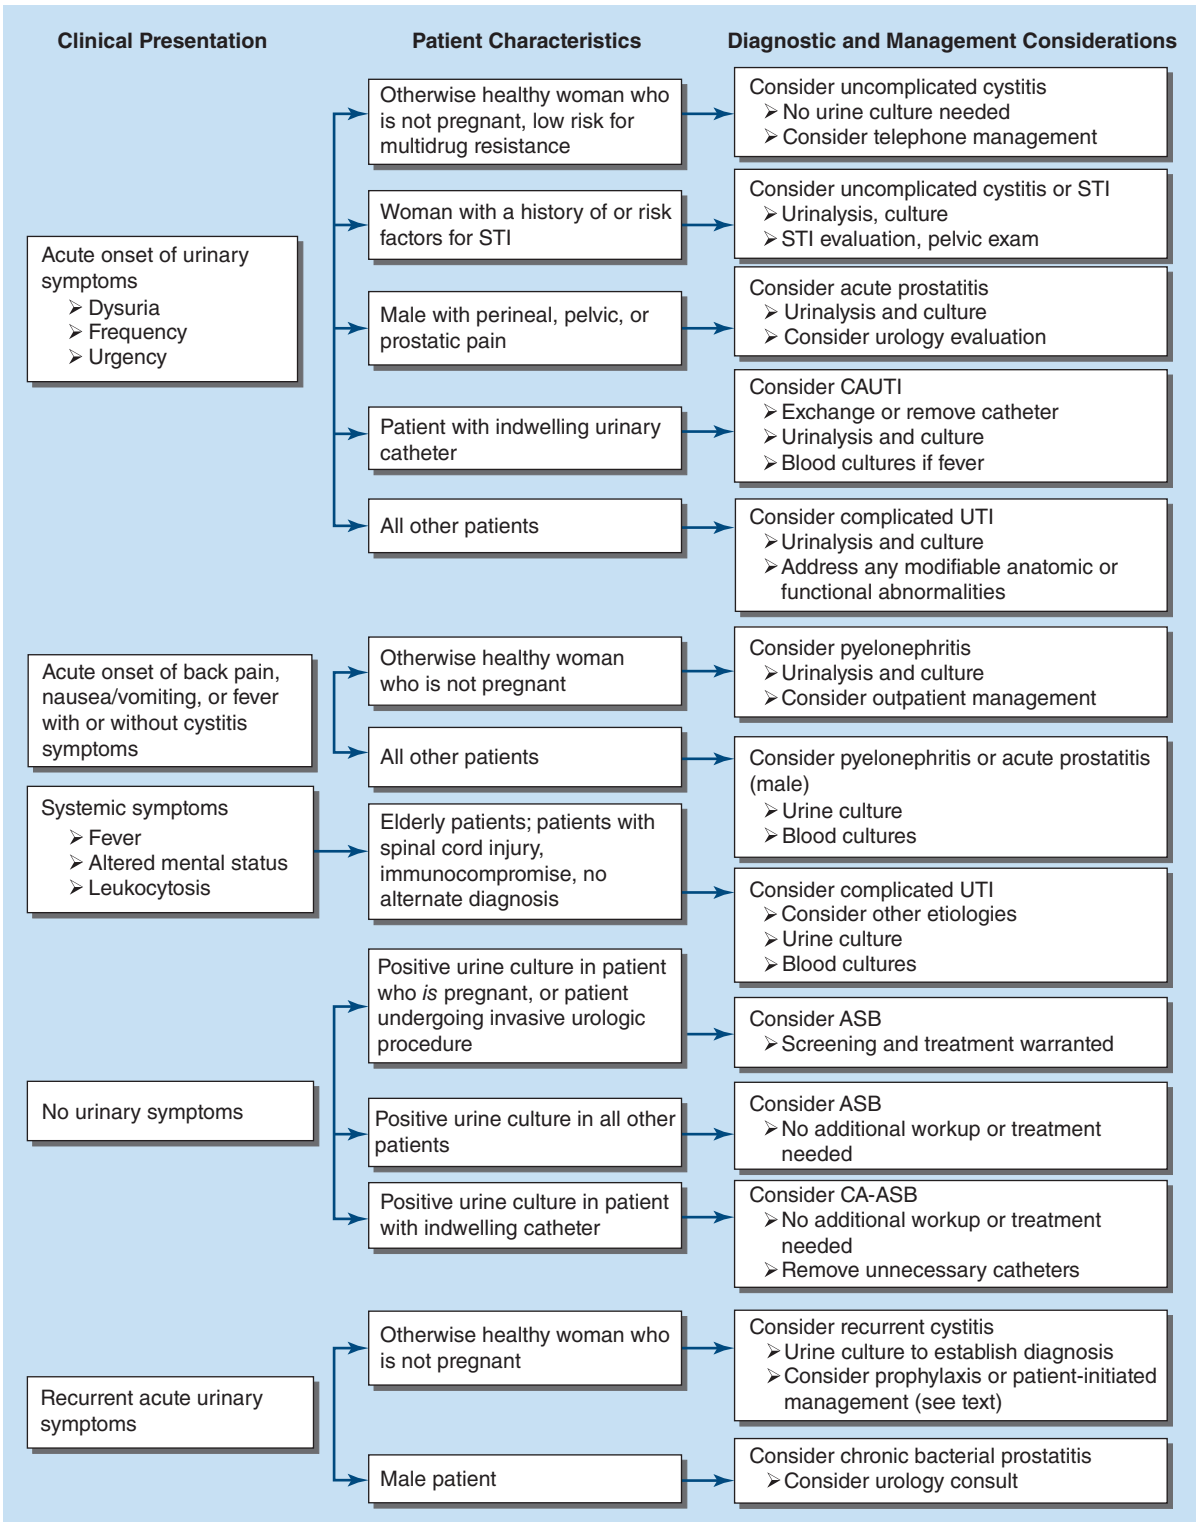

FIGURE 140-4 Diagnostic approach to urinary tract infection (UTI). NTF, nitrofurantoin; TMP-SMX, trimethoprim-sulfamethoxazole; UTI, urinary tract infection.

be given to STI screening either at the time of empirical treatment for UTI or if symptoms do not resolve with treatment.

Urine Dipstick Test, Urinalysis, and Urine Culture Useful tools in the diagnosis of UTI include the urine dipstick test (for nitrite and leukocyte esterase) and microscopic urinalysis (for counts of red and white blood cells), both of which provide point-of-care information that can primarily be used for ruling out UTI in patients who do not have a clear clinical diagnosis. Urine culture, another diagnostic tool, can retrospectively provide proof that bacteria were present in the urinary tract and can provide information on susceptibilities of the isolated organism(s). A key point is that patients with urinary catheterization will almost *always* have both pyuria and bacteriuria. *Therefore, presence of pyuria and bacteriuria alone in the absence of symptoms do not indicate a diagnosis of UTI.*

Understanding the parameters of the dipstick test is important in interpreting its results. Only members of the *Enterobacterales* family convert nitrate to nitrite, and enough nitrite must accumulate in the urine to reach the threshold of detection. This poses three problems limiting nitrites' sensitivity and specificity. First, nitrites could be positive in a patient with Enterobacterales ASB. Second, nitrites would be negative in a patient with UTI due to non-*Enterobacterales* organisms.

Third, nitrites might also be falsely negative in a woman with acute cystitis who is voiding frequently because of significant oral fluid intake.

The leukocyte esterase test detects this enzyme in neutrophils present in the host's urine, whether the cells are intact or lysed. Practically speaking, it is a less sensitive and specific surrogate for pyuria as measured by urine microscopy. Many reviews have attempted to describe the diagnostic accuracy of dipstick testing for UTI. The most important point for practicing clinicians is that a dipstick test negative for both nitrite and leukocyte esterase should prompt consideration of diagnoses other than UTI to explain the patient's symptoms, keeping in mind that the dipstick results can be falsely negative in a small percentage of cases. Importantly, a negative urine dipstick test is not sufficiently sensitive to rule out bacteriuria in pregnant women, for whom ASB screening should be performed via urine culture.

Urine microscopy reveals pyuria in nearly all cases of cystitis and hematuria in approximately 30% of cases. Pyuria has historically been defined as >10 leukocytes per high-powered microscopy field (HPF). Modern data indicate that, at least for older women, median urine white blood cells (WBCs) per HPF are far higher in UTI. As such, the cutoff of >10 WBCs/HPF has poor specificity (36%) for UTI, and a cutoff closer to 250 WBCs/HPF might better correlate with presence of urinary symptoms. However, at present, >10 WBCs/HPF remains the generally accepted standard for what defines presence of pyuria.

Detection of bacteria in a urine culture from a patient with symptoms of cystitis can confirm the diagnosis of UTI. However, culture results often do not become available until at least 24 h after a patient presents for care, with identification of individual organisms and their susceptibilities usually requiring an additional 24–48 h. Furthermore, identifying the presence of bacteria in the urine does not necessarily imply the presence of symptoms; therefore, a positive urine culture is consistent with both UTI and ASB. This issue is a perennial source of inaccuracy for retrospective studies of UTI, which are often flawed by defining UTI as the combination of pyuria and bacteriuria without requiring clinical documentation of symptoms. Studies of women with symptoms of cystitis have found that a colony count threshold of $>10^2$ bacteria/mL is more sensitive (95%) than a threshold of 10^5/mL for the diagnosis of acute cystitis in women. Fewer data are available in men about the threshold of bacteriuria to establish cystitis. When interpreting urine culture results, the clinician should consider that contamination with the normal microbial flora of the distal urethra, vagina, or skin is common and that these contaminants can grow to high numbers when the collected urine is allowed to stand at room temperature. In most instances, a culture that yields mixed bacterial species is contaminated except in settings of long-term catheterization, chronic urinary retention, or the presence of a fistula between the urinary tract and the gastrointestinal or genital tract.

TREATMENT

Urinary Tract Infections

The approach to diagnosis and treatment is influenced by which of the UTI clinical syndromes is suspected and presence of risk factors for resistant pathogens (Fig. 140-4).

GENERAL CONSIDERATIONS FOR ANTIMICROBIAL THERAPY

Studies indicate that treatment of UTI is usually the first or second most common indication for antimicrobials in ambulatory, inpatient, and long-term-care settings. Responsible use of antimicrobials for this common infection has broad implications for preserving antibiotic effectiveness into the future.

Importantly, antimicrobial therapy is warranted for any true (symptomatic) UTI. Studies of nonantibiotic treatment for UTI (e.g., with nonsteroidal anti-inflammatory drugs alone) suggest that this approach delays clinical response and predisposes patients to more invasive infections. Delayed therapy, in which a patient receives a prescription for antibiotics but fills it only if symptoms fail to resolve in a day or two, has the potential advantage of avoiding antibiotic use in those patients who do not have cystitis to begin with; however, this approach has the downsides of prolonging discomfort and a small increased risk of progression to pyelonephritis in patients who do have true UTI. Potentially higher-yield antimicrobial stewardship interventions in UTI management include encouraging clinicians to avoid unnecessary treatment of ASB, to avoid ordering urine cultures in patients who lack urinary or systemic symptoms suggestive of UTI, and to avoid prescribing overly long antibiotic durations for UTI.

In 1999, trimethoprim-sulfamethoxazole (TMP-SMX) was recommended as the treatment of choice for uncomplicated cystitis in the first published UTI guidelines of the Infectious Diseases Society of America. However, local uropathogen resistance patterns and national differences in the availability of certain antimicrobial agents are such that providing a global or even national recommendation for a single preferred empirical antibiotic for UTI is challenging. Instead, clinicians must use their knowledge of local resistance patterns and individual patient factors (e.g., allergies and potential for drug–drug interactions) to select from groups of antimicrobials based on their efficacy, toxicity risks, and potential for collateral damage (defined below). The choice of antimicrobial agent, the dose, and the duration of therapy also depend on the clinical syndrome (that is, which type of UTI specifically is being treated) and the rapidity of clinical improvement.

Collateral damage refers to the adverse ecologic effects of antimicrobial therapy, including killing of the patient's normal flora (predisposing to *Clostridioides difficile* infection) and selection of drug-resistant organisms. The implication of collateral damage for UTI management is that a drug that is highly efficacious for treatment of UTI is not necessarily the optimal first-line agent if it also has pronounced secondary effects on the normal flora or is likely to significantly adversely affect resistance patterns. Drugs used for UTI that have a minimal effect on fecal flora include pivmecillinam, fosfomycin, and nitrofurantoin. In contrast, TMP-SMX, quinolones, and β-lactams (particularly the late-generation cephalosporins) affect the fecal flora more significantly and are notably the agents for which rising resistance has been documented.

Choosing judiciously whether to initiate antibiotic therapy and then selecting the agent with the least potential for collateral damage to be given for the shortest effective duration are important factors in global efforts to stem the rise of antimicrobial-resistant organisms. Common risk factors for resistance to specific antimicrobials in UTI include prior urine or blood cultures with an organism resistant to that antimicrobial, recent exposure to that antimicrobial, or travel to an area where resistance to that antimicrobial is especially prevalent. For each of these factors, the magnitude of risk is greater with more recent exposures in the preceding year; the greatest increase in risk occurs with fluoroquinolones. More data is available documenting this risk of resistance with prior exposure to the antibiotic for fluoroquinolones than for other antibiotics. Other general risk factors for antimicrobial resistance in UTI include urinary catheterization, prior exposure to antibiotics of any class, and residence in a healthcare facility.

ASYMPTOMATIC BACTERIURIA

Critically, treatment of ASB does not decrease frequency of subsequent true UTIs. Clinical trial data from renal transplant recipients suggest that ASB treatment might even increase future risk of infection. Importantly, though, treatment of ASB in pregnant patients and patients undergoing high-risk urologic procedures is recommended to reduce risk of complications (see discussion above) and should be guided by urine culture results. In all other populations, screening for and treating ASB are discouraged. Specifically, a urine culture does not need to be obtained at the time of placement or removal of a urinary catheter if the patient is asymptomatic. The majority of cases of catheter-associated bacteriuria are asymptomatic and do not warrant antimicrobial therapy.

CYSTITIS

Many episodes of uncomplicated cystitis in women (i.e., cystitis without systemic symptoms, symptoms of pyelonephritis, or urinary

TABLE 140-1 Treatment Strategies for Acute Uncomplicated Cystitis

DRUG	DOSE	DURATION	COMMON SIDE EFFECTS
Nitrofurantoin	100 mg bid	Women or men: 5–7 days	Nausea, headache
TMP-SMX	1 DS tablet bid	Women: 3 days Men: 7 days	Rash, urticaria, nausea, vomiting, hematologic abnormalities
Fosfomycin	3-g sachet	Women: 1 day Men: qod × 3 doses	Diarrhea, nausea, headache
Pivmecillinam	400 mg bid	Women: 3–7 days	Nausea, vomiting, diarrhea
Fluoroquinolones	Dose varies by agent	Women: 3 days Men: 7 days	Nausea, vomiting, diarrhea, headache, drowsiness, insomnia
β-Lactams	Dose varies by agent	Women or men: 5–7 days	Diarrhea, nausea, vomiting, rash, urticaria

Abbreviations: DS, double-strength; TMP-SMX, trimethoprim-sulfamethoxazole; bid, twice a day; qod every other day.

catheterization) can be managed remotely (Fig. 140-4). Studies of telephone-management algorithms for UTI indicate low risk of serious complications, with the important caveat that such algorithms have generally involved otherwise healthy women who are at low risk of complications of UTI; thus, patients with other UTI syndromes or more complicated prior histories require further diagnostic evaluation and might not be as adequately managed remotely.

As described above, cystitis in men is unusual except in the setting of urinary catheterization or obstructive uropathy. Before settling on this diagnosis in men, however, the clinician should be confident that ABP, CBP, and pyelonephritis with or without urinary obstruction have been excluded. True uncomplicated cystitis in afebrile men can be treated with only 7 days of antimicrobial therapy; the durations shorter than 7 days used for uncomplicated cystitis in women have not been adequately studied in men.

Several effective therapeutic regimens are available for acute uncomplicated cystitis in women; data are very limited on therapy for cystitis in men **(Table 140-1)**. Preferred agents for treatment of acute uncomplicated cystitis include TMP-SMX, nitrofurantoin, fosfomycin, and pivmecillinam. Fosfomycin is somewhat less studied than TMP-SMX and nitrofurantoin, but it is also effective and is preferred in cystitis because of its selective concentration in urine, low risk for collateral damage, and potential to retain efficacy against MDR *E. coli*. Pivmecillinam was approved for treatment of cystitis in the United States in 2024. It also often retains activity against MDR *E. coli*, including some expressing extended-spectrum β-lactamases.

Alternative agents for treatment of cystitis include fluoroquinolones and β-lactams. β-lactams require longer durations of therapy (5–7 days) even in uncomplicated cystitis and are associated with higher clinical failure rates (compared with either fluoroquinolones or TMP-SMX) in some randomized controlled trials. Despite these limitations, β-lactams are favored over fluoroquinolones as an alternative agent for treatment of uncomplicated cystitis because of the bacterial resistance and side effects associated with fluoroquinolones. Fluoroquinolones are highly effective for treating UTI but cause high collateral damage as well as numerous rare but serious drug toxicities (e.g., collagen vascular pathology such as tendon rupture, retinal detachment, and aortic aneurysm), leading the U.S. Food and Drug Administration (FDA) to advise against using fluoroquinolones for uncomplicated cystitis in women unless no alternatives are available. Importantly, in men, if there is concern for prostatic involvement, fluoroquinolones or TMP-SMX are preferred over β-lactams because fluoroquinolones have superior penetration into the prostate. The pros and cons of each specific agent are discussed in more detail below.

TMP-SMX remains an excellent option for treatment of cystitis in areas where local uropathogen antibiogram data do not clearly favor other preferred agents or when the patient has recent microbiology demonstrating a TMP-SMX–susceptible uropathogen. Otherwise, the optimal setting for empirical use of TMP-SMX is uncomplicated cystitis in a patient who has an established relationship with the practitioner and has no barriers to seeking further care if their symptoms do not respond promptly.

Resistance to nitrofurantoin remains low despite >70 years of use, probably because several mutational steps are required for bacterial resistance to this drug. Nitrofurantoin remains highly active against *E. coli*. However, importantly, most *Proteus*, *Providencia*, *Morganella*, *Pseudomonas*, and *Serratia* and some *Klebsiella* and *Enterobacter* strains are intrinsically resistant to this drug. A 5-day course of nitrofurantoin is as effective as a 3-day course of TMP-SMX for treatment of acute uncomplicated cystitis in women. Nitrofurantoin should not be used in patients with a creatinine clearance <30 mL/min. It does not reach significant levels in tissue and so cannot be used to treat pyelonephritis or prostatitis. Additionally, we advise against long-term (i.e., multiple years) prescription of nitrofurantoin as prophylaxis for recurrent UTIs because of the risk of sometimes irreversible pulmonary toxicities.

Guidelines also recommend fosfomycin, which interferes with bacterial cell-wall formation, as an option for uncomplicated cystitis, given its easy dosing and low collateral damage. While fosfomycin is active against *E. coli*, its activity against other Enterobacterales species is less reliable. Moreover, fosfomycin susceptibility testing is difficult to perform, and the results of such testing are not typically included in standard automated microbiologic susceptibility reports. Oral fosfomycin is given as a single 3-g dose sachet (powder) that is dissolved in a glass of water and swallowed. Similar to nitrofurantoin, renal tissue levels of fosfomycin are low, and a different antibiotic should be used if treating pyelonephritis. While not extensively studied for this indication, fosfomycin has been used in the treatment of prostatitis to manage pathogens resistant to other oral agents.

Despite their often high rates of urinary secretion, β-lactams as a class have not performed as well as TMP-SMX or fluoroquinolones for treatment of acute cystitis. Rates of pathogen eradication are lower, and relapse rates are higher with β-lactam drugs compared with other agents. The generally accepted explanation for this observation is that β-lactams fail to eradicate uropathogens from the vaginal reservoir, which is specific to female patients with UTI. Supporting this hypothesis are limited indirect data indicating that treatment success with cephalexin is as good as or better than success with other classes in male UTI. Amoxicillin resistance has become widespread in *E. coli*, and many strains resistant to TMP-SMX are also resistant to some or all of the other oral β-lactams. Thus, as described for TMP-SMX above, β-lactams such as cefpodoxime or cefixime are optimally used for patients known to have susceptible uropathogens or in areas where local antibiograms demonstrate that resistance remains uncommon.

The fluoroquinolones ciprofloxacin and levofloxacin are highly effective as short-course therapy for cystitis due to susceptible flora. By contrast, moxifloxacin in particular might not reach adequate urinary levels. The two main concerns about using fluoroquinolones for acute cystitis are the propagation of fluoroquinolone resistance, not only among uropathogens but also among other organisms causing more serious and difficult-to-treat infections at other sites, and fluoroquinolones' rare but potentially serious adverse effects (increased risk of Achilles' tendon rupture, neuropathy, and aortic dissection). In light of these potential detrimental

effects, the FDA issued an advisory against using fluoroquinolones to treat acute cystitis in patients who have other effective therapeutic options.

Urinary analgesics are appropriate in certain situations to help the patient with resolution of bladder discomfort in cystitis. The urinary tract analgesic phenazopyridine is widely used but can cause significant nausea. Combination analgesics containing urinary antiseptics (such as methenamine and methylene blue), a urine-acidifying agent (sodium phosphate), and an antispasmodic agent (hyoscyamine) also are available. There are no well-established criteria for when to use these agents, although as mentioned above, multiple clinical trials demonstrate that symptomatic treatments alone are not an adequate substitute for antimicrobials when patients have true UTI.

PROSTATITIS

The prostate is involved in the majority of cases of febrile UTI in men and can also be a source of recurrent cystitis. ABP should specifically be suspected in men presenting with UTI with systemic symptoms without another clear anatomic location of UTI, such as pyelonephritis. CBP should be suspected when patients have recurrent UTI, especially if not in the context of urinary catheterization). Both ABP and CBP should be suspected when patients have prostatic symptoms. If ABP is suspected, antimicrobial therapy should be promptly initiated after urine and blood cultures are obtained. For ABP, at least 2 weeks and potentially up to 4 weeks of a fluoroquinolone or TMP-SMX is recommended for susceptible uropathogens. Identification of a prostatic abscess should prompt consultation to urologic specialists. For CBP, a 4- to 6-week course of antibiotics is typically given, and recurrences (not uncommon) may warrant up to a 12-week course of therapy. These durations are based on older observational studies and historic norms of practice and need be to clarified with modern randomized controlled trials.

PYELONEPHRITIS

Patients with pyelonephritis have tissue-invasive disease and are often systemically ill. Therefore, empirical therapy should be reliable and rapidly reach therapeutic levels in both renal parenchyma and blood. In years past, increasing TMP-SMX resistance made fluoroquinolones the empirical treatment of choice for pyelonephritis, and quinolones remain among the best-studied agents for acute pyelonephritis. However, quinolone resistance is now also increasingly prevalent.

For hospitalized patients, we recommend empirical therapy with an IV β-lactam for pyelonephritis, with attention to choosing an agent to which the patient has not recently had a resistant uropathogen in urine or blood and appears highly reliable based on the local antibiogram. For patients with pyelonephritis who are not and do not need to be hospitalized, we recommend empirical therapy with TMP-SMX, ciprofloxacin, or levofloxacin based on local antibiogram data, along with urine culture collection and short-term follow-up. Optimally, an initial dose of IV or IM β-lactam or an aminoglycoside to ensure effective empirical therapy can be prescribed, where this is practical and feasible. Ambulatory patients with pyelonephritis should be hospitalized if they are unable to tolerate oral medications (e.g., due to nausea and vomiting) or are unlikely to adhere to short-term follow-up.

For susceptible isolates, clinical trial data indicate that 5–7 days of an oral fluroquinolone or 7–14 days of oral TMP-SMX (depending on rapidity of clinical improvement) are highly effective options for pyelonephritis. Oral β-lactam agents are less effective and should be used with caution and close follow-up. Nitrofurantoin, pivmecillinam, and fosfomycin should not be used for pyelonephritis. Options for parenteral therapy for uncomplicated pyelonephritis include late-generation cephalosporins (such as ceftriaxone or cefepime), piperacillin-tazobactam, a carbapenem, or fluoroquinolones (although the high bioavailability of this class makes IV administration superfluous for patients with who can tolerate and absorb oral medications). Alternative parenteral antibiotics include novel β-lactam/β-lactamase inhibitors (e.g., meropenem-vaborbactam) and aminoglycosides, which are considered alternative due to cost and toxicity profiles, respectively.

In general, the treatment of pyelonephritis should be guided by urine culture results and clinical resolution of symptoms. Pyelonephritis due to drug-resistant uropathogens requiring nonpreferred antibiotics should be treated in consultation with infectious disease specialists. Once the patient has responded clinically, oral therapy can be substituted for parenteral therapy. Treatment can be concluded at 7 days for patients who have clinically responded (i.e., resolution of fever and return to hemodynamic stability with adequate source control) within that timeframe and who can be treated with a fluoroquinolone or TMP-SMX. Oral β-lactams may necessitate a longer course of treatment for pyelonephritis.

Patients with pyelonephritis who have not had a clinical response within 72 h should undergo further evaluation for an uncontrolled source of infection. Pyelonephritis can be complicated by acute papillary necrosis causing urinary obstruction, which requires intervention to relieve the obstruction, overcome the infection, and preserve renal function. Perinephric and renal cortical abscesses may require drainage percutaneous drainage. Percutaneous drainage can also be used as the initial therapy in emphysematous pyelonephritis and can be followed by elective nephrectomy as needed depending upon the patient's clinical status in consultation with urologic specialists. Xanthogranulomatous pyelonephritis (XGP) is treated with close collaboration with urologic colleagues and often requires nephrectomy; antibiotic treatment duration should be individualized in cases of XGP.

CATHETER-ASSOCIATED UTI

The bacteriology of CAUTI is diverse, and urine culture results are essential to guide treatment. The catheter should be exchanged (or, if possible, removed entirely) during treatment for CAUTI, the purpose of which is to remove biofilm-associated organisms that could serve as a nidus for reinfection. When possible, this should be done prior to sending urine cultures to ensure that the culture results reflect the microbiology of the bladder rather than the catheter walls.

Most clinicians treat CAUTI for 7–14 days based on clinical response; the need for longer therapy than is used in uncomplicated cystitis is supported by a randomized controlled trial that identified more relapses after 3 versus 14 days of antimicrobials. Further studies on the optimal duration of therapy in CAUTI are needed.

The best strategy for prevention of CAUTI is to avoid insertion of unnecessary catheters and to remove catheters once they are no longer necessary. Quality-improvement collaboratives that have addressed technical aspects of CAUTI prevention (such as avoidance of inappropriate catheterization) and team-communication strategies have shown the benefit of such approaches in decreasing rates of CAUTI in both acute- and long-term-care settings. Antimicrobial catheters impregnated with silver or nitrofurazone have not been shown to provide significant clinical benefit with regard to reducing CAUTI rates and should not be used routinely. Evidence is insufficient to systematically recommend suprapubic catheters and condom urinary catheters as alternatives to indwelling urinary catheters as a way to prevent bacteriuria. Intermittent catheterization may be preferable to long-term indwelling urethral catheterization in certain populations (e.g., patients with spinal cord injury) to prevent both infectious and anatomic complications.

UTI IN PREGNANT PATIENTS

Aminopenicillins (ampicillin and amoxicillin) and cephalosporins have been used extensively in pregnancy and are the drugs of choice for treatment of ASB or UTI in pregnant patients. Importantly, though, widespread resistance to aminopenicillins precludes their use for pregnant patients with UTI if urine culture results are not already available. One retrospective case-control study suggested an association between nitrofurantoin use in the first trimester and birth defects, but this association has not been confirmed, and the

American College of Obstetrics and Gynecology (ACOG) suggests that nitrofurantoin can be used during all trimesters if β-lactam agents are not an option. Sulfonamides (including TMP-SMX) should be avoided both in the first trimester (because of possible teratogenic effects) and near term (because of a possible role in the development of neonatal kernicterus), although ACOG suggests TMP-SMX can be used as a potential treatment option at both times if no alternatives are available. Fluoroquinolones are avoided during pregnancy because of possible adverse effects on fetal cartilage development. Pregnant patients with ASB or cystitis are generally treated for 5–7 days because of the absence of evidence to support shorter durations of therapy in this patient population. For pregnant patients with pyelonephritis, guidelines recommend parenteral β-lactam therapy with or without aminoglycosides based on limited observational data and historic norms of practice.

CANDIDURIA

The appearance of *Candida* in the urine is an increasingly common complication of indwelling catheterization, particularly for patients in the intensive-care unit, those taking broad-spectrum antimicrobial drugs, and those with underlying diabetes mellitus. In many studies, >50% of urinary *Candida* isolates have been found to be non–*C. albicans* species. The clinical presentation of candiduria varies widely—from asymptomatic colonization to pyelonephritis and sepsis—thereby making management challenging in some instances, particularly for patients with multiple other ongoing medical conditions. Removal of the urinary catheter results in resolution of candiduria in more than one-third of asymptomatic cases. As with ASB, treatment of asymptomatic patients with candiduria has not been found to reduce recurrence of candiduria or subsequent infection. Therefore, treatment of asymptomatic patients is not routinely recommended for most patients.

By contrast, candiduria should be treated in patients who have symptomatic cystitis or pyelonephritis or those who are asymptomatic but are at high risk for disseminated disease (e.g., patients with neutropenia, patients who will undergo urologic manipulation, and low-birth-weight infants). Fluconazole (200–400 mg/d for 7–14 days) reaches high levels in the urine and is the first-line regimen for *Candida* infections of the urinary tract. Although instances of successful eradication of candiduria by some of the newer azoles and echinocandins have been reported, these agents are relatively unstudied and are not recommended as first-line agents but can be considered in certain cases. For *Candida* isolates with high levels of resistance to fluconazole, oral flucytosine and/or parenteral amphotericin B are additional options. Bladder irrigation with amphotericin B is generally not recommended.

PREVENTION OF RECURRENT UTI IN WOMEN

Recurrence of uncomplicated cystitis in women is common, and a preventive strategy is indicated if recurrent UTIs are interfering with a patient's lifestyle. The threshold of three or more symptomatic episodes per year to intervene or develop a specific preventive strategy is not absolute; clinicians are recommended to engage in shared decision-making with each individual patient to make determinations about a UTI preventive strategy.

Initial evaluation of a patient with recurrent cystitis should include confirmation of the diagnosis of recurrent UTI, imaging to identify renal calculi or another potential nidus of infection, and assessment for urinary retention. Referrals to urology, urogynecology, and/or pelvic physical therapy might be helpful when the diagnosis is unclear or an anatomic abnormality is suspected.

Nonantimicrobial prophylactic approaches to recurrent UTI are increasingly being studied. Observational data indicate that increasing fluid intake might reduce recurrent UTIs, and such an approach is generally well tolerated by healthy adults. Two recent clinical trials found that methenamine hippurate (converted to the antiseptic formaldehyde in the bladder) is well tolerated and might reduce recurrent UTIs as much as antibiotic prophylaxis. A recent Cochrane review of randomized clinical trials of cranberry products also found a significant benefit for adult women and children with recurrent UTI. Less is known about which products and what precise dosing are optimal. *Lactobacillus* probiotics are under investigation for UTI prevention, with one recent factorial trial suggesting that intravaginal but not oral lactobacilli products reduce recurrent UTIs. We advise caution, however, in recommending probiotics to immunocompromised patients, in whom probiotic-associated invasive infections have been described. Studies of mannose products for UTI prevention have produced mixed results.

Three antibiotic prophylactic strategies are available: continuous (using daily or thrice-weekly dosing), postcoital (one dose after intercourse), and patient-initiated therapy. For the continuous and postcoital strategies, low doses of TMP-SMX or nitrofurantoin are typically utilized. Such approaches are usually highly effective during the period of active antibiotic intake. A prophylactic regimen is typically prescribed for 6 months and then discontinued. If bothersome infections recur, the prophylactic program can be reinstituted for the same duration or for a longer period.

Selection of resistant strains in the fecal flora has been documented in studies of patients taking prophylactic antibiotics. An approach of alternating antibiotic prophylaxis with periods of nonantimicrobial prevention could hypothetically allow for intermittent recovery of the gut microbiome. The choice between methenamine and cranberry products should be based on shared decision-making and individual patient response. Some studies suggest that although the rate of UTI will be decreased when using nonantimicrobial prophylaxis compared with no prophylaxis, the rate of UTI might be slightly higher than during the antibiotic-suppression period.

Patient-initiated therapy involves supplying the patient with materials for urine culture and with a course of antibiotics for self-medication at the first symptoms of infection. The urine culture is refrigerated and delivered to the physician's office for confirmation of the diagnosis. When an established and reliable patient–provider relationship exists, the urine culture can be omitted as long as the symptomatic episodes respond completely to short-course therapy and are not followed by relapse.

PROGNOSIS

Cystitis is a risk factor for recurrent cystitis and pyelonephritis. ASB is common among elderly and catheterized patients but does not in itself increase risk of infection or death. The relationships among recurrent UTI, chronic pyelonephritis, and renal insufficiency have been widely studied. In the absence of anatomic abnormalities such as reflux, recurrent infections in children and adults do not lead to chronic pyelonephritis or renal failure. Additionally, infection does not play a primary role in chronic interstitial nephritis; the primary etiologic factors in this condition are analgesic overuse, obstruction, reflux, and toxin exposure. By contrast, in the presence of underlying renal abnormalities (particularly obstructing stones), infection as a secondary factor can accelerate renal parenchymal damage.

141 Sexually Transmitted Infections: Overview and Clinical Approach

Jeanne M. Marrazzo

CLASSIFICATION AND EPIDEMIOLOGY

Worldwide, most adults acquire at least one sexually transmitted infection (STI), and many remain at risk for complications. Each day, for example, more than 1 million STIs are acquired worldwide, placing many affected persons at risk for adverse reproductive health outcomes and neoplasia. Certain STIs, such as syphilis, gonorrhea, HIV infection, hepatitis B, and chancroid, often occur in highly interconnected sexual networks characterized by high rates of partner change or multiple concurrent partners. Such networks, for example, often include persons who engage in transactional sex, some men who have sex with men (MSM), and persons involved in the use of illicit drugs. Other STIs are distributed more evenly throughout populations. For example, chlamydial infections, genital human papillomavirus (HPV) infections, and genital herpes can spread efficiently even in relatively low-risk populations. Finally, modern technologies based on detection of nucleic acid have accelerated elucidation of the role of sexual transmission in the spread of some viruses, including Ebola virus and Zika virus, and have provided new evidence of apparent sexual transmission of several bacteria, including group C *Neisseria meningitidis* and anaerobes associated with bacterial vaginosis (BV).

In general, the product of three factors determines the initial rate of spread of any STI within a population: rate of sexual exposure of susceptible to infectious people, efficiency of transmission per exposure, and duration of infectivity of those infected. Accordingly, efforts to prevent and control STIs aim to decrease the rate of sexual exposure of susceptible to infected persons (e.g., through education and efforts to change sexual behavior norms and through control efforts aimed at reducing the proportion of the population infected, including post-exposure prophylaxis [PEP]); to decrease the duration of infectivity (through early diagnosis and curative or suppressive treatment); and to decrease the efficiency of transmission (through promotion of condom use and safer sexual practices, use of effective vaccines, and male medical circumcision).

In all societies, STIs rank among the most common of all infectious diseases, with at least 40 microorganisms now classified as predominantly sexually transmitted or as frequently sexually transmissible (Table 141-1). In developing countries, with three-quarters of the world's population and 90% of the world's STIs, factors such as population growth (especially in adolescent and young-adult age groups), rural-to-urban migration, wars, limited or no provision of reproductive health services for women, and poverty create exceptional vulnerability to disease resulting from unprotected sex. During the 1990s in China, Russia, the other states of the former Soviet Union, and South Africa, internal social structures changed rapidly as borders opened to the West, unleashing enormous new epidemics of HIV infection and other STIs; such patterns persist in the face of ongoing conflicts. Despite advances in the provision of highly effective antiretroviral therapy worldwide, HIV remains the leading cause of death in some developing countries, and HPV and hepatitis B virus (HBV) remain important causes of cervical and hepatocellular carcinoma, respectively—two of the most common (and preventable) malignancies in the developing world. Sexually transmitted herpes simplex virus (HSV) infection causes most genital ulcer disease throughout the world, and an increasing proportion of cases of genital herpes occur in developing countries with generalized HIV epidemics, where the positive feedback loop between HSV and HIV transmission remains intractable. Despite this consistent link, randomized trials evaluating the efficacy of antiviral therapy in suppressing HSV in both HIV-uninfected and HIV-infected persons have demonstrated no protective effect against acquisition or transmission of HIV. The World Health Organization estimated that 357 million new cases of four curable STIs—gonorrhea, chlamydial infection, syphilis, and trichomoniasis—occurred annually in recent years. Up to 50% of women of reproductive age in developing countries have BV (arguably acquired sexually). All of these curable STIs have been associated with increased risk of HIV transmission or acquisition.

In the United States, the prevalence of antibody to HSV-2 began to fall in the late 1990s, especially among adolescents and young adults; the decline was presumably due to delayed sexual debut, increased condom use, and lower rates of multiple (four or more) sex partners—all well documented by the U.S. Youth Risk Behavior Surveillance System. The estimated annual incidence of HBV infection has also declined dramatically since the mid-1980s; this decrease is probably attributable to now-widespread administration of hepatitis B vaccine in infancy. Genital HPV remains the most common sexually transmitted pathogen in the United States, infecting 60% of a cohort of initially

TABLE 141-1 Sexually Transmitted and Sexually Transmissible Microorganisms

BACTERIA	VIRUSES	OTHER[a]
Transmitted in Adults Predominantly by Sexual Intercourse		
Neisseria gonorrhoeae *Chlamydia trachomatis* *Treponema pallidum* *Haemophilus ducreyi* *Klebsiella (Calymmatobacterium) granulomatis* *Ureaplasma urealyticum* *Mycoplasma genitalium*	HIV (types 1 and 2) Human T-cell lymphotropic virus type 1 Herpes simplex virus type 2 Human papillomavirus (multiple genital genotypes) Hepatitis B virus[b] Molluscum contagiosum virus	*Trichomonas vaginalis* *Pthirus pubis*
Sexual Transmission Repeatedly Described but Not Well Defined or Not the Predominant Mode		
Mycoplasma hominis *Gardnerella vaginalis* and other vaginal bacteria Group B *Streptococcus* *Mobiluncus* spp. *Helicobacter cinaedi* *Helicobacter fennelliae* Anaerobes associated with bacterial vaginosis *Leptotrichia/Sneathia* Group C *Neisseria meningitidis*	Cytomegalovirus Human T-cell lymphotropic virus type 2 Hepatitis C virus (?) Hepatitis D virus Herpes simplex virus type 1 Zika virus Ebola virus (?) Epstein-Barr virus Human herpesvirus type 8	*Candida albicans* *Sarcoptes scabiei*
Transmitted by Sexual Contact Involving Oral–Fecal Exposure; of Declining Importance in Men Who Have Sex with Men		
Shigella spp. *Campylobacter* spp.	Hepatitis A virus	*Giardia lamblia* *Entamoeba histolytica*

[a]Includes protozoa, ectoparasites, and fungi. [b]Among U.S. patients for whom a risk factor can be ascertained, most hepatitis B virus infections are transmitted sexually.

HPV-negative, sexually active Washington state college women within 5 years in a study conducted from 1990 to 2000—i.e., during the pre–HPV immunization era. Global expansion of HPV vaccine coverage among young women has already shown promise in reducing the incidence of infection with the HPV types included in the vaccines and of conditions associated with these viruses, including invasive cervical cancer; however, gaps in immunization coverage remain.

In industrialized countries, fear of HIV infection in the mid-1980s and through the mid-2000s, coupled with widespread behavioral interventions and better-organized systems of care for the curable STIs, initially helped curb the transmission of several STDs. However, with current antiretroviral therapy, HIV has become for many a chronic disease associated with a normal life span and high quality of life, and HIV pre-exposure prophylaxis (PrEP) has proven highly effective in preventing HIV acquisition, further reducing motivation to use barrier protection such as condoms. Rates of gonorrhea and syphilis remain higher in the United States than in any other Western industrialized country.

In the United States, the Centers for Disease Control and Prevention (CDC) has compiled reported rates of STIs since 1941. The incidence of reported gonorrhea peaked at 468 cases per 100,000 population in the mid-1970s and fell to a low of 98 cases per 100,000 in 2012; in 2018, the case rate was 179.1 per 100,000 persons, which is more than an 80% increase since 2009 when the number of new cases reached an all-time low. With increased testing and more sensitive tests, the incidence of reported *Chlamydia trachomatis* infection has been increasing steadily since reporting began in 1984, reaching an all-time peak of 457.6 cases per 100,000 in 2011. The incidence of primary and secondary syphilis per 100,000 peaked at 71 cases in 1946, fell rapidly to 3.9 cases in 1956, ranged from ~10 to 15 cases through 1987 (with markedly increased rates among MSM and African Americans), and then fell to a nadir of 2.1 cases in 2000–2001 (with rates falling most rapidly among heterosexual African Americans). However, since 1996, with the introduction of highly active antiretroviral therapy, gonorrhea, syphilis, and chlamydial infection have had a remarkable resurgence among MSM in North America and Europe, where outbreaks of a rare type of chlamydial infection (lymphogranuloma venereum [LGV]) that had virtually disappeared during the AIDS era have occurred. In 2022, 207,255 cases of syphilis (all stages and congenital syphilis) were reported in the United States, which is the greatest number of cases reported since 1950 and an increase of 17.3% since 2021. In 2022, 45% of primary and secondary syphilis cases among males reported to the CDC were in MSM, but incidence has also increased in women, with a concomitant increase in congenital syphilis. In 2022, 3755 cases of congenital syphilis were reported, including 282 congenital syphilis-related stillbirths and infant deaths. The national congenital syphilis rate of 102.5 cases per 100,000 live births in 2022 represents a 30.6% increase relative to 2021 and is the highest reported rate since 1991.

Moreover, the uptake of oral PrEP for HIV-1 acquisition has increased among MSM since its initial approval for this purpose in 2012 and has been associated with reports of reduced condom-use frequency and concomitantly increased STI acquisition. These developments have resulted in a soaring incidence of STIs, with increasing co-infection with HIV and other sexually transmitted pathogens (particularly *Treponema pallidum*, the cause of syphilis; and *Neisseria gonorrhoeae*, the cause of gonorrhea), primarily among MSM.

MANAGEMENT OF COMMON SEXUALLY TRANSMITTED DISEASE SYNDROMES

Although other chapters discuss management of specific STIs, most patients are managed (at least initially) on the basis of presenting symptoms and signs and associated risk factors, even in industrialized countries. **Table 141-2** lists some of the most common clinical sexually transmitted disease (STD) syndromes and their microbial etiologies. Strategies for their management are outlined below. **Chapters 207 and 208 address the management of infections with human retroviruses.**

STD care and management begin with risk assessment and proceed to clinical assessment, diagnostic testing or screening, treatment, and prevention. Risk assessment guides detection and interpretation of symptoms that could denote an STD; decisions on screening or prophylactic/preventive treatment; risk reduction counseling and intervention (e.g., hepatitis B vaccination); treatment of partners of patients with known infections; and behavioral risk reduction by the patient. Consideration of routine demographic data (e.g., identified gender, age, area of residence) is a simple first step in this risk assessment. For example, national guidelines strongly recommend routine screening of

TABLE 141-2 Major Sexually Transmitted Disease Syndromes and Sexually Transmitted Microbial Etiologies

SYNDROME	SEXUALLY TRANSMITTED MICROBIAL ETIOLOGIES
AIDS	HIV types 1 and 2
Urethritis: males	*Neisseria gonorrhoeae, Chlamydia trachomatis, Mycoplasma genitalium, Ureaplasma urealyticum* (subspecies *urealyticum*), *Trichomonas vaginalis,* HSV, some anaerobic bacteria, *Leptotrichia/Sneathia*
Epididymitis	*C. trachomatis, N. gonorrhoeae,* and (in older men or men who have sex with men) coliform bacteria
Lower genital tract infections: females	
Cystitis/urethritis	*C. trachomatis, N. gonorrhoeae,* HSV
Mucopurulent cervicitis	*C. trachomatis, N. gonorrhoeae, M. genitalium*
Vulvitis	*Candida albicans,* HSV
Bartholinitis	*C. albicans, T. vaginalis*
Vulvovaginitis	*C. albicans, T. vaginalis*
BV	BV-associated bacteria (see text)
Acute pelvic inflammatory disease	*N. gonorrhoeae, C. trachomatis,* BV-associated bacteria, *M. genitalium,* group B streptococci
Infertility	*N. gonorrhoeae, C. trachomatis,* BV-associated bacteria
Ulcerative lesions of the genitalia	HSV-1, HSV-2, *Treponema pallidum, Haemophilus ducreyi, C. trachomatis* (LGV strains), *Klebsiella (Calymmatobacterium) granulomatis*
Complications of pregnancy/puerperium	Several pathogens implicated
Intestinal infections	
Proctitis	*C. trachomatis, N. gonorrhoeae,* HSV, *T. pallidum*
Proctocolitis or enterocolitis	*Campylobacter* spp., *Shigella* spp., *Entamoeba histolytica, Helicobacter* spp., other enteric pathogens
Enteritis	*Giardia lamblia*
Acute arthritis with urogenital infection or viremia	*N. gonorrhoeae* (e.g., DGI), *C. trachomatis* (e.g., reactive arthritis), HBV
Genital and anal warts	HPV (30 genital types)
Mononucleosis syndrome	CMV, HIV, EBV
Hepatitis	Hepatitis viruses, *T. pallidum,* CMV, EBV
Neoplasias	
Squamous cell dysplasias and cancers of the cervix, anus, vulva, vagina, or penis	HPV (especially types 16, 18, 31, 45)
Kaposi's sarcoma, body-cavity lymphomas	HHV-8
T-cell leukemia	HTLV-1
Hepatocellular carcinoma	HBV
Tropical spastic paraparesis	HTLV-1
Scabies	*Sarcoptes scabiei*
Pubic lice	*Pthirus pubis*

Abbreviations: BV, bacterial vaginosis; CMV, cytomegalovirus; DGI, disseminated gonococcal infection; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HHV-8, human herpesvirus type 8; HPV, human papillomavirus; HSV, herpes simplex virus; HTLV, human T-cell lymphotropic virus; LGV, lymphogranuloma venereum.

TABLE 141-3 Eleven-Question Sexually Transmitted Disease (STD)/HIV Risk Assessment

Framing Statement
In order to provide the best care for you today and to understand whether we should consider certain infections, I'd like to talk about your sexual behavior.
Screening Questions
(1) Do you have any reason to think you might have a sexually transmitted infection? If so, what reason?
(2) For all adolescents <18 years old: Have you begun having any kind of sex yet?
STD History
(3) Have you ever had any sexually transmitted infections or any genital infections? If so, which ones?
Sexual Preference
(4) Have you had sex with men, women, or both?
Injection Drug Use
(5) Have you ever injected yourself with drugs? (If yes, have you ever shared needles or injection equipment?)
(6) Have you ever had sex with anyone who had ever injected drugs?
Characteristics of Partner(s)
(7) Have any of your sex partners had any sexually transmitted infections? If so, which ones?
(8) Have any of your sex partners had other sex partners during the time you've been together?
STD Symptoms Checklist
(9) Have you recently developed any of these symptoms?

For Men	For Women
(a) Discharge of pus (drip) from the penis	(a) Abnormal vaginal discharge (increased amount, abnormal odor, abnormal yellow color)
(b) Genital sores (ulcers) or rash	(b) Genital sores (ulcers), rash, or itching

Sexual Practices, Past 2 Months (for patients answering yes to any of the above questions, to guide examination and testing)
(10) Now I'd like to ask what parts of your body may have been sexually exposed to an STD (e.g., your penis, mouth, vagina, anus).
Query About Interest in STD Screening Tests (for patients answering no to all of the above questions)
(11) Would you like to be tested for HIV or any other STDs today? (If yes, clinician can explore which STD and why.)

Source: Adapted from JR Curtis, KK Holmes, in KK Holmes et al (eds): *Sexually Transmitted Diseases,* 4th ed. New York, McGraw-Hill, 2008.

sexually active females ≤25 years of age for *C. trachomatis* infection. Table 141-3 provides a set of 11 STD/HIV risk-assessment questions that clinicians can pose verbally or that health care systems can adapt (with yes/no responses) into a routine self-administered questionnaire. The initial framing statement gives permission to discuss topics that may be difficult for the patient to disclose.

Risk assessment is followed by clinical assessment (elicitation of information on specific current symptoms and signs of STDs). Confirmatory diagnostic tests (for persons with symptoms or signs) or screening tests (for those without symptoms or signs) may involve microscopic examination, culture, nucleic acid amplification tests (NAATs), or serology. Initial syndrome-based treatment should cover the most likely causes. For certain syndromes, results of rapid tests can narrow the spectrum of this initial therapy (e.g., pH of vaginal fluid for women with vaginal discharge, Gram's stain of urethral discharge for men with urethral discharge, rapid plasma reagin test for genital ulcer to assess the probability of syphilis). After the institution of treatment, STD management proceeds to the "4 Cs" of prevention and control: *c*ontact tracing (see "Prevention and Control of STIs," below), ensuring *c*ompliance with therapy, and *c*ounseling on risk reduction, including *c*ondom promotion and provision as well as motivational interviewing for risk reduction.

Consistent with current guidelines, all adults should be screened for infection with HIV-1 at least once, and more frequently if they are at elevated risk for acquisition of this infection.

URETHRITIS IN MEN

Urethritis in men produces urethral discharge, dysuria, or both, usually without frequency of urination. Causes include *N. gonorrhoeae, C. trachomatis, Mycoplasma genitalium, Ureaplasma urealyticum, Trichomonas vaginalis*, HSV, and (rarely) adenovirus.

Until recently, *C. trachomatis* caused ~30–40% of cases of nongonococcal urethritis (NGU), particularly in heterosexual men; however, the proportion of cases due to this organism has probably declined in some populations served by effective chlamydial control programs, and older men with urethritis appear less likely to have chlamydial infection. HSV and *T. vaginalis* each cause a small proportion of NGU cases in the United States. Recently, multiple studies have consistently implicated *M. genitalium* as a probable cause of many *Chlamydia*-negative cases. Fewer studies than in the past have implicated *Ureaplasma*; the ureaplasmas have been differentiated into *U. urealyticum* and *Ureaplasma parvum*, and a few studies suggest that *U. urealyticum*—but not *U. parvum*—is associated with NGU; for this reason, neither testing nor presumptive treatment for ureaplasmas in the setting of urethritis is recommended. Coliform bacteria can cause urethritis in men who engage in insertive anal intercourse. More recently, anaerobic bacteria that are characteristically involved in BV, especially *Leptotrichia/Sneathia* species, have occasionally been associated with urethritis in heterosexual men. Recommendations for the initial diagnosis of urethritis in men currently include specific tests only for *N. gonorrhoeae* and *C. trachomatis*; they do not yet include testing for *M. genitalium,* although a NAAT is now commercially available for the latter.

APPROACH TO THE PATIENT

Urethritis in Men

The following summarizes the approach to the male patient with suspected urethritis:

1. *Establish the presence of urethritis*. If proximal-to-distal "milking" of the urethra does not express a purulent or mucopurulent discharge, even after the patient has not voided for several hours (or preferably overnight), a Gram's-stained smear of an anterior urethral specimen obtained by passage of a small urethrogenital swab 2–3 cm into the urethra usually reveals ≥2 neutrophils per 1000× field when urethritis is present; in gonococcal infection, such a smear usually reveals gram-negative intracellular diplococci as well. Patients with symptoms who lack objective evidence of urethritis generally do not benefit from repeated courses of antibiotics, and other etiologies of such symptoms may be considered.
2. *Evaluate for complications or alternative diagnoses*. A brief history and examination can exclude epididymitis and systemic complications, such as disseminated gonococcal infection (DGI) and reactive arthritis. Although digital examination of the prostate gland seldom contributes to the evaluation of sexually active young men with urethritis, men with dysuria who lack evidence of urethritis as well as sexually inactive men with urethritis should undergo prostate palpation, urinalysis, and urine culture to exclude bacterial prostatitis and cystitis.
3. *Evaluate for gonococcal and chlamydial infection*. An absence of typical gram-negative diplococci on Gram's-stained smear of urethral exudate containing inflammatory cells warrants a preliminary diagnosis of NGU, as this test is 98% sensitive for the diagnosis of gonococcal urethral infection. However, most men with symptoms and/or signs of urethritis are simultaneously assessed for infection with *N. gonorrhoeae* and *C. trachomatis* by NAATs of first-catch urine. The urine specimen tested should consist of the first 10–15 mL of the stream, and if possible, patients should not have voided for the prior 2 h. Culture or NAAT for *N. gonorrhoeae* may yield positive results even when

Gram's staining is negative; certain strains of *N. gonorrhoeae* can result in negative urethral Gram's stains in up to 30% of cases of urethral infection. Results of tests for gonococcal and chlamydial infection predict the patient's prognosis (with greater risk for recurrent NGU if neither chlamydiae nor gonococci are found than if either is detected) and can guide both the counseling given to the patient and the management of the patient's sexual partner(s).

4. *Treat urethritis promptly while test results are pending.*

TREATMENT

Urethritis in Men

Table 141-4 summarizes the steps in management of urethral discharge and/or dysuria in sexually active men.

In practice, if Gram's stain does not reveal gonococci, urethritis is treated with a regimen effective for NGU, such as azithromycin or doxycycline. Both are generally effective. Although azithromycin has been more effective than doxycycline for *M. genitalium* infection, the efficacy of azithromycin for treatment of *M. genitalium* is rapidly declining. Alternatives include moxifloxacin and pristinamycin, a streptogramin antibiotic available in some countries. If gonococci are demonstrated by Gram's stain or if no diagnostic tests are performed to exclude gonorrhea definitively, treatment should include parenteral cephalosporin therapy for gonorrhea **(Chap. 161)**. Doxycycline is the preferred antibiotic for treating *C. trachomatis* infection, which can cause urethral co-infection in men with gonococcal urethritis. Sexual partners with contact to the index patient in the past 60 days should also be tested for gonorrhea and chlamydial infection. Regardless of whether they are tested for these infections, however, they should receive the same regimen given to the index case. Patients with confirmed persistence or recurrence of urethritis after treatment should be re-treated with the initial regimen if they did not comply with the original treatment or were reexposed to an untreated partner. Most persistent urethritis is due to *M. genitalium*, and prompt diagnostic testing and/or treatment for *M. genitalium* is recommended.

TABLE 141-4 Management of Urethral Discharge in Men

USUAL CAUSES	USUAL INITIAL EVALUATION
Chlamydia trachomatis	Demonstration of urethral discharge or pyuria
Neisseria gonorrhoeae	Exclusion of local or systemic complications
Mycoplasma genitalium	Urethral Gram's stain to confirm urethritis, detect gram-negative diplococci
Ureaplasma urealyticum	Test for *N. gonorrhoeae, C. trachomatis, M. genitalium* (if indicated and available)
Trichomonas vaginalis	
Herpes simplex virus	
Initial Treatment for Patient and Partners	
Treat gonorrhea (unless excluded): Ceftriaxone (500 mg IM[a]) For persons weighing ≥150 kg, 1 gram of ceftriaxone IM should be administered	
Management of Recurrence	
Confirm objective evidence of urethritis. If patient was reexposed to untreated or new partner, repeat treatment of patient and partner. If patient was not reexposed, consider infection with *T. vaginalis*[b] or antibiotic-resistant *M. genitalium*[c], and treat accordingly (metronidazole for trichomoniasis; azithromycin for *M. genitalium* followed by moxifloxacin if needed).	

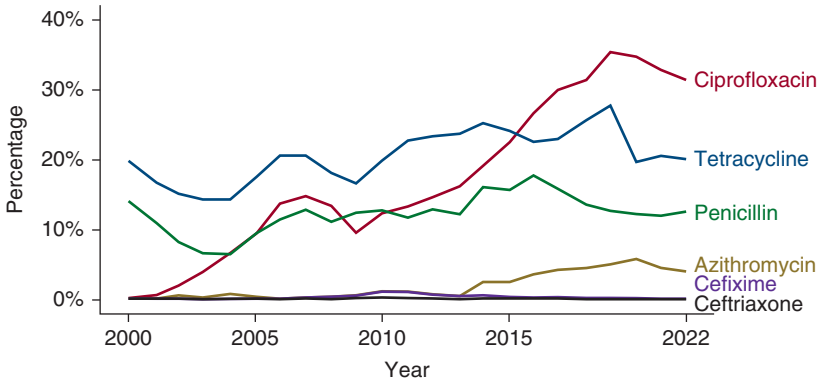
[a]Neither oral cephalosporins nor fluoroquinolones are recommended for treatment of gonorrhea in the United States because of the emergence of increasing fluoroquinolone resistance in *N. gonorrhoeae,* especially (but not only) among men who have sex with men, and the decreasing susceptibility of a small proportion of gonococci to ceftriaxone **(Fig. 136-1)**. Updates on the emergence of antimicrobial resistance in *N. gonorrhoeae* can be obtained from the Centers for Disease Control and Prevention at *http://www.cdc.gov/std.* [b]In men, the diagnosis of *T. vaginalis* infection requires nucleic acid amplification testing of a urethral swab specimen obtained before voiding. [c]*M. genitalium* is often resistant to doxycycline and azithromycin but is usually susceptible to the fluoroquinolone moxifloxacin. Moxifloxacin can be considered for treatment of refractory nongonococcal, nonchlamydial urethritis.

National and international guidelines exist for treatment of gonococcal urethritis, typically with ceftriaxone. However, consensus is still lacking on treatment of urethritis that persists after treatment and cure of gonorrhea. Ideally, the approach would involve testing for potential causes of persistent urethritis (e.g., *M. genitalium*) and antimicrobial susceptibility testing in settings and populations where antimicrobial resistance is emerging. Currently, assays are available that can detect *M. genitalium*, and some experts believe it is time to integrate such testing into STD care. If *M. genitalium* is detected, the persistent urethritis can be treated with azithromycin or moxifloxacin in light of local patterns of antimicrobial susceptibility.

In heterosexual men with a high likelihood of exposure to trichomoniasis, an intraurethral swab specimen and a first-voided urine sample should be tested for *T. vaginalis* using NAAT. Presumptive treatment with metronidazole or tinidazole (2 g by mouth in a single dose) should be given. For MSM, trichomoniasis is unlikely, and consideration of a course of moxifloxacin is warranted. Because MSM also have the highest prevalence rates of antimicrobial-resistant *N. gonorrhoeae*, this possibility, even if apparently ruled out at the initial presentation, should be kept in mind.

EPIDIDYMITIS

Acute epididymitis, almost always unilateral, produces pain, swelling, and tenderness of the epididymis, with or without symptoms or signs of urethritis. This condition must be differentiated from testicular torsion, tumor, and trauma. Torsion, a surgical emergency, usually occurs in the second or third decade of life and produces a sudden onset of pain, elevation of the testicle within the scrotal sac, rotation of the epididymis from a posterior to an anterior position, and absence of blood flow on Doppler ultrasound. Persistence of symptoms after a course of therapy for epididymitis suggests the possibility of testicular tumor or of a chronic granulomatous disease, such as tuberculosis. In sexually active men under age 35, acute epididymitis is caused most frequently by *C. trachomatis* and less commonly by *N. gonorrhoeae* and is usually associated with overt or subclinical urethritis. Acute epididymitis occurring in older men or following urinary tract instrumentation is usually caused by urinary pathogens. These older men usually have no urethritis but do have bacteriuria. Similarly, epididymitis in MSM who have practiced insertive rectal intercourse is often caused by Enterobacteriaceae.



TREATMENT

Epididymitis

Ceftriaxone (500 mg as a single dose IM) followed by doxycycline (100 mg by mouth twice daily for 10 days) constitutes effective treatment for epididymitis caused by *N. gonorrhoeae* or *C. trachomatis*. Neither oral cephalosporins nor fluoroquinolones are recommended for treatment of gonorrhea in the United States because of resistance in *N. gonorrhoeae,* especially (but not only) among MSM **(Fig. 141-1)**. Given rapidly escalating rates of resistance in *N. gonorrhoeae* to azithromycin, this antibiotic is no longer recommended as co-therapy with a parenteral ceftriaxone for gonorrhea. When infection with Enterobacteriaceae is suspected, oral levofloxacin (500 mg once daily for 10 days) added to parenteral ceftriaxone (500 mg IM once) is effective for syndrome-based initial treatment.

URETHRITIS AND THE URETHRAL SYNDROME IN WOMEN

C. trachomatis, N. gonorrhoeae, and occasionally HSV cause symptomatic urethritis—known as *the urethral syndrome* in women—that is characterized by "internal" dysuria (usually without urinary urgency or frequency), pyuria, and an absence of *Escherichia coli* and other uropathogens at counts of $\geq 10^2$/mL in urine. In contrast, the dysuria associated with vulvar herpes or vulvovaginal candidiasis (and perhaps with trichomoniasis) is often described as "external," being caused

FIGURE 141-1 Percentage of Tetracycline, Penicillin, or Ciprofloxacin Resistance* or Elevated Cefixime, Ceftriaxone, or Azithromycin Minimum Inhibitory Concentrations (MICs)† by Year, Gonococcal Isolate Surveillance Project (GISP), 2001-2022.

*Resistance: ciprofloxacin MIC ≥1.0 μg/mL; penicillin MIC ≥2.0 μg/mL or β-lactamase positive; tetracycline MIC ≥2.0 μg/mL.

†Elevated MICs: azithromycin MIC ≥1.0 μg/mL (2000–2004), MIC ≥2.0 μg/mL (2005–2022); ceftriaxone MIC ≥0.125 μg/mL; cefixime MIC ≥0.25 μg/mL. Cefixime susceptibility was not tested in 2007 and 2008.

by painful contact of urine with the inflamed or ulcerated labia or introitus. Acute onset, association with urinary urgency or frequency, hematuria, or suprapubic bladder tenderness suggests bacterial cystitis. Among women with symptoms of acute bacterial cystitis, costovertebral pain and tenderness or fever suggest acute pyelonephritis. **The management of bacterial urinary tract infection (UTI) is discussed in Chap. 140.**

Signs of vulvovaginitis, coupled with symptoms of external dysuria, suggest vulvar infection (e.g., with HSV or *Candida albicans*). Among dysuric women without signs of vulvovaginitis, bacterial UTI must be differentiated from the urethral syndrome by assessment of risk, evaluation of the pattern of symptoms and signs, and specific microbiologic testing. An STI etiology of the urethral syndrome is suggested by young age, more than one current sexual partner, a new partner within the past month, a partner with urethritis, or coexisting mucopurulent cervicitis (see below). The finding of a single urinary pathogen, such as *E. coli* or *Staphylococcus saprophyticus*, at a concentration of $\geq 10^2$/mL in a properly collected specimen of midstream urine from a dysuric woman with pyuria indicates probable bacterial UTI, whereas pyuria with $<10^2$ conventional uropathogens per milliliter of urine ("sterile" pyuria) suggests acute urethral syndrome due to *C. trachomatis* or *N. gonorrhoeae*. Gonorrhea and chlamydial infection should be sought by specific tests (e.g., NAATs of vaginal secretions collected with a swab). Among dysuric women with sterile pyuria caused by infection with *N. gonorrhoeae*

or *C. trachomatis*, appropriate treatment alleviates dysuria. The role of *M. genitalium* in the urethral syndrome in women remains undefined.

VULVOVAGINAL INFECTIONS

Abnormal Vaginal Discharge If directly questioned about vaginal discharge during routine health checkups, many women acknowledge having nonspecific symptoms of vaginal discharge that do not correlate with objective signs of inflammation or with actual infection. However, unsolicited reporting of abnormal vaginal discharge often denotes BV or trichomoniasis. Specifically, an abnormally increased amount or an abnormal odor of the discharge is associated with one or both of these conditions. Cervical infection with *N. gonorrhoeae* or *C. trachomatis* does not often cause an increased amount or abnormal odor of discharge; however, when these pathogens cause cervicitis, they—like *T. vaginalis*—often result in an increased number of neutrophils in vaginal fluid, which thus takes on a yellow color. Vulvar conditions such as genital herpes or vulvovaginal candidiasis can cause vulvar pruritus, burning, irritation, or lesions as well as external dysuria (as urine passes over the inflamed vulva or areas of epithelial disruption) or vulvar dyspareunia.

Certain vulvovaginal infections may have serious sequelae. Trichomoniasis, BV, and vulvovaginal candidiasis have all been associated with increased risk of acquisition of HIV infection; BV promotes HIV transmission from HIV-infected women to their male sex partners. Vaginal trichomoniasis and BV early in pregnancy independently predict premature onset of labor. BV can also lead to anaerobic bacterial infection of the endometrium and salpinges. Vaginitis may be an early and prominent feature of toxic shock syndrome, and recurrent or chronic vulvovaginal candidiasis develops with increased frequency among women who have systemic illnesses, such as diabetes mellitus or HIV-related immunosuppression (although only a very small proportion of women with recurrent vulvovaginal candidiasis in industrialized countries actually have a serious predisposing illness).

Thus, vulvovaginal symptoms or signs warrant careful evaluation, including speculum and pelvic examination, diagnostic testing, and appropriate therapy specific for the infection identified. Unfortunately, clinicians do not always perform the tests required to establish the cause of such symptoms. Further, self-diagnosis of a specific type of infection—including vulvovaginal candidiasis—is often incorrect. The diagnosis and treatment of the three most common types of vaginal infection are summarized in **Table 141-5**.

Inspection of the vulva and perineum may reveal tender genital ulcerations or fissures (typically due to HSV infection or vulvovaginal candidiasis) or discharge visible at the introitus before insertion of a speculum (suggestive of BV or trichomoniasis). Speculum examination permits the clinician to discern whether the discharge appears abnormal and whether it emanates from the cervical os (mucoid and, if abnormal, yellow) or from the vagina (not mucoid, since the vaginal epithelium does not produce mucus). Symptoms or signs of abnormal vaginal discharge should prompt testing of vaginal fluid for pH, for a fishy odor when mixed with 10% KOH, and for certain microscopic

TABLE 141-5 Diagnostic Features and Management of Vaginal Infection

FEATURE	NORMAL VAGINAL EXAMINATION	VULVOVAGINAL CANDIDIASIS	TRICHOMONAL VAGINITIS	BACTERIAL VAGINOSIS (BV)
Etiology	Uninfected; lactobacilli predominant	*Candida albicans*	*Trichomonas vaginalis*	Associated with *Gardnerella vaginalis*, various anaerobic bacteria, and mycoplasmas
Typical symptoms	None	Vulvar itching and/or irritation	Profuse discharge; vulvar itching	Malodorous, slightly increased discharge
Discharge				
Amount	Variable; usually scant	Scant	Often profuse	Moderate
Color[a]	Clear or translucent	White	White or yellow	White or gray
Consistency	Nonhomogeneous, flocculent	Clumped; adherent plaques	Homogeneous	Homogeneous, low viscosity; uniformly coats vaginal walls
Inflammation of vulvar or vaginal epithelium	None	Erythema of vaginal epithelium, introitus; vulvar dermatitis, fissures common	Erythema of vaginal and vulvar epithelium; colpitis macularis	None
pH of vaginal fluid[b]	Usually ≤4.5	Usually ≤4.5	Usually ≥5	Usually >4.5
Amine ("fishy") odor with 10% KOH	None	None	May be present	Present
Microscopy[c]	Normal epithelial cells; lactobacilli predominant	Leukocytes, epithelial cells; mycelia or pseudomycelia in up to 80% of *C. albicans* culture–positive persons with typical symptoms	Leukocytes; motile trichomonads seen in 80–90% of symptomatic patients, less often in the absence of symptoms	Clue cells; few leukocytes; no lactobacilli or only a few outnumbered by profuse mixed microbiota, nearly always including *G. vaginalis* plus anaerobic species on Gram's stain (Nugent's score ≥7)
Other laboratory findings		Isolation of *Candida* spp.	Isolation of *T. vaginalis* or positive NAAT[d]	Diagnosis of BV by NAAT[d]
Usual treatment	None	Azole cream, tablet, or suppository—e.g., miconazole (100-mg vaginal suppository) or clotrimazole (100-mg vaginal tablet) once daily for 7 days Fluconazole, 150 mg orally (single dose)	Metronidazole or tinidazole, 2 g orally (single dose) Metronidazole, 500 mg PO bid for 7 days	Metronidazole, 500 mg PO bid for 7 days Metronidazole gel, 0.75%, one applicator (5 g) intravaginally once daily for 5 days Clindamycin, 2% cream, one full applicator vaginally each night for 7 days
Usual management of sexual partner	None	None; topical treatment if candidal dermatitis of penis is detected	Examination for sexually transmitted infection; treatment with metronidazole, 2 g PO (single dose)	None

[a]Color of discharge is best determined by examination against the white background of a swab. [b]A pH determination is not useful if blood is present or if the test is performed on endocervical secretions. [c]To detect fungal elements, vaginal fluid is digested with 10% KOH prior to microscopic examination; to examine for other features, fluid is mixed (1:1) with physiologic saline. Gram's stain is also excellent for detecting yeasts (less predictive of vulvovaginitis) and pseudomycelia or mycelia (strongly predictive of vulvovaginitis) and for distinguishing normal flora from the mixed flora seen in bacterial vaginosis, but it is less sensitive than the saline preparation for detection of *T. vaginalis*. [d]NAAT, nucleic acid amplification test (where available). NAAT for diagnosis of BV typically tests for combinations of BV-associated bacteria and absence of *Lactobacillus* species.

features when mixed with saline (motile trichomonads and/or "clue cells") and with 10% KOH (pseudohyphae or hyphae indicative of vulvovaginal candidiasis). Additional objective laboratory tests, described below, are useful for establishing the cause of abnormal vaginal discharge. Gram's staining of vaginal fluid can be used to characterize the vaginal bacteria using the Nugent score but is used primarily for research purposes and requires familiarity with the morphotypes and scale involved. Of note, NAATs that characterize relative concentrations of BV-associated bacteria and certain *Lactobacillus* species are now available and offer comparable performance to clinical diagnostic criteria.

TREATMENT

Vaginal Discharge

Patterns of treatment for abnormal vaginal discharge vary widely. In developing countries, where clinics or pharmacies often dispense treatment based on symptoms alone without examination or testing, oral treatment with metronidazole—particularly with a 7-day regimen—provides reasonable coverage against both trichomoniasis and BV, the usual causes of symptoms of vaginal discharge. Metronidazole treatment of sex partners prevents reinfection of women with *T. vaginalis*, although it does not help prevent the recurrence of BV. Guidelines for syndromic management promulgated by the World Health Organization suggest consideration of treatment for cervical infection and for trichomoniasis, BV, and vulvovaginal candidiasis in women with symptoms of abnormal vaginal discharge. However, it is important to note that the majority of chlamydial and gonococcal cervical infections produce no symptoms.

In industrialized countries, clinicians treating symptoms and signs of abnormal vaginal discharge should, at a minimum, differentiate between BV and trichomoniasis because optimal management of patients and partners differs for these two conditions.

Vaginal Trichomoniasis (See also Chap. 236) Symptomatic trichomoniasis characteristically produces a profuse, yellow, purulent, homogeneous vaginal discharge and vulvar irritation, sometimes with visible inflammation of the vaginal and vulvar epithelium and petechial lesions on the cervix (the so-called strawberry cervix, best visualized by colposcopy). The pH of vaginal fluid—normally <4.7—usually rises to ≥5. Microscopic examination of vaginal discharge mixed with saline reveals motile trichomonads in most culture-positive cases. However, saline microscopy detects fewer than one-half of all cases, and, especially in the absence of symptoms or signs, culture or NAAT is usually required for detection of the organism. NAAT for *T. vaginalis* is more sensitive than culture. Treatment of asymptomatic as well as symptomatic cases reduces rates of transmission and prevents later development of symptoms.

TREATMENT

Vaginal Trichomoniasis

Only nitroimidazoles (e.g., metronidazole and tinidazole) consistently cure trichomoniasis. A single 2-g oral dose of metronidazole has been the standard treatment for decades, but it is less effective than a weeklong course; the latter is preferred. Tinidazole has a longer half-life than metronidazole, causes fewer gastrointestinal symptoms, and may be useful in treating trichomoniasis that fails to respond to metronidazole. Treatment of sexual partners, facilitated by dispensing metronidazole to the female patient to give to her partner(s), significantly reduces both the risk of reinfection and the reservoir of infection; treating partners is the standard of care. Intravaginal treatment with 0.75% metronidazole gel is not reliable for vaginal trichomoniasis. Thus, systemic use of metronidazole is still recommended throughout pregnancy for treatment of trichomoniasis. In a large randomized trial, metronidazole treatment of trichomoniasis during pregnancy was associated with an increased frequency of perinatal morbidity. However, most studies, including randomized controlled trials, have shown no adverse effects of metronidazole use during pregnancy on preterm birth or birth defects.

Bacterial Vaginosis BV is a syndrome characterized by symptoms of vaginal malodor and increased white-gray discharge, which appears homogeneous, is low in viscosity, and uniformly covers the vaginal mucosa. BV has been associated with an increased risk of acquiring several other genital infections, including those caused by HIV, *C. trachomatis*, and *N. gonorrhoeae*. Other possible risk factors include recent unprotected vaginal intercourse, having a female sex partner, and vaginal douching. Although bacteria associated with BV have been detected under the foreskin of uncircumcised men and have been associated with urethritis, metronidazole treatment of male partners has not reduced the rate of recurrence of BV among affected women.

Among women with BV, culture of vaginal fluid has shown markedly increased prevalences and concentrations of *Gardnerella vaginalis, Mycoplasma hominis*, and several anaerobic bacteria (e.g., *Mobiluncus, Prevotella* [formerly *Bacteroides*], and some *Peptostreptococcus* species) as well as an absence of hydrogen peroxide–producing *Lactobacillus* species that constitute most of the normal vaginal microbiota and help protect against cervical and vaginal infections. Broad-range polymerase chain reaction (PCR) amplification of 16S rDNA in vaginal fluid, with subsequent identification of specific bacterial species by various methods, has documented even greater bacterial diversity, including several unique species not previously identified in culture **(Fig. 141-2)** and *Atopobium vaginae*, an organism that is strongly associated with BV and is resistant to metronidazole. Other genera newly implicated in BV include *Megasphaera, Leptotrichia, Eggerthella*, and *Dialister*.

BV is conventionally diagnosed clinically with the Amsel criteria, which include any three of the following four clinical abnormalities: (1) objective signs of increased white homogeneous vaginal discharge; (2) a vaginal discharge pH of >4.5; (3) liberation of a distinct fishy odor (attributable to volatile amines such as trimethylamine) immediately after vaginal secretions are mixed with a 10% solution of KOH; and (4) microscopic demonstration of "clue cells" (vaginal epithelial cells coated with coccobacillary organisms, which have a granular appearance and indistinct borders; **Fig. 141-3**) on a wet mount prepared by mixing vaginal secretions with normal saline in a ratio of ~1:1. More recently, NAAT targeting the absence of *Lactobacillus crispatus* and presence of BV-associated anaerobes have offered accurate options for diagnosing BV.

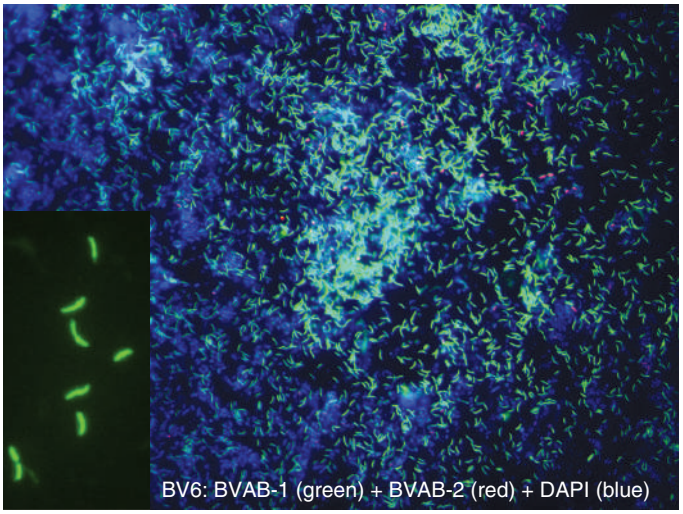

FIGURE 141-2 Broad-range polymerase chain reaction amplification of 16S rDNA in vaginal fluid from a woman with bacterial vaginosis (BV) shows a field of bacteria hybridizing with probes for BV-associated bacterium 1 (BVAB-1, *visible as a thin, curved green rod*) and for BVAB-2 (*red*). The *inset* shows that BVAB-1 has a morphology similar to that of *Mobiluncus* (curved rod). *(Adapted from DN Fredricks et al: Molecular identification of bacteria associated with bacterial vaginosis. N Engl J Med 353:1899, 2005.)*

Note the obscured epithelial cell margins and the granular appearance attributable to many adherent bacteria (×400). *(Photograph provided by Lorna K. Rabe, reprinted with permission from S Hillier et al, in KK Holmes et al [eds]: Sexually Transmitted Diseases, 4th ed. New York, McGraw-Hill, 2008.)*

TREATMENT

Bacterial Vaginosis

The standard dosage of oral metronidazole for the treatment of BV is 500 mg twice daily for 7 days. Intravaginal treatment with 2% clindamycin cream (one full applicator [5 g containing 100 mg of clindamycin phosphate] each night for 7 nights) or with 0.75% metronidazole gel (one full applicator [5 g containing 37.5 mg of metronidazole] twice daily for 5 days) is also approved for use in the United States and does not elicit systemic adverse reactions; the response to both of these treatments is similar to the response to oral metronidazole. Another nitroimidazole given orally, secnidazole, is also effective (single 2-g dose). Other alternatives include oral clindamycin (300 mg twice daily for 7 days), clindamycin ovules (100 g intravaginally once at bedtime for 3 days), and oral tinidazole (1 g daily for 5 days or 2 g daily for 3 days). Unfortunately, recurrence over the long term (i.e., several months later) is distressingly common after either oral or intravaginal treatment. A randomized trial comparing intravaginal gel containing 37.5 mg of metronidazole with a suppository containing 500 mg of metronidazole plus nystatin (the latter not marketed in the United States) showed significantly higher rates of recurrence with the 37.5-mg regimen; this result suggests that higher metronidazole dosages may be important in topical intravaginal therapy. Recurrences can be significantly lessened with the twice-weekly use of suppressive intravaginal metronidazole gel. The goal of replenishing the vaginal lactobacilli that sustain vaginal health has recently been bolstered by a randomized trial that demonstrated that weekly vaginal administration of *L. crispatus* CTV-05 (LACTIN-V) reduced rates of recurrent BV by approximately one-third.

A meta-analysis of 18 studies concluded that BV during pregnancy substantially increased the risk of preterm delivery and of spontaneous abortion. However, in most studies, topical intravaginal treatment of BV with clindamycin during pregnancy has not reduced adverse pregnancy outcomes. Numerous trials of oral metronidazole treatment during pregnancy have given inconsistent results, and recent reviews have concluded that antenatal treatment of women with BV—including those with previous preterm delivery—did not reduce the risk of preterm delivery. The U.S. Preventive Services Task Force thus recommends against routine screening of pregnant women for BV.

Vulvovaginal Pruritus, Burning, or Irritation Vulvovaginal candidiasis produces vulvar pruritus, burning, or irritation, generally without symptoms of increased vaginal discharge or malodor. Genital herpes can produce similar symptoms, with lesions sometimes difficult to distinguish from the fissures and inflammation caused by candidiasis. Signs of vulvovaginal candidiasis include vulvar erythema, edema, fissures, and tenderness. With candidiasis, a white scanty vaginal discharge sometimes takes the form of white thrush-like plaques or cottage cheese–like curds adhering loosely to the vaginal epithelium. *C. albicans* accounts for nearly all cases of symptomatic vulvovaginal candidiasis, which probably arise from endogenous strains of *C. albicans* that have colonized the vagina or the intestinal tract. Complicated vulvovaginal candidiasis includes cases that recur four or more times per year; are unusually severe; are caused by non-*albicans Candida* species; or occur in women with uncontrolled diabetes, debilitation, immunosuppression, or pregnancy.

In addition to compatible clinical symptoms, the diagnosis of vulvovaginal candidiasis involves the demonstration of pseudohyphae or hyphae by microscopic examination of vaginal fluid mixed with saline or 10% KOH or subjected to Gram's staining. Microscopic examination is less sensitive than culture but correlates better with symptoms. Culture is typically reserved for cases that do not respond to standard first-line antimycotic agents and is undertaken to rule out imidazole or azole resistance (often associated with *Candida glabrata*) or before the initiation of suppressive antifungal therapy for recurrent disease.

TREATMENT

Vulvovaginal Pruritus, Burning, or Irritation

Symptoms and signs of vulvovaginal candidiasis warrant treatment, usually intravaginal administration of any of several imidazole antibiotics (e.g., miconazole or clotrimazole) for 3–7 days or of a single dose of oral fluconazole (Table 141-5). Over-the-counter marketing of such preparations has reduced the cost of care and made treatment more convenient for many women with recurrent yeast vulvovaginitis. However, most women who purchase these preparations do not have vulvovaginal candidiasis, whereas many have other vaginal infections that require different treatment. Therefore, only women with classic symptoms of vulvar pruritus and a history of previous episodes of yeast vulvovaginitis documented by an experienced clinician should self-treat. Short-course topical intravaginal azole drugs are effective for the treatment of uncomplicated vulvovaginal candidiasis (e.g., clotrimazole, two 100-mg vaginal tablets daily for 3 days; or miconazole, a 1200-mg vaginal suppository as a single dose). Single-dose oral treatment with fluconazole (150 mg) is also effective and is preferred by many patients. Management of complicated cases (see above) and those that do not respond to the usual intravaginal or single-dose oral therapy often involves prolonged or periodic oral therapy; this situation is discussed extensively in the 2015 CDC STD treatment guidelines (*https://www.cdc.gov/sti/hcp/clinical-guidance/?CDC_AAref_Val=https://www.cdc.gov/std/treatment/*). Treatment of sexual partners is not routinely indicated.

Other Causes of Vaginal Discharge or Vaginitis In the ulcerative vaginitis associated with staphylococcal toxic shock syndrome, *Staphylococcus aureus* should be promptly identified in vaginal fluid by Gram's stain and by culture. In desquamative inflammatory vaginitis, smears of vaginal fluid reveal neutrophils, massive vaginal epithelial cell exfoliation with increased numbers of parabasal cells, and gram-positive cocci; this syndrome may respond to treatment with 2% clindamycin cream, often given in combination with topical steroid preparations for several weeks. Additional causes of vaginitis and vulvovaginal symptoms include retained foreign bodies (e.g., tampons), cervical caps, vaginal spermicides, vaginal antiseptic preparations or douches, vaginal epithelial atrophy (in postmenopausal women or during prolonged breast-feeding in the postpartum period), allergic reactions to latex condoms, vaginal aphthae associated with HIV infection or Behçet's syndrome, and vestibulitis.

MUCOPURULENT CERVICITIS

Mucopurulent cervicitis (MPC) refers to inflammation of the columnar epithelium and subepithelium of the endocervix and of any contiguous

columnar epithelium that lies exposed in an ectopic position on the ectocervix. MPC in women represents the "silent partner" of urethritis in men, being equally common and often caused by the same agents (*N. gonorrhoeae*, *C. trachomatis*, *M. genitalium*); however, MPC is more difficult than urethritis to recognize, given the nonspecific nature of symptoms (e.g., abnormal vaginal discharge) and the need for visualization by pelvic examination. As the most common manifestation of these serious bacterial infections in women, MPC can be a harbinger or sign of upper genital tract infection, also known as *pelvic inflammatory disease* (PID; see below). In pregnant women, MPC can lead to obstetric complications. In the pre-NAAT era, more than one-third of cervicovaginal specimens tested for *C. trachomatis, N. gonorrhoeae, M. genitalium*, HSV, and *T. vaginalis* revealed no identifiable etiology for MPC **(Fig. 141-4)**. More recent studies employing NAATs for these pathogens have still failed to identify a microbiologic etiology in nearly one-half of women with MPC. Individual bacteria associated with BV may also elicit an inflammatory reaction at the cervix; thus, BV may be a cause of MPC.

The diagnosis of MPC rests on the detection of cardinal signs at the cervix, including yellow mucopurulent discharge from the cervical os, endocervical bleeding upon gentle swabbing, and edematous cervical ectopy (see below); the latter two findings are somewhat more common with MPC due to chlamydial infection, but signs alone do not allow a distinction among the causative pathogens. Unlike the endocervicitis produced by gonococcal or chlamydial infection, cervicitis caused by HSV produces ulcerative lesions on the stratified squamous epithelium of the ectocervix as well as on the columnar epithelium. Yellow cervical mucus on a white swab removed from the endocervix indicates the presence of polymorphonuclear leukocytes (PMNs). Gram's staining may confirm their presence, although it adds relatively little to the diagnostic value of assessment for cervical signs. The presence of ≥20 PMNs per 1000× microscopic field within strands of cervical mucus not contaminated by vaginal squamous epithelial cells or vaginal bacteria indicates endocervicitis. Detection of intracellular gram-negative diplococci in carefully collected endocervical mucus is quite specific but ≤50% sensitive for gonorrhea. Therefore, NAATs for *N. gonorrhoeae* and *C. trachomatis* are always indicated in the evaluation of MPC, as is a careful evaluation of vaginal discharge for the causes of vaginitis discussed above.

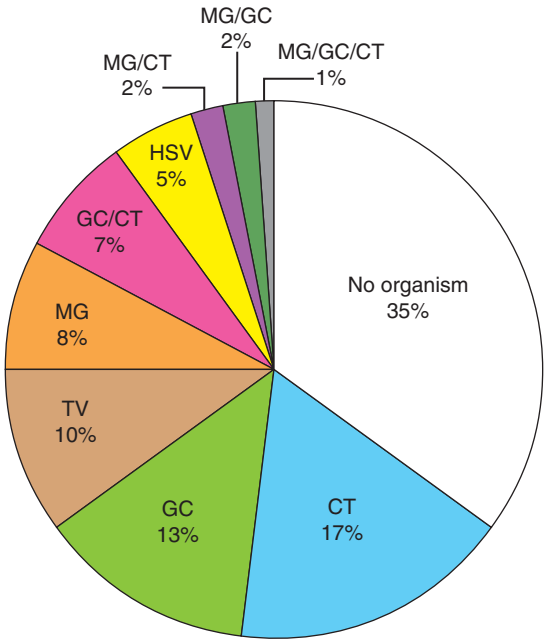

FIGURE 141-4 Organisms detected among female sexually transmitted disease clinic patients with mucopurulent cervicitis (n = 167). CT, *Chlamydia trachomatis*; GC, gonococcus; HSV, herpes simplex virus; MG, *Mycoplasma genitalium*; TV, *Trichomonas vaginalis. (Courtesy of Dr. Lisa Manhart.)*

TREATMENT

Mucopurulent Cervicitis

Although the above criteria for MPC are neither highly specific nor highly predictive of gonococcal or chlamydial infection in some settings, the 2015 CDC STD guidelines call for consideration of empirical treatment for MPC, pending test results, in most cases. Presumptive treatment with antibiotics active against *C. trachomatis* should be provided for women at increased risk for this common STI (risk factors: age <25 years, new or multiple sex partners, and unprotected sex), especially if follow-up cannot be ensured. Concurrent therapy for gonorrhea is indicated if the prevalence of this infection is substantial in the relevant patient population (e.g., young adults, a clinic with documented high prevalence). In this situation, therapy should include a single-dose regimen effective for gonorrhea plus treatment for chlamydial infection, as outlined in Table 141-4 for the treatment of urethritis. In settings where gonorrhea is much less common than chlamydial infection, initial therapy for chlamydial infection alone suffices, pending test results for gonorrhea. The etiology and potential benefit of treatment for endocervicitis not associated with gonorrhea or chlamydial infection have not been established. Although the antimicrobial susceptibility of *M. genitalium* is not yet well defined, the organism frequently persists after doxycycline therapy, and it currently seems reasonable to use azithromycin to treat possible *M. genitalium* infection in such cases. With resistance of *M. genitalium* to azithromycin now recognized, moxifloxacin may be a reasonable alternative. The sexual partner(s) of a woman with MPC should be examined and given a regimen similar to that chosen for the woman unless results of tests for gonorrhea or chlamydial infection in either partner warrant different therapy or no therapy.

CERVICAL ECTOPY

Cervical ectopy, often mislabeled "cervical erosion," is easily confused with infectious endocervicitis. Ectopy represents the presence of the one-cell-thick columnar epithelium extending from the endocervix out onto the visible ectocervix. In ectopy, the cervical os may contain clear or slightly cloudy mucus but usually not yellow mucopus. Colposcopy shows intact epithelium. Normally found during adolescence and early adulthood, ectopy gradually recedes through the second and third decades of life, as squamous metaplasia replaces the ectopic columnar epithelium. Oral contraceptive use favors the persistence or reappearance of ectopy, while smoking apparently accelerates squamous metaplasia. Cauterization of ectopy is not warranted. Ectopy may render the cervix more susceptible to infection with *N. gonorrhoeae, C. trachomatis*, or HIV.

PELVIC INFLAMMATORY DISEASE

The term *pelvic inflammatory disease* (PID) usually refers to infection that ascends from the cervix or vagina to involve the endometrium and/or fallopian tubes. Infection can extend beyond the reproductive tract to cause pelvic peritonitis, generalized peritonitis, perihepatitis, perisplenitis, or pelvic abscess. Rarely, infection not related to specific sexually transmitted pathogens extends secondarily to the pelvic organs (1) from adjacent foci of inflammation (e.g., appendicitis, regional ileitis, or diverticulitis) or BV, (2) as a result of hematogenous dissemination (e.g., of tuberculosis or staphylococcal bacteremia), or (3) as a complication of certain tropical diseases (e.g., schistosomiasis). Intrauterine infection can be primary (spontaneously occurring and usually sexually transmitted) or secondary to invasive intrauterine surgical procedures (e.g., dilation and curettage, termination of pregnancy, insertion of an intrauterine device [IUD], or hysterosalpingography) or to parturition.

Etiology The agents most often implicated in acute PID include the primary causes of endocervicitis (*N. gonorrhoeae, C. trachomatis*, and *M. genitalium*) and anaerobes associated with BV. In general, PID is most often caused by *N. gonorrhoeae* in settings where there is a

high incidence of gonorrhea. *M. genitalium* has also been significantly associated with histopathologic diagnoses of endometritis and with salpingitis.

Anaerobic and facultative organisms (especially *Prevotella* species, peptostreptococci, *E. coli, Haemophilus influenzae*, and group B streptococci) as well as genital mycoplasmas have been isolated from the peritoneal fluid or fallopian tubes in a varying proportion (typically one-fourth to one-third) of women with PID studied in the United States. The difficulty of determining the exact microbial etiology of an individual case of PID—short of using invasive procedures for specimen collection—has implications for the approach to empirical antimicrobial treatment of this infection.

Epidemiology In the United States, the estimated annual number of initial visits to physicians' offices for PID by women 15–44 years of age fell from an average of 400,000 during the 1980s to 250,000 in 1999 and then to 51,000 in 2014. Hospitalizations for acute PID in the United States also declined steadily throughout the 1980s and early 1990s but have remained fairly constant at 70,000–100,000 per year since 1995. Important risk factors for acute PID include the presence of endocervical infection or BV, a history of salpingitis or of recent vaginal douching, and recent insertion of an IUD. Certain other iatrogenic factors, such as dilation and curettage or cesarean section, can increase the risk of PID, especially among women with endocervical gonococcal or chlamydial infection or BV. Symptoms of *N. gonorrhoeae*–associated and *C. trachomatis*–associated PID often begin during or soon after the menstrual period; this timing suggests that menstruation is a risk factor for ascending infection from the cervix and vagina. Experimental inoculation of the fallopian tubes of nonhuman primates has shown that repeated exposure to *C. trachomatis* leads to the greatest degree of tissue inflammation and damage; thus, immunopathology probably contributes to the pathogenesis of chlamydial salpingitis. Women using oral contraceptives appear to be at decreased risk of symptomatic PID, and tubal sterilization reduces the risk of salpingitis by preventing intraluminal spread of infection into the tubes.

Clinical Manifestations • **ENDOMETRITIS: A CLINICAL PATHOLOGIC SYNDROME** A study of women with clinically suspected PID who were undergoing both endometrial biopsy and laparoscopy showed that those with endometritis alone differed from those who also had salpingitis in significantly less often having lower quadrant, adnexal, or cervical motion or abdominal rebound tenderness; fever; or elevated C-reactive protein levels. In addition, women with endometritis alone differed from those with neither endometritis nor salpingitis in more often having gonorrhea, chlamydial infection, and risk factors such as douching or IUD use. Thus, women with endometritis alone were intermediate between those with neither endometritis nor salpingitis and those with salpingitis with respect to risk factors, clinical manifestations, cervical infection prevalence, and elevated C-reactive protein level. Women with endometritis alone are at lower risk of subsequent tubal occlusion and resulting infertility than are those with salpingitis.

SALPINGITIS Symptoms of nontuberculous salpingitis classically evolve from a yellow or malodorous vaginal discharge caused by MPC and/or BV to midline abdominal pain and abnormal vaginal bleeding caused by endometritis and then to bilateral lower abdominal and pelvic pain caused by salpingitis, with nausea, vomiting, and increased abdominal tenderness if peritonitis develops.

The abdominal pain in nontuberculous salpingitis is usually described as dull or aching. In some cases, pain is lacking or atypical, but active inflammatory changes are found in the course of an unrelated evaluation or procedure, such as a laparoscopic evaluation for infertility. Abnormal uterine bleeding precedes or coincides with the onset of pain in ~40% of women with PID, symptoms of urethritis (dysuria) occur in 20%, and symptoms of proctitis (anorectal pain, tenesmus, and rectal discharge or bleeding) are occasionally seen in women with gonococcal or chlamydial infection.

Speculum examination shows evidence of MPC (yellow endocervical discharge, easily induced endocervical bleeding) in the majority of women with gonococcal or chlamydial PID. Cervical motion tenderness is produced by stretching of the adnexal attachments on the side toward which the cervix is pushed. Bimanual examination reveals uterine fundal tenderness due to endometritis and abnormal adnexal tenderness due to salpingitis that is usually, but not necessarily, bilateral. Adnexal swelling is palpable in about one-half of women with acute salpingitis, but evaluation of the adnexae in a patient with marked tenderness is not reliable. The initial temperature is >38°C in only about one-third of patients with acute salpingitis. Laboratory findings include elevation of the erythrocyte sedimentation rate (ESR) in 75% of patients with acute salpingitis and elevation of the peripheral white blood cell count in up to 60%.

Unlike nontuberculous salpingitis, genital tuberculosis often occurs in older women, many of whom are postmenopausal. Presenting symptoms include abnormal vaginal bleeding, pain (including dysmenorrhea), and infertility. About one-quarter of these women have had adnexal masses. Endometrial biopsy shows tuberculous granulomas and provides optimal specimens for culture.

PERIHEPATITIS AND PERIAPPENDICITIS Pleuritic upper abdominal pain and tenderness, usually localized to the right upper quadrant (RUQ), develop in 3–10% of women with acute PID. Symptoms of perihepatitis arise during or after the onset of symptoms of PID and may overshadow lower abdominal symptoms, thereby leading to a mistaken diagnosis of cholecystitis. In perhaps 5% of cases of acute salpingitis, early laparoscopy reveals perihepatic inflammation ranging from edema and erythema of the liver capsule to exudate with fibrinous adhesions between the visceral and parietal peritoneum. When treatment is delayed and laparoscopy is performed late, dense "violin-string" adhesions can be seen over the liver; chronic exertional or positional RUQ pain ensues when traction is placed on the adhesions. Although perihepatitis, also known as the *Fitz-Hugh–Curtis syndrome*, was for many years specifically attributed to gonococcal salpingitis, most cases are now attributed to chlamydial salpingitis. In patients with chlamydial salpingitis, serum titers of microimmunofluorescent antibody to *C. trachomatis* are typically much higher when perihepatitis is present than when it is absent.

Physical findings include RUQ tenderness and usually include adnexal tenderness and cervicitis, even in patients whose symptoms do not suggest salpingitis. Results of liver function tests and RUQ ultrasonography are nearly always normal. The presence of MPC and pelvic tenderness in a young woman with subacute pleuritic RUQ pain and normal ultrasonography of the gallbladder points to a diagnosis of perihepatitis.

Periappendicitis (appendiceal serositis without involvement of the intestinal mucosa) has been found in ~5% of patients undergoing appendectomy for suspected appendicitis and can occur as a complication of gonococcal or chlamydial salpingitis.

Among women with salpingitis, HIV infection is associated with increased severity of salpingitis and with tuboovarian abscess requiring hospitalization and surgical drainage. Nonetheless, among women with HIV infection and salpingitis, the clinical response to conventional antimicrobial therapy (coupled with drainage of tuboovarian abscess, when found) has usually been satisfactory.

Diagnosis Treatment appropriate for PID must not be withheld from patients who have an equivocal diagnosis; it is better to err on the side of overdiagnosis and overtreatment. On the other hand, it is essential to differentiate between salpingitis and other pelvic pathology, particularly surgical emergencies such as appendicitis and ectopic pregnancy or the chronic syndrome of endometriosis.

Nothing short of laparoscopy definitively identifies salpingitis, but routine laparoscopy to confirm suspected salpingitis is generally impractical. Most patients with acute PID have lower abdominal pain of <3 weeks' duration, pelvic tenderness on bimanual pelvic examination, and evidence of lower genital tract infection (e.g., MPC). Approximately 60% of such patients have salpingitis at laparoscopy, and perhaps 10–20% have endometritis alone. Among the patients with these findings, a rectal temperature >38°C, a palpable adnexal mass, and elevation of the ESR to >15 mm/h also raise the probability

of salpingitis, which has been found at laparoscopy in 68% of patients with one of these additional findings, 90% of patients with two, and 96% of patients with three. However, only 17% of all patients with laparoscopy-confirmed salpingitis have had all three additional findings.

In a woman with pelvic pain and tenderness, increased numbers of PMNs (30 per 1000× microscopic field in strands of cervical mucus) or leukocytes outnumbering epithelial cells in vaginal fluid (in the absence of trichomonal vaginitis, which also produces PMNs in vaginal discharge) increase the predictive value of a clinical diagnosis of acute PID, as do onset with menses, history of recent abnormal menstrual bleeding, presence of an IUD, history of salpingitis, and sexual exposure to a male with urethritis. Appendicitis or another disorder of the gut is favored by the early onset of anorexia, nausea, or vomiting; the onset of pain later than day 14 of the menstrual cycle; or unilateral pain limited to the right or left lower quadrant. Whenever the diagnosis of PID is being considered, serum assays for human β-chorionic gonadotropin should be performed; these tests are usually positive with ectopic pregnancy. Ultrasonography and magnetic resonance imaging (MRI) can be useful for the identification of tuboovarian or pelvic abscess. MRI of the tubes can also show increased tubal diameter, intratubal fluid, or tubal wall thickening in cases of salpingitis.

The primary value of laparoscopy in women with lower abdominal pain is for the exclusion of other surgical problems that cannot be resolved with noninvasive imaging. Some of the most common or serious problems that may be confused with salpingitis (e.g., acute appendicitis, ectopic pregnancy, corpus luteum bleeding, ovarian tumor) are unilateral. Unilateral pain or pelvic mass, although not incompatible with PID, is a strong indication for laparoscopy unless the clinical picture warrants laparotomy instead. Atypical clinical findings such as the absence of lower genital tract infection, a missed menstrual period, a positive pregnancy test, or failure to respond to appropriate therapy are other common indications for laparoscopy. Endometrial biopsy is relatively sensitive and specific for the diagnosis of endometritis, which correlates well with the presence of salpingitis.

Vaginal or endocervical swab specimens should be obtained for NAATs for *N. gonorrhoeae* and *C. trachomatis*. At a minimum, vaginal fluid should be evaluated for the presence of PMNs, and endocervical secretions ideally should be assessed by Gram's staining for PMNs and gram-negative diplococci, which indicate gonococcal infection. The clinical diagnosis of PID made by expert gynecologists is confirmed by laparoscopy or endometrial biopsy in ~90% of women who also have cultures positive for *N. gonorrhoeae* or *C. trachomatis*. Even among women with no symptoms suggestive of acute PID who were attending an STD clinic or a gynecology clinic in Pittsburgh, endometritis was significantly associated with endocervical gonorrhea or chlamydial infection or with BV, being detected in 26%, 27%, and 15% of women with these conditions, respectively.

TREATMENT

Pelvic Inflammatory Disease

Recommended combination regimens for ambulatory or parenteral management of PID are presented in **Table 141-6**. Women managed as outpatients should receive a combined regimen with broad activity, such as ceftriaxone (to cover possible gonococcal infection) followed by doxycycline (to cover possible chlamydial infection). Metronidazole should be added to enhance activity against anaerobes; in a randomized trial, the addition of metronidazole to ceftriaxone and doxycycline effected reduction in endometrial anaerobes, *M. genitalium,* and pelvic tenderness.

The CDC STD treatment guidelines recommend initiation of empirical treatment for PID in sexually active young women and other women at risk for PID if they are experiencing pelvic or lower abdominal pain, if no other cause for the pain can be identified, and if pelvic examination reveals one or more of the following criteria for PID: cervical motion tenderness, uterine tenderness, or adnexal tenderness. Women with suspected PID can be treated as either outpatients or inpatients. In the multicenter Pelvic Inflammatory Disease Evaluation and Clinical Health (PEACH) trial, 831 women with mild to moderately severe symptoms and signs of PID were randomized to receive either inpatient treatment with IV cefoxitin and doxycycline or outpatient treatment with a single IM dose of cefoxitin plus oral doxycycline. Short-term clinical and microbiologic outcomes and long-term outcomes were equivalent in the two groups. Nonetheless, hospitalization should be considered when (1) the diagnosis is uncertain and surgical emergencies such as appendicitis and ectopic pregnancy cannot be excluded, (2) the patient is pregnant, (3) pelvic abscess is suspected, (4) severe illness or nausea and vomiting preclude outpatient management, (5) the patient has HIV infection, (6) the patient is assessed as unable to follow or tolerate an outpatient regimen, or (7) the patient has failed to respond to outpatient therapy. Some experts also prefer to hospitalize adolescents with PID for initial therapy, although younger women do as well as older women on outpatient therapy.

TABLE 141-6 Combination Antimicrobial Regimens Recommended for Outpatient Treatment or for Parenteral Treatment of Pelvic Inflammatory Disease

OUTPATIENT REGIMENS[a]	PARENTERAL REGIMENS
Ceftriaxone (500 mg IM once) ***plus*** Doxycycline (100 mg PO bid for 14 days) ***plus***[b] Metronidazole (500 mg PO bid for 14 days)	Initiate parenteral therapy with either of the following regimens; continue parenteral therapy until 48 h after clinical improvement; then change to outpatient therapy, as described in the text **Regimen A** Cefotetan (2 g IV q12h) *or* cefoxitin (2 g IV q6h) ***plus*** Doxycycline (100 mg IV or PO q12h) **Regimen B** Clindamycin (900 mg IV q8h) ***plus*** Gentamicin (loading dose of 2 mg/kg IV or IM, then maintenance dose of 1.5 mg/kg q8h)

[a]See text for discussion of options in the patient who is intolerant of cephalosporins.
[b]The addition of metronidazole is recommended particularly if bacterial vaginosis or trichomoniasis is present.

Source: Adapted from Centers for Disease Control and Prevention: MMWR Recomm Rep 70(RR-04):1, 2021.

Currently, no agents other than parenteral cephalosporins provide reliable coverage for gonococcal infection. Thus, adequate oral treatment of women with serious intolerance to cephalosporins is a challenge. If penicillins are an option, amoxicillin/clavulanic acid combined with doxycycline has elicited a short-term clinical response in one trial. Clinical trials performed outside the United States support the effectiveness of oral moxifloxacin. For women whose PID involves quinolone-resistant *N. gonorrhoeae*, treatment is uncertain but could include parenteral gentamicin or ertapenem.

For hospitalized patients, the following two parenteral regimens (Table 141-6) have given nearly identical results in a multicenter randomized trial:

1. Doxycycline plus either cefotetan or cefoxitin: Administration of these drugs should be continued by the IV route for at least 48 h after the patient's condition improves and then followed with oral doxycycline (100 mg twice daily) to complete 14 days of therapy.
2. Clindamycin plus gentamicin in patients with normal renal function: Once-daily administration of gentamicin (with combination of the total daily dose into a single daily dose) has not been evaluated in PID but has been efficacious in other serious infections and could be substituted. Treatment with these drugs should be continued for at least 48 h after the patient's condition improves and then followed with oral doxycycline (100 mg twice daily) or clindamycin (450 mg four times daily) to complete 14 days of therapy. In cases with tuboovarian abscess, clindamycin rather than doxycycline for continued therapy provides better coverage for anaerobic infection.

FOLLOW-UP

Hospitalized patients should show substantial clinical improvement within 3–5 days. Women treated as outpatients should be clinically reevaluated within 72 h. A follow-up telephone survey of women seen in an emergency department and given a prescription for 10 days of oral doxycycline for PID found that 28% never filled the prescription and 41% stopped taking the medication early (after an average of 4.1 days), often because of persistent symptoms, lack of symptoms, or side effects. Women not responding favorably to ambulatory therapy should be hospitalized for parenteral therapy and further diagnostic evaluations, including a consideration of laparoscopy. Sex partners should be evaluated and treated empirically for gonorrhea and chlamydial infection. After completion of treatment, tests for persistent or recurrent infection with *N. gonorrhoeae* or *C. trachomatis* should be performed if symptoms persist or recur or if the patient has not complied with therapy or has been reexposed to an untreated sex partner.

SURGERY

Surgery is necessary for the treatment of salpingitis only in the face of life-threatening infection (such as rupture or threatened rupture of a tuboovarian abscess) or for drainage of an abscess. Conservative surgical procedures are usually sufficient. Pelvic abscesses can often be drained by posterior colpotomy, and peritoneal lavage can be used for generalized peritonitis.

Prognosis Late sequelae include infertility due to bilateral tubal occlusion, ectopic pregnancy due to tubal scarring without occlusion, chronic pelvic pain, and recurrent salpingitis. The overall post-salpingitis risk of infertility due to tubal occlusion in a large study in Sweden was 11% after one episode of salpingitis, 23% after two episodes, and 54% after three or more episodes. A University of Washington study found a sevenfold increase in the risk of ectopic pregnancy and an eightfold increase in the rate of hysterectomy after PID.

Prevention A randomized controlled trial designed to determine whether selective screening for chlamydial infection reduces the risk of subsequent PID showed that women randomized to undergo screening had a 56% lower rate of PID over the following year than did women receiving the usual care without screening. This report helped prompt U.S. national guidelines for risk-based chlamydial screening of young women to reduce the incidence of PID and the prevalence of post-PID sequelae, while also reducing sexual transmission of *C. trachomatis*. The CDC and the U.S. Preventive Services Task Force recommend that sexually active women ≤25 years of age be screened annually for genital chlamydial infection.

ULCERATIVE GENITAL OR PERIANAL LESIONS

Genital ulceration reflects a set of important STIs, most of which sharply increase the risk of sexual acquisition and shedding of HIV. In a 1996 study of genital ulcers in 10 of the U.S. cities with the highest rates of primary syphilis, PCR testing of ulcer specimens demonstrated HSV in 62% of patients, *T. pallidum* in 13%, and *Haemophilus ducreyi* (the cause of chancroid) in 12–20%. Today, genital herpes represents an even higher proportion of genital ulcers in the United States and other industrialized countries, even with a marked increase in early syphilis.

In Asia and Africa, chancroid **(Fig. 141-5)** was once considered the most common type of genital ulcer, followed in frequency by primary syphilis and then genital herpes **(Fig. 141-6)**. With increased efforts to control chancroid and syphilis and widespread use of broad-spectrum antibiotics to treat STI-related syndromes, together with more frequent recurrences or persistence of genital herpes attributable to HIV infection, PCR testing of genital ulcers now clearly implicates genital herpes as by far the most common cause of genital ulceration in most developing countries. LGV due to *C. trachomatis* **(Fig. 141-7)** and donovanosis (granuloma inguinale, due to *Klebsiella granulomatis*; **see Fig. 178-1**) continue to cause genital ulceration in some developing countries. LGV virtually disappeared in industrialized countries during the first 20 years of the HIV pandemic, but outbreaks are again occurring in Europe (including the United Kingdom), in North America, and in Australia. In these outbreaks, LGV typically presents as proctitis, with or without anal lesions, in men who report unprotected receptive anal intercourse, very often in association with HIV and/or hepatitis C virus infection; the latter may be an acute infection acquired through the same exposure. Other causes of genital ulcers include (1) candidiasis and traumatized genital warts; (2) lesions due to genital involvement by more widespread dermatoses; (3) cutaneous manifestations of systemic diseases such as genital mucosal ulceration in Stevens-Johnson syndrome or Behçet's disease; (4) superinfections of lesions that may originally have been sexually acquired (for example, methicillin-resistant *S. aureus* complicating a genital ulcer due to HSV-2); and (5) localized drug reactions, such as the ulcers occasionally seen with topical paromomycin cream or boric acid preparations.

FIGURE 141-5 Chancroid: multiple, painful, punched-out ulcers with undermined borders on the labia occurring after autoinoculation.

Diagnosis Although most genital ulcerations cannot be diagnosed confidently on clinical grounds alone, clinical findings **(Table 141-7)** and epidemiologic considerations can guide initial management **(Table 141-8)** pending results of specific tests. Clinicians should order a rapid serologic test for syphilis in all cases of genital ulcer and treat presumptively while awaiting serology in a patient at increased

FIGURE 141-6 Genital herpes. A relatively mild, superficial ulcer is typically seen in episodic outbreaks. *(Courtesy of Michael Remington, University of Washington Virology Research Clinic.)*

FIGURE 141-7 Lymphogranuloma venereum (LGV): striking tender lymphadenopathy occurring at the femoral and inguinal lymph nodes, separated by a groove made by Poupart's ligament. This "sign-of-the-groove" is not considered specific for LGV; for example, lymphomas may present with this sign.

epidemiologic risk (for example, MSM) or in pregnancy. To evaluate lesions except those highly characteristic of infection with HSV (i.e., those with herpetic vesicles), dark-field microscopy, direct immunofluorescence, and a NAAT for *T. pallidum* can be useful but are rarely available. It is important to note that 30% of syphilitic chancres—the primary ulcer of syphilis—are associated with an initially nonreactive syphilis serology. All patients presenting with genital ulceration should be counseled and tested for HIV infection.

Typical vesicles or pustules or a cluster of painful ulcers preceded by vesiculopustular lesions suggest genital herpes. These typical clinical manifestations make detection of the virus optional; however, many patients want confirmation of the diagnosis, and differentiation of HSV-1 from HSV-2 has prognostic implications, because the latter causes more frequent genital recurrences and is more infectious to vulnerable sex partners.

Painless, nontender, indurated ulcers with firm, nontender inguinal adenopathy suggest primary syphilis. If results of dark-field examination and a rapid serologic test for syphilis are initially negative, or if these tests are not available, presumptive therapy should be provided on the basis of the individual's risk. With historically high rates of syphilis among MSM in the United States, therapy for this infection should not be withheld pending watchful waiting and/or subsequent detection of seroconversion. Repeated serologic testing for syphilis 1 or 2 weeks after treatment of seronegative primary syphilis usually demonstrates seroconversion.

"Atypical" or clinically trivial ulcers may be more common manifestations of genital herpes than classic vesiculopustular lesions. Specific tests for HSV in such lesions are therefore indicated **(Chap. 197)**. Commercially available type-specific serologic tests for serum antibody to HSV-2 may give negative results, especially when patients present early with the initial episode of genital herpes or when HSV-1 is the cause of genital herpes. Furthermore, a positive test for antibody to HSV-2 does not prove that the current lesions are herpetic because nearly one-fifth of the general population of the United States becomes seropositive for HSV-2 during early adulthood. Although even "type-specific" tests for HSV-2 that are commercially available in the United States are not 100% specific, a positive HSV-2 serology does enable the clinician to tell the patient that they have probably had genital herpes, should learn to recognize symptoms, and should avoid sex during recurrences. In addition, because genital shedding and sexual transmission of HSV-2 often occur in the absence of symptoms and signs of recurrent herpetic lesions, persons who have a history of genital herpes or who are seropositive for HSV-2 should consider disclosure of serostatus to partners and the use of condoms or suppressive antiviral therapy, both of which can reduce the risk of HSV-2 transmission to a sexual partner.

Demonstration of *H. ducreyi* by culture (or by PCR, where available) is most useful when ulcers are painful and purulent, especially if inguinal lymphadenopathy with fluctuance or overlying erythema is noted; if chancroid is prevalent in the community; or if the patient has recently had a sexual exposure elsewhere in a chancroid-endemic area (e.g., a developing country). Enlarged, fluctuant lymph nodes should be aspirated for culture or PCR to detect *H. ducreyi* as well as for Gram's staining and culture to rule out the presence of other pyogenic bacteria.

When genital ulcers persist beyond the natural history of initial episodes of herpes (2–3 weeks) or of chancroid or syphilis (up to 6 weeks) and do not resolve with syndrome-based antimicrobial therapy, then—in addition to the usual tests for herpes, syphilis, and chancroid—biopsy is indicated to exclude donovanosis as well as carcinoma and other nonvenereal dermatoses.

TREATMENT

Ulcerative Genital or Perianal Lesions

Immediate syndrome-based treatment for acute genital ulcer (after collection of all necessary diagnostic specimens at the first visit) is often appropriate before all test results become available because patients with typical initial or recurrent episodes of genital or

TABLE 141-7 Clinical Features of Genital Ulcers

FEATURE	SYPHILIS	HERPES	CHANCROID	LYMPHOGRANULOMA VENEREUM	DONOVANOSIS
Incubation period	9–90 days	2–7 days	1–14 days	3 days–6 weeks	1–4 weeks (up to 6 months)
Early primary lesions	Papule	Vesicle	Pustule	Papule, pustule, or vesicle	Papule
Number of lesions	Usually one	Multiple	Usually multiple, may coalesce	Usually one; often not detected, despite lymphadenopathy	Variable
Diameter	5–15 mm	1–2 mm	Variable	2–10 mm	Variable
Edges	Sharply demarcated, elevated, round, or oval	Erythematous	Undermined, ragged, irregular	Elevated, round, or oval	Elevated, irregular
Depth	Superficial or deep	Superficial	Excavated	Superficial or deep	Elevated
Base	Smooth, nonpurulent, relatively nonvascular	Serous, erythematous, nonvascular	Purulent, bleeds easily	Variable, nonvascular	Red and velvety, bleeds readily
Induration	Firm	None	Soft	Occasionally firm	Firm
Pain	Uncommon	Frequently tender	Usually very tender	Variable	Uncommon
Lymphadenopathy	Firm, nontender, bilateral	Firm, tender, often bilateral with initial episode	Tender, may suppurate, loculated, usually unilateral	Tender, may suppurate, loculated, usually unilateral	None; pseudobuboes

TABLE 141-8 Initial Management of Genital or Perianal Ulcer
Causative Pathogens
HSV
Treponema pallidum (primary syphilis)
Haemophilus ducreyi (chancroid)
Usual Initial Laboratory Evaluation
Dark-field examination (if available), direct FA, or PCR for *T. pallidum*
RPR, VDRL, or EIA serologic test for syphilis[a]
Culture, direct FA, ELISA, or PCR for HSV
HSV-2-specific serology (consider)
In chancroid-endemic area: PCR or culture for *H. ducreyi*
Initial Treatment
Herpes confirmed or suspected (history or sign of vesicles):
Treat for genital herpes with acyclovir, valacyclovir, or famciclovir.
Syphilis confirmed (dark-field, FA, or PCR showing *T. pallidum*, or RPR reactive):
Benzathine penicillin (2.4 million units IM once to patient, to recent [e.g., within 3 months] seronegative partner[s], and to all recent partners)[b]
Chancroid confirmed or suspected (diagnostic test positive, or HSV and syphilis excluded, and persistent lesion):
Ciprofloxacin (500 mg PO as single dose) *or*
Ceftriaxone (250 mg IM as single dose) *or*
Azithromycin (1 g PO as single dose)

[a]If results are negative but primary syphilis is suspected, treat presumptively when indicated by epidemiologic and sexual risk assessment; repeat in 1 week. [b]The same treatment regimen is also effective in HIV-infected persons with early syphilis.

Abbreviations: EIA, enzyme immunoassay; ELISA, enzyme-linked immunosorbent assay; FA, fluorescent antibody; HSV, herpes simplex virus; PCR, polymerase chain reaction; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory.

anorectal herpes can benefit from prompt oral antiviral therapy (Chap. 197); because early treatment of sexually transmitted causes of genital ulcers decreases further transmission; and because some patients do not return for test results and treatment. A thorough assessment of the patient's sexual-risk profile and medical history is critical in determining the course of initial management. The patient who has risk factors consistent with exposure to syphilis (e.g., a male patient who reports sex with other men or who has HIV infection) should generally receive initial treatment for syphilis. Empirical therapy for chancroid should be considered if there has been an exposure in an area of the world where chancroid occurs or if regional lymph node suppuration is evident. Finally, empirical antimicrobial therapy may be indicated if ulcers persist and the diagnosis remains unclear after a week of observation despite attempts to diagnose herpes, syphilis, and chancroid.

PROCTITIS, PROCTOCOLITIS, ENTEROCOLITIS, AND ENTERITIS

Sexually acquired *proctitis*, with inflammation limited to the rectal mucosa (the distal 10–12 cm), results from direct rectal inoculation of typical STD pathogens. In contrast, inflammation extending from the rectum to the colon (*proctocolitis*), involving both the small and the large bowel (*enterocolitis*), or involving the small bowel alone (*enteritis*) can result from ingestion of typical intestinal pathogens through oral–anal exposure during sexual contact. Anorectal pain and mucopurulent, bloody rectal discharge suggest proctitis or proctocolitis. Proctitis commonly produces tenesmus (causing frequent attempts to defecate, but not true diarrhea) and constipation, whereas proctocolitis and enterocolitis more often cause true diarrhea. In all three conditions, anoscopy usually shows mucosal exudate and easily induced mucosal bleeding (i.e., a positive "wipe test"), sometimes with petechiae or mucosal ulcers. Exudate should be sampled for Gram's staining and other microbiologic studies. Sigmoidoscopy or colonoscopy shows inflammation limited to the rectum in proctitis or disease extending at least up into the sigmoid colon in proctocolitis.

Acquisition of HSV, *N. gonorrhoeae*, or *C. trachomatis* (including LGV strains of *C. trachomatis*) during receptive anorectal intercourse causes most cases of infectious proctitis in women and MSM. Primary and secondary syphilis can also produce anal or anorectal lesions, with or without symptoms. Gonococcal or chlamydial proctitis typically involves the most distal rectal mucosa and the anal crypts and is clinically mild, without systemic manifestations. In contrast, primary proctitis due to HSV and proctocolitis due to the strains of *C. trachomatis* that cause LGV usually produce severe anorectal pain and often cause fever. Perianal ulcers and inguinal lymphadenopathy, most commonly due to HSV, can also occur with LGV or syphilis. Sacral nerve root radiculopathies, usually presenting as urinary retention, laxity of the anal sphincter, or constipation, may complicate primary herpetic proctitis. In LGV, rectal biopsy typically shows crypt abscesses, granulomas, and giant cells—findings resembling those in Crohn's disease; such findings should always prompt rectal culture and serology for LGV, which is a curable infection. Syphilis can also produce rectal granulomas, usually in association with infiltration by plasma cells or other mononuclear cells. Syphilis, LGV, and HSV infection involving the rectum can produce perirectal adenopathy that is sometimes mistaken for malignancy; syphilis, LGV, HSV infection, and chancroid involving the anus can produce inguinal adenopathy because anal lymphatics drain to inguinal lymph nodes.

Diarrhea and abdominal bloating or cramping pain without anorectal symptoms and with normal findings on anoscopy and sigmoidoscopy occur with inflammation of the small intestine (enteritis) or with proximal colitis. In MSM without HIV infection, enteritis is often attributable to *Giardia lamblia*. Sexually acquired proctocolitis is most often due to *Campylobacter* or *Shigella* species.

TREATMENT

Proctitis, Proctocolitis, Enterocolitis, and Enteritis

Acute proctitis in persons who have practiced receptive anorectal intercourse is usually sexually acquired. Such patients should undergo anoscopy to detect rectal ulcers or vesicles and petechiae after swabbing of the rectal mucosa; to examine rectal exudates for PMNs and gram-negative diplococci; and to obtain rectal swab specimens for testing for rectal gonorrhea, chlamydial infection, herpes, and syphilis. Pending test results, patients with proctitis should receive empirical syndromic treatment—e.g., with ceftriaxone (a single IM dose of 500 mg for gonorrhea) plus doxycycline (100 mg by mouth twice daily for 7 days for possible chlamydial infection) plus treatment for herpes or syphilis if indicated. If LGV proctitis is proven or suspected, the recommended treatment is doxycycline (100 mg by mouth twice daily for 21 days); alternatively, 1 g of azithromycin once a week for 3 weeks is likely to be effective but is little studied.

PREVENTION AND CONTROL OF STIs

Prevention and control of STIs require the following:

1. Reduction of the average rate of sexual exposure to STIs through alteration of sexual risk behaviors and behavioral norms among both susceptible and infected persons in all population groups. The necessary changes include reduction in the total number of sexual partners and the number of concurrent sexual partners. The U.S. Preventive Services Task Force recommends intensive behavioral counseling for all sexually active adolescents and adults who are at increased risk for STIs (grade B recommendation). Motivational interviewing is one approach that has elicited behavioral changes, including safer sex practices and more consistent contraception, that contribute to these goals.
2. Reduction of the efficiency of transmission through the promotion of safer sexual practices, the use of condoms during casual or commercial sex, vaccination against HBV and HPV infection, male circumcision (which reduces risk of acquisition of HIV infection, chancroid, and perhaps other STIs), and a growing number of other approaches (e.g., early detection and treatment of other STIs to reduce the efficiency of sexual transmission of HIV; provision of

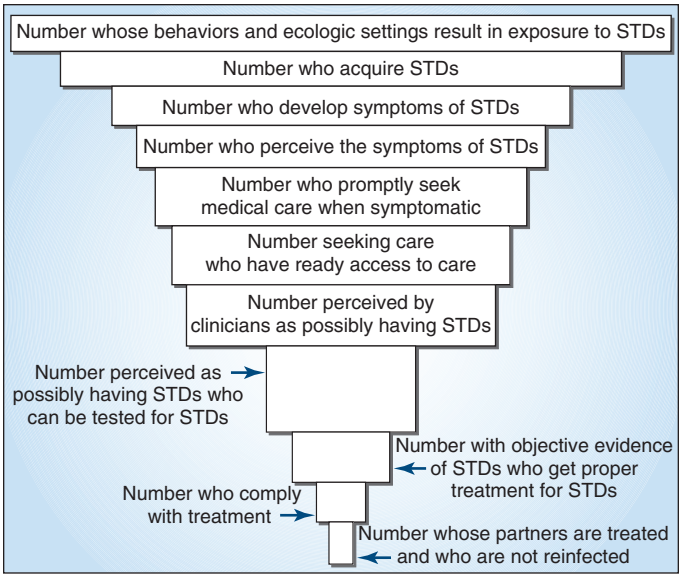

FIGURE 141-8 Critical control points for preventive and clinical interventions against sexually transmitted diseases (STDs). *(Adapted from HT Waller and MA Piot: Bull World Health Organ 41:75, 1969 and 43:1, 1970; and from "Resource allocation model for public health planning—a case study of tuberculosis control," Bull World Health Organ 48[Suppl], 1973.)*

doxycycline for PEP). Among MSM and transgender women, doxycycline PEP (200 mg taken once orally within 72 h of condomless sex, with a maximum dose of 200 mg each day) can reduce the risk of chlamydia, syphilis, and, in some studies, gonorrhea. However, studies have failed to demonstrate efficacy among cisgender women.

3. Shortening of the duration of infectivity of STIs through early detection and curative or suppressive treatment of patients and their sexual partners.

Financial and time constraints imposed by many clinical practices, along with the reluctance of some clinicians to ask questions about stigmatized sexual behaviors, often curtail screening and prevention services. As outlined in **Fig. 141-8**, the success of clinicians' efforts to detect and treat STIs depends in part on societal efforts to teach young people how to recognize symptoms of STIs; to motivate individuals with symptoms to seek care promptly; to educate persons who are at risk but have no symptoms about what tests they should undergo routinely; and to make high-quality, appropriate care accessible, affordable, and acceptable, especially to the young indigent patients most likely to acquire an STI.

STI RISK ASSESSMENT

Because many infected individuals develop no symptoms or fail to recognize and report symptoms, clinicians should routinely perform an STI risk assessment for teenagers and young adults as a guide to selective screening. As stated earlier, the U.S. Preventive Services Task Force recommends screening sexually active female patients ≤25 years of age for *C. trachomatis* whenever they present for health care (at least once a year); older women should be tested if they have more than one sexual partner, have begun a new sexual relationship since the previous test, or have another STI diagnosed. In women 25–29 years of age, chlamydial infection is uncommon but still may reach a prevalence of 3–5% in some settings; information provided by women in this age group on a sex partner's concurrency (whether a male partner has had another sex partner during the time they have been together) is helpful in identifying women at increased risk. In some regions of the United States, widespread selective screening and treatment of young women for cervical *C. trachomatis* infection have been associated with a 50–60% drop in prevalence. Such screening and treatment also protect the individual woman from PID. Sensitive urine-based genetic amplification tests permit expansion of screening to men, teenage boys, and girls in settings where examination is not planned or is impractical (e.g., during preparticipation sports examinations or during initial medical evaluation of adolescent girls). Vaginal swabs—collected either by the health care provider at a pelvic examination or by the woman herself—are highly sensitive and specific for the diagnosis of chlamydial and gonococcal infection; they are now the preferred type of specimen for screening and diagnosis of these infections.

Although gonorrhea is now substantially less common than chlamydial infection in women in industrialized countries, screening tests for *N. gonorrhoeae* are still appropriate for women and teenage girls attending STD clinics and for sexually active teens and young women from areas of high gonorrhea prevalence. Multiplex NAATs that combine screening for *N. gonorrhoeae* and *C. trachomatis*—and, more recently, for *T. vaginalis*—in a single low-cost assay now facilitate the prevention and control of these infections for populations at high risk.

All patients who have newly detected STIs or are at high risk for STIs according to routine risk assessment as well as all pregnant women should be encouraged to undergo serologic testing for syphilis and HIV infection, with appropriate counseling. Randomized trials have shown that risk-reduction counseling of patients with STIs significantly lowers subsequent risk of acquiring an STI; such counseling should now be considered a standard component of STI management. Preimmunization serologic testing for antibody to HBV is indicated for unvaccinated persons who are known to be at high risk, such as MSM and people who use injection drugs. In most young persons, however, it is more cost-effective to vaccinate against HBV without serologic screening. It is important to recognize that, while immunization against HBV has contributed to marked reductions in the incidence of infection with this virus, the majority of new cases that occur are acquired through sex. In 2006, the CDC's Advisory Committee on Immunization Practices (ACIP) recommended the following: (1) Universal hepatitis B vaccination should be implemented for all unvaccinated adults in settings in which a high proportion of adults have risk factors for HBV infection (e.g., STD clinics, HIV testing and treatment facilities, drug-abuse treatment and prevention settings, health care settings targeting services to injection drug users or MSM, and correctional facilities). (2) In other primary care and specialty medical settings that provide care to adults at risk for HBV infection, health care providers should inform all patients about the health benefits of vaccination, the risk factors for HBV infection, and the persons for whom vaccination is recommended; they should vaccinate adults who report risk factors for HBV infection as well as any adult who requests protection from HBV infection. To promote vaccination in all settings, health care providers should implement standing orders to identify adults recommended for hepatitis B vaccination, should administer hepatitis B vaccine as part of routine clinical services, should not require acknowledgment of an HBV infection risk factor for adult vaccination, and should use available reimbursement mechanisms to remove financial barriers to hepatitis B vaccination.

In 2007, the ACIP made its first recommendation for routine immunization of 9- to 26-year-old girls and women with the quadrivalent HPV vaccine (against HPV types 6, 11, 16, and 18). In 2011, the ACIP recommended routine administration of quadrivalent HPV vaccine to boys at 11 or 12 years of age and to males 13–21 years of age who have not yet been vaccinated or who have not completed the three-dose vaccine series; HBV vaccination of men 22–26 years of age has also been recommended. Since that time, a nonavalent HPV vaccine has become available and has largely replaced the earlier vaccines. Moreover, single-dose HPV vaccine has great promise to simplify implementation without compromising efficacy. The optimal age for recommended vaccination is 11–12 years because of the very high risk of HPV infection after sexual debut.

Partner management is the process of identifying and informing partners of infected patients about possible exposure to an STI and of examining, testing, vaccinating, and treating partners as appropriate. In a series of 22 reports concerning partner notification during the 1990s, index patients with gonorrhea or chlamydial infection named a mean of 0.75–1.6 partners, of whom one-fourth to one-third were infected; those with syphilis named 1.8–6.3 partners, with one-third to one-half infected; and those with HIV infection named 0.76–5.31 partners, with

up to one-fourth infected. Persons who transmit infection or who have recently been infected and are still in the incubation period usually have no symptoms or only mild symptoms and seek medical attention only when notified of their exposure. Therefore, the clinician must encourage patients to participate in partner notification, must ensure that exposed persons are notified and treated, and must guarantee confidentiality to all involved. In the United States, local health departments often offer assistance in partner notification, treatment, and/or counseling. It seems both feasible and most useful to notify those partners exposed within the patient's likely period of infectiousness, which is often considered the preceding 1 month for gonorrhea, 1–2 months for chlamydial infection, and up to 3 months for early syphilis.

Persons with a new-onset STI have a *source* contact who gave them the infection; in addition, they may have a *secondary* (*spread* or *exposed*) contact with whom they had sex after becoming infected. The identification and treatment of these two types of contacts have different objectives. Treatment of the source contact (often a casual contact) benefits the community by preventing further transmission and benefits the source contact; treatment of the recently exposed secondary contact (typically a spouse or another steady sexual partner) prevents the development of serious complications (such as PID) in the partner, reinfection of the index patient, and further spread of infection. A randomized trial compared patients' delivery of therapy to partners exposed to gonorrhea or chlamydial infection with conventional notification and advice to partners to seek evaluation for STD; patients' delivery of partners' therapy, also known as *expedited partner therapy* (EPT), significantly reduced combined rates of reinfection of the index patient with *N. gonorrhoeae* or *C. trachomatis*. EPT, which is now commonly used by many practicing physicians, is currently permissible in 46 states and potentially allowable in the remaining four. (Updated information on the legal status of EPT is available at *https://www.cdc.gov/sti/hcp/clinical-guidance/expedited-partner-therapy.html?CDC_AAref_Val=https://www.cdc.gov/std/ept/*.)

In summary, clinicians and public health agencies share responsibility for the prevention and control of STIs. In the current health care environment, the role of primary care clinicians has become increasingly important in STI prevention as well as in diagnosis and treatment, and the resurgence of bacterial STIs like congenital syphilis—particularly in the setting of HIV co-infection—emphasizes the need for risk assessment and routine screening.

142 Encephalitis

Karen L. Roos, Michael R. Wilson, Kenneth L. Tyler

DEFINITION

Encephalitis is defined as an inflammation of the brain caused either by infection, usually with a virus, or from a primary autoimmune process. This chapter will focus on infectious causes of encephalitis. Many patients with encephalitis also have evidence of associated meningitis (meningoencephalitis) and, in some cases, involvement of the spinal cord or nerve roots (encephalomyelitis, encephalomyeloradiculitis).

CLINICAL MANIFESTATIONS

Similar to meningitis, encephalitis is typically an acute febrile illness. The patient with encephalitis commonly has an altered state of consciousness (confusion, behavioral abnormalities), or a depressed level of consciousness ranging from mild lethargy to coma, and evidence of either focal or diffuse neurologic signs and symptoms. Patients with encephalitis may have hallucinations, agitation, personality change, behavioral disorders, and, at times, a frankly psychotic state. Focal or generalized seizures occur in many patients with encephalitis. Virtually every possible type of focal neurologic disturbance has been reported in viral encephalitis; the signs and symptoms reflect the sites of infection and inflammation. The most commonly encountered focal findings are aphasia, ataxia, upper or lower motor neuron patterns of weakness, involuntary movements (e.g., myoclonic jerks, tremor), and cranial nerve deficits (e.g., ocular palsies, facial weakness). Involvement of the hypothalamic-pituitary axis may result in temperature dysregulation, diabetes insipidus, or the development of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Even though neurotropic viruses typically cause injury in distinct regions of the central nervous system (CNS), variations in clinical presentations make it impossible to reliably establish the etiology of a specific case of encephalitis on clinical grounds alone (see "Differential Diagnosis," below).

ETIOLOGY

In the United States, there are an estimated ~20,000 cases of encephalitis per year, although the actual number of cases is likely to be significantly higher. Despite comprehensive diagnostic efforts, most cases of acute encephalitis with a suspected viral etiology remain of unknown cause. Hundreds of viruses are capable of causing encephalitis, although only a limited subset is responsible for most cases in which a specific cause is identified **(Table 142-1)**. The most commonly identified viruses causing sporadic cases of acute encephalitis in immunocompetent adults are herpesviruses (herpes simplex virus [HSV] **[Chap. 197]**, varicella-zoster virus [VZV] **[Chap. 198]**, and Epstein-Barr virus [EBV] **[Chap. 199]**). Epidemics of encephalitis are caused by arboviruses **(Chap. 215)**, which belong to several different viral taxonomic groups including *Alphaviruses* (e.g., eastern equine encephalitis [EEE] virus and chikungunya virus), *Flaviviruses* (e.g., West Nile virus [WNV], St. Louis encephalitis virus, Japanese encephalitis virus,

TABLE 142-1 Viruses Causing Acute Encephalitis in North America

Powassan virus, Zika virus, dengue virus, and tick-borne encephalitis virus), and *Bunyaviruses* (e.g., California encephalitis virus serogroup, La Crosse virus, Jamestown Canyon virus). Historically, the largest number of cases of arbovirus encephalitis in the United States has been due to St. Louis encephalitis virus and the California encephalitis virus serogroup. However, since 2002, WNV has been responsible for the majority of arbovirus meningitis and encephalitis cases in the United States. WNV caused 28,684 confirmed cases of neuroinvasive disease (encephalitis, meningitis, or myelitis) in the years 1999–2022 with 2641 deaths. In 2023, there were 1599 reported cases of neuroinvasive disease (encephalitis, meningitis, acute flaccid paralysis). The majority of cases occur in August and September. It is important to recognize that WNV epidemics are unpredictable and that cases have occurred in every state in the continental United States. Since 2006, there have been increasing numbers of cases of the tick-borne Powassan virus primarily in the northeastern United States and Minnesota and Wisconsin. New causes of viral CNS infections are constantly appearing, as evidenced by multiple outbreaks of cases of encephalitis in Southeast Asia caused by Nipah virus, a member of the Paramyxoviridae family; meningitis in Europe caused by Toscana virus, an arbovirus belonging to the Bunyavirus family; neurologic disorders associated with Zika virus, a flavivirus, in South America; and neurologic disorders associated with major epidemics of chikungunya virus, a togavirus, in Africa, India, and Southeast Asia. Dengue virus is common in >100 countries worldwide with cases on the rise in the Caribbean and Puerto Rico and rare cases reported in the United States in Florida and in southern Texas. Parechoviruses including human parechovirus 3 (HPeV3), members of the Picornavirus family, have been reported as causes of fever, sepsis, and meningitis in infants (age <3 months) in the United States and abroad.

LABORATORY DIAGNOSIS

CSF Examination Cerebrospinal fluid (CSF) examination should be performed in all patients with suspected viral encephalitis unless contraindicated by the presence of severely increased intracranial pressure (ICP). Ideally, at least 20 mL of the initial CSF sample should be collected, with 5–10 mL stored frozen for later studies, including additional direct detection tests like virus-specific polymerase chain reaction (PCR) or metagenomic next-generation sequencing, since many neuroinvasive viruses are only transiently present in the CSF. The characteristic CSF profile is indistinguishable from that of viral meningitis **(Chap. 143)** and typically consists of a lymphocytic pleocytosis, a mildly elevated protein concentration, and a normal glucose concentration. A CSF pleocytosis (>5 cells/μL) occurs in >95% of immunocompetent patients with documented viral encephalitis. In rare cases, a pleocytosis may be absent on the initial lumbar puncture (LP) but present on subsequent LPs. Patients who are severely immunocompromised by HIV infection, glucocorticoid or other immunosuppressant drugs, chemotherapy, or lymphoreticular malignancies may fail to mount a CSF inflammatory response. CSF cell counts exceed 500/μL in only about 10% of patients with encephalitis. Infections with certain arboviruses (e.g., EEE virus or California encephalitis virus), mumps, and lymphocytic choriomeningitis virus (LCMV) may occasionally result in cell counts >1000/μL, but this degree of pleocytosis should suggest the possibility of nonviral infections or other inflammatory processes. Atypical lymphocytes in the CSF may be seen in EBV infection and less commonly with other viruses, including cytomegalovirus (CMV), HSV, and enteroviruses. Increased numbers of plasmacytoid or Mollaret-like large mononuclear cells have been reported in WNV encephalitis. Polymorphonuclear pleocytosis occurs in ~45% of patients with WNV encephalitis and is also a common feature in CMV myeloradiculitis in immunocompromised patients. Large numbers of CSF polymorphonuclear leukocytes may be present in patients with encephalitis due to EEE virus, echovirus 9, and, more rarely, other enteroviruses. However, persisting CSF neutrophilia should prompt consideration of bacterial infection, leptospirosis, amebic infection, and noninfectious processes such as acute hemorrhagic leukoencephalitis **(Chap. 456)**. About 20% of patients with encephalitis will have a significant number of red blood cells (>500/μL) in the CSF in a nontraumatic tap. The pathologic correlate of this finding may be punctate microhemorrhages of the type seen with HSV; however, CSF red blood cells occur with similar frequency and in similar numbers in patients with nonherpetic focal encephalitides. A decreased CSF glucose concentration is distinctly unusual in viral encephalitis and should suggest the possibility of bacterial, fungal, tuberculous, parasitic, leptospiral, syphilitic, sarcoid, or neoplastic meningitis. Rare patients with mumps, LCMV, VZV, or advanced HSV encephalitis and many patients with CMV myeloradiculitis have low CSF glucose concentrations.

CSF POLYMERASE CHAIN REACTION

CSF PCR has become the primary diagnostic test for CNS infections caused by HSV, CMV, EBV, HHV-6, and enteroviruses. In the case of VZV CNS infection, CSF PCR and detection of virus-specific IgM or intrathecal antibody synthesis both provide important aids to diagnosis. The sensitivity and specificity of CSF PCRs vary with the virus being tested. The sensitivity (~96%) and specificity (~99%) of HSV CSF PCR are equivalent to or exceed those of brain biopsy. It is important to recognize that HSV CSF PCR results need to be interpreted after considering the likelihood of disease in the patient being tested, the timing of the test in relationship to onset of symptoms, and the prior use of antiviral therapy. A negative HSV CSF PCR test performed by a qualified laboratory at the appropriate time during illness in a patient with a high likelihood of HSV encephalitis based on clinical and laboratory abnormalities significantly reduces the likelihood of HSV encephalitis but does not exclude it. For example, in a patient with a pretest probability of 35% of having HSV encephalitis, a negative HSV CSF PCR reduces the posttest probability to ~2%, and for a patient with a pretest probability of 60%, a negative test reduces the posttest probability to ~6%. In both situations, a positive test makes the diagnosis almost certain (98–99%). There have been reports of initially negative HSV CSF PCR tests that were obtained early (≤72 h) following symptom onset and that became positive when repeated 1–3 days later. The frequency of positive HSV CSF PCRs in patients with herpes encephalitis also decreases as a function of the duration of illness, with only ~20% of cases remaining positive after ≥14 days. PCR results are generally not affected by ≤1 week of antiviral therapy. In one study, 98% of CSF specimens remained PCR positive during the first week of antiviral therapy, but the numbers fell to ~50% by 8–14 days and to ~21% by >15 days after initiation of antiviral therapy.

The sensitivity and specificity of CSF PCR tests for viruses other than HSV have not been definitively characterized. Enteroviral (EV) CSF RT-PCR appears to have a sensitivity and specificity of >95%. EV RT-PCR sensitivity for EV-A71 may be considerably lower (~30% in some reports). Patients with EV-D68-associated acute flaccid myelitis (AFM) only rarely have a positive CSF RT-PCR (<3%) but may have a positive test on nasopharyngeal swab specimens. Parechoviruses are also not detected by standard EV RT-PCRs. The specificity of EBV

CSF PCR has not been established. Positive EBV CSF PCRs associated with positive tests for other pathogens have been reported and may reflect reactivation of EBV latent in lymphocytes that enter the CNS as a result of an unrelated infectious or inflammatory process. In patients with CNS infection due to VZV, CSF antibody and PCR studies should be considered complementary because patients may have evidence of intrathecal synthesis of VZV-specific antibodies and negative CSF PCRs. In the case of WNV infection, CSF PCR appears to be less sensitive than detection of WNV-specific CSF IgM, although PCR testing remains useful in immunocompromised patients who may not mount an effective anti-WNV antibody response. The recent pandemic due to SARS-CoV-2 (COVID-19) has been associated with cases of encephalopathy due to the indirect effects on the nervous system of multiorgan system failure and/or to a hyperinflammatory syndrome and disseminated intravascular coagulation, but also with rare cases of true encephalitis caused by viral CNS invasion. In both sets of patients, nasopharyngeal reverse transcriptase (RT)-PCR tests for SARS-CoV-2 are positive, but only cases with encephalitis have a positive CSF RT-PCR for SARS-CoV-2. Rare cases of neuroinvasion by SARS-CoV-2 has also been detected by RT-PCR of brain tissue.

Unbiased metagenomic sequencing technologies capable of identifying infectious genomes in CSF, brain, and other tissues have recently shown great promise for rapid diagnosis of obscure cases of encephalitis and other brain infections, especially in immunocompromised patients.

CSF Culture CSF culture is generally of limited utility in the diagnosis of acute viral encephalitis. Culture may be insensitive (e.g., >95% of patients with HSV encephalitis have negative CSF cultures, as do virtually all patients with EBV-associated CNS disease) and often takes too long to significantly affect immediate therapy.

Serologic Studies and Antigen Detection For many arboviruses including WNV, serologic studies remain important diagnostic tools. Serum antibody determination is less useful for viruses with high seroprevalence rates in the general population such as HSV, VZV, CMV, and EBV. For viruses with low seroprevalence rates, diagnosis of acute viral infection can be made by documenting seroconversion between acute-phase and convalescent sera (typically obtained after 2–4 weeks) or by demonstrating the presence of virus-specific IgM antibodies. For viruses with high seroprevalence such as VZV and HSV, demonstration of synthesis of virus-specific antibodies in CSF, as shown by an increased IgG index or the presence of CSF IgM antibodies, may be useful and can provide presumptive evidence of CNS infection. Unfortunately, the delay between onset of infection and the host's generation of a virus-specific antibody response often means that serologic data are useful mainly for the retrospective establishment of a diagnosis, rather than in aiding acute diagnosis or management.

In patients with HSV encephalitis, antibodies to HSV-1 glycoproteins and HSV glycoprotein antigens have been detected in the CSF. Optimal detection of both HSV antibodies and antigen typically occurs after the first week of illness, limiting the utility of these tests in acute diagnosis. Nonetheless, HSV CSF antibody testing is of value in selected patients whose illness is >1 week in duration and who are CSF PCR negative for HSV. In the case of VZV infection, CSF IgM antibody tests may be positive when PCR fails to detect viral DNA, and both tests should be considered complementary rather than mutually exclusive.

Demonstration of CSF WNV IgM antibodies is diagnostic of WNV encephalitis because the high molecular weight of IgM antibodies restricts their passage from serum to CSF through the blood-brain barrier and their presence in CSF is therefore indicative of intrathecal synthesis. Timing of antibody testing may be important because the rate of CSF WNV IgM seropositivity increases during the first week after illness onset, reaching 80% or higher on day 7 after symptom onset. Although serum and CSF IgM antibodies generally persist for only a few months after acute infection, there are exceptions to this rule, and WNV serum IgM has been shown to persist in some patients for >1 year following acute infection.

MRI, CT, and EEG Patients with suspected encephalitis almost invariably undergo neuroimaging studies and often electroencephalogram (EEG). These tests help identify or exclude alternative diagnoses and assist in the differentiation between a focal and a diffuse encephalitic process. Specific focal findings in a patient with encephalitis should always raise the possibility of HSV encephalitis. Examples of focal findings found in HSV encephalitis include: (1) areas of increased signal intensity in the frontotemporal, cingulate, or insular regions of the brain on T2-weighted, fluid-attenuated inversion recovery (FLAIR), or diffusion-weighted magnetic resonance imaging (MRI) **(Fig. 142-1)**; (2) focal areas of low absorption, mass effect, and contrast enhancement in frontotemporal areas on computed tomography (CT); or (3) periodic focal temporal lobe spikes on a background of slow or low-amplitude ("flattened") activity on EEG. Approximately 10% of patients with PCR-documented HSV encephalitis may have a normal MRI, although nearly 80% will have asymmetric abnormalities in the temporal lobe, and an additional 10% in extratemporal regions. The addition of FLAIR and diffusion-weighted images to the standard MRI sequences enhances sensitivity. Children with HSV encephalitis may have atypical patterns of MRI lesions and often show involvement of brain regions outside the frontotemporal areas. CT is less sensitive than MRI and is normal in up to 20–35% of patients. EEG abnormalities occur in >75% of PCR-documented cases of HSV encephalitis; they typically involve the temporal lobes but are often nonspecific. Some patients with HSV encephalitis have a distinctive EEG pattern consisting of periodic, stereotyped, sharp-and-slow complexes originating in one or both temporal lobes and repeating at regular intervals of 2–3 s. The periodic complexes are typically noted between days 2 and 15 of the illness and are present in two-thirds of pathologically proven cases of HSV encephalitis.

Significant MRI abnormalities are found in only approximately two-thirds of patients with WNV encephalitis, a frequency less than that found with HSV encephalitis. When present, abnormalities often involve deep brain structures, including the thalamus, basal ganglia, and brainstem, rather than the cortex, and may only be apparent on T2/FLAIR images. Similar MRI patterns can be observed in patients infected with other arboviruses, including other flaviviruses such as Japanese encephalitis virus and St. Louis encephalitis virus, as well the *Alphavirus* EEE virus. EEGs in patients with WNV encephalitis typically show generalized slowing that may be more anteriorly prominent rather than the temporally predominant pattern of sharp or periodic discharges more characteristic of HSV encephalitis. Patients with VZV encephalitis may show multifocal areas of hemorrhagic and ischemic infarction, reflecting the tendency of this virus to produce a CNS vasculopathy rather than a true encephalitis. Immunocompromised

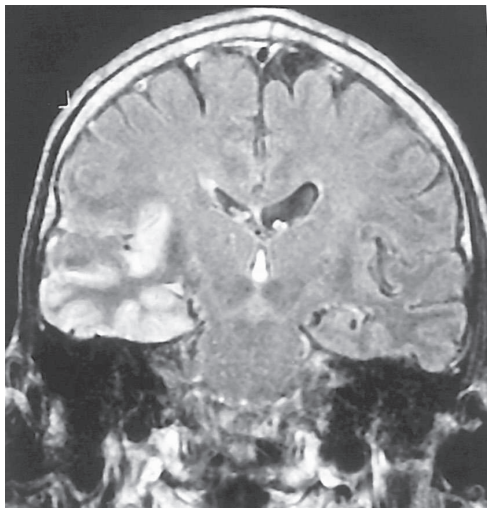

FIGURE 142-1 Coronal fluid-attenuated inversion recovery (FLAIR) magnetic resonance image from a patient with herpes simplex encephalitis. Note the area of increased signal in the right temporal lobe (*left side of image*) confined predominantly to the gray matter. This patient had predominantly unilateral disease; bilateral lesions are more common but may be quite asymmetric in their intensity.

TABLE 142-2 Use of Diagnostic Tests in Encephalitis

The best test for WNV encephalitis is the *CSF IgM antibody test.* The prevalence of positive CSF IgM tests increases by about 10% per day after illness onset and reaches 70–80% by the end of the first week. Serum WNV IgM can provide evidence for recent WNV infection, but in the absence of other findings does not establish the diagnosis of neuroinvasive disease (meningitis, encephalitis, acute flaccid paralysis).
Approximately 80% of patients with proven HSV encephalitis have *MRI* abnormalities involving the temporal lobes. This percentage likely increases to >90% when FLAIR and diffusion-weighted MRI sequences are also used. The absence of temporal lobe lesions on MRI reduces the likelihood of HSV encephalitis and should prompt consideration of other diagnostic possibilities.
The *CSF HSV PCR* test may be negative in the first 72 h of symptoms of HSV encephalitis. A repeat study should be considered in patients with an initial early negative PCR in whom diagnostic suspicion of HSV encephalitis remains high and no alternative diagnosis has yet been established.
Detection of *intrathecal synthesis* (increased CSF/serum HSV antibody ratio corrected for breakdown of the blood-brain barrier) of *HSV-specific antibody* may be useful in diagnosis of HSV encephalitis in patients in whom only late (>1 week after onset) CSF specimens are available and PCR studies are negative. Serum serology alone is of no value in diagnosis of HSV encephalitis due to the high seroprevalence rate in the general population.
Negative *CSF viral cultures* are of no value in excluding the diagnosis of HSV or EBV encephalitis.
VZV CSF IgM antibodies may be present in patients with a negative VZV CSF PCR. Both tests should be performed in patients with suspected VZV CNS disease.
The specificity of *EBV CSF PCR* for diagnosis of CNS infection is unknown. Positive tests may occur in patients with a CSF pleocytosis due to other causes. Detection of EBV CSF IgM or intrathecal synthesis of antibody to VCA supports the diagnosis of EBV encephalitis. Serologic studies consistent with acute EBV infection (e.g., IgM VCA, presence of antibodies against EA but not against EBNA) can help support the diagnosis.
In addition to broad-based PCR assays for bacterial and fungal infections, metagenomic next-generation sequencing (mNGS) allows for unbiased detection of nucleic acids from the whole range of infectious agents (except prions), which can then be confirmed by independent pathogen-specific techniques. Due to the sensitivity of this technology, there is a risk of false-positive results. As this technology becomes refined and the turnaround time faster, mNGS is likely to become a routine test on CSF for the diagnosis of encephalitis.

Abbreviations: CNS, central nervous system; CSF, cerebrospinal fluid; DWI, diffusion-weighted imaging; EA, early antigen; EBNA, EBV-associated nuclear antigen; EBV, Epstein-Barr virus; FLAIR, fluid-attenuated inversion recovery; HSV, herpes simplex virus; IgM, immunoglobulin M; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; VCA, viral capsid antibody; VZV, varicella-zoster virus; WNV, West Nile virus.

adult patients with CMV often have enlarged ventricles with areas of increased T2 signal on MRI outlining the ventricles and subependymal enhancement on T1-weighted postcontrast images. Prominent cerebellar T2/FLAIR abnormalities have been observed with Powassan virus encephalitis and in children with herpesviruses like EBV and VZV. Table 142-2 highlights specific diagnostic test results in encephalitis that can be useful in clinical decision-making.

Brain Biopsy Brain biopsy is now generally reserved for patients in whom CSF PCR studies fail to lead to a specific diagnosis and who have focal abnormalities on MRI, no serologic evidence of autoimmune disease, and continue to show progressive clinical deterioration despite treatment with acyclovir and supportive therapy.

DIFFERENTIAL DIAGNOSIS

Infection by a variety of other organisms can mimic viral encephalitis. In studies of biopsy-proven HSV encephalitis, common infectious mimics of focal viral encephalitis included mycobacteria, fungi, rickettsiae, *Listeria, Mycoplasma*, and other bacteria (including *Bartonella* sp.) as well as neurosyphilis. There are an increasing number of antibodies reported that cause autoimmune encephalitis and mimic those caused by viral infection, including those associated with antibodies against *N*-methyl-D-aspartate (NMDA) receptor, two components of the voltage-gated potassium channels/leucine-rich glioma inactivated protein-1 (LGI-1) and contracting-associated protein-like 2 (CASPR2), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), γ-aminobutyric acid (GABA) receptors, and glutamic acid decarboxylase (GAD 65) (Chap. 99). In most cases, diagnosis is made by detection of the specific autoantibodies in serum and/or CSF. NMDA receptor antibodies have been reported in up to 25% of patients who have recovered from HSV encephalitis, and their presence should not exclude appropriate testing and treatment for HSV encephalitis. The development of NMDA receptor antibodies in patients with HSV encephalitis may contribute to new or worsening symptoms in the weeks following recovery from HSV encephalitis. Autoimmune encephalitis may also be associated with specific cancers (paraneoplastic) and onconeuronal antibodies (e.g., anti-Hu, Yo, Ma2, amphiphysin, CRMP5, CV2). Subacute or chronic forms of encephalitis may occur in association with autoantibodies against thyroglobulin and thyroperoxidase (Hashimoto's encephalopathy) and with prion diseases.

Infection caused by the ameba *Naegleria fowleri* can also cause acute meningoencephalitis (primary amebic meningoencephalitis), whereas that caused by *Acanthamoeba* and *Balamuthia* more typically produces subacute or chronic granulomatous amebic meningoencephalitis. *Naegleria* thrive in warm, iron-rich pools of water, including those found in drains, canals, and both natural and human-made outdoor pools (Chap. 230). Infection has typically occurred in immunocompetent children with a history of swimming in potentially infected water. The CSF, in contrast to the typical profile seen in viral encephalitis, often resembles that of bacterial meningitis with a neutrophilic pleocytosis and hypoglycorrhachia. Motile trophozoites can be seen in a wet mount of warm, fresh CSF. There have been an increasing number of cases of *Balamuthia mandrillaris* amebic encephalitis in children and immunocompetent adults, mimicking acute viral encephalitis. This organism has also been associated with encephalitis in recipients of transplanted organs from a donor with unrecognized infection. No effective treatment has been approved, and mortality approaches 100%. There have been a few case reports of patients who recovered with nitroxoline therapy.

Encephalitis can be caused by the raccoon pinworm *Baylisascaris procyonis*. Clues to the diagnosis include a history of raccoon exposure, especially of playing in or eating dirt potentially contaminated with raccoon feces. Most patients are children, and many have an associated eosinophilia.

Once nonviral causes of encephalitis have been excluded, the major diagnostic challenge is to distinguish HSV from other viruses that cause encephalitis. This distinction is particularly important because in virtually every other instance the therapy is supportive, whereas specific and effective antiviral therapy is available for HSV, and its efficacy is enhanced when it is instituted early in the course of infection. HSV encephalitis should be considered when clinical features suggest involvement of the inferomedial frontotemporal regions of the brain, including prominent olfactory or gustatory hallucinations, anosmia, unusual or bizarre behavior or personality alterations, or memory disturbance. HSV encephalitis should always be suspected in patients with signs and symptoms consistent with acute encephalitis who have focal findings on clinical examination, neuroimaging studies, or EEG. The diagnostic procedure of choice in these patients is CSF PCR analysis for HSV. A positive CSF PCR establishes the diagnosis, and a negative test dramatically reduces the likelihood of HSV encephalitis (see above).

The anatomic distribution of lesions may provide an additional clue to diagnosis. Patients with rapidly progressive encephalitis and prominent brainstem signs, symptoms, or neuroimaging abnormalities may be infected by flaviviruses (WNV, St. Louis encephalitis virus, Japanese encephalitis virus), HSV, enterovirus A71 (EV-A71), rabies, or *Listeria monocytogenes*. Significant involvement of deep gray matter structures, including the basal ganglia and thalamus, should also suggest possible flavivirus infection. These patients may present clinically with prominent movement disorders (tremor, myoclonus) or other parkinsonian features. Patients with WNV infection can also present with a poliomyelitis-like AFM, as can patients infected with EV-A71, EV-D68, and less commonly, other enteroviruses. Acute flaccid paralysis is characterized by the acute onset of a lower motor neuron type of weakness with flaccid tone, reduced or absent reflexes, and relatively

preserved sensation. Patients often have multisegmental increased FLAIR and T2 signal in the anterior horns of the spinal cord and a CSF lymphocytic pleocytosis.

Epidemiologic factors may provide important clues to the diagnosis of viral encephalitis. Particular attention should be paid to the season of the year; the geographic location and travel history; and possible exposure to animal bites or scratches, rodents, and ticks. Although transmission from the bite of an infected dog remains the most common cause of rabies **(Chap. 214)** worldwide, in the United States very few cases of dog rabies occur, and the most common risk factor is exposure to bats—although a clear history of a bite or scratch is often lacking. The classic clinical presentation of encephalitic (furious) rabies is fever, fluctuating consciousness, and autonomic hyperactivity. Phobic spasms of the larynx, pharynx, neck muscles, and diaphragm can be triggered by attempts to swallow water (*hydrophobia*) or by inspiration (*aerophobia*). Patients may also present with paralytic (dumb) rabies characterized by acute ascending paralysis. Rabies due to the bite of a bat has a different clinical presentation than classic rabies due to a dog or wolf bite. Patients present with focal neurologic deficits, myoclonus, seizures, and hallucinations; phobic spasms are not a typical feature. Patients with rabies have a CSF lymphocytic pleocytosis and may show areas of increased T2 signal abnormality in the brainstem, hippocampus, and hypothalamus. Diagnosis can be made by finding rabies virus antigen in brain tissue or in the neural innervation of hair follicles at the nape of the neck. PCR amplification of viral nucleic acid from CSF and saliva or tears may also enable diagnosis. Serology is frequently negative in both serum and CSF in the first week after onset of infection, which limits its acute diagnostic utility. No specific therapy is available, and cases are almost invariably fatal, with isolated survivors having devastating neurologic sequelae.

State public health authorities provide a valuable resource concerning isolation of particular agents in individual regions. Regular updates concerning the number, type, and distribution of cases of arboviral encephalitis can be found on the Centers for Disease Control and Prevention and U.S. Geological Survey (USGS) websites (*http://www.cdc.gov* and *http://diseasemaps.usgs.gov*).

TREATMENT

Viral Encephalitis

Specific antiviral therapy should be initiated when appropriate. Vital functions, including respiration and blood pressure, should be monitored continuously and supported as required. In the initial stages of encephalitis, many patients will require care in an intensive care unit. Basic management and supportive therapy should include careful monitoring of ICP, fluid restriction, avoidance of hypotonic intravenous solutions, and suppression of fever. Seizures should be treated with standard anticonvulsant regimens, and prophylactic therapy should be considered in view of the high frequency of seizures in severe cases of encephalitis. As with all seriously ill, immobilized patients with altered levels of consciousness, encephalitis patients are at risk for aspiration pneumonia, stasis ulcers and decubiti, contractures, deep venous thrombosis and its complications, and infections of indwelling lines and catheters.

Acyclovir is of benefit in the treatment of HSV and should be started empirically in patients with suspected viral encephalitis, especially if focal features are present, while awaiting viral diagnostic studies. Treatment should be discontinued in patients found not to have HSV encephalitis, with the possible exception of patients with severe encephalitis due to VZV or EBV. HSV, VZV, and EBV all encode an enzyme deoxypyrimidine (thymidine) kinase that phosphorylates acyclovir to produce acyclovir-5′-monophosphate. Host cell enzymes then phosphorylate this compound to form a triphosphate derivative. It is the triphosphate that acts as an antiviral agent by inhibiting viral DNA polymerase and by causing premature termination of nascent viral DNA chains. The specificity of action depends on the fact that uninfected cells do not phosphorylate significant amounts of acyclovir to acyclovir-5′-monophosphate. A second level of specificity is provided by the fact that the acyclovir triphosphate is a more potent inhibitor of viral DNA polymerase than of the analogous host cell enzymes.

Adults should receive a dose of 10 mg/kg of acyclovir intravenously every 8 h (30 mg/kg per day total dose) for 21 days. Neonatal HSV CNS infection is less responsive to acyclovir therapy than HSV encephalitis in adults; it is recommended that neonates with HSV encephalitis receive 20 mg/kg of acyclovir every 8 h (60 mg/kg per day total dose) for a minimum of 21 days.

Prior to intravenous administration, acyclovir should be diluted to a concentration ≤7 mg/mL. (A 70-kg person would receive a dose of 700 mg, which would be diluted in a volume of 100 mL.) Each dose should be infused slowly over 1 h, rather than by rapid or bolus infusion, to minimize the risk of renal dysfunction. Care should be taken to avoid extravasation or intramuscular or subcutaneous administration. The alkaline pH of acyclovir can cause local inflammation and phlebitis (9%). Dose adjustment is required in patients with impaired renal glomerular filtration. Penetration into CSF is excellent, with average drug levels ~50% of serum levels. Complications of therapy include elevations in blood urea nitrogen and creatinine levels (5%), thrombocytopenia (6%), gastrointestinal toxicity (nausea, vomiting, diarrhea) (7%), and neurotoxicity (lethargy or obtundation, disorientation, confusion, agitation, hallucinations, tremors, seizures) (1%). Acyclovir resistance may be mediated by changes in either the viral deoxypyrimidine kinase or DNA polymerase. To date, acyclovir-resistant isolates have not been a significant clinical problem in immunocompetent individuals. It is now appreciated that some patients with worsening symptoms in the weeks following recovery from HSV encephalitis have developed NMDA receptor encephalitis requiring immunosuppression rather than having developed an acyclovir-resistant isolate. However, there have been reports of clinically virulent acyclovir-resistant HSV isolates from sites outside the CNS in immunocompromised individuals, including those with AIDS.

Oral antiviral drugs with efficacy against HSV, VZV, and EBV, including acyclovir, famciclovir, and valacyclovir, have not been evaluated in the treatment of encephalitis as primary therapy. Additional oral valaciclovir following a 14- to 21-day course of intravenous acyclovir does not improve outcomes in adult patients with HSV encephalitis. The role of adjunctive intravenous glucocorticoids in treatment of HSV and VZV infection remains unclear. Experimental models and case reports of HSV encephalitis suggest that glucocorticoids may be efficacious, although no data from randomized controlled human trials are available. Ganciclovir and foscarnet, as combination therapy, are used in the treatment of CMV-related CNS infections. Cidofovir (see below) may provide an alternative in patients who fail to respond to ganciclovir and foscarnet, although data concerning its use in CMV CNS infections are extremely limited.

Ganciclovir is a synthetic nucleoside analogue of 2′-deoxyguanosine. The drug is preferentially phosphorylated by virus-induced cellular kinases. Ganciclovir triphosphate acts as a competitive inhibitor of the CMV DNA polymerase, and its incorporation into nascent viral DNA results in premature chain termination. Following intravenous administration, CSF concentrations of ganciclovir are 25–70% of coincident plasma levels. The usual dose for treatment of severe neurologic illnesses is 5 mg/kg every 12 h given intravenously at a constant rate over 1 h. Induction therapy is followed by maintenance therapy of 5 mg/kg every day for an indefinite period. Induction therapy should be continued until patients show a decline in CSF pleocytosis and a reduction in CSF CMV DNA copy number on quantitative PCR testing (where available). Doses should be adjusted in patients with renal insufficiency. Treatment is often limited by the development of granulocytopenia and thrombocytopenia (20–25%), which may require reduction in or discontinuation of therapy. Gastrointestinal side effects, including nausea, vomiting, diarrhea, and abdominal pain, occur in ~20% of patients. Some patients treated with ganciclovir for CMV retinitis have developed retinal detachment, but the causal relationship to

ganciclovir treatment is unclear. Valganciclovir is an orally bioavailable prodrug that can generate high serum levels of ganciclovir, although studies of its efficacy in treating CMV CNS infections are limited.

Foscarnet is a pyrophosphate analogue that inhibits viral DNA polymerases by binding to the pyrophosphate-binding site. Following intravenous infusion, CSF concentrations range from 15 to 100% of coincident plasma levels. The usual dose for serious CMV-related neurologic illness is 60 mg/kg every 8 h administered by constant infusion over 1 h. Induction therapy for 14–21 days is followed by maintenance therapy (60–120 mg/kg per day). Induction therapy may need to be extended in patients who fail to show a decline in CSF pleocytosis and a reduction in CSF CMV DNA copy number on quantitative PCR tests (where available). Approximately one-third of patients develop renal impairment during treatment, which is reversible following discontinuation of therapy in most, but not all, cases. This is often associated with elevations in serum creatinine and proteinuria and is less frequent in patients who are adequately hydrated. Many patients experience fatigue and nausea. Reductions in serum calcium, magnesium, and potassium occur in ~15% of patients and may be associated with tetany, cardiac rhythm disturbances, or seizures.

Cidofovir is a nucleotide analogue that is effective in treating CMV retinitis and equivalent to or better than ganciclovir in some experimental models of murine CMV encephalitis, although data concerning its efficacy in human CMV CNS disease are limited. The usual dose is 5 mg/kg intravenously once weekly for 2 weeks, then biweekly for two or more additional doses, depending on clinical response. Patients must be prehydrated with normal saline (e.g., 1 L over 1–2 h) prior to each dose and treated with probenecid (e.g., 1 g 3 h before cidofovir and 1 g 2 and 8 h after cidofovir). Nephrotoxicity is common; the dose should be reduced if renal function deteriorates.

Intravenous ribavirin (15–25 mg/kg per day in divided doses given every 8 h) has been reported to be of benefit in isolated cases of severe encephalitis due to California encephalitis (La Crosse) virus. Ribavirin might be of benefit for the rare patients, typically infants or young children, with severe adenovirus or rotavirus encephalitis and in patients with encephalitis due to LCMV or other arenaviruses. However, clinical trials are lacking. Hemolysis, with resulting anemia, has been the major side effect limiting therapy.

No specific antiviral therapy of proven efficacy is currently available for treatment of WNV encephalitis. Patients have been treated with interferon-α, ribavirin, an Israeli IVIg preparation that contains high-titer anti-WNV antibody (Omr-IgG-am), and humanized monoclonal antibodies directed against the viral envelope glycoprotein (*www.clinicaltrials.gov*, identifiers NCT00927953 and 00515385). Omr-IgG-am did not improve outcomes in patients with WNV neuroinvasive disease, but the study design was potentially flawed as some patients received drug up to a week after symptom onset, when expected benefit may have been minimal. Of the six West Nile virus human vaccines that advanced into phase I clinical trials, only two live attenuated virus vaccines have advanced to phase II clinical trials. There has been success with four equine vaccines, but all require multiple primary doses and annual boosters. The ideal human WNV vaccine needs to provide complete and long-lasting protective immunity after the administration of a single dose. Effective vaccines are already in human use for prevention of other flavivirus infections including Japanese encephalitis and yellow fever.

The Centers for Disease Control and Prevention (CDC) Clinical Considerations for COVID-19 treatment in outpatients as of January 2024 state that the preferred treatment for mild to moderate COVID-19 infection in adults is oral ritonavir-boosted nirmatrelvir. This antiviral is U.S. Food and Drug Administration (FDA) approved in adults with mild-to-moderate COVID-19 with symptoms of <5 days in duration who are at high risk of developing severe COVID-19 due to older age (>50 years) or other risk factors. It has also been approved under emergency use authorization (EUA) for 12- to 17-year-olds. A 3-day course of intravenous remdesivir is the second preferred treatment option after ritonavir-boosted nirmatrelvir for adults and pediatric patients as young as 28 days. Immunocompromised patients may be treated with longer or additional courses. The FDA has issued an EUA for the use of COVID-19 convalescent plasma with high titers of anti–SARS-CoV-2 antibodies for the treatment of COVID-19 in immunocompromised patients from disease or immunosuppressive therapy. The antiviral molnupiravir can be used for therapy according to the CDC but has been less effective in clinical trials than ritonavir-boosted nirmatrelvir or remdesivir.

SEQUELAE

There is considerable variation in the incidence and severity of sequelae in patients surviving viral encephalitis. In the case of EEE virus infection, nearly 80% of survivors have severe neurologic sequelae. At the other extreme are infections due to EBV, California encephalitis virus, and Venezuelan equine encephalitis virus, where severe sequelae are unusual. For example, ~5–15% of children infected with La Crosse virus have a residual seizure disorder, and 1% have persistent hemiparesis. Detailed information about sequelae in patients with HSV encephalitis treated with acyclovir is available from the NIAID-Collaborative Antiviral Study Group (CASG) trials. Of 32 acyclovir-treated patients, 26 survived (81%). Of the 26 survivors, 12 (46%) had no or only minor sequelae, 3 (12%) were moderately impaired (gainfully employed but not functioning at their previous level), and 11 (42%) were severely impaired (requiring continuous supportive care). The incidence and severity of sequelae were directly related to the age of the patient and the level of consciousness at the time of initiation of therapy. Patients with severe neurologic impairment (Glasgow Coma Scale score 6) at initiation of therapy either died or survived with severe sequelae. Young patients (<30 years) with good neurologic function at initiation of therapy did substantially better (100% survival, 62% with no or mild sequelae) compared with their older counterparts (>30 years; 64% survival, 57% no or mild sequelae). Many patients with WNV infection have sequelae, including cognitive impairment; weakness; and hyper- or hypokinetic movement disorders, including tremor, myoclonus, and parkinsonism. In a large longitudinal study of prognosis in 156 patients with WNV infection, the mean time to achieve recovery (defined as 95% of maximal predicted score on specific validated tests) was 112–148 days for fatigue, 121–175 days for physical function, 131–139 days for mood, and 302–455 days for mental function (the longer interval in each case representing patients with invasive CNS disease).

CHRONIC ENCEPHALITIS

PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY

Clinical Features and Pathology Progressive multifocal leukoencephalopathy (PML) is characterized pathologically by multifocal areas of demyelination of varying size distributed throughout the brain but sparing the spinal cord and optic nerves. In addition to demyelination, there are characteristic cytologic alterations in both astrocytes and oligodendrocytes. Astrocytes are enlarged and contain hyperchromatic, deformed, and bizarre nuclei and frequent mitotic figures. Oligodendrocytes have enlarged, densely staining nuclei that contain viral inclusions formed by crystalline arrays of JC virus (JCV) particles. Patients often present with visual deficits (45%), typically a homonymous hemianopia; mental impairment (38%) (dementia, confusion, personality change); weakness, including hemi- or monoparesis; and ataxia. Seizures occur in ~20% of patients, predominantly in those with lesions abutting the cortex.

Almost all patients have an underlying immunosuppressive disorder or are receiving immunomodulatory therapy. The most common immunosuppressive disorder associated with PML is AIDS, followed by hematologic malignancies, solid organ and hematopoietic stem cell transplant, and chronic inflammatory diseases, including sarcoidosis. It

has been estimated that up to 5% of AIDS patients will develop PML. There has been considerable progress in the development of disease-modifying therapies (DMTs) for multiple sclerosis and inflammatory bowel disease. Of the DMTs, the highest risk of PML is associated with natalizumab, a humanized monoclonal antibody that inhibits lymphocyte trafficking into CNS and bowel mucosa by binding to α_4 integrins. Overall risk in these patients has been estimated at ~4 PML cases per 1000 treated patients, but the risk depends on a variety of factors including anti-JCV antibody serostatus and the magnitude of the JCV antibody response, prior immunosuppressive therapy use, and duration of natalizumab therapy. Patients who lack detectable JCV antibody have a risk of developing PML of <0.1 case/1000 patients, whereas those who are JCV seropositive and have been exposed to prior immunosuppressive therapy and have received >24 months of natalizumab therapy have a risk of >1.3 cases/100 treated patients. Some recent studies suggest that extended dosing interval regimens of natalizumab (at 6- to 8-week intervals rather than the conventional 4-week interval) may significantly reduce the risk of PML. Among JCV-seropositive individuals, those with higher JCV antibody index values, presumably due to the "immunizing" effects of more frequent JCV reactivations, appear to be at higher risk than those with low antibody indices. Alternative therapies are preferred in patients who are JCV seropositive. PML cases have also been reported in patients receiving other immunomodulatory agents including rituximab, ocrelizumab, fingolimod, and dimethyl fumarate, although the relative risks have not been clearly established, and many individual cases are complicated by previous exposure to other therapies including natalizumab. Prolonged lymphopenia, a side effect of dimethyl fumarate, is associated with an increased risk of PML. The basic clinical and diagnostic features appear to be similar in HIV-associated PML and PML associated with immunomodulatory drugs with the exception of an increased likelihood of MRI enhancement of PML lesions in immunomodulatory cases. In natalizumab-associated PML, patients will also almost invariably develop clinical and radiographic worsening of lesions with discontinuation of therapy, attributed to development of immune reconstitution inflammatory syndrome (IRIS).

Diagnostic Studies The diagnosis of PML is frequently suggested by MRI. MRI reveals multifocal asymmetric, coalescing white matter lesions located periventricularly, in the centrum semiovale, in the parietal-occipital region, and in the cerebellum. These lesions have increased signal on T2 and FLAIR images and decreased signal on T1-weighted images. HIV-PML lesions are classically nonenhancing (90%), but patients with immunomodulatory drug-associated PML may have peripheral ring enhancement. PML lesions are not typically associated with edema or mass effect. CT scans, which are less sensitive than MRI for the diagnosis of PML, often show hypodense nonenhancing white matter lesions. JCV infection may also induce rare cases of encephalitis and cerebellitis in immunocompromised patients that are distinct from PML and have differing neuroimaging features.

The CSF is typically normal, although mild elevation in protein and/or IgG may be found. Pleocytosis occurs in <25% of cases, is predominantly mononuclear, and rarely exceeds 25 cells/μL. PCR amplification of JCV DNA from CSF has become an important diagnostic tool. The presence of a positive CSF PCR for JCV DNA in association with typical MRI lesions in the appropriate clinical setting is diagnostic of PML, reflecting the assay's relatively high specificity (92–100%); however, sensitivity is variable, and a negative CSF PCR does not exclude the diagnosis. In HIV-negative patients and HIV-positive patients not receiving antiretroviral therapy (ART), sensitivity is likely 70–90%. In ART-treated patients, sensitivity may be closer to 60%, reflecting the lower JCV CSF viral load in this relatively more immunocompetent group. Patients with natalizumab-associated PML have highly variable amounts of JCV DNA in CSF. Some patients may have negative CSF PCRs performed in commercial laboratories, where assay detection thresholds are typically >100 JCV DNA copies/μL, but positive results in reference laboratories using supersensitive techniques (detection of 10 JCV copies/μL or less). CSF studies with quantitative JCV PCR indicate that patients with low JCV loads (<100 copies/μL) have a generally better prognosis than those with higher viral loads. Patients with negative CSF PCR studies may require brain biopsy for definitive diagnosis. In biopsy or necropsy specimens of brain, JCV antigen and nucleic acid can be detected by immunocytochemistry, in situ hybridization, or PCR amplification.

Serologic studies of JCV antibody are of modest value in diagnosis of PML due to the high basal seroprevalence level, although the absence of detectable JCV antibody may be useful in reducing the likelihood of PML in the differential diagnosis, as PML results from viral reactivation in previously infected individuals and virtually all confirmed cases have been JCV seropositive at diagnosis. Antibody testing may also be useful in risk stratification of patients receiving immunomodulatory therapies.

TREATMENT

Progressive Multifocal Leukoencephalopathy

No consistently effective therapy for PML is available. There are case reports of potential beneficial effects of the 5-HT_{2a} receptor antagonist mirtazapine, which may inhibit binding of JCV to its receptor on oligodendrocytes. Retrospective noncontrolled studies have also suggested a possible beneficial effect of treatment with interferon-α. Neither of these agents has been tested in randomized controlled clinical trials. A prospective multicenter clinical trial to evaluate the efficacy of the antimalarial drug mefloquine failed to show benefit. Intravenous and/or intrathecal cytarabine were not shown to be of benefit in a randomized controlled trial in HIV-associated PML, although some experts suggest that cytarabine may have therapeutic efficacy in situations where breakdown of the blood-brain barrier allows sufficient CSF penetration. A randomized controlled trial of cidofovir in HIV-associated PML also failed to show significant benefit. Because PML almost invariably occurs in immunocompromised individuals, any therapeutic interventions designed to enhance or restore immunocompetence should be considered; a small series of patients treated with the PD-1 inhibitor pembrolizumab demonstrated clinical improvement and stabilization. Positive results in small case series have also been reported in patients receiving infusions of BK or JC virus–specific cytotoxic T lymphocytes. Perhaps the most dramatic demonstration of the benefit of restoring immune competence is disease stabilization and, in rare cases, improvement associated with an improved immune status of HIV-positive patients with AIDS following institution of ART. In HIV-positive PML patients treated with ART, 1-year survival is ~50%, although up to 80% of survivors may have significant neurologic sequelae. HIV-positive PML patients with higher CD4 counts (>300/μL) and low or nondetectable HIV viral loads have a better prognosis than those with lower CD4 counts and higher viral loads. Although institution of ART enhances survival in HIV-positive PML patients, the associated immune reconstitution in patients with an underlying opportunistic infection such as PML may also result in a severe CNS inflammatory syndrome (IRIS) associated with clinical worsening, CSF pleocytosis, and the appearance of new enhancing MRI lesions. Patients receiving natalizumab or other immunomodulatory therapies who are suspected of having PML should have therapy immediately halted. Patients should be closely monitored for development of IRIS, which is generally treated with intravenous glucocorticoids, although controlled clinical trials of efficacy remain lacking.

SUBACUTE SCLEROSING PANENCEPHALITIS

Subacute sclerosing panencephalitis (SSPE) is a rare, chronic, progressive demyelinating disease of the CNS associated with a chronic nonpermissive infection of brain tissue with measles virus. The frequency has been estimated at 1 in 100,000–500,000 measles cases. An average of five cases per year is reported in the United States. The incidence has declined dramatically since the introduction of a measles vaccine, but we may expect a rise in cases over the coming decades with increasing vaccine hesitancy and rising measles cases in the United States and

Europe in children from countries where routine childhood immunizations are not available. Most patients give a history of primary measles infection at an early age (2 years), which is followed after a latent interval of 6–8 years by the development of a progressive neurologic disorder. Some 85% of patients are between 5 and 15 years old at diagnosis. Initial manifestations include poor school performance and mood and personality changes. Typical signs of a CNS viral infection, including fever and headache, do not occur. As the disease progresses, patients develop progressive intellectual deterioration, focal and/or generalized seizures, myoclonus, ataxia, and visual disturbances. In the late stage of the illness, patients are unresponsive, quadriparetic, and spastic, with hyperactive tendon reflexes and extensor plantar responses.

Diagnostic Studies MRI is often normal early, although areas of increased T2 signal develop in the white matter of the brain and brainstem as disease progresses. The EEG may initially show only nonspecific slowing, but with disease progression, patients develop a characteristic periodic pattern with bursts of high-voltage, sharp, slow waves every 3–8 s, followed by periods of attenuated ("flat") background. The CSF is acellular with a normal or mildly elevated protein concentration and a markedly elevated gamma globulin level (>20% of total CSF protein). CSF antimeasles antibody levels are invariably elevated, and oligoclonal antimeasles antibodies are often present. Measles virus can be cultured from brain tissue using special cocultivation techniques. Viral antigen can be identified immunocytochemically, and viral genome can be detected by in situ hybridization or PCR amplification.

TREATMENT

Subacute Sclerosing Panencephalitis

No definitive therapy for SSPE is available. Treatment with isoprinosine (Inosiplex, 100 mg/kg per day), alone or in combination with intrathecal or intraventricular interferon-α, has been reported to prolong survival and produce clinical improvement in some patients but has never been subjected to a controlled clinical trial.

PROGRESSIVE RUBELLA PANENCEPHALITIS

This is an extremely rare disorder that primarily affects males with congenital rubella syndrome, although isolated cases have been reported following childhood rubella. After a latent period of 8–19 years, patients develop progressive neurologic deterioration. The manifestations are similar to those seen in SSPE. CSF shows a mild lymphocytic pleocytosis, slightly elevated protein concentration, markedly increased gamma globulin, and rubella virus–specific oligoclonal bands. No therapy is available. Universal prevention of both congenital and childhood rubella through the use of the available live attenuated rubella vaccine would be expected to eliminate the disease.

143 Acute Meningitis

Karen L. Roos, Kenneth L. Tyler

BACTERIAL MENINGITIS

DEFINITION

Bacterial meningitis is an acute purulent infection within the subarachnoid space (SAS). It is associated with a central nervous system (CNS) inflammatory reaction that may result in decreased consciousness, seizures, raised intracranial pressure (ICP), and stroke. The meninges, SAS, and brain parenchyma are all frequently involved in the inflammatory reaction (*meningoencephalitis*).

EPIDEMIOLOGY

Bacterial meningitis is the most common form of suppurative CNS infection, with an annual incidence in the United States of ~1.4 cases/100,000 population. The organisms most often responsible for community-acquired bacterial meningitis are *Streptococcus pneumoniae* (~50%), *Neisseria meningitidis* (~25%), group B streptococci (~15%), and *Listeria monocytogenes* (~10%). *Haemophilus influenzae* type b accounts for <10% of cases of bacterial meningitis in most series. *N. meningitidis* is the causative organism of recurring epidemics of meningitis every 8–12 years.

ETIOLOGY

S. pneumoniae **(Chap. 151)** is the most common cause of meningitis in adults >20 years of age, accounting for nearly half the reported cases (1.1 per 100,000 persons per year). There are a number of predisposing conditions that increase the risk of pneumococcal meningitis, the most important of which is pneumococcal pneumonia. Additional risk factors include coexisting acute or chronic pneumococcal sinusitis or otitis media, alcoholism, diabetes, splenectomy, hypogammaglobulinemia, complement deficiency, and head trauma with basilar skull fracture and cerebrospinal fluid (CSF) rhinorrhea. The mortality rate remains ~20% despite antibiotic therapy.

The incidence of meningitis due to *N. meningitidis* **(Chap. 160)** has decreased with the routine immunization of 11- to 18-year-olds with the quadrivalent (serogroups A, C, W-135, and Y) meningococcal glycoconjugate vaccine, and adolescents and young adults (16–23 years old) with the serogroup B meningococcal vaccine. A pentavalent meningococcal vaccine (serogroups A, B, C, W-135, and Y) has recently become available. Individuals being treated with complement inhibitors are at increased risk of meningococcal disease and should receive either the quadrivalent vaccine and a serogroup B meningococcal vaccine, or the pentavalent meningococcal vaccine, prior to beginning therapy. Individuals with complement component deficiencies are at increased risk for meningococcal disease and similarly should receive either the quadrivalent and a serogroup B meningococcal vaccine or the pentavalent meningococcal vaccine. The meningococcal vaccines use outer membrane proteins as the vaccine antigens. The serogroup B polysaccharide capsule is poorly immunogenic. The serogroup B meningococcal vaccines do not reduce the risk of bacterial spread of group B meningococcus from vaccinated persons to *unimmunized* persons as the vaccines do not significantly reduce nasopharyngeal carriage of meningococci, and this remains the major source of person-to-person bacterial transmission. In contrast, nasopharyngeal carriage is reduced in vaccinated individuals who have received the conjugate vaccines that cover groups A, C, W, and Y. The presence of petechial or purpuric skin lesions can provide an important clue to the diagnosis of meningococcal infection. In some patients, the disease is fulminant, progressing to death within hours of symptom onset. Infection may be initiated by nasopharyngeal colonization, which can result in either an asymptomatic carrier state or invasive meningococcal disease. The risk of invasive disease following nasopharyngeal colonization depends on both bacterial virulence factors and host immune defense mechanisms, including the host's capacity to produce antimeningococcal antibodies

and to lyse meningococci by both classic and alternative complement pathways. Individuals with deficiencies of any of the complement components, including properdin, are highly susceptible to meningococcal infections.

Gram-negative bacilli cause meningitis in individuals with chronic and debilitating diseases such as diabetes, cirrhosis, or alcoholism and in those with urinary tract infections. Gram-negative meningitis can also complicate neurosurgical procedures, particularly craniotomy, and head trauma associated with CSF rhinorrhea or otorrhea.

Otitis, mastoiditis, and sinusitis are predisposing and associated conditions for meningitis due to *Streptococcus* spp., gram-negative anaerobes, *Staphylococcus aureus, Haemophilus* spp., and Enterobacteriaceae. Meningitis complicating endocarditis may be due to viridans streptococci, *S. aureus, Streptococcus bovis,* the HACEK group (*Haemophilus* spp., *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, Kingella kingae*), or enterococci.

Group B streptococcus., or *Streptococcus agalactiae* **(Chap. 153)**, was previously responsible for meningitis predominantly in neonates, but it has been reported with increasing frequency in individuals aged >50 years, particularly those with underlying diseases.

L. monocytogenes **(Chap. 156)** is an increasingly important cause of meningitis in neonates (<1 month of age), pregnant women, individuals >60 years, and immunocompromised individuals of all ages. Infection is acquired by ingesting foods contaminated by *Listeria*. Foodborne human listerial infection has been reported from contaminated coleslaw, milk, soft cheeses, and several types of "ready-to-eat" foods, including delicatessen meat and uncooked hotdogs.

The frequency of *H. influenzae* type b (Hib) meningitis in children has declined dramatically since the introduction of the Hib conjugate vaccine, although rare cases of Hib meningitis in vaccinated children have been reported. More frequently, *H. influenzae* causes meningitis in unvaccinated children and older adults, and non-b *H. influenzae* is an emerging pathogen **(Chap. 162)**.

S. aureus and coagulase-negative staphylococci **(Chap. 152)** are important causes of meningitis that occurs following invasive neurosurgical procedures, particularly shunting procedures for hydrocephalus, or as a complication of the use of subcutaneous Ommaya reservoirs for administration of intrathecal chemotherapy.

PATHOPHYSIOLOGY

The most common bacteria that cause meningitis, *S. pneumoniae* and *N. meningitidis*, initially colonize the nasopharynx by attaching to nasopharyngeal epithelial cells. Bacteria are transported across epithelial cells in membrane-bound vacuoles to the intravascular space or invade the intravascular space by creating separations in the apical tight junctions of columnar epithelial cells. Once in the bloodstream, bacteria are able to avoid phagocytosis by neutrophils and classic complement-mediated bactericidal activity because of the presence of a polysaccharide capsule. Bloodborne bacteria can reach the intraventricular choroid plexus, directly infect choroid plexus epithelial cells, and gain access to the CSF. Some bacteria, such as *S. pneumoniae*, can adhere to cerebral capillary endothelial cells and subsequently migrate through or between these cells to reach the CSF. Bacteria are able to multiply rapidly within CSF because of the absence of effective host immune defenses. Normal CSF contains few white blood cells (WBCs) and relatively small amounts of complement proteins and immunoglobulins. The paucity of the latter two prevents effective opsonization of bacteria, an essential prerequisite for bacterial phagocytosis by neutrophils. Phagocytosis of bacteria is further impaired by the fluid nature of CSF, which is less conducive to phagocytosis than a solid tissue substrate.

A critical event in the pathogenesis of bacterial meningitis is the inflammatory reaction induced by the invading bacteria. Many of the neurologic manifestations and complications of bacterial meningitis result from the immune response to the invading pathogen rather than from direct bacteria-induced tissue injury. As a result, neurologic injury can progress even after the CSF has been sterilized by antibiotic therapy.

The lysis of bacteria with the subsequent release of cell-wall components into the SAS is the initial step in the induction of the inflammatory response and the formation of a purulent exudate in the SAS **(Fig. 143-1)**. Bacterial cell-wall components, such as the lipopolysaccharide (LPS) molecules of gram-negative bacteria and teichoic acid and peptidoglycans of *S. pneumoniae*, induce meningeal inflammation by stimulating the production of inflammatory cytokines and chemokines by microglia, astrocytes, monocytes, microvascular endothelial cells, and CSF leukocytes. In experimental models of meningitis, cytokines including tumor necrosis factor alpha (TNF-α) and interleukin 1β (IL-1β) are present in CSF within 1–2 h of intracisternal inoculation of LPS. This cytokine response is quickly followed by an increase in CSF protein concentration and leukocytosis. Chemokines (cytokines that induce chemotactic migration in leukocytes) and a variety of other proinflammatory cytokines are also produced and secreted by leukocytes and tissue cells that are stimulated by IL-1β and TNF-α. In addition, bacteremia and the inflammatory cytokines induce the production of excitatory amino acids, reactive oxygen and nitrogen species (free oxygen radicals, nitric oxide, and peroxynitrite), and other mediators that can induce death of brain cells, especially in the dentate gyrus of the hippocampus.

Much of the pathophysiology of bacterial meningitis is a direct consequence of elevated levels of CSF cytokines and chemokines. TNF-α and IL-1β act synergistically to increase the permeability of the blood-brain barrier, resulting in induction of vasogenic edema and the leakage of serum proteins into the SAS (Fig. 143-1). The subarachnoid exudate of proteinaceous material and leukocytes obstructs the flow of CSF through the ventricular system and diminishes the resorptive capacity of the arachnoid granulations in the dural sinuses, leading to obstructive and communicating hydrocephalus and concomitant interstitial edema.

Inflammatory cytokines upregulate the expression of selectins on cerebral capillary endothelial cells and leukocytes, promoting leukocyte adherence to vascular endothelial cells and subsequent migration into the CSF. The adherence of leukocytes to capillary endothelial cells increases the permeability of blood vessels, allowing for the leakage of plasma proteins into the CSF, which adds to the inflammatory exudate. Neutrophil degranulation results in the release of toxic metabolites that contribute to cytotoxic edema, cell injury, and death. Contrary to previous beliefs, CSF leukocytes probably do little to contribute to the clearance of CSF bacterial infection.

During the very early stages of meningitis, there is an increase in cerebral blood flow, soon followed by a decrease in cerebral blood flow and a loss of cerebrovascular autoregulation **(Chap. 318)**. Narrowing of the large arteries at the base of the brain due to encroachment by the purulent exudate in the SAS and infiltration of the arterial wall by inflammatory cells with intimal thickening (*vasculitis*) also occur and may result in ischemia and infarction, obstruction of branches of the middle cerebral artery by thrombosis, thrombosis of the major cerebral venous sinuses, and thrombophlebitis of the cerebral cortical veins. The combination of interstitial, vasogenic, and cytotoxic edema leads to raised ICP and coma. Cerebral herniation usually results from the effects of cerebral edema, either focal or generalized; hydrocephalus and dural sinus or cortical vein thrombosis may also play a role.

CLINICAL PRESENTATION

Meningitis can present as either an acute fulminant illness that progresses rapidly in a few hours or as a subacute infection that progressively worsens over several days. The classic clinical triad of meningitis is fever, headache, and nuchal rigidity, and these features each occur in >80% of adult cases of acute bacterial meningitis, although the complete classic triad is not always present. A decreased level of consciousness occurs in >75% of patients and can vary from lethargy to coma. Nausea, vomiting, and photophobia are also common complaints.

Nuchal rigidity ("stiff neck") is the pathognomonic sign of meningeal irritation and is present when the neck resists passive flexion. Kernig's and Brudzinski's signs are also classic signs of meningeal irritation. *Kernig's sign* is elicited with the patient in the supine position. The thigh is flexed on the abdomen, with the knee flexed; attempts to passively extend the knee elicit pain when meningeal irritation is present. *Brudzinski's sign* is elicited with the patient in the supine

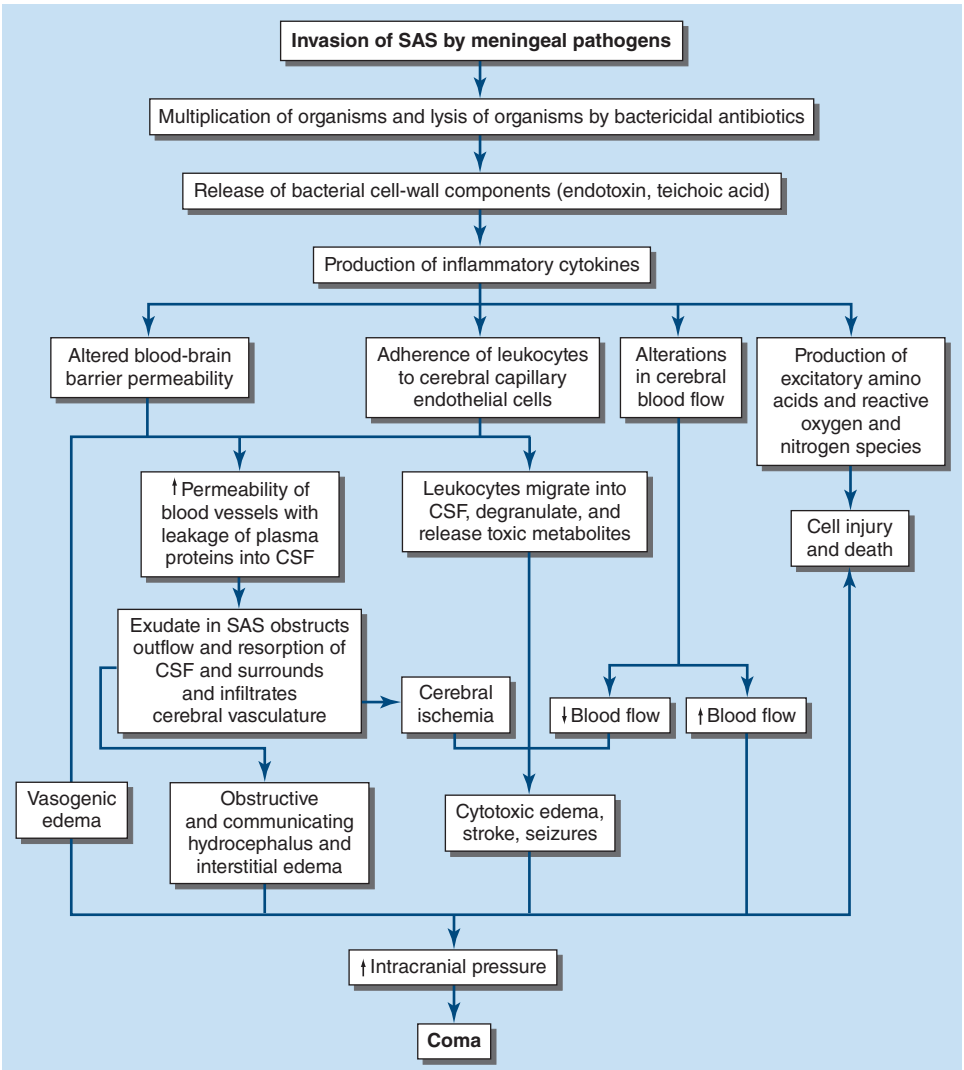

FIGURE 143-1 The pathophysiology of the neurologic complications of bacterial meningitis. CSF, cerebrospinal fluid; SAS, subarachnoid space.

position and is positive when passive flexion of the neck results in spontaneous flexion of the hips and knees. Although commonly tested on physical examinations, the sensitivity and specificity of Kernig's and Brudzinski's signs are uncertain. Both may be absent or reduced in very young or elderly patients, immunocompromised individuals, or patients with a severely depressed mental status. The high prevalence of cervical spine disease in older individuals may result in false-positive tests for nuchal rigidity.

Seizures occur as part of the initial presentation of bacterial meningitis or during the course of the illness in 15–40% of patients. Focal seizures are usually due to focal arterial ischemia or infarction, cortical venous thrombosis with hemorrhage, or focal edema. Generalized seizure activity and status epilepticus may be due to hyponatremia, cerebral anoxia, or, less commonly, the toxic effects of antimicrobial agents.

Raised ICP is an expected complication of bacterial meningitis and the major cause of obtundation and coma in this disease. More than 90% of patients will have a CSF opening pressure >180 mmH_2O, and 20% have opening pressures >400 mmH_2O. Signs of increased ICP include a deteriorating or reduced level of consciousness, papilledema, dilated poorly reactive pupils, sixth nerve palsies, decerebrate posturing, and the Cushing reflex (bradycardia, hypertension, and irregular respirations). The most disastrous complication of increased ICP is cerebral herniation. The incidence of herniation in patients with bacterial meningitis has been reported to occur in as few as 1% to as many as 8% of cases.

Specific clinical features may provide clues to the diagnosis of individual organisms and are discussed in more detail in specific chapters devoted to individual pathogens. The most important of these clues is the rash of meningococcemia, which begins as a diffuse erythematous maculopapular rash resembling a viral exanthem; however, the skin lesions of meningococcemia rapidly become petechial. Petechiae are found on the trunk and lower extremities, in the mucous membranes and conjunctiva, and occasionally on the palms and soles.

DIAGNOSIS

When bacterial meningitis is suspected, blood cultures should be immediately obtained and empirical antimicrobial and adjunctive dexamethasone therapy initiated without delay **(Table 143-1)**. Therapy with dexamethasone should ideally be started 20 min before, or not later than concurrent with, the first dose of antibiotics. The diagnosis of bacterial meningitis is made by examination of the CSF **(Table 143-2)**. The need to obtain neuroimaging studies (computed tomography [CT] or magnetic resonance imaging [MRI]) prior to lumbar puncture (LP) requires clinical judgment. In an immunocompetent patient with no known history of recent head trauma, a normal level of consciousness, and no evidence of papilledema or focal neurologic deficits, it is considered safe to perform LP without prior neuroimaging studies. If LP is delayed in order to obtain neuroimaging studies, empirical antibiotic therapy should be initiated after blood cultures are obtained. Antibiotic therapy initiated a few hours prior to LP will not significantly alter the CSF WBC count or glucose concentration, nor is it likely to prevent visualization of organisms by Gram's stain or detection of bacterial nucleic acid by polymerase chain reaction (PCR) assay.

The classic CSF abnormalities in bacterial meningitis (Table 143-2) are (1) polymorphonuclear (PMN) leukocytosis (>100 cells/μL in 90%), (2) decreased glucose concentration (<2.2 mmol/L [<40 mg/dL] and/or CSF/serum glucose ratio of <0.4 in ~60%), (3) increased protein concentration (>0.45 g/L [>45 mg/dL] in 90%), and (4) increased opening pressure (>180 mmH_2O in 90%). CSF bacterial cultures are positive in >70% of patients, and CSF Gram's stain demonstrates organisms in >60%.

CSF glucose concentrations <2.2 mmol/L (<40 mg/dL) are abnormal, and a CSF glucose concentration of zero can be seen in bacterial meningitis. Use of the CSF/serum glucose ratio corrects for hyperglycemia that may mask a relative decrease in the CSF glucose concentration. The CSF glucose concentration is low when the CSF/serum glucose ratio is <0.6. A CSF/serum glucose ratio <0.4 is highly suggestive of bacterial meningitis but may also be seen in other conditions, including fungal, tuberculous, and carcinomatous meningitis. It takes from 30 min to several hours for the concentration of CSF glucose to reach equilibrium with blood glucose levels; therefore, administration of 50 mL of 50% glucose (D50) prior to LP, as commonly occurs in emergency room settings, is unlikely to alter CSF glucose concentration significantly unless more than a few hours have elapsed between glucose administration and LP.

The presently available CSF multiplex PCR pathogen assays, the most common of which is the FilmArray Meningitis/Encephalitis panel (BioFire Diagnostics), detect the nucleic acid of *S. pneumoniae,*

TABLE 143-1 Antibiotics Used in Empirical Therapy of Bacterial Meningitis and Focal Central Nervous System Infections[a]

INDICATION	ANTIBIOTIC
Preterm infants to infants <1 month	Ampicillin + cefotaxime
Infants 1–3 months	Ampicillin + cefotaxime or ceftriaxone
Immunocompetent children >3 months and adults <55	Cefotaxime, ceftriaxone, or cefepime + vancomycin
Adults >55 and adults of any age with alcoholism or other debilitating illnesses	Ampicillin + cefotaxime, ceftriaxone, or cefepime + vancomycin
Hospital-acquired meningitis, posttraumatic or postneurosurgery meningitis, neutropenic patients, or patients with impaired cell-mediated immunity	Ampicillin + ceftazidime or meropenem + vancomycin

	TOTAL DAILY DOSE AND DOSING INTERVAL	
ANTIMICROBIAL AGENT	CHILD (>1 MONTH)	ADULT
Ampicillin	300 (mg/kg)/d, q6h	12 g/d, q4h
Cefepime	150 (mg/kg)/d, q8h	6 g/d, q8h
Cefotaxime	225–300 (mg/kg)/d, q6h	12 g/d, q4h
Ceftriaxone	100 (mg/kg)/d, q12h	4 g/d, q12h
Ceftazidime	150 (mg/kg)/d, q8h	6 g/d, q8h
Gentamicin	7.5 (mg/kg)/d, q8h[b]	7.5 (mg/kg)/d, q8h
Meropenem	120 (mg/kg)/d, q8h	6 g/d, q8h
Metronidazole	30 (mg/kg)/d, q6h	1500–2000 mg/d, q6h
Nafcillin	200 (mg/kg)/d, q6h	12 g/d, q4h
Penicillin G	400,000 (U/kg)/d, q4h	20–24 million U/d, q4h
Vancomycin	45–60 (mg/kg)/d, q6h	45–60 (mg/kg)d, q6–12h[b]

[a]All antibiotics are administered intravenously; doses indicated assume normal renal and hepatic function. [b]Doses should be adjusted based on serum peak and trough levels: gentamicin therapeutic level: peak: 5–8 µg/mL; trough: <2 µg/mL; vancomycin therapeutic level: peak: 25–40 µg/mL; trough: 5–15 µg/mL.

N. meningitidis, Escherichia coli, L. monocytogenes, H. influenzae, and *S. agalactiae* (group B streptococci). Although these PCR assays have a rapid turnaround time, the sensitivity and specificity for the bacterial meningeal pathogens they test for are not known. The CSF multiplex PCR pathogen assays do not include *S. aureus*, coagulase-negative staphylococci, and many gram-negative organisms. The PCR assays cannot replace CSF bacteria culture, as culture is required for antimicrobial susceptibility testing. Almost all patients with bacterial meningitis will have neuroimaging studies performed during the course of their illness. MRI is preferred over CT because of its superiority in demonstrating areas of cerebral edema and ischemia. In patients with bacterial meningitis, diffuse meningeal enhancement is often seen after the administration of gadolinium. Meningeal enhancement is not diagnostic of meningitis but occurs in any CNS disease associated with increased blood-brain barrier permeability.

TABLE 143-2 Cerebrospinal Fluid (CSF) Abnormalities in Bacterial Meningitis

Opening pressure	>180 mmH_2O
White blood cells	10/µL to 10,000/µL; neutrophils predominate
Red blood cells	Absent in nontraumatic tap
Glucose	<2.2 mmol/L (<40 mg/dL)
CSF/serum glucose	<0.4
Protein	>0.45 g/L (>45 mg/dL)
Gram's stain	Positive in >60%
Culture	Positive in >80%
PCR	Detects bacterial DNA

Abbreviation: PCR, polymerase chain reaction.

Petechial skin lesions, if present, should be biopsied. The rash of meningococcemia results from the dermal seeding of organisms with vascular endothelial damage, and biopsy may reveal the organism on Gram's stain.

DIFFERENTIAL DIAGNOSIS

Viral meningoencephalitis, and particularly herpes simplex virus (HSV) encephalitis **(Chap. 142)**, can mimic the clinical presentation of bacterial meningitis (encephalitis). HSV encephalitis typically presents with headache, fever, altered consciousness, focal neurologic deficits (e.g., dysphasia, hemiparesis), and focal or generalized seizures. The findings on CSF studies, neuroimaging, and electroencephalogram (EEG) distinguish HSV encephalitis from bacterial meningitis. The typical CSF profile with viral CNS infections is a lymphocytic pleocytosis with a normal glucose concentration, in contrast to the PMN pleocytosis and hypoglycorrhachia characteristic of bacterial meningitis. The CSF HSV PCR has a 96% sensitivity and a 99% specificity when CSF is examined 72 h following symptom onset and in the first week of antiviral therapy. MRI abnormalities (other than meningeal enhancement) are not seen in uncomplicated bacterial meningitis. By contrast, in HSV encephalitis, on T2-weighted, fluid-attenuated inversion recovery (FLAIR), and diffusion-weighted MRI images, high-signal-intensity lesions are seen in the orbitofrontal, anterior, and medial temporal lobes in the majority of patients within 48 h of symptom onset. Some patients with HSV encephalitis have a distinctive periodic pattern on EEG.

Rickettsial disease **(Chap. 192)** can resemble bacterial meningitis. Rocky Mountain spotted fever (RMSF) is transmitted by a tick bite and caused by the bacteria *Rickettsia rickettsii*. The disease may present acutely with high fever, prostration, myalgia, headache, nausea, and vomiting. Most patients develop a characteristic rash within 96 h of the onset of symptoms. The rash is initially a diffuse erythematous maculopapular rash that may be difficult to distinguish from that of meningococcemia. It progresses to a petechial rash, then to a purpuric rash, and if untreated, to skin necrosis or gangrene. The color of the lesions changes from bright red to very dark red, then yellowish-green to black. The rash typically begins in the wrist and ankles and then spreads distally and proximally within a matter of a few hours, involving the palms and soles. Diagnosis is made by immunofluorescent staining of skin biopsy specimens. Ehrlichioses are also transmitted by a tick bite. These are small gram-negative coccobacilli of which two species cause human disease. *Anaplasma phagocytophilum* causes human granulocytic ehrlichiosis (anaplasmosis), and *Ehrlichia chaffeensis* causes human monocytic ehrlichiosis. The clinical and laboratory manifestations of the infections are similar. Patients present with fever, headache, confusion, nausea, and vomiting. Twenty percent of patients have a maculopapular or petechial rash. There is laboratory evidence of leukopenia, thrombocytopenia, and anemia, and mild to moderate elevations in alanine aminotransferases, alkaline phosphatase, and lactate dehydrogenase. Patients with RMSF and those with ehrlichial infections may have an altered level of consciousness ranging from mild lethargy to coma, confusion, focal neurologic signs, cranial nerve palsies, hyperreflexia, and seizures.

Focal suppurative CNS infections, including subdural and epidural empyema and brain abscess, should also be considered **(Chap. 145)**, especially when focal neurologic findings are present. MRI should be performed promptly in all patients with suspected meningitis who have focal features, both to detect the intracranial infection and to search for associated areas of infection in the sinuses or mastoid bones.

A number of noninfectious CNS disorders can mimic bacterial meningitis. Subarachnoid hemorrhage (SAH; **Chap. 440**) is generally the major consideration. Other possibilities include medication-induced hypersensitivity meningitis; chemical meningitis due to rupture of tumor contents into the CSF (e.g., from a cystic glioma, craniopharyngioma, epidermoid or dermoid cyst); carcinomatous or lymphomatous meningitis; meningitis associated with inflammatory disorders such as sarcoid, systemic lupus erythematosus (SLE), and

Behçet's syndrome; pituitary apoplexy; and uveomeningitic syndromes (Vogt-Koyanagi-Harada syndrome).

On occasion, subacutely evolving meningitis (see below and **Chap. 144**) may be considered in the differential diagnosis of acute meningitis. The principal causes include *Mycobacterium tuberculosis* **(Chap. 183)**, *Cryptococcus neoformans* **(Chap. 221)**, *Histoplasma capsulatum* **(Chap. 218)**, *Coccidioides immitis* **(Chap. 219)**, and *Treponema pallidum* **(Chap. 187)**.

TREATMENT

Acute Bacterial Meningitis

EMPIRICAL ANTIMICROBIAL THERAPY

(Table 143-1) Bacterial meningitis is a medical emergency. The goal is to begin antibiotic therapy within 60 min of a patient's arrival in the emergency room. Empirical antimicrobial therapy is initiated in patients with suspected bacterial meningitis before the results of CSF multiplex PCR assays, Gram's stain, and culture are known. *S. pneumoniae* **(Chap. 151)** and *N. meningitidis* **(Chap. 160)** are the most common etiologic organisms of community-acquired bacterial meningitis. Due to the emergence of penicillin- and cephalosporin-resistant *S. pneumoniae*, empirical therapy of community-acquired suspected bacterial meningitis in children and adults should include a combination of dexamethasone, a third- or fourth-generation cephalosporin (e.g., ceftriaxone, cefotaxime, or cefepime), and vancomycin, plus acyclovir, as HSV encephalitis is the leading disease in the differential diagnosis, and doxycycline during tick season to treat tick-borne bacterial infections. Ceftriaxone or cefotaxime provides good coverage for susceptible *S. pneumoniae*, group B streptococci, and *H. influenzae* and adequate coverage for *N. meningitidis*. Cefepime is a broad-spectrum fourth-generation cephalosporin with in vitro activity similar to that of cefotaxime or ceftriaxone against *S. pneumoniae* and *N. meningitidis* and greater activity against *Enterobacter* species and *Pseudomonas aeruginosa*. In clinical trials, cefepime has been demonstrated to be equivalent to cefotaxime in the treatment of penicillin-sensitive pneumococcal and meningococcal meningitis, and it has been used successfully in some patients with meningitis due to *Enterobacter* species and *P. aeruginosa*. Cefepime has been associated with seizures, myoclonus, and encephalopathy, any of which may limit its use in critically ill patients. Ampicillin should be added to the empirical regimen for coverage of *L. monocytogenes* in individuals <3 months of age, those >55, or those with suspected impaired cell-mediated immunity because of chronic illness, organ transplantation, pregnancy, malignancy, or immunosuppressive therapy. Metronidazole is added to the empirical regimen to cover gram-negative anaerobes in patients with otitis, sinusitis, or mastoiditis. In hospital-acquired meningitis, and particularly meningitis following neurosurgical procedures, staphylococci and gram-negative organisms including *P. aeruginosa* are the most common etiologic organisms. In these patients, empirical therapy should include a combination of vancomycin and ceftazidime or meropenem. Ceftazidime or meropenem should be substituted for ceftriaxone or cefotaxime in neurosurgical patients and in neutropenic patients because ceftriaxone and cefotaxime do not provide adequate activity against CNS infection with *P. aeruginosa*. Meropenem is a carbapenem antibiotic that is highly active in vitro against *L. monocytogenes*, has been demonstrated to be effective in cases of meningitis caused by *P. aeruginosa*, and shows good activity against penicillin-resistant pneumococci. In experimental pneumococcal meningitis, meropenem was comparable to ceftriaxone and inferior to vancomycin in sterilizing CSF cultures. When *S. pneumoniae*, *H. influenzae*, *L. monocytogenes*, or aerobic gram-negative bacilli (including *P. aeruginosa* and *E. coli*) are possible meningeal pathogens, based on predisposing and associated conditions, the combination of vancomycin plus meropenem can be recommended as empiric therapy for bacterial meningitis in children and adults. Meropenem should not be used as monotherapy.

TABLE 143-3 Antimicrobial Therapy of Central Nervous System Bacterial Infections Based on Pathogen[a]

ORGANISM	ANTIBIOTIC
Neisseria meningitides	
Penicillin-sensitive	Penicillin G or ampicillin
Penicillin-resistant	Ceftriaxone or cefotaxime
Streptococcus pneumoniae	
Penicillin-sensitive	Penicillin G
Penicillin-intermediate	Ceftriaxone or cefotaxime or cefepime
Penicillin-resistant	Ceftriaxone (or cefotaxime or cefepime) + vancomycin
Gram-negative bacilli (except *Pseudomonas* spp.)	Ceftriaxone or cefotaxime
Pseudomonas aeruginosa	Ceftazidime or cefepime or meropenem
Staphylococci spp.	
Methicillin-sensitive	Nafcillin
Methicillin-resistant	Vancomycin
Listeria monocytogenes	Ampicillin + gentamicin
Haemophilus influenzae	Ceftriaxone or cefotaxime if β-lactamase positive; ampicillin if β-lactamase negative
Streptococcus agalactiae	Penicillin G or ampicillin
Bacteroides fragilis	Metronidazole
Fusobacterium spp.	Metronidazole

[a]Doses are as indicated in Table 143-1.

SPECIFIC ANTIMICROBIAL THERAPY

Meningococcal Meningitis (Table 143-3) Although ceftriaxone and cefotaxime provide adequate empirical coverage for *N. meningitidis*, penicillin G remains the antibiotic of choice for meningococcal meningitis caused by susceptible strains. Isolates of *N. meningitidis* with moderate resistance to penicillin have been identified and are increasing in incidence worldwide. CSF isolates of *N. meningitidis* should be tested for penicillin and ampicillin susceptibility, and if resistance is found, cefotaxime or ceftriaxone should be substituted for penicillin. A 7-day course of intravenous antibiotic therapy is adequate for uncomplicated meningococcal meningitis. The index case and all close contacts should receive chemoprophylaxis with a 2-day regimen of rifampin (600 mg every 12 h for 2 days in adults and 10 mg/kg every 12 h for 2 days in children >1 year). Rifampin is not recommended in pregnant women. Alternatively, adults can be treated with one dose of azithromycin (500 mg) or one intramuscular dose of ceftriaxone (250 mg). Close contacts are defined as those individuals who have had contact with oropharyngeal secretions, either through kissing or by sharing toys, beverages, or cigarettes.

Pneumococcal Meningitis Antimicrobial therapy of pneumococcal meningitis is initiated with a cephalosporin (ceftriaxone, cefotaxime, or cefepime) and vancomycin. All CSF isolates of *S. pneumoniae* should be tested for sensitivity to penicillin and the cephalosporins. Once the results of antimicrobial susceptibility tests are known, therapy can be modified accordingly (Table 143-3). For *S. pneumoniae* meningitis, an isolate of *S. pneumoniae* is considered to be susceptible to penicillin with a minimal inhibitory concentration (MIC) <0.06 μg/mL and to be resistant when the MIC is >0.12 μg/mL. Isolates of *S. pneumoniae* that have cephalosporin MICs ≤0.5 μg/mL are considered sensitive to the cephalosporins (cefotaxime, ceftriaxone, cefepime). Those with MICs of 1 μg/mL are considered to have intermediate resistance, and those with MICs ≥2 μg/mL are considered resistant. For meningitis due to pneumococci, with cefotaxime or ceftriaxone MICs ≤0.5 μg/mL, treatment with cefotaxime or ceftriaxone is usually adequate. For MIC >1 μg/mL, vancomycin is the antibiotic of choice. Rifampin can be added to vancomycin for its synergistic effect but is inadequate as monotherapy because resistance develops rapidly when it is used alone.

A 2-week course of intravenous antimicrobial therapy is recommended for pneumococcal meningitis.

Patients with *S. pneumoniae* meningitis should have a repeat LP performed 24–36 h after the initiation of antimicrobial therapy to document sterilization of the CSF. Failure to sterilize the CSF after 24–36 h of antibiotic therapy should be considered presumptive evidence of antibiotic resistance. Patients with penicillin- and cephalosporin-resistant strains of *S. pneumoniae* who do not respond to intravenous vancomycin alone may benefit from the addition of intraventricular vancomycin. The intraventricular route of administration is preferred over the intrathecal route because adequate concentrations of vancomycin in the cerebral ventricles are not always achieved with intrathecal administration.

Listeria Meningitis Meningitis due to *L. monocytogenes* is treated with ampicillin for at least 3 weeks (Table 143-3). Gentamicin is added in critically ill patients (2 mg/kg loading dose, then 7.5 mg/kg per day given every 8 h and adjusted for serum levels and renal function). The combination of trimethoprim (10–20 mg/kg per day) and sulfamethoxazole (50–100 mg/kg per day) given every 6 h may provide an alternative in penicillin-allergic patients.
