Given the fundamental platform of breathing, a summary of the essence of this *Learned Mindfulness* model founded on emotional intelligence, mindful awareness, and self-observation follows. Starting with a basic familiarity of how one's sensations emerge, one can be taught to label them as feelings. Grasping, releasing, contracting, and expanding attend these. Breathing affords a model of such fundamental dynamics. For example, releasing the breath follows the pause between inhalation and exhalation. This act establishes a sense of muting and not impulsively reacting that transfers to grasping, holding, and releasing objects arising in the mind. The emerging realization of gracefully letting go can progress further in the refinement of emotional processing: perception, conception, and performance. This emotional intelligence practice correlates the mind's "objects," for example, sensations, feelings, and thoughts, with their mindful management.

Special mention of the current widespread use of interventions derived from complementary, alternative, and integrative medicine may have a place in overall treatment because motivated families often first initiate these aids with enthusiasm not only to promote but also to enhance well-being. Healthy food choices, exercise, stress management, and even prenatal health measures (i.e., primary prevention) can be important components of a successful treatment

Telegram: @medical_k

www.konkur.in

plan. When used adjunctively, rationally, and collaboratively, they may help sustain a positively engaged therapeutic trajectory.

Proper recognition, together with remediation, enhances both cognitive and adaptive reserve. This long-term perspective optimizes potentials that extend benefits beyond the identified individual's immediate needs with BIF. Risk reduction may reach across generations. The young children of such individuals are thereby given a significantly increased chance of success in all quality-of-life measures. The adult children of persons with borderline intelligence can be given a rational explanation of insights into parents' long-standing intellectual limitations. This epiphany may afford them a capacity for a forgiving attitude toward what might have erroneously been perceived as intentionally motivated, less-than-optimal parenting.

Telegram: @medical_k

www.konkur.in

A 10-year-old boy was referred for consultation because of failing grades since first grade and disruptive classroom behaviors, including expressing aggression toward peers, breaking things, and having temper tantrums. He would purposefully break any toys or gifts he was given; he would tear his clothes at times. He was the only child of a single mother who reported normal gestation, delivery, and no medical problems in the child. The boy was mildly overweight in the interview and had some facial dysmorphic features but appeared otherwise healthy. His mood was sullen. In the past, his mother had been given a variety of diagnoses for the child by school and pediatrician: ADHD, bipolar disorder, ASD, and CD. No psychotropic medications had been helpful. A comprehensive assessment included multiple interviews with the child and the mother, school consultation with intelligence, adaptive and scholastic testing, and routine blood work. Verbal and performance IQ scores were in the low 70s, adaptive skills were marginal, and grades were 1 to 2 years behind. Laboratory values were within normal limits. A primary diagnosis of BIF with a mood disorder, unspecified, was made.

Intensive treatment was three pronged: child, mother, and school. School consultation provided psychoeducation about diagnoses and the need for special education, which was approved. Family therapy also included psychoeducation about borderline intelligence, the child's strengths and limitations, and his need for a structured, straightforward, and routine environment of expectations and behavioral performance. Individual therapy for the mother also began. His mother was eager to use a range of health-oriented dietary and exercise guidelines. This therapeutic alliance with the mother was crucial to holding and integrating all prongs in an effective and collaborative way. Intensive individual psychotherapy with the child included aspects of cognitive, behavioral, and age-appropriate psychodynamic work. The child's sense of self, self-esteem, peer relations, and the effects of his behaviors on others were reviewed. During play therapy, several conflictual problems

Telegram: @medical_k

www.konkur.in

were uncovered. The boy revealed his envy of other boys on multiple levels. He envied their having a father, their perceived sense of being "smarter and not retarded," their physical competence in sports, and their acceptance and facile participation in peer-group activities. His envy created a hatred of, and a wish to destroy, both them and, moreover, aspects of himself, as illustrated in either spoiling his clothing or breaking gifts he received. He often stated: "I'm angry because I just don't fit in with everybody else." Even though he was cognitively limited, he showed an interest in and some aptitude for understanding the complex envy dynamic of excessive idealization, spoiling, destructiveness, and resentment—when put into simple language and delivered flexibly at his level of readiness over time.

Play therapy and interpretive discourse were sensitive to engage him on the specific and changing levels of cognition and affect that he presented at each session. Changes were slow but significant. This developing level of emotional insight, basic emotional and cognitive understanding, appeared to enhance his everyday cognition because it diminished a great deal of anxiety and preoccupying resentment. The acquisition of "envy management skills" over time helped him understand cause-and-effect sequences and constrain destructive behaviors. Once-weekly psychotherapy was supplemented using low doses of quetiapine (Seroquel) to target irritability, anxiety, and mood. After approximately 6 months, his behavior stabilized, his aggressive outbursts were significantly eliminated, and his academic performance began to approach chronologic and developmental expectations. His mother remarked that his demeanor appeared more relaxed and that his affect brightened.

ACADEMIC OR EDUCATIONAL PROBLEM

Definition

DSM-5 describes another condition (Z55.9) *academic or educational problem* as follows:

Telegram: @medical_k

www.konkur.in

This category should be used when an academic or educational problem is the focus of clinical attention or impacts the individual's diagnosis, treatment, or prognosis. Problems to be considered include illiteracy or low-level illiteracy; lack of access to schooling owing to unavailability or unattainability; problems with academic performance (e.g., failing school examinations, receiving failing marks or grades) or underachievement (below what would be expected given the individuals intellectual capacity); discord with teachers, school staff, or other students; and any other problems related to education and literacy. (Adapted from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, p. 830 [Copyright © 2022]. American Psychiatric Association. All Rights Reserved.)

The title of this entry now includes the added phrase "…or educational problem." Unlike the DSM-IV-TR description, no mention is made of this condition not being "…due to a mental disorder or, if due to a mental disorder, is sufficiently severe to warrant independent clinical attention." About seven additional problems are now mentioned: illiteracy, low-level illiteracy, lack of access to schooling, discord with teachers, school staff, students, and other issues related to education or literacy besides the previous two in DSM-IV-TR: failing grades and significant underachievement. No mention is made of requiring the absence of a specific learning or communication disorder or any other mental disorder that would account for the problem, as DSM-IV-TR had required. Therefore, the term "illiteracy" is not defined in a specific fashion; some impairment in the ability to read and write is implied. Some of the associated factors causing academic or educational problems are remediable extrinsic agents (e.g., access, discord, implied bullying, and victimization) that, if addressed, would assuage or eliminate the designated academic problem. The way DSM-5 defines this condition suggests that it can be a focus of attention or a secondary problem affecting an already present diagnosis, its treatment, or progress. DSM-5 coding is Z55.9.

DSM-5-TR (2022) describes several specifically coded conditions under the single category, Educational Problems (Z55.0 -Z55.9) with the subcategory Z55.9, now called "Other Problems Related to Education and Literacy," that DSM-5, Z55.9, previously termed "Academic or Educational Problem" as described above.

DSM-5-TR now describes the entire range of Educational Problems as follows:

Telegram: @medical_k

www.konkur.in

These categories may be used when an academic or educational problem is the focus of clinical attention or has an impact on the individual's diagnosis, treatment, or prognosis. Problems to be considered include illiteracy or low-level literacy; lack of access to schooling owing to unavailability or unattainability; problems with academic performance (e.g., failing school examinations, receiving failing marks or grades) or underachievement (below what would be expected given the individual's intellectual capacity); discord with teachers, school staff, or other students; problems related to inadequate teaching; and any other problems related to education and/or literacy. (p. 830)

Etiology

The presentation of significant academic or educational problems or those impacting diagnosis, treatment, or progress denotes this condition. Risk factors include genetic, constitutional, premature birth, congenital atypicalities, and various early and later environmental stressors, for example, poor nutrition, less than optimal care, and maltreatment. English as a second language may also be considered. DSM-5 also clearly lists several causatives and clear-cut associative factors, leading to academic and educational problems. Some of these may have intrinsic causes, such as illiteracy associated with dyslexia or LDs. Most related causative agents are apparent environmental difficulties such as lack of access to schooling (e.g., transportation, attendance in-school, online school, tele school access, tutoring, etc.), interpersonal conflict, and perhaps behavioral dissonance, as delineated in the DSM-5 description. Bullying and victimization must be primary considerations.

Identification and Clinical Features

Scholastic problems, acute or chronic, associated with the particular factors clearly mentioned in this code's description best characterize academic or educational difficulties. Specific medical conditions, disabilities, or primarily overshadowing psychiatric disorders such as psychosis, schizophrenia, bipolar, depression, ASD, substance-related disorders, or PTSD may be comorbid but not sufficient to account for this coding. Clinical judgment is required.

Differential Diagnosis

Telegram: @medical_k

www.konkur.in

Adequate psychological and intellectual testing and academic performance profiles derived from standardized scholastic testing need to rule out forms of ID, BIF, specific LDs, and communications disorders. All medical conditions (including, e.g., vision, hearing, motor) and disabilities that might contribute to illiteracy, poor school performance, or access must also be explored. Major psychiatric disorders, along with severe oppositional defiant disorder, must be considered. Substance abuse or dependence and CD must be ruled out.

One must also rule out clinical and subclinical states of anxiety and depression, as well as environmental stressors, either hidden or explicit, which significantly affect the child in the family (e.g., marital discord, divorce, abuse, and mental illness in the parent), the socioeconomic environment (e.g., poverty, malnutrition), and the suitability of the school setting (e.g., accessibility, presence of bullying, and so forth). Significant medical conditions (e.g., anemia, seizures, hypothyroidism, chronic infections, heavy metal loads, motor and ambulation impairments, and genetic disorders) must be considered. Adolescent developmental concerns, such as preoccupation with burgeoning sexuality, identity issues, and peer relations, should not be underestimated as factors that contribute to academic problems. Typically, such preoccupations are highly significant and may contribute to academic problems. Also, motivational issues and associated family and socially influenced contextual values may directly affect scholastic performance. Socialization and developing social skills and exposure to community values take place in the school environment. With the onset of remote learning, many of these venues have been disrupted, thus posing additional risk exposure.

With the advent of COVID-19, remote academic learning is prevalent. Home learning with technology and electronics and access to these are used. Hybrid combinations, including at-home remote, partial attendance, and full attendance, are possibilities. Absenteeism, for various reasons, including illness in the child or family, needs consideration. Inappropriate or excessive use of individually chosen screen time, including the lack of needed

Telegram: @medical_k

www.konkur.in

technologies such as electronics and lack of internet access, adds other emerging layers of concern related to academic or educational problems.

A 15-year-old boy was admitted to an intensive outpatient program to evaluate insidiously declining grades at school, isolative behavior, and incipient anhedonia occurring for the first time over the last semester in his second year in high school. The student told his family that he was being bullied in school. The patient had no previous psychiatric history and was in good health. School reports showed a full-scale IQ score to be 100 and no previous behavior or academic problems. Interviews with family and patient revealed that the boy had an intact family with no apparent or unusual conflicts noted. His mother found evidence of drug paraphernalia—cigarette papers, small pipe, matches, and a suspicious-looking dried substance—in the patient's bedroom. When confronted, the patient revealed a 6-month history of regular use of marijuana associated with his statement of being bullied in school. A primary diagnosis of cannabis abuse, along with an academic problem, was made. A secondary depression was to be ruled out. Referral to a therapeutic program with a drug and alcohol rehabilitation component was immediately implemented. A comprehensive school meeting was called to investigate and address the allegation of bullying.

Telegram: @medical_k

www.konkur.in

A 10-year-old girl was admitted to an intensive outpatient program because of various disruptive, impulsive, hyperkinetic behaviors and intermittent rage reactions only in the home environment. The patient was well behaved in school and considered bright. Her grades, for the first time over the last year, were failing. Onset began about 2 years previously when her parents separated and her mother's new male companion moved in. The child's pediatrician made a diagnosis of ADHD and started methylphenidate (Ritalin). The child's condition worsened and was marked by mood instability and periodic temper outbursts, now also in school. The medical assessment showed the patient to be in good health, and she was referred for further examination. A psychiatric interview showed a guarded, hypervigilant child with a constricted affect. No other data were forthcoming. The patient's mother was reluctant to take part in treatment. The initial diagnostic impression was of disruptive behavior disorder, along with an academic problem. After several weeks and months, the patient revealed that she was sexually abused.

Further investigation and involvement with the Department of Child and Family Services uncovered that the home's adult male was the perpetrator. He was removed. Family and individual work began and continued for several months. All psychostimulant medication was discontinued. A primary diagnosis of PTSD was made, along with abuse and secondary academic problem. Over time, the child became less irritable, her rages stopped, and her grades in school improved.

Treatment

Identifying and addressing environmental—family, school, and socioeconomic—stressors are essential. Substance abuse and traumatic exposure must be ruled out. Any concurrent major psychiatric disorders require diagnosis and treatment. Since referred children and adolescents are typically prescribed multiple psychotropic medications, careful medication assessment is crucial.

Telegram: @medical_k

www.konkur.in

Side effects, adverse drug effects, behavioral toxicity, and iatrogenic effects (e.g., hypothyroidism from lithium, or overactivation, irritability, mood instability, underweight, tics, stereotypies, and insomnia from psychostimulants) must be ruled out. When clinically indicated, taper and discontinuation or change of medications may be beneficial. With informed consent, school consultation can provide teachers with insight into the student's difficulties and suggest enhanced teaching strategies, especially conflict resolution techniques. Matters concerning bullying are now common and require careful consideration and treatment team coordinated efforts.

Child, family, school, and professional collaboration are essential. Illiteracy, underachievement, and failing grades need to be evaluated and appropriately addressed. If academic problems are severe enough, accommodations for individual educational programming, psychotherapeutic interventions such as counseling, guidance, family therapy, or residential schooling should be recommended even though this condition may not meet current stringent criteria for formal special education eligibility.

FUTURE DIRECTIONS

Intellectual *abilities*, social and emotional cognition, motivation, and successful adaptive performance skills coalesce through integrated thinking and behavior. Innovating emotional intelligence magnifies what I term *emotion performance utilization* (EPU). EPU is not a phase but the target of emotional intelligence. Viewing children and adolescents in this integral fashion calls for assessments and interventions that are comprehensive, multimodal, and flexible through the biopsychosocial paradigm.

In the introductory comments to this section, ongoing international efforts promoting evidence-based research and implementing recognition and intervention into BIAF are active. Perhaps, a case can be made for translating such patient-centered clinical practice into universally applicable research across the world. A global initiative is imperative to speed up BIF coordinated research, development, policy, and dissemination of pragmatic interventions.

Telegram: @medical_k

www.konkur.in

In the United States, the AAIDD (2010) has proposed a rationale for formalizing a continuum of Intellectual and Developmental Disabilities. Included is a support framework spanning IQ limitations on either side of the definitional dividing line, typically full-scale IQ 70 to 75. AAIDD urges that individuals with BIF or persons with mild limitations falling marginally above this "cutoff" should become eligible for services already in place for those with mild ID. This bold yet accurate proposal attests to BIF being significant, let alone a vital area needing clinical intervention. BIF can, and usually does, interfere with activities of daily living and instrumental activities of living in the real world. This admonition for a broader breadth of the intelligence and adaptive continuum is consonant with this section's call to integrate BIF into the mainstream of official psychiatric nosology. This clinical improvement reflects the art guiding scientific psychiatry. Dimensional measures of severity between diagnostic entities transcend the limits of categories. The *Journal of the American Medical Association* (August 2014) advances the view that investing in prevention should be a strategic national priority to improve the United States' lagging population health compared with peer countries.

A new paradigm, the *biomental* perspective, has recently been introduced into psychiatric theory and has been applied to child development and parenting. The integral confluence of brain, mind, and behavior is proposed regarding neuroscience, developmental psychology, and pragmatic parenting strategies. Adaptive intelligence, a hypothetical construct, is presumed in this model. It denotes the central plexus subtending the wide range of conceptual, emotional, and motivational abilities underlying ease of effective response to change. This hub includes a tacit reserve of potential capabilities comprising an individual's innate resilience. We can make this intelligence potential active by therapeutic techniques that foster "instinctive resourcefulness," the repository of silent compensatory adaptive aptitudes. Here, "instinctive" is not impulsive but a visceral resilience made practical by a facilitating environment. These are learning-sensitive mediators between mental and emotional resources and their timely, spontaneous, and successful

Telegram: @medical_k

www.konkur.in

implementation as practical problem-solving performance skills. This innate capacity of resourcefulness—possibly distinct from abilities currently measured by and solely dependent on IQ scores—is considered a fundamental life tool. Although its functioning may be significantly limited in those with borderline cognition and adaptive skills, therapeutic initiatives may activate its enhanced operation as described in the treatment section.

By integrating insights from genetics, neuroscience, and neuropsychiatry, behavioral and clinical studies aim to construct valid and reliable phenotypes. They span the heterogeneous range of typical to atypical and include “borderline” with its inevitable problems and interferences in daily life. The aim is not to medicalize or pathologize but to enhance BIF. Having a rational probabilistic mindset for risk provides for formal and resource-rich interventions. Circumventing quality-of-life hazards for these individual’s underdeveloped potentials expands possibilities. Incorporating such contemporary perspectives eschews considering only single categorical models. It pays tribute to heterogeneity as a fact in complex psychiatric presentations.

Studies show that emotional awareness is diminished in those with BIF, that is, alexithymia—the inability to meaningfully label emotions sensed and felt. Inclusive treatments for BIF may also embrace guidelines that recognize *emotional management skills*. These assets promote understanding, reduce cognitive and emotional dissonance, and foster greater cognitive clarity and emotional stability. This upgrade optimizes both intellectual and adaptive functioning and proficiency. Emotions are a common experience. Language offers an organizing principle to share our common experiences with one another. Helping those with BIF expand their understanding, and use of mindful language may be an underestimated, high-impact emotional management skill. These management skills and various mindfulness techniques are now commonly available. They may be adapted as part of BIF’s individualized support resources.

A paradox of COVID-19 is the need for physical distance and attendant social spacing to minimize the disease spread. This distancing has brought children apart and intensified their already

Telegram: @medical_k

www.konkur.in

overinvolvement with electronic devices (e.g., the current need to use remote learning such as Zoom classrooms, etc.). In the COVID-19 era, the academic environment has undergone dramatic changes. The prevalence of distance, hybrid and at-home learning attests to this. Besides its inherent difficulties, the lack of regular socialization is paramount. Socialization includes material contact, interaction, and face-to-face feedback for correction and improvement. This interface comprises social learning with adults and a range of peers. Social learning fosters personal growth, maturation, and social skills development. Teamwork is enhanced. Being in a school setting also affords children access to both free and structured playtime. Play is essential to healthy development in childhood and those with borderline intellectual and adaptive skills needing improvement. COVID-19 has brought a new layer of multifaceted problems as an additional toll on marginally functioning persons.

Remote learning and home-based education are established in current educational approaches. Computer hardware, access, and having internet connectivity are potential problems. Improving accessibility and usability is evolving. Home-based education's complexity involves technology and teacher training to optimize access and the user-friendliness of educational materials. Addressing the social issues around remote learning remains and will continue to be a significant challenge.

The environmental embeddedness—*eco-corporeality*—of each individual is assumed in these approaches. Our entire corpus—human being—is embedded interactively in the fabric making up the world. The integrated use of inclusive interactional paradigms enhances a sustainable, successful, and satisfactory quality of life. This significant advance denotes a life imbued with meaning and dignity—disabilities becoming newfound abilities. This integration crosses multiple eco-contexts, including personal, interpersonal, social, academic, familial, occupational, cultural, and spiritual. Identification and active interventions cross the adaptive intelligence threshold; integrating those with BIF into this *nuanced norm* is necessary. More than a human right, this piece of social participation is the right to be human to the fullest extent.

28.4 Relational Problems

WILLIAM BERNET, M.D.

Telegram: @medical_k

www.konkur.in

As social creatures, individuals cannot be completely understood without considering their interpersonal relationships. A person's identity is determined, in part, by how others see and value them. Likewise, clinicians cannot understand a person's symptoms out of the context of the individual's social relationships. These relationships can be promotive and protective of good mental and physical health —or neutral—or detrimental to health outcomes. There is a long history of competition—and perhaps some conflict—between the proponents of biologic psychiatry and the practitioners and researchers who emphasize the psychosocial and relational underpinnings of mental illness. No doubt, both these perspectives are essential in understanding and intervening with the mental disorders that trouble the individuals and the families with whom we work.

DEFINITIONS

Relational problems are maladaptive patterns of feelings, behavior, and perceptions involving two or more members of a relational unit. They can be distinguished from a broad range of interpersonal difficulties by four features: (1) repeated, fixed patterns of painful and destructive patterns of feelings, behavior, and perceptions can be clearly recognized; (2) the patterns are long-standing and are not a response to a recent stressful event; (3) the maladaptive patterns are nonresponsive to supportive features that may occur naturally in the social environment; (4) there is clear evidence of a major impact of these patterns on psychological functioning, physical health, social adaptation, and/or occupational activities in one or more persons in the relationship. A relational problem may come to clinical attention as the primary reason that the individual consults with a physician or therapist, or it may be a problem that affects the course, prognosis, or treatment of the individual's mental or medical disorder.

Relational problems are included in a chapter that occurs toward the end of the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR), "Other Conditions That May Be a Focus of Clinical Attention." With regard to

Telegram: @medical_k

www.konkur.in

terminology, the topics discussed in this chapter are called *problems* or *conditions;* in contrast, most of the topics discussed in other parts of DSM-5 are called *disorders,* such as delusional disorder and panic disorder. A common explanation for the distinction is that mental disorders are "located" inside the affected individual, while relational problems are "located" between the affected individual and another person.

Previous editions of the DSM employed a multiaxial system that included the documentation of mental disorders (Axes I and II), other medical disorders (Axis III), psychosocial and contextual factors (Axis IV), and level of disability (Axis V). Thus, relational problems were listed under Axis IV of the multiaxial system. As DSM-5 was developed, the Task Force decided to abandon the use of the multiaxial system. Mental disorders, other medical disorders, and relational problems are now included in one list, typically in the order of importance in understanding and conveying why the individual client is undergoing assessment and/or treatment. Some writers have had the misunderstanding that relational problems and other conditions (identified as V codes) may not be diagnosed because they are not mental disorders; that is incorrect since mental disorders, problems, and conditions may all be listed as diagnoses.

COMPARATIVE NOSOLOGY

Relational problems were not considered or alluded to in the first DSM (1952). In DSM-II (1968), however, a new diagnostic category was introduced called "social maladjustments without manifest psychiatric disorder." It was noted that "this category is for recording the conditions of individuals who are psychiatrically normal but who nevertheless have severe enough problems to warrant examination by a psychiatrist." One of the conditions included in that category was *marital maladjustment,* which was intended "for individuals who are psychiatrically normal but who have significant conflicts or maladjustments in marriage." The authors of DSM-II were prescient in saying, "The far-reaching implications of this set of terms for forensic

Telegram: @medical_k

www.konkur.in

psychiatry and for insurance compensation will become clearer with time."

DSM-III (1980) featured a new chapter called "V Codes for Conditions Not Attributable to a Mental Disorder That are a Focus of Attention or Treatment." That chapter included several diagnoses that were precursors to conditions that ultimately were classified as relational problems: *uncomplicated bereavement (UB), marital problem, parent–child problem,* and *other specified family circumstances.* The last mental condition included sibling rivalry. DSM-III-R (1987) provided the same terms and definitions for those mental conditions.

In DSM-IV (1994), the title of the chapter changed to "Other Conditions That May Be a Focus of Clinical Attention." That chapter included a separate section called "Relational Problems," which included the following: *relational problem related to a mental disorder or general medical condition, parent–child relational problem (PCRP), partner relational problem, sibling relational problem (SRP),* and *relational problem not otherwise specified.* DSM-IV was criticized because the descriptions of these relational problems were overly vague. However, DSM-IV also featured the Global Assessment of Relational Functioning (GARF) Scale, which was included in the chapter, "Criteria Sets and Axes Provided for Further Study." The GARF was intended to indicate an overall judgment of a family relationship on a hypothetical continuum ranging from optimal relational functioning to a disrupted, dysfunctional relationship. It was analogous to the Global Assessment of Functioning (GAF) Scale that constituted Axis V of DSM-IV. The GARF and GAF Scales were continued in DSM-IV-TR (2000) but not in DSM-5 (2010).

Even before the publication of the DSM-IV, the Group for the Advancement of Psychiatry and the Family Psychology Division of the American Psychological Association was joined by 13 other professional societies interested in relational problems; they formed the Coalition of Family Diagnosis. The Coalition compiled further information about family dysfunction and relational problems and published the classic, *Handbook of Relational Diagnosis and Dysfunctional Family Patterns* (1996). The first sentence of the

Telegram: @medical_k

www.konkur.in

Handbook stated, “Relational diagnosis is a concept whose time has come.” The contributors to that book were disappointed in the minimalistic presentation of relational problems in DSM-IV and hoped to influence the discussion of those topics in DSM-5. For example, they criticized the traditional principle in DSM that a mental disorder is something that occurs *in a person;* that approach seemed to exclude problems that emerge from disturbed relational patterns and dysfunctional family systems. Another consideration has been financial: “Other conditions” and V codes are typically not acceptable to third-party payers.

When the DSM-5 Task Force got underway, there was not a separate workgroup dedicated to relational problems. However, liaisons from the field of family therapy were included in some of the other workgroups. The *Research Agenda for DSM-5* (2002) included a chapter that emphasized both personality disorders and relational problems. It was suggested that relational problems should have the following features, which are ambitious goals not only for relational problems but also for traditional mental disorders:

- The diagnostic description must be of the relationship, not just of the individual.
- Relational problems should have distinctive features.
- Relational problems should cause severe emotional, social, and occupational impairment.
- Relational problems should have a recognizable clinical course.
- Relational problems should show recognized patterns of comorbidity.
- Relational problems are expected to appear in patterns of family aggregation.
- Relational problems should involve both biologic and psychosocial factors.
- Relational problems should show a response to specific treatments.
- Relational problems should be preventable.

A group of family researchers was organized to collect the scientific evidence and to create the conceptual frameworks necessary to

Telegram: @medical_k

www.konkur.in

clarify the place of interpersonal relationships in clinical practice. That team of researchers, the Relational Processes Working Group, advised both the DSM-5 Task Force and the component of the World Health Organization (WHO) that was revising the *International Classification of Diseases* (ICD). The Working Group published a book, *Relational Processes and DSM-V: Neuroscience, Assessment, Prevention, and Intervention,* which DSM-5 personnel utilized in revising the chapter on "Other Conditions." The Working Group published a second book, *Family Problems and Family Violence,* which was directed more closely at ICD-11. In general, the importance and prominence of relational problems have gradually increased in both DSM-5 and ICD-11.

Eight relational problems—which all relate to psychosocial issues within families or couples—are included in DSM-5: (1) *parent-child relational problem (PCRP),* (2) *sibling relational problem (SRP),* (3) *upbringing away from parents,* (4) *child affected by parental relationship distress (CAPRD),* (5) *relationship distress with spouse or intimate partner (RDSIP),* (6) *disruption of family by separation or divorce,* (7) *high expressed emotion (EE) level within family,* and (8) *UB.* This is a rather disparate potpourri of mental conditions, which have a variety of manifestations, circumstances, and implications. The descriptions and definitions of relational problems in DSM-5-TR are more detailed and robust than those in DSM-IV, but there remains room for improvement in developing specific criteria for these mental conditions. These eight conditions are included in their own section, "Relational Problems," which distinguish them from "Abuse and Neglect," and the various additional topics that are included in the chapter, "Other Conditions That May Be a Focus of Clinical Attention."

Table 28.4–1.
Comparable Terminology for Relational Problems in DSM-5 and ICD-11

DSM-5-TR	ICD-11
Parent–child relational problem, V61.20	Caregiver–child relationship problem, QE52.0
Sibling relational problem, V61.8	Relationship with parents, in-laws, or other family members, QE50.4
Upbringing away from parents, V61.8	Removal from home in childhood Institutional upbringing, QE93
Child affected by parental relationship distress, V61.29	Problems related to primary support group, including family circumstances, unspecified, QE70.Z
Relationship distress with spouse or intimate partner, V61.10	Relationship distress with spouse or partner, QE51.0
Disruption of family by separation or divorce, V61.03	Disruption of family by separation or divorce, QE70.1
High expressed emotion level within family, V61.8	Problems related to primary support group, including family circumstances, unspecified, QE70.Z
Uncomplicated bereavement, V62.82	Uncomplicated bereavement, QE62

There was considerable discussion among the writers of DSM-5 and ICD-11 when those manuals were being developed, with the hope of coordinating definitions as much as possible. See Table 28.4–1 for comparisons of terminology regarding relational problems in DSM-5-TR and ICD-11. Relational problems are included in a much broader concept called social determinants of health

Telegram: @medical_k

www.konkur.in

(SDOH), which the WHO has introduced. SDOH are the “conditions in the environments in which people are born, live, learn, work, play, worship, and age that affect a wide range of health, functioning, and quality-of-life outcomes and risks.”

PARENT–CHILD RELATIONAL PROBLEM

Definition

DSM-5-TR specifies that PCRP (V61.20) should be used when the main focus of clinical attention is to address the quality of the parent–child relationship or when the quality of the parent–child relationship is affecting the course, prognosis, or treatment of a mental or other medical disorder. The DSM-5-TR further explains that PCRP is associated with impaired functioning in behavioral, cognitive, or affective domains. Examples of behavioral problems include inadequate parent control, supervision, and involvement with the child; parental overprotection; excessive parental pressure; arguments that escalate to threats of physical violence; and avoidance without resolution of problems. Cognitive problems may include negative attributions of the other’s intentions, hostility toward or scapegoating of the other, and unwarranted feelings of estrangement. Affective problems may include feelings of sadness, apathy, or anger about the other individual in the relationship.

Etiology

There are multiple risk factors for PCRP. They include the child’s genetic predisposition, the child’s having a difficult temperament, parental psychopathology, parent–child attachment problems, inadequate supervision, parental relationship distress, family violence, negative peer interactions, poverty, neighborhood problems, and stressful life events. Maladaptive methods of parenting are frequently the cause of PCRPs. A common system of classifying parenting styles uses the two dimensions of parental *demandingness* (behavioral control, supervision, maturity demands) and *responsiveness* (warmth, acceptance, involvement). This model

Telegram: @medical_k

www.konkur.in

results in subclassification into four parenting styles: (1) *authoritative,* with high demandingness and responsiveness, (2) *authoritarian,* with high demandingness and low responsiveness, (3) *permissive,* with low demandingness and high responsiveness, and (4) *neglectful,* with low demandingness and low responsiveness (Table 28.4–2). One can see that there is a broad range of adequate, good enough parenting, and problematic parenting can range from too much of a good thing (being overly protective) to too little (being neglectful). Most practitioners encourage parents to strive for an authoritative approach with their children. Parents who are overly authoritarian, permissive, or neglectful are more likely to create PCRP between themselves and their children.

Table 28.4–2.
Parenting Styles Diagram

		Parental Responsiveness	
		Supportive Parent is accepting and child centered	**Unsupportive** Parent is rejecting and parent centered
Parental Demandingness	**Demanding** Parent expects much of child	**Authoritative Parenting** Relationship is reciprocal, responsive, high in mutual communication	**Authoritarian Parenting** Relationship is controlling, power assertive, low in mutual communication
	Undemanding Parent expects little of the child	**Permissive Parenting** Relationship is indulgent, low in limit setting	**Rejecting–Neglecting Parenting** Relationship is rejecting, neglecting, uninvolved

Data from Baumrind D. The influence of parenting style on adolescent competence and substance use. *J Early Adolesc.* 1991;11(1):56–95.

Diagnosis and Clinical Features

PCRP pertains to the behaviors and attitudes of both the child and the parent; one or the other or both individuals may contribute to their dysfunctional relationship. Of course, this diagnosis may also apply to the relationship between the child and other caregivers who are actively involved in raising the child, such as extended family or even close family friends. The Semistructured Interview for Caregiver–Child Relationship Problem has been introduced, which may be useful in both research and clinical settings.

In cases of PCRP, it is common for one or both parties to experience personal mental health issues—such as depression in the parent or separation anxiety in the child—which drive the PCRP that occurs between them. In order to fully express what is happening in

Telegram: @medical_k

www.konkur.in

the family, it is necessary to identify the mental disorders (if any) of both the child and the parent, as well as the dysfunction (if any) that occurs in their relationship.

The parent–child relationship is particularly important in infancy, and early childhood, when the development of the brain is essential and thus affects the child's mental maturation. A healthy parent–child relationship buffers and modulates psychopathologic risks arising from the child, the parent, or elsewhere. Impaired parent–child relationships can exacerbate and even create psychopathology. The organization, Zero to Three has focused on the assessment, diagnosis, treatment, and prevention of mental health problems in infants and toddlers. Their book, *DC:0–5,* is a diagnostic manual for young children that complements DSM-5.

Differential Diagnosis and Comorbidity

PCRP is intended to capture dysfunctional parenting, but not child maltreatment. If physical, sexual, or psychological abuse is occurring, those conditions should be the diagnosis, not PCRP. The parent participant in PCRP may have a mental disorder that is contributing to the problem, such as a substance use disorder, a mood disorder, or an anxiety disorder. The child participant in PCRP may also have a mental disorder that is aggravating their family relationships, such as oppositional defiant disorder or conduct disorder. Parents who are in conflict with their children may also be in conflict with each other, so one should consider an additional diagnosis such as relationship distress with a spouse or intimate partner or spouse or partner violence (SPV). Also, one should consider the possibility of parental alienation, where a child is manipulated by one parent to reject the other parent; that condition could explain symptoms that may occur in PCRP, such as negative attributions to the intentions of the rejected parent, extreme hostility toward that parent, and unwarranted feelings of estrangement.

SIBLING RELATIONAL PROBLEM

Telegram: @medical_k

www.konkur.in

Definition

DSM-5-TR states that SRP (V61.8) should be used when the focus of clinical attention is a pattern of interaction among siblings that is associated with significant impairment in individual or family functioning or with development of symptoms in one or more of the siblings, or when an SRP is affecting the course, prognosis, or treatment of a sibling's mental or other medical disorder.

Etiology

Retrospective research indicates that the majority of adults have experienced sibling rivalry in some form. The birth of a new sibling usually results in an older sibling becoming competitive with the infant for the attention and affection of parents. Such rivalry becomes disordered when it is associated with extremely negative affects, overt hostility, or attempts to injure the new sibling or any other sibling.

SRP is exacerbated by marital conflict and parental displays of favoritism. When a child is idealized or is made a parental scapegoat, rivalry may become violent. Certain cultures may sanction favoritism, for example, favoring the oldest male, without increasing the risk for pathologic sibling rivalry.

A poignant form of an SRP may occur when a child experiences serious illness or death, which may be a life-altering event for that child's siblings and other family members. Such an event changes family dynamics, disrupts the family routines, and captures the parents' time and attention. The affected child's siblings may be marginalized just when they most need to feel like important members of the family.

Diagnosis and Clinical Features

Sibling rivalry refers to competition among siblings for the attention, affection, and esteem of their parents or for other recognition or reward. It typically consists of jealousy, competition, and fighting between brothers and sisters. The child may feel that they are receiving unequal amounts of the parent's attention, discipline, or

Telegram: @medical_k

www.konkur.in

responsiveness. *Sibling rivalry* is a more general term that refers to common interactions among siblings; in contrast, *SRP* is a less common and more serious mental condition that—like all mental disorders and conditions—is associated with clinically significant impairment in functioning.

In cases of SRP, the maladaptive sibling relationship adversely affects family function, is the cause of significant impairment, or contributes to problematic behaviors in one or more siblings. Behaviors that occur in SRP include recurring arguments and conflicts that distract from the activities of daily life, avoiding interaction with the sibling who is causing the stress, threats of a child's running away, a pattern of anger toward a sibling that does not resolve because of a lack of conflict resolution strategies, and excessive jealousy between siblings. SRPs may occur between full, half, step, foster, or adopted siblings.

Although verbal and physical conflicts among siblings are common, major violence and abuse present a more serious challenge. There are no bright lines to distinguish them, but it seems obvious that extreme SRP may lead to sibling violence that becomes sibling abuse. The latter features injurious behaviors such as hitting hard enough to leave a mark, cutting, burning, and putting a child in dangerous circumstances; also, the victim becomes fearful of the perpetrator. However, parents may downplay fighting between siblings and regard it as child's play. Even the children are confused about what is abusive.

Differential Diagnosis and Comorbidity

In assessing for possible SRP, there needs to be a determination as to whether there is a partner relationship problem in the family that may have destabilized the family system, resulting in an intensification of sibling needs, parental needs, the showing of favoritism, or other more pathologic means of differentiating between siblings. SPV must be ruled out as well. The presence of serious psychiatric disorders or substance use disorders in the parents must be determined.

Telegram: @medical_k

www.konkur.in

The siblings need to be evaluated for a variety of psychiatric diagnoses and psychosocial stressors. Being teased or bullied at school may exacerbate sibling violence at home. Having been sexually abused either within or outside of the family might predispose a child to be sexually abusive of a less powerful or younger sibling. Violent siblings need to be evaluated for past or current history of physical abuse, the witnessing of intimate partner violence (IPV), and specific psychiatric disorders. Specific disorders that might predispose a child to be abusive to a sibling include attention deficit hyperactivity disorder, conduct disorder, and mood disorders. Psychotic disorders, impulse disorders, and any neurologic conditions that might result in increased impulsivity or decreased inhibition and judgment should be considered.

UPBRINGING AWAY FROM PARENTS

Definition

DSM-5-TR states that *upbringing away from parents* (V61.8) should be used when the main focus of clinical attention pertains to issues regarding a child's being raised away from the parents or when this separate upbringing affects the course, prognosis, or treatment of a mental or other medical disorder. The child could be one who is under state custody and placed in kin care or foster care. The child could also be one who is living in a nonparental relative's home or with friends but whose out-of-home placement is not mandated or sanctioned by the courts. Problems related to a child living in a group home or orphanage are also included.

Etiology

Some children require out-of-home placement, most often due to parental neglect and inability to provide adequate care, less often because of physical abuse, sexual abuse, parental incarceration, and abandonment. Foster care—including shelters, orphanages, nonrelative foster parents, and relative foster parents—constitute a temporary form of out-of-home care; adoption is intended to be a

Telegram: @medical_k

www.konkur.in

permanent assumption of parental responsibilities by individuals other than the biologic parents. Government data indicate that more than 420,000 children are in formal foster care—arranged and monitored by a social service agency—in the United States each year. The number of children placed through informal fostering arrangements outside of the public system, for example, with grandparents, is several times that.

Diagnosis and Clinical Features

Most children enter foster care with pre-existing handicaps and vulnerabilities, such as chronic medical and mental health problems. Separation from their families of origin and also the loss of peers, schools, and neighborhoods constitute enormous stressors. Although many children show resilience in the face of these stressors, the risk for continuing physical and mental health problems in children in foster care is higher than that of the general population. It is sadly common for children to experience multiple disruptions in placements over time, which add to their vulnerability for serious and prolonged mental health problems. Frequently the goal for the youngster is reunification with their biologic parents, which occurs in more than one-half of cases. However, many children who are reunified with their families of origin are subsequently placed again into foster care.

Various initiatives have been introduced with the goal of reducing the morbidity associated with foster care. For example, social service agencies strive to avoid unnecessary separation of children from their families in the first place by providing services for the prevention of removal. Permanency planning is a goal, with reunification, adoption, or long-term foster placement as possible options. Social service agencies also aim to free a child for adoption—by the termination of parental rights—sooner rather than later. All of these initiatives are intended to reduce the unstable and continuous cycle of children being in multiple foster homes over extended periods of time.

Kinship care—most often with the child's grandparents—is a popular option in lieu of reunification with the child's biologic parents. Typically, the grandparents hope that the child's parents will resolve the problem that led to the family crisis, such as substance abuse,

Telegram: @medical_k

www.konkur.in

homelessness, etc. The advantages of placement with grandparents include the child's pre-existing attachment to the grandparents; preservation of a connection to the extended family of origin; greater stability and permanence; and maintenance of religious, racial, and ethnic values. There are also concerns regarding placement with grandparents: These are older individuals with health concerns and physical limitations; they may be unemployed and have limited financial resources, and difficulty maintaining restrictions on parental visitation. Fostering by grandparents and other relatives is often arranged informally rather than through a social service agency. In order for the family member to access medical care, educational services, etc., it may be necessary for the caregiver to secure guardianship or legal custody.

Practitioners will face other challenges associated with the relational problem, upbringing away from parents. (1) For example, children come to the United States from all over the world, fleeing desperate circumstances, becoming separated from family, and now experiencing a new culture and language. There is a surge of unaccompanied minors from the southern border of the United States, having been exposed to violence and severe deprivation. (2) A concern for child and adolescent psychiatrists is that children in foster care are prescribed a disproportionate amount of psychotropic medication. Prescribers and consultants try to put more emphasis on psychosocial interventions. (3) Finally, both practitioners and caregivers are concerned when foster children "age out" of the system. When that occurs—typically at age 18 or 21—everyone involved in their program should create an adequate transition plan, which relates to social supports, housing, education, employment, and medical insurance.

CHILD AFFECTED BY PARENTAL RELATIONSHIP DISTRESS

Definition

Telegram: @medical_k

www.konkur.in

This diagnosis, CAPRD (V61.29), was new to DSM-5, which provided a very brief account of its meaning. DSM-5 simply states that CAPRD should be used when the focus of clinical attention is the negative effects of parental relationship discord (e.g., high levels of conflict, distress, or disparagement) on a child in the family, including effects on the child's mental or other medical disorders.

Etiology

About 55% of American marriages end in divorce. The divorce rate in second marriages is even high than for first marriages. Also, a large percentage of unmarried parents separate when they have young children. Approximately one-half of the children in the United States will experience parental separation or divorce.

A conflict between parents is common even in harmonious and stable relationships; most children, even in high-conflict homes, do not develop emotional or behavioral problems. Nevertheless, negative child outcomes are more strongly associated with parental conflict than with the parents' divorce. In fact, children from divorced families appear to have higher levels of well-being than children from intact, high-conflict families. Of course, continued conflict between parents after divorce exacerbates the children's poor adjustment.

Diagnosis and Clinical Features

Parental relationship distress may refer to persistent disparagement of one or both parents by the other parent; high levels of conflict; intimate partner distress (IPD: dissatisfaction with the relationship as well as difficulty resolving conflicts, lack of positive exchanges, coercive exchanges, or persistently perceiving negative intentions in the partner); and IPV (physical force such as hitting, slapping, and biting; extreme psychological manipulation; and/or coercive sexual acts). A CAPRD may display impaired functioning in behavioral, cognitive, affective, and/or physical domains. Examples of behavioral problems include oppositionality and the child's reluctance or refusal to have a relationship with a parent (contact refusal). Cognitive problems may include cognitive dissonance, attempting to maintain

Telegram: @medical_k

www.konkur.in

affection for both parents simultaneously (loyalty conflict), and/or adopting the false belief that the rejected parent is evil or dangerous (parental alienation.). Affective problems may include anger, anxiety, depressed mood, and post-traumatic symptoms. Physical symptoms may include stomachaches, headaches, and exacerbation of general medical conditions.

Differential Diagnosis and Comorbidity

The scope of CAPRD includes the following four scenarios:

RDSIP, also called intimate partner distress, is the most common cause of acute emotional distress in treatment-seeking couples. RDSIP features relationship issues such as conflict resolution difficulty, withdrawal versus overinvolvement, chronic negative attributions of the other's intentions, dismissal of the partner's positive behavior, and chronic sadness, apathy, and/or anger about the other partner. Of course, the hurtful effects of marital conflict on children are well documented. Specifically, the level of marital conflict predicts children's internalizing and externalizing disorders.

SPV is also called IPV. SPV is always more serious than RDSIP. RDSIP is more amenable to treatment; SPV is more likely to be associated with antisocial personality disorder. The latter is a pattern of behavior in which one partner uses physical violence, coercion, threats, intimidation, isolation, or emotional, sexual, or economic abuse to control the other partner. There has been considerable research regarding the effects on children who have been exposed to IPV. It is traumatic for a child to witness persistent or substantial conflict between parents. When high levels of violence occur, the child may develop post-traumatic stress disorder. When low levels of violence occur over a period of time, the child may develop anxiety (such as separation anxiety disorder or generalized anxiety disorder) or depression. The clinician may use both terms together—for example, CAPRD with post-traumatic stress disorder—to convey clearly the child's condition.

A **Loyalty Conflict** occurs in a child when they try to maintain affection and good feelings toward each of their parents, even though the parents are angry and hostile toward each other. A child may

Telegram: @medical_k

www.konkur.in

experience a significant degree of divided loyalty if parental conflicts are obvious and persistent. Also, a more serious loyalty conflict may develop if one or both parents pressure the child to support that parent's side. Children frequently develop physical and psychological symptoms—such as headaches and stomachaches—when they experience intense loyalty conflict stress. These physical symptoms typically occur when the time approaches for the child to transition from the household of one parent to that of the other parent.

Parental alienation is almost always more serious than a loyalty conflict. Those mental conditions involve different psychic mechanisms for coping with parental conflict. A child with a loyalty conflict puts mental energy into maintaining a good relationship with both parents; that effort evokes cognitive dissonance, which causes discomfort and anxiety. The child may resolve those uncomfortable emotional states by aligning with one parent against the other, especially if the favored parent was able to manipulate the child into believing that the rejected parent was abusive or neglectful. In cases of parental alienation, the child typically adopts false beliefs that the rejected parent was abusive or neglectful, which drive strongly expressed contact refusal and hostility. It is important for both clinicians and forensic practitioners to distinguish parental alienation (rejection of a parent without a good reason) from realistic parental estrangement (rejection of a parent for a good reason, such as a history of abuse or neglect by that parent).

Telegram: @medical_k

www.konkur.in

Heather was a 6-year-old girl whose parents recently divorced, and her mother was the primary residential parent. Before the divorce, Heather had a close relationship with her father. Their relationship slowly deteriorated after the divorce to the point that Heather refused to visit her father and clung to her mother during the scheduled exchanges. Beginning when the parents separated, Heather's mother cried at the transition times and repetitively told Heather, "I love you. I miss you. I can't wait for you to come back." During her time with her father, the mother telephoned Heather repeatedly, asking if she was all right, and then said, "I miss you so much. I can't wait for you to come home." When Heather returned to her mother, her mother ran to her, became tearful, and said, "I'm so happy you're back. I've been worried sick about you. I don't know what to do when you're gone." The father noticed that Heather gravitated away from him. Just before Heather began to refuse visitation with her father, she told him, "Stop being so mean to Mommy. I hate you." This is an example of a child affected by parental relationship distress, specifically parental alienation. (Adapted from Lorandos D, Bernet W. *Parental Alienation: Science and Law*. Charles C Thomas, Publisher, Ltd; 2020.)

RELATIONSHIP DISTRESS WITH SPOUSE OR INTIMATE PARTNER

Definition

DSM-5-TR states that *RDSIP* (V61.10) should be used when the major focus of the clinical contact is to address the quality of the intimate (spouse or partner) relationship or when the quality of that relationship is affecting the course, prognosis, or treatment of a mental or other medical disorder. Examples of behavioral problems include conflict resolution difficulty, withdrawal, and overinvolvement. Cognitive problems can manifest as chronic negative attributions of the other's intentions or dismissals of the partner's positive behaviors.

Telegram: @medical_k

www.konkur.in

Affective problems may include chronic sadness, apathy, and/or anger about the other partner.

Etiology

A satisfying marriage is one of the most important goals in life. Marital happiness is more strongly associated with overall life satisfaction than is satisfaction in areas involving health, work, and children. A survey in the United States found that the most frequently cited causes of acute emotional distress were problems in intimate relationships, including separation, divorce, and other problems with intimate partners.

General etiologic factors of RDSIP include genetic and neurobiologic contributions to temperament and style of interaction. Several studies have identified genetic factors related to partner relationship problems as modestly to moderately heritable, including divorce risk, marital satisfaction, conflict, and warmth. Most personality studies have focused on temperament, which is highly heritable. The most commonly used rating scale, the Five-Factor Model (FFM) of Temperament, categorizes temperament along five dimensions: neuroticism, extraversion, openness, agreeableness, and conscientiousness. High neuroticism and low agreeableness are the most consistent predictors of marital dissatisfaction, conflict, divorce, and abuse.

Childhood attachment patterns are remarkably stable through adulthood. Adult attachment patterns are described along two domains: seeking or avoiding attachment and fear of intimacy. Securely attached adults usually have a positive view of themselves and others; they feel loved, expect responses to self-disclosures, minimize negative affects, and engage in effective conflict resolution. Developmental factors, psychosocial factors, and sociocultural expectations within and outside the family, all contribute to stability in the partner relationship or lack thereof. A history of parental divorce increases the risk for partner separation, especially if both spouses' parents are divorced.

There is a circular pattern of causation between mental illness and stressful experiences such as relationship distress. For example,

Telegram: @medical_k

www.konkur.in

individuals with symptoms of depression are less supportive toward their partner and have lower expectations regarding support from the partner. These negative behaviors and expectations lead to greater intimate partner distress. Then, the level of marital or partner stress predicts subsequent depressive symptoms. This feedback loop serves to maintain symptoms and reduce the effectiveness of interventions.

Diagnosis and Clinical Features

There are psychological tests that highlight possible marital or intimate partner relational problems. The Relationship Conflict Inventory consists of 114 items that ask how many times particular forms of conflict occurred and the distress level of each occurrence for the participant. The Marital Satisfaction Inventory-Revised (MSI-R)—which consists of 150 true/false questions—is designed to identify the nature and intensity of distress in distinct areas of partner interaction. A short form of the MSI-R can be used as a screening tool. It consists of only 10 questions, such as, “Does your partner often fail to understand your point of view on things?” Of course, if the screening test reveals a possible relational problem, a more complete assessment of RDSIP would include clinical interviews and perhaps more elaborate questionnaires.

Dysfunctional relationships are characterized by an increase in negative affects, cognitive distortions, communication problems, and difficulties in conflict resolution. Negative affect is the most significant sign of RDSIP, particularly when accompanied by negative reciprocity. Negative reciprocity exists when negative affect is countered with more negative affect, resulting in affect amplification. Dysfunctional couples tend to attribute hurtful encounters to events outside of their control, for example, their partner’s “unchangeable” personality traits, and view negative behaviors as undeserved, intentional, or malevolent. Attributions may also be affected by transference, with characteristics of a person’s partner being associated with earlier attachment figures, evoking re-enactments of earlier feelings and experiences. Relational stability is negatively affected by unrealistic expectations and conflicting personal and relational goals, for

Telegram: @medical_k

www.konkur.in

example, the desire to have children, parenting strategies, money, sex, religion, and so on.

Strategies for problem solving are critical to relationship stability. The maladaptive characteristics of conflict resolution that are highly predictive of divorce in dysfunctional couples are harsh start-ups or arguments, frequent use of criticism and contempt, defensive reactions, withdrawal and stonewalling, and failed repair mechanisms. Abrupt criticism at the beginning of a conflict results in affective and autonomic flooding. Men are more prone to feeling flooded due to their higher physiologic reactivity; however, both genders may experience autonomic flooding. Cognitive cascading is another characteristic of dysfunctional relationships, with criticism turning into contempt and contempt triggering a loss of feelings of admiration and memories about positive aspects of the relationship, producing a loss of motivation for preserving the relationship. With escalating intensity, stonewalling and emotional withdrawal follow. Intervention is required if healthy communication patterns are to be restored.

Differential Diagnosis and Comorbidity

Having a successful intimate relationship is a major developmental task of adulthood. Consequently, the failure of a relationship affects a person's sense of self and self-esteem, resulting in sadness, despondency, and possibly suicidal risk. Because risk is high when there is a comorbid psychiatric illness, such as an affective disorder or substance abuse, a thorough psychiatric assessment is essential because untreated disorders may exacerbate the relational problem. Conversely, a relational problem may exacerbate a pre-existing psychiatric disorder.

Past history of violent behavior and the presence of a gun in the house pose significant risks. Personality characteristics associated with violence include pathologic jealousy, verbally abusive behavior, and progressive isolation of one's partner from family and friends. Risk is particularly high when separation is imminent, and the violent partner indicates, "If I can't have you, no one will." If there are children in the family, it becomes important to determine whether they

Telegram: @medical_k

www.konkur.in

are being maltreated. It is likely that when there is an RDSIP, there will also be present relational problems such as CAPRD or PCRP, as children struggle to manage in the midst of their parent's difficulties.

DISRUPTION OF FAMILY BY SEPARATION OR DIVORCE

Definition

DSM-5-TR states that *disruption of family by separation or divorce* (V61.03) should be used when partners in an intimate adult couple are living apart due to relationship problems or are in the process of divorce.

Etiology

Marital distress predicts divorce, which is strongly associated with symptoms of depression for the parents and also child mental health outcomes. Separation and divorce are common: in the United States, 41% of first marriages, 60% of second marriages, and 73% of third marriages end in divorce. The median duration of first and second marriages is 7 to 8 years. The U.S. divorce rate varies by the occupation of the parties: dancers, bartenders, and massage therapists have the highest divorce rates; dentists, farmers, podiatrists, clergy, and optometrists have the lowest divorce rates. Between 2000 and 2019, both the marriage rate and the divorce rate in the United States have declined: the annual marriage rate fell from 8.2 per 1,000 population to 6.1; the annual divorce rate fell from 4.0 per 1,000 population to 2.7. This low rate continued during the pandemic, with 2.3 divorces per 1,000 population in 2020, and 2.5 in 2021.

Diagnosis and Clinical Features

Parental divorce places children at risk for a range of negative sequelae in childhood, adolescence, and adulthood. In childhood, parental divorce is associated with internalizing and externalizing

Telegram: @medical_k

www.konkur.in

behavior problems, academic problems, social difficulties, and poor physical health. When parental divorce occurs during adolescence, there are continued academic, mental health, and physical health problems, as well as risk for substance use and pregnancy. Adults who experienced parental divorce during childhood have an increased risk for major depression, dysthymia, anxiety disorders, personality disorder, and alcohol and drug dependence. Parental divorce also predicts lower educational attainment, occupational problems, physical health problems, and poorer relationships with spouses, parents, and peers in adulthood.

HIGH EXPRESSED EMOTION LEVEL WITHIN FAMILY

Definition

DSM-5-TR states that *high EE level within family* (V61.8) should be used when a family's high level of EE is the focus of clinical attention or is affecting the course, prognosis, or treatment of a family member's mental or other medical disorder. *EE* is a construct used as a qualitative measure of the "amount" of emotion—in particular, hostility, emotional overinvolvement, and criticism directed toward a family member who is an identified patient—displayed in the family environment.

Etiology

It should be noted that contemporary perspectives on EE are distinct from early attempts at developing models of the influence of family processes on severe mental illness. While historical notions—such as "poor parenting," "double-bind messages," and "schizophrenogenic" mothering—were overly parent blaming, current terminology avoids censuring the family for a person's mental illness. For example, modern theories do not regard the family as the primary causal agent of the patient's illness. Instead, the emphasis is on how the family reacts to a psychiatrically impaired relative and how these reactions protect against or contribute to the risk of recurrence of illness.

Diagnosis and Clinical Features

An established assessment device for EE is a semistructured interview known as the Camberwell Family Interview (CFI), which is conducted with the parents or spouse without the patient being present. This instrument provides ratings on the dimensions of criticism, hostility, emotional overinvolvement, warmth, and positive remarks, which allow family members to be classified as high or low on EE. The CFI is a lengthy, complex process and is practical in research settings but not in clinical practice. The Five Minute Speech Sample simply requires the family to talk about the patient for 5 uninterrupted minutes. The speech is recorded and later coded for the overall level of EE, criticism, and emotional overinvolvement. The Level of Expressed Emotion (LEE) scale is a 60-item self-report, which is completed by either the patient's important relationships or by the patient themself. The Family Attitude Scale is a 30-item self-report measure of EE; either relatives or patients may complete it. Finally, the test of Perceived Criticism (PC) consists of only two questions: "How critical do you think [your relative] is of you?" and "When [your relative] criticizes you, how upset do you get?"

High levels of EE may be benign in many family contexts, and in other families may be elicited by the stress associated with physical and mental health problems. For example, parents or family members of severely mentally ill individuals may find themselves confronted with difficult situations for which they are poorly prepared, resulting in excessive EE by the family member toward the mentally ill individual. Thus, some serious mental disorders appear to be induced—in part—by high EE in the family. For instance, genetic load plus high EE in a patient's parents appear to predict the onset of schizophrenia. That phenomenon illustrates the biosocial hypothesis, that is, that major psychotic disorders are the result of the continual interaction of specific biologic disorders of the brain with specific psychosocial and other environmental factors.

It has been observed that relatives of individuals with a major psychiatric disorder tend to respond with negative and increasingly intense emotions to subtle symptoms and negative behavior during

Telegram: @medical_k

www.konkur.in

the prodromal phase of the illness. As symptoms and functioning worsen, parents manifest more rejection and less warmth. Also, EE levels typically decline as patients are treated, and their condition improves. There are implications for interventions with these families, that is, that onset of illness might be delayed and relapses prevented if family members remain low in criticism and rejection of the patient. The family's therapist can help family members view the patient's behavioral symptoms as signs of their illness, not indications of an evil disposition.

During the first family session, JJ's father began with a list of all of the things JJ had done in the past several months to "destroy the family atmosphere." These included inconsistent school performance, staying up too late playing video games, being irritable, especially when asked to interrupt his game playing; being grumpy at the dinner table; getting into altercations with kids at school in situations where he felt insulted or left out; and more generally, "poisoning the atmosphere wherever he goes." JJ responded by intermittently crying and cursing at his father. In the next session, conducted just with JJ and his mother, JJ cursed loudly and repeatedly jumped out of his chair when his mother spoke, threatening to physically hurt her with pieces of cardboard, pens, or other implements he found in the therapy room. Despite this behavior, JJ showed some insight into his problems. He complained bitterly that his father "is always after me to do better… he never tells me I'm doing good enough." This is an example of a high expressed emotion level within the family. (Reprinted with permission of Hooley JM, Miklowiz DJ. Perceived criticism in the treatment of a high-risk adolescent. *J Clin Psychol.* 2017;73(5): 570–578. doi:10.1002/jclp.22454.)

UNCOMPLICATED BEREAVEMENT

Definition

Telegram: @medical_k

www.konkur.in

DSM-5-TR states that *UB* (V62.82) may be used when the focus of clinical attention is a normal reaction to the death of a loved one. As part of their reaction to such a loss, some grieving individuals present with symptoms such as feelings of sadness and associated symptoms such as insomnia, poor appetite, and weight loss. The bereaved individual typically regards the depressed mood as "normal," although the individual may seek professional help for relief of associated symptoms such as insomnia or anorexia.

Diagnosis and Clinical Features

Questionnaires have been used for decades to screen for symptoms of grief. The Texas Revised Inventory of Grief (TRIG) assesses typical symptoms of UB, such as acceptance of loss, crying, and intrusive thoughts. The Inventory of Complicated Grief (ICG) assesses indicators of complicated bereavement, such as anger, disbelief, and hallucinations. Bereavement is also called "grief" and "mourning." After the loss of a loved one, the bereaved individual may experience sadness, loneliness, and perhaps anger. In some circumstances—for example, involving long-term caregivers—the process of bereavement may begin even before death occurs, which is called anticipatory grief. Cultural expectations may influence how a person experiences grief. In some cultures, a death in the family is manifested in a quiet and private manner; in other cultures, there may be loud, intense displays of emotion.

In contrast to the relational problem of UB, complicated or complex grief makes it harder for the bereaved person to adapt to the loss of the loved one. These individuals may ruminate over the timing or manner of the death. They may put excessive energy into avoiding reminders of the loss. They may question whether their own experience of grief is too much or too little. In complicated grief, these symptoms persist longer than 6 months following the death of the loved one.

Differential Diagnosis and Comorbidity

Telegram: @medical_k

www.konkur.in

The DSM-5-TR discusses how to distinguish bereavement or grief from a major depressive episode (MDE). In UB, the predominant affect is feelings of emptiness and loss, while in an MDE, it is persistent depressed mood and the inability to anticipate happiness or pleasure. The dysphoria in UB is likely to decrease in intensity over days to weeks and occurs in waves, which tend to be associated with thoughts or reminders of the deceased. The depressed mood of an MDE is more persistent and not tied to specific thoughts or preoccupations. The pain of UB may be accompanied by positive emotions and humor that are uncharacteristic of the pervasive unhappiness and misery characteristic of an MDE. If a bereaved individual thinks about death and dying, such thoughts are generally focused on the deceased and possibly about “joining” the deceased, whereas, in an MDE, such thoughts are focused on ending one’s own life because of feeling worthless, undeserving of life, or unable to cope with the pain of depression.

CONCLUSIONS AND FUTURE RESEARCH

The relational problems are concepts that clinicians and research personnel will find useful once they become familiar with their meaning, scope, and implications. In clinical practice, it adds important information to say that a child with a generalized anxiety disorder is also experiencing the relational problem, high EE level within the family. Or to say that an adult with persistent depressive disorder is also experiencing the relational problem, disruption of the family by separation or divorce. Thus, traditional DSM-5-TR diagnoses focus solely on symptoms exhibited by individual patients, while relational problems identify the context and often the precipitating cause of the individual’s symptoms. Identification of the contextual component may lead to a more comprehensive treatment plan. The relevance of relational problems goes well beyond psychiatric disorders since they pertain to many disorders across all branches of medical practice. For example, the strategies for managing chronic medical illnesses may include an assessment of

Telegram: @medical_k

www.konkur.in

family factors and interventions with families, which creates a role for the relational problems described in DSM-5-TR.

Researchers can achieve greater specificity by using both traditional diagnoses and relational problems in describing or classifying their study participants. For example, treatment studies for children with specific disorders—for example, anxiety, depression, or disruptive behavior disorders—can assess outcomes using the occurrence of IPD or IPV in parents as covariates to determine whether the presence of CAPRD affects treatment outcomes. Or, screening for parental relationship distress may be accomplished during well-baby appointments. If there are relational problems involving the parents, they could be randomized to couples therapy or treatment as usual, and tracking participant outcomes could test whether that intervention prevents the onset or progression of child mental health problems.

It seems counterproductive for clinicians and researchers to “choose sides” between biologic and psychosocial methods for conceptualizing mental illness. These are simply different ways of understanding the same reality, along with acknowledging that biologic and mental factors mutually influence each other. For example, genetic risk for major depression puts a person at risk for marital and family problems, which in turn are risk factors for depression.

Of course, there are opportunities for further research and improvements in the classification of relational problems, which may play out in future iterations of the DSM. Many family therapists would like to see a broader range of mental and interpersonal conditions included in this section. They would prefer more detailed descriptions of each condition, and they probably would like to include well-known terms and concepts such as triangulation and cross-generational coalition. Also, it is apparent that relational problems must be described in terms that are clearly operationalized. Studies can be designed to see if clinicians who observe the same interpersonal processes make the same relational diagnosis. It is important to distinguish relational problems from similar, perhaps overlapping, conditions: for example, what criteria distinguish PCRP from

Telegram: @medical_k

www.konkur.in

CAPRD? Finally, researchers may be able to sort out how specific relational problems lead to specific mental disorders.

Cultural Concepts of Distress and Assessment

29.1 Cultural Concepts of Distress

ROBERTO LEWIS-FERNÁNDEZ, M.D., M.T.S., LAURENCE J. KIRMAYER, M.D., AND BRANDON A. KOHRT, M.D., PH.D.

Cultural psychiatry has documented wide variations in the experience and expression of mental distress around the world. Historically, these variations were often characterized in terms of "culture-bound syndromes"—distinctive patterns of co-occurring symptoms and signs that were assumed to be rooted in or "bound" to local cultural or contextual features. With advances in research, this view has been challenged, and a more refined set of terms have been proposed to capture the ways in which symptoms, explanations, and expressions of distress vary across cultural contexts. This chapter reviews these newer concepts and approaches, which are included in DSM-5-TR, and illustrates how they can be used to better understand the causes, course, and consequences of mental health problems in the community and the clinic.

Telegram: @medical_k

www.konkur.in

Contemporary cultural psychiatry and psychology recognize that all classification schemes are rooted in particular cultural and historical frames. In turn, the diagnostic language of psychiatry influences popular culture and everyday understandings of mental health problems, ensuring that professionally defined categories help pattern social experience. Hence, Western psychiatric nosologies need to be subjected to the same kind of social, historical, and contextual analysis applied to diverse local nosologies.

Despite local variations, however, similar forms of distress have been documented in many regions of the globe, resulting in clusters of symptoms or syndromes, such as depression or schizophrenia, that can be described at a level of abstraction that allows broad cross-cultural application. Local cultural variations in symptom interpretation and experience will nonetheless influence the recognition, response, and outcome of these disorders. Moreover, some local variations may depend on specific culturally based attributions, behavioral responses, and patterns of interpersonal interaction so that they only occur where those modes of explanation and interaction are present. These indigenous illness forms may occur in Western as well as non-Western contexts. The study of cultural variations in the presentation of illness and distress yields a valuable critique of Western classification schemes by highlighting the assumptions of existing nosology and identifying alternate, indigenous categories that may better fit the experience of patients from diverse backgrounds.

Terminology and Conceptualization

Cross-cultural mental health researchers have introduced several terms to refer to and describe culturally specific forms of expressing and diagnosing emotional distress, including cultural syndromes, popular or folk illness categories, idioms of distress, and illness explanations or attributions. The need for multiple terms reflects the complexity of the ways in which people experience, understand, and communicate distress.

Telegram: @medical_k

www.konkur.in

The term “culture-bound syndrome” was used in the past to describe patterned behaviors of distress and/or illness that appeared to be distinct from existing psychiatric categories and were considered unique to particular cultural settings. The clear implication was that Western psychiatric categories were not culture-bound but rather universal and that proper characterization would disclose a simple mapping of non-Western syndromes onto the categories of international nosology.

The term “syndrome” generally refers to (1) a collection of co-occurring symptoms and signs with (2) a distinctive temporal course, which may include an immediate precipitating cause or etiologic context and response to treatment. Most of the entities described in the DSM as disorders are syndromes in that their identification depends on symptoms and signs since their underlying causes and mechanisms remain uncertain, and there are no reliable biomarkers. The categories are clinically useful largely because they have implications for treatment choice and prognosis. As underlying mechanisms become clear, new distinctions can be made, and specific symptoms, signs, and behaviors may be distinguished and given more diagnostic weight. However, the symptom cluster itself may remain important as a central feature of patients’ experience.

The notion of a syndrome being bound by culture is more problematic. The attribution of “boundedness” emerged early in the history of cultural psychiatry in colonialist contexts in which observers had limited understanding of local cultural contexts. Hence, there was a strong tendency to exaggerate differences, generate stereotypes, and “exoticize” the other. Reports that focused on a particular cultural group in a community noted patterns of problematic behavior, which appeared distinctive or unique to the (usually) Western observers, whether they were missionaries, anthropologists, or clinicians. In some cases, the behavior pattern had a specific popular label and treatment within an indigenous medical system. The foreign observers often believed that the communities in question had been socially isolated, and therefore, saw the patterns of distress as unique and locality bound. Considering the massive migrations and cultural diffusions that have occurred throughout

Telegram: @medical_k

www.konkur.in

human history, this assumption of boundedness has rarely been tenable. For example, in the late 1950s, Raymond Prince described a Nigerian culture-bound syndrome of “brain fag” characterized by feelings of mental fatigue, difficulty concentrating, heat in the head, and myriad other somatic symptoms. Brain fag was found among students who were the first in their families or communities to pursue higher education and was linked to local ethnophysiologic ideas about the importance of central heat and the head in African psychology. However, recent historical evidence shows that “brain fag” was commonly described in England in the late 1800s, and presumably, traveled to Nigeria as part of the colonial system to be adopted as a local mode of expressing distress. Hence, while there may indeed be an important fit between the syndrome of brain fag and local cultural concepts, it must also be understood in relation to these colonial cultural influences.

It would be more accurate, therefore, to term these conditions *cultural syndromes*, de-emphasizing their boundedness because, while they originate in particular cultural areas, they spread with migration and communication and are incorporated into local concepts of illness and expressions of distress. In the contemporary global market of intensified cultural exchanges, exportable syndromes readily become detached from geographical areas. Whatever boundedness they have inheres not in specific locales but in their adoption by ethnic or linguistic groups and links to the sociocultural patterns of which they form part, whether in their countries of origin or in new homes.

The term “syndrome” implies a relatively fixed pattern of symptoms. Only a subset of culture-specific expressions of distress around the world shows this level of organization. Many are typified instead by a more diffuse set of complaints, symptoms, and predicaments that vary across situations and settings, age cohorts, and social subgroups. Rather than representing separate illnesses, they constitute a general category of distress, part of an indigenous system of classifying suffering, sometimes encompassing not only illness but also other forms of misfortune or adversity. Reports of *nervios* (nerves) in Latin America, for example, comprise a

Telegram: @medical_k

www.konkur.in

continuum of conditions, labeled with different but related terms (e.g., “being nervous since childhood,” “suffering from nerves,” “being ill with nerves,” and “attacked by my nerves”), all denoting different gradations of vulnerability and of the effects of adverse events on the nervous system, including symptoms, signs, and causal attributions. As another example, Haitians may distinguish broadly between “*maladi dyab*” and “*maladi bon Dieu*”—the first referring to a set of illnesses (“maladi”) triggered in association with evil forces (“*dyab*,” literally “devil”), usually through spiritual means, and the latter referring to diseases of the natural order, sent by God (“*bon Dieu*”). A great diversity of human afflictions fall under these general headings. Anthropologists use the term *folk illness* to refer to local illness categories like these that are based on particular systems of medicine or broader cultural ontologies, independently of whether they are organized as discrete syndromes or not. A related term is *popular illness category*, which simply reflects the fact that these are labels or constructs commonly used by lay people in the general population.

Telegram: @medical_k

www.konkur.in

Table 29.1–1.
Key Elements of the Constructs Used to Describe the Cultural Concepts of Distress

Folk Illness Categories	Cultural Syndromes	Idioms of Distress	Causal Explanations
▶ Encompass cultural syndromes, idioms of distress, and causal explanations ▶ May include afflictions and predicaments not considered illnesses in the local cultural context	▶ Organized as a collection of co-occurring symptoms and signs ▶ Have distinctive temporal courses, precipitants, causal attributions, and treatment responses	▶ Constitute a linguistic or nonverbal mode of communication ▶ Represent a local "language" for expressing distress ▶ Do not presuppose pathology	▶ Reference etiologies rooted in local systems of knowledge ▶ Are not necessarily linked to particular signs and symptoms ▶ Guide help seeking

One drawback to the term "folk illness" is that the descriptor "folk" tends to connote less affluent and formally educated sectors of society and ignores the fact that these categories are used in complex medical systems embraced by large segments of the population in modern, urban, industrialized societies. Thus, traditional Chinese medicine or Indian Ayurveda has many categories of illness defined in terms of the imbalance of energies or vital essences, respectively. Another disadvantage of the term is that many local illness labels are used to describe afflictions and expressions of distress that are on a continuum with folk illnesses but are not strictly illnesses themselves (much as the term "depression" refers to a psychiatric disorder as well as to lay descriptions of much milder

Telegram: @medical_k

www.konkur.in

reactions to adversity). DSM-5-TR uses the more general term *cultural concepts of distress* to encompass folk illnesses, cultural syndromes, and two other types of cultural expressions of distress described below.

One of these is the notion of a *cultural idiom of distress*, a key concept in recent medical anthropology. Introduced by anthropologist Mark Nichter in 1981, the term "idiom" emphasizes the idea of a local linguistic or nonverbal mode of communication. It highlights the communicative function of the cultural concepts of distress, the notion that suffering is expressed in particular local "languages of distress," which are shaped by cultural understandings of what are appropriate and meaningful ways of denoting affliction. "Idiom" also does not presuppose pathology. Many idioms—like "thinking too much," "stressed out," or lay notions of "depression"—can be used to express everyday concerns or levels of distress that may be subclinical. However, idioms of distress also provide a way to express more severe suffering that leads to help seeking. Hence, the clinician must be able to decode the significance of such expressions to identify dimensions of the problem that require intervention.

A final cultural category encompassed under the term "cultural concepts of distress" involves the many expressions of distress pointing to *causal explanations* that are rooted in local systems of knowledge. These, in turn, may reference particular ontologies involving ethnophysiologic ideas about humors, energies, or other processes, ethnopsychological theories about the mind, sociomoral explanations in terms of problems in the social order, or spiritual or other religious and cosmologic systems. As etiologies, these causes are not necessarily linked to particular signs and symptoms but rather denote explanations for the source of the problem that usually guide help seeking. Table 29.1–1 summarizes the key elements of the constructs used in this chapter to describe the cultural concepts of distress.

Cultural syndromes, folk or popular illness categories, idioms of distress, and explanations commonly coexist, and the same local term, or closely related terms, may refer to more than one of these types of concepts. For example, *nervios* terms in Latin America can

Telegram: @medical_k

www.konkur.in

be used to describe a syndrome (e.g., as the subcategory *ataque de nervios*, a stereotyped sequence of precipitants, behaviors, and sequelae), a folk illness category (e.g., when denoting an illness "affecting the nervous system," as in "she is ill with nerves"), an idiom (e.g., when communicating the nature of the affliction, such as, "my nerves are killing me"), or an explanatory cause (e.g., "he was born with emotional problems because his mother suffered from nerves during her pregnancy"). Moreover, usage may change over time, reflecting cultural changes and the influence of the health care system itself. Despite this complexity, the concepts provide a window into the ways that patients and their families understand their problems and are essential for accurate epidemiologic research, clinical diagnosis, and assessment, as well as designing appropriate and effective interventions. The following sections further trace the origins and use of these terms in psychiatric theory, research, and practice.

HISTORICAL BACKGROUND

Pioneering Work

In 1962, Pow Meng Yap, an early exponent of cultural psychiatry, introduced the term *atypical, culture-bound psychogenic psychoses* to denote what he later called "forms of psychopathology produced by certain systems of implicit values, social structure and obviously shared beliefs indigenous to certain areas." In response to changing nosologic paradigms, this term evolved over time into "atypical, culture-bound reactive syndromes," from which the label of "culture-bound syndromes" emerged. Yap's selection of the term "culture-bound" was based on his view that aspects of culture (i.e., implicit and explicit values and notions, social structure, and folk practices) pattern the expression of psychopathology to such a degree that particular forms of illness may be confined to the geographical boundaries of the cultural group in question. He expected that once analyzed further, these apparently unique forms of mental illness would prove to be atypical variations in generally distributed

Telegram: @medical_k

www.konkur.in

psychogenic disorders. Basic to Yap's formulation was an acceptance of the universality of psychoanalytic constructs, on which culture could exert pathoplastic effects. This implied it should be possible to locate all of these "exotic" syndromes within the classificatory systems of clinical psychiatry, and Yap proposed a formal ordering of these syndromes within a universal nosologic schema for clinical, didactic, forensic, and administrative purposes. Yap also suggested that attempts should be made to distinguish "essential" from "accessory" symptoms as well as to establish the "natural history" of each disorder in its "elementary psychogenic form" in order to accurately parcel the syndromes among psychiatric and somatic illness categories. His expectation was that such studies would lead first to a consistent definition of each disorder in the form of modal symptoms and then to universally valid mechanisms of psychopathology, providing a firm basis for cross-cultural clinical research.

In the 1980s, Raymond Prince and coworkers expanded on Yap's writings. They proposed a definition of these phenomena as a "collection of signs and symptoms (excluding notions of cause), which is restricted to a limited number of cultures primarily by reason of certain of their psychosocial features." This definition attempted to narrow Yap's "culture-bound syndromes" exclusively to the medical denotation of "syndrome" as a collection of descriptively defined symptoms that are "a reasonably complete descriptive picture of nature, remain fairly constant over time and are verifiable by all investigators." This kind of nosologic entity was distinguished from "labels" and "causal notions" superimposed idiosyncratically on universal psychopathologic entities. In this view, these terms conveyed much less scientific accuracy and were prone to nonverifiable misconceptions. Prince attributed some of the controversy surrounding the "culture-bound syndromes" to the lack of focus on descriptive categories defined by recurrent symptom patterns. "Culture-bound syndromes" were portrayed as useful to medical anthropologists and cross-cultural psychiatrists as well as to epidemiologists. The former can use them to explain the relationships between symptom patterns and cultural processes,

Telegram: @medical_k

www.konkur.in

while the latter need to take them into account to accurately and completely measure the full range of psychopathology in a given population.

Following on the methods of Yap and Prince, other authors continued to categorize “culture-bound syndromes” according to contemporary professional paradigms, usually adhering to Prince’s formula of stressing their descriptive aspects. For instance, Ronald Simons emphasized the phenomenologic similarity of groupings of these conditions across historically unrelated and culturally dissimilar times and places, despite differences in the meaning assigned to the experiences and behaviors. He contended that it is feasible to insert the “culture-bound syndromes” into contemporary diagnostic systems, particularly once they are grouped as a cluster of related syndromes. The term *taxon*, borrowed from biologic classification, was employed to denote a grouping of similar items, but without specifying the level of abstraction of the similarity or suggesting that the grouping as presently elaborated is in any way exhaustive or final. In their 1985 text, *The Culture-Bound Syndromes*, Simons and his colleague Charles Hughes used the taxonomic principle to group the cultural concepts based on their phenomenologic similarity across diverse cultural settings. For example, under a “Startle Matching Taxon,” they listed *latah* (from Malayo-Indonesia) and *imu* (from Japan), defined in purely behavioral terms, roughly as follows: someone is startled, after which they say things that are normally socially taboo, talks in a manner locally considered nonsensical and amusing, matches the movements of others, and obeys or defies commands in an exaggerated and stereotyped way. Like Yap and Prince, this kind of classification method focused on a verifiable cluster of behaviors and experiences as the defining elements of the cultural concepts of distress and de-emphasized other aspects of the illness experience, such as causal attributions or social meanings that are dependent on the context in which the cultural concepts arise.

Subsequent Work in Cultural Psychiatry

Telegram: @medical_k

www.konkur.in

Ruth Levine and Albert Gaw distinguished several kinds of cultural concepts of distress. “True” “culture-bound syndromes” were organized as recurrent collections of symptoms, which should be classified according to their “predominant symptom or symptoms” and listed as culturally patterned versions of the most relevant DSM category (e.g., *amok* [from Malayo-Indonesia] under the dissociation phenomena and *boufée delirante* [from Western Africa and other settings] under the psychoses). By contrast, “illnesses of attribution” were organized around indigenous etiologic notions (e.g., *susto* [from Mexico and other Latin American regions] in which sudden fright will cause the soul to leave the body, making the individual vulnerable to a variety of ills) rather than discrete symptom clusters. And “idioms of distress” are more general terms that do not have specific correspondences to psychiatric categories (e.g., *nervios* [from Latin America], a general term used as an idiom for stress-related illnesses that can apply to disparate psychiatric disorders, from adjustment problems to psychosis). The authors themselves acknowledged some of the arbitrariness of this approach, however, as well as the technical difficulties involved in parceling out indigenous expressions of psychopathology into their three categories. For instance, in *hwa-byung*, suppression of anger is seen as a causative factor in the development of a somatic symptom cluster (indigestion, dyspnea, fatigue, and the sensation of a mass in the stomach) associated with emotional symptoms (anxiety and depression). The fact that this folk condition is organized around a Korean etiologic notion that ascribes to anger (*hwa*) the capacity to produce illness (*byung*) led these authors to categorize *hwa-byung* as an illness of attribution, whereas it has been described as a cultural syndrome by others due to its usual presentation as a recurrent symptom cluster. In fact, most cultural syndromes contain embedded notions of attribution as organizing elements for the symptom clusters.

Other authors have taken a more mixed approach, combining universalistic views with the notion that each social group creates unique forms of psychopathology that are fundamentally inseparable from the cultural preoccupations that gave rise to them. Notable among these is John Carr, who hypothesized that all forms of

Telegram: @medical_k

www.konkur.in

psychopathology, including the folk illnesses, represent *culturally authorized final common behavioral pathways*. These are behavioral responses, part of a limited number of behavioral repertoires that individuals use in response to stressful conditions that are common to humanity. Although significantly shaped by cultural contexts, these pathways are mediated by universal mechanisms of learning and cognition. To elucidate the relationship between *amok* and depression, for example, Carr and his colleague Peter Vitaliano contended that these alternate expressions of distress are culturally determined variants of response to comparable life stress conditions. The critical question, in their view, is why some people respond with aggression, some with depression, and still, others cope adaptively to similar aversive events. Culture-specific and idiosyncratic responses to stress result from complex interactions between physiologic processes, predisposing personality styles, cognitive processes, and learned problem-solving skills.

Perspectives from Clinically Applied Medical Anthropology

Ethnographic studies of folk illnesses have approached them as indigenous expressions of distress found within specific cultural contexts. From the anthropologic perspective, these expressions represent local patterns of distress that reference common preoccupations or concerns of particular cultural groups. According to this view, all expressions of distress, including those incorporated into the DSM and ICD systems as diagnostic entities like major depression or schizophrenia, are culturally shaped and are thus equally “culture-bound.” This specificity does not negate the role of biology or personal biography in the formation of any of these concepts, much as universal biologic parameters constrain the features of all languages, yet cultural groups produce multiple variants of human speech.

Medical anthropologists and sociologists, such as Byron Good, Mary-Jo Delvecchio Good, and Margaret Lock, have noted that illness expressions may be organized culturally into nosologies not only on the basis of descriptive, symptom-based approaches but also

Telegram: @medical_k

www.konkur.in

according to diverse cultural logics that are rooted in distinct ontologies (e.g., the reality of spirit-mediated illness). Many cultural groups use symbolic methods of classification, including the literate medical traditions of the ancient civilizations, in which illnesses are often categorized by analogy to various aspects of the cosmos, social relations, objects in nature, and other contextual factors. The Goods noted that current Western nosologic thinking is predicated on an empiricist theory of language, which posits the existence of a one-to-one correlation between *words* and *things in the world*, with the notion that the latter will remain fixed and unchanging despite evolving social situations. Other cultural groups and periods have considered instead that things in the world are mutable and depend for their meaning on their associations with the social, environmental, and even supernatural context and that human categorizations should reflect this fundamental embeddedness.

Ethnographic work reveals that cultural concepts of distress identify socially constructed patterns of interpretation of suffering that serve pragmatic communicative functions. Clarifying these functions requires what Good and Delvecchio Good called a "meaning-centered medical anthropology" that investigates illness forms from the perspective of *semantic networks*, the clusters of experiences, words, and interpretations that give rise to particular illness forms as modes of experience and expression. These meaning networks are called "semantic" because they reveal the role of interpretation and communication in shaping reality and may include "personal trauma, life stresses, fears and expectations about the illness . . . the metaphors associated with a disease, the ethnomedical theories, the basic values, and conceptual forms, and the care patterns that shape the experience of the illness and the social reactions to the sufferer in a given society." By taking this contextual approach, the basic organizational principle underlying a particular illness form can be established to assess the degree to which it is descriptive, etiologic, or expressive of particular concerns.

The anthropologist and psychiatrist Arthur Kleinman approached the meaning-centered approach through the concept of an *explanatory model*. This concept refers to the more-or-less

Telegram: @medical_k

www.konkur.in

systematic explanations of an illness among different actors in any given illness episode (e.g., patient, relative, and caregiver). Kleinman showed how the explanatory model approach could be incorporated into clinical assessment through the use of practical questions about basic aspects of illness experience, addressing perceived etiology, time and mode of onset of symptoms, pathophysiology, course of sickness, and treatment that can be used by clinicians and investigators to clarify the interaction of cultural, physiologic, and psychological elements in an illness episode. The Explanatory Model approach was operationalized by Mitchell G. Weiss in the form of a semistructured instrument for clinical ethnographic research, called the Explanatory Model Interview Catalogue which can be adapted for research on any illness form.

In later work, Kleinman deepened this approach to explore the ways in which the intersubjective processes of interpersonal agency —communication, engagement, transaction, and negotiation—create the flow of *social experience* that links the body–self with collective meanings and social institutions. Individuals transact their lives, including basic processes of health and illness, within relational networks of social experience, which provides "the medium through which moral commitments and negotiations join the corporeal with the collective." For Kleinman, all of life is lived in "local worlds" that constitute the moral contexts of the illness experience. The importance of local categories of suffering then lies, not primarily in identifying discrete syndromes, but in understanding what is "at stake" for individual patients, families, and communities in terms of power, prestige, material resources, ethnic identity, social order, or survival. This intersection of vital interests and values was well illustrated in Kleinman's studies of neurasthenia in China, which revealed the importance of relational networks at the levels of supernatural and natural worlds, human interactions, bodily processes, and politics. In traditional Chinese thought, each level affects the functioning of all the other levels. This fundamental interdependence can be seen in the existence of illnesses whose pathology is at the network level, such as the concept of *shenjing shuairuo,* "weakness of the nervous system" in Mandarin. In this

Telegram: @medical_k

www.konkur.in

cultural syndrome, the internal nervous system (*shenjing*) has become devitalized (weak or run down, *shuairuo*) in correspondence with a demoralized network of interpersonal and societal relations. The symptoms of *shenjing shuairuo* can thus be understood as embodied signs of a devitalized world, both internally and externally, which are linked by contextually located emotions.

Ethnographic fieldwork by Allan Young, Laurence Kirmayer, and their colleagues has shown the complexity of types of knowledge and modes of narration embedded in everyday explanatory accounts of illness. Individuals may link symptoms to explanations based on *chain complexes* because they were closely connected in time and space (contiguity) or as a result of logical shortcuts to denote complex experiences (e.g., metonymy), such as using the term "nerves" to refer to the anatomical and functional aspects of the nervous system, including the feelings and sensations it mediates, much as journalists use the term "Washington" to refer to the entire U.S. government. People also commonly use *illness prototypes*—illness episodes, experienced previously by the person or by others, that provide salient examples used to reason analogically about one's own experience. In effect, patients' illness narratives may combine models common to a cultural group, idiosyncratic assemblies of possibly disconnected events, and assumptions based on past experiences. These approaches were operationalized by Danielle Groleau in collaboration with Young and Kirmayer to develop the McGill Illness Narrative Interview, a semistructured interview designed to obtain illness narratives based on (a) contiguity of events, (b) cultural prototypes of the illness for the patient, and (c) explanatory models of illness.

Atwood Gaines's concept of *sickness history* was another important contribution to the anthropologic understanding of concepts of distress. Gaines's constructivist argument held that folk and professional notions of sickness evolve historically, in association with other aspects of culture, and that individuals' understanding and experience of illness are patterned on this accumulated social knowledge. In this way, cultural concepts of distress may reflect distinct cultural histories of societies. Gaines

Telegram: @medical_k

www.konkur.in

presented the examples of *spasmophilie* (spasmophilia), *fatigué* (fatigued), and *triste/fatigué tout le temps* (sad/fatigued all the time) as sicknesses that are considered physical diseases in France but are unknown in the United States and would actually be considered nonpathologic forms of dysphoria if they came to the attention of American nosologists. Gaines showed how these concepts emerged from a common sickness history that evolved from medieval understandings of dejection as a sin (acedia) to a positive valuation of existential world-weariness as a sign of maturity and a possible and accepted etiology of a physical disease characterized by various states of fatigue, bodily aches, and irritability, among other symptoms.

Much recent work has pursued similar constructivist and historical approaches to both local constructs and the diagnostic entities of the DSM. Combining anthropologic and clinical methods, Roland Littlewood and Maurice Lipsedge traced the historical contexts of constructs like hysteria, medication overdosing, agoraphobia, anorexia nervosa, and shoplifting and linked their phenomenologies and demographic distribution to culturally patterned gender and class constraints prevalent in the United States and United Kingdom in the 19th and 20th centuries. They described these syndromes or idioms as deeply embodied expressions of societal conflicts about which the participants were frequently only marginally aware. The field of *critical medical anthropology* emphasizes the contribution of societal structures of oppression (e.g., racism, class hierarchies, restrictive immigration laws) to the prevalence, phenomenology, and course of mental health conditions, including their comorbidity with physical illnesses. The work of Nancy Scheper-Hughes, Merrill Singer, Philippe Bourgois, and others reveal the impact on the expression of illness of adverse social determinants of health that often go unnoticed or unaddressed in routine clinical care.

A constructivist approach to the ethnopsychologies underlying culturally specific expressions of illness and distress can be elaborated in terms of pragmatic, linguistic, communicative, and interactional processes, including (a) the handling of the gap between experience and expression; (b) the labeling of deviant

Telegram: @medical_k

www.konkur.in

behavior as voluntary or accidental; and (c) the interpretation of symptoms as symbols or meaningless events. This conceptual grid helps explain why in North America, it is possible to privilege "psychologized" understandings of illness since these arise out of local commitments to individual autonomy, expressiveness, and personal goals. Commitments to other values in other cultural settings may produce different ethnopsychologies.

RELATIONSHIP TO PSYCHIATRIC CLASSIFICATION

At present, most investigators consider cultural concepts of distress to be *orthogonal* to psychiatric diagnoses; that is, the cultural concepts comprise alternate systems of classification that describe in distinct ways the same realm of suffering as professional nosologies. This means that, at the level of global categories, the cultural concepts cannot be easily subsumed into existing psychiatric disorders. Instead, each cultural concept exhibits a *degree of overlap* with a group of Western diagnoses, which can be represented by percentages or by a series of correlations, as with any set of comorbid relationships within professional categories.

Rather than one-to-one, the correspondence between diagnoses and cultural concepts tends to be one-to-many in either direction. Symptoms or behaviors that might be sorted by nosologies like ICD or DSM into several disorders—including across distinct diagnostic clusters—may be included in a single cultural concept, and diverse presentations that might be classified by Western nosologies as variants of a single disorder may be sorted into several distinct concepts by an indigenous diagnostic system. Therefore, cases identified by a single indigenous label often cut across diagnostic clusters. For example, the symptoms of *amok* in Malayo-Indonesia exhibit diverse combinations of anxiety, depressive, somatic, dissociative, psychotic, and characterologic symptoms. The obverse is also true; homogeneous psychiatric cohorts will appear locally diverse. In Latin America, for example, different cases of major

Telegram: @medical_k

www.konkur.in

depression may be labeled as distinct conditions according to locally salient features of phenomenology, causation, context, or the healing ideology of the practitioner. These include cases of *padecer de los nervios* (suffering from nerves), *susto, fallo mental* (mental failure), *cólera* (rage), *facultades* (faculties, for *espiritistas*), and demonic influence (e.g., for Pentecostals), among other categories. Cross-cultural variation in the assembling of the "metastructure" of psychiatric disorders—the fact that different nosologies distribute individual illness categories into diagnostic groupings in distinct ways—as well as the changes over time in this classification process (e.g., the reassigning of post-traumatic stress disorder [PTSD] away from the anxiety disorders and into a new category of trauma and stressor-related disorders) reveals the cultural underpinnings and social evolution of any classification system.

The lack of one-to-one correspondence between diagnoses and cultural concepts is intensified by the substantial phenomenologic variation that exists even across individuals who endorse the same cultural concept of distress. A given instance of *ataque de nervios*, for example, may present as an acute dissociative episode, with seizure-like symptoms in a state akin to trance, for which amnesia is later reported. Other episodes may resemble cases of panic disorder, albeit with more suicidal and aggressive features, such as breaking things and verbally or physically attacking those around them. Some episodes may present as uncontrollable fits of nervous laughter, which evolve into bouts of crying and screaming and subsequent depression. Others may constitute episodes of acute grief at the funeral of a loved one without any pathologic sequelae. What links all four instances in the popular classification system in the Latino Caribbean is their presentation as acute episodes of uncontrolled emotionality, precipitated by interpersonal stressors that overwhelm the person's coping ability, usually in a context of insufficient social and familial support. Yet from the psychiatric perspective, these presentations would be considered phenomenologically distinct. Clinical translation between the cultural concepts and psychiatric diagnoses must therefore be conducted at the level of the *individual*,

Telegram: @medical_k

www.konkur.in

describing for that person the overlap between both systems of classification.

Two other differences ensure that cultural concepts of distress and contemporary psychiatric nosologies overlap only partially as global systems. First, Western nosologies are based at present nearly exclusively on formal, descriptive definitions of psychopathology. Most indigenous nosologies, however, distinguish pathology from normality at least as much based on contextual characteristics and causal theories as on descriptive ones. These include assessments regarding the appropriateness of the symptom in the specific setting and time in question, the relative sufficiency of the precipitating stressors, and the nature and quality of the human, and sometimes spiritual, relationships of the sufferer.

Second, while psychiatric nosologies contain only pathologic conditions, cultural concepts of distress may apply to a wide range of severity, including presentations that do not meet DSM criteria for any mental disorder. As described in DSM-5-TR, “an individual with acute grief or a social predicament may use the same idiom of distress or display the same cultural syndrome as another individual with more severe psychopathology.” The indigenous classification systems thus tend to describe broader realms of behavior and adaptation than the narrower purview of psychiatric classification.

Despite the differences between local and professional nosologies, information on cultural concepts of distress is vital to clinical care for at least five reasons, which are outlined in DSM-5-TR. First, the use of cultural concepts in screening instruments or in reviews of systems may facilitate the identification of patients’ concerns and improve the detection of psychopathology, as individuals may be more familiar with these local concepts than with professional terminology. For example, including questions about “thinking too much” can elicit illness accounts that may not be evoked by typical symptom queries. Second, clinician awareness of cultural concepts may prevent misdiagnosis, as cultural variation in symptoms and explanatory models associated with these concepts may lead clinicians to misjudge the severity or a problem or assign the wrong diagnosis (e.g., socially warranted suspicion may be misunderstood as

Telegram: @medical_k

www.konkur.in

paranoia). Third, cultural variations in symptoms and attributions related to the cultural concepts can be associated with particular features of risk, resilience, and outcome. Clinical exploration of cultural concepts can elicit information on the role that specific contexts play in symptom development, course, and coping strategies. For example, the interpretation of trauma-related symptoms as spiritual afflictions may prompt the use of effective forms of healing and self-coping, such as church-based social support or meditation. Conversely, the presence of a cultural syndrome may be associated with specific types of risk and morbidity —for instance, endorsement of *ataque de nervios* is related to higher suicidal ideation after adjusting for psychiatric diagnosis, demographic characteristics, and trauma exposure. Fourth, understanding the messages being communicated by the patient in the idiom of the cultural concept (e.g., social isolation, being overwhelmed) can improve clinical rapport and engagement and help patients and clinicians select a mutually acceptable treatment plan. Some patients come to care expecting to be treated for the cultural concept of distress and may become disengaged if their understanding is not negotiated effectively with that of the clinician. Fifth, cultural concepts can illustrate key psychological mechanisms which need to be understood and addressed to improve clinical efficacy. For example, catastrophic cognitions can contribute to symptom escalation into panic attacks in culturally specific ways, such as through the cultural salience of certain symptom–outcome pairings. The popular linkage made in the United States between chest pain and heart attacks can precipitate panic episodes when chest pain occurs as part of an anxiety reaction but is interpreted as a harbinger of myocardial infarction. In Cambodia, by contrast, the association is more commonly between neck soreness and stroke due to the interpretation of panic attacks as signs of disordered *khyâl* circulation, a wind-like substance important in local ethnophysiology. Being aware of these linkages can help clinicians identify how cultural interpretations can constitute the actual “cogs” of the disorder.

Telegram: @medical_k

www.konkur.in

Attending to these aspects of the relationship between cultural concepts and psychiatric diagnoses can help clinicians meet patients' treatment expectations. Moreover, the inclusion of cultural concepts in research can reveal patterns of comorbidity—between the diagnoses linked by the idiom or cultural syndrome—and clarify the epidemiologic distribution of cultural features of the illness. Information on the cultural concept of distress can be incorporated into the process of diagnostic assessment and treatment planning by eliciting an account of the person's definitions of pathology, idioms of distress, unique symptoms, contextual embeddedness, and other associated factors that are contained in the experience of the cultural concept. A systematic approach for eliciting and documenting this information is the Cultural Formulation Interview, which is included in DSM-5-TR and will be described later in this chapter.

EXAMPLES OF CULTURAL CONCEPTS OF DISTRESS

Only a few of the thousands of cultural concepts of distress have received sustained research attention integrating cultural and psychiatric research methods. This chapter focuses on three concepts from diverse cultural regions that have been the object of intensive research, including studies of their relationship with psychiatric diagnoses: *ataques de nervios*, possession syndrome, and *shenjing shuairuo*. Other examples of cultural concepts of distress are included in the DSM-5-TR chapter on culture and psychiatric diagnosis. These three examples and the few cultural concepts listed in the DSM-5-TR are meant to be illustrative of the wide gamut of folk illness categories relevant to particular populations or contexts.

Ataque de Nervios

Ataque de nervios ("attack of nerves" in Spanish) is a syndrome indigenous to various Latin American cultural contexts, notably those of the Latino Caribbean (Puerto Rico, Cuba, and the Dominican

Telegram: @medical_k

www.konkur.in

Republic). It has received considerable attention in the psychiatric and anthropologic literature since the mid-1950s, mostly in Puerto Rican communities in the Island and in the United States. Early reports of presentations in male recruits to the U.S. armed forces by military psychiatrists in Puerto Rico mislabeled *ataque* as "the Puerto Rican Syndrome." In keeping with psychoanalytic theory at the time, these investigators attributed the *ataque* to specific indigenous child-rearing practices allegedly predisposing to the hysterical discharge of aggressive drives. The power relationships embodied in the military, and the colonial situation represented by the presence of the U.S. armed forces in Puerto Rico, were usually left unanalyzed in these discussions.

Subsequent research focused on the role of *ataque* as a culturally recognized and sanctioned expression of emotion, mostly by women, that should be understood as a form of communication about family relationships in contexts of social and economic powerlessness. These investigations located the psychosocial etiology of *ataques* in experiences of acute family discord and individual suffering—such as grief, fear, and anger—in the context of collective distress—such as migration, poverty, and discrimination. This research emphasizes the role of *ataque* as an idiom of distress in Latino communities and illustrates how the same folk term may represent different kinds of cultural concepts—that is, a folk category such as *ataque* is a cultural syndrome that functions as an idiom of distress.

Contemporary clinical–anthropologic studies have further clarified the phenomenology, cultural meanings, epidemiology, and relationship of *ataque* to psychiatric diagnoses. The work of Peter Guarnaccia and Roberto Lewis-Fernández has identified loss of control of emotions, behaviors, and a social world out of control as the core experiences of *ataques de nervios*. Their work suggests a popular nosology based on various categories of *nervios* (nerves), several of which require more systematic research.

Phenomenology. Guarnaccia, Glorisa Canino, and colleagues surveyed a representative community sample of Puerto Rico residents (N = 912) for the presence of *ataque de nervios*. Qualitative

Telegram: @medical_k

www.konkur.in

coding of general descriptions of the syndrome among a subsample of 145 respondents in this larger study—of whom 77 were *ataque* sufferers—yielded four domains of *ataque* experience. These were emotional expressions, bodily sensations, action dimensions, and alterations in consciousness. Based on these data, a prototypical *ataque de nervios* can be described as composed of the elements described in Table 29.1–2.

Epidemiology. A 1987 survey by Guarnaccia and Canino in a probability sample of the population of Puerto Rico (*N* = 912), using the Diagnostic Interview Schedule (DIS), found a weighted lifetime prevalence of *ataque* of 13.8%, making it one of the most frequently reported syndromes in the Island. Twelve percent of respondents had *ataques* that met DIS criteria for a positive psychological syndrome—that is, the *ataque* met severity criteria (consulting a physician or other professional, taking medications, or reporting some functional impairment) and could not be explained as resulting from physical illness or substance use. The Latino cohort of the 2002 to 2003 National Latino and Asian American Survey, led by Margarita Alegría, also obtained lifetime *ataque* prevalence in a nationally representative sample of U.S. Latinos using a diagnostic module that followed the format of the Composite International Diagnostic Interview. *Ataque* prevalence was 10.9% in Puerto Ricans, 6.2% in Cubans, 6.0% in Mexicans, and 5.4% in other Latinos, suggesting both that *ataque* is common across Latino subgroups and that it is more prevalent among Puerto Ricans.

Telegram: @medical_k

www.konkur.in

Table 29.1–2.
Phenomenology of *Ataque de Nervios* (Attack of Nerves)

a. Exposure to a frequently sudden, stressful stimulus, typically eliciting feelings of fear, grief, or anger, and involving a person close to the subject, such as a spouse, child, family member, or friend. Severity of the trigger ranges from mild to moderate (i.e., marital argument and disclosure of migration plans) to extreme (i.e., physical or sexual abuse and acute bereavement).
b. Initiation of the episode immediately upon exposure to the stimulus or after a period of brooding or emotional "shock."
c. Once the acute attack begins, rapid evolution of an intense affective storm characterized by a primary affect usually congruent with the stimulus (such as anger, fear, grief) and a sense of loss of control (*emotional expressions*).
d. These are accompanied by all or some of the following:
   i. *Bodily sensations*: trembling, chest tightness, headache, difficulty breathing, heart palpitations, heat in the chest, paresthesias of diverse location, difficulty moving limbs, faintness, blurred vision, or dizziness (*mareos*).
   ii. Behaviors (*action dimension*): shouting, crying, swearing, moaning, breaking objects, striking out at others or at self, attempting to harm self with nearest implement, falling to the ground, shaking with convulsive movements, or lying "as if dead."
e. Cessation may be abrupt or gradual, but it is usually rapid, and often results from the ministration of others, involving expressions of concern, prayers, or use of rubbing alcohol (*alcoholado*). There is return of ordinary consciousness and reported exhaustion.
f. The attack is frequently followed by partial or total amnesia for the events of the episode, and descriptions of the following for the acute attack: loss of consciousness, depersonalization, derealization, mind going blank, and/or general unawareness of surroundings (*alterations in consciousness*). However, some *ataques* appear to exhibit no alterations in consciousness.

Telegram: @medical_k

www.konkur.in

Guarnaccia and Canino found a prevalence of *ataques de nervios* of 8.9% in a representative sample of youth in Puerto Rico aged 4 to 17 years (*N* = 1,897). A second, community-based probabilistic sample of Puerto Rican children aged 5 to 13 years in San Juan (*N* = 1,353) and the South Bronx (*N* = 1,138), led by Héctor Bird and Canino, found a lifetime prevalence of *ataque* of 5.4% and 4.3%, respectively.

Risk factors for *ataque* span a range of social and demographic characteristics. Adults reporting an *ataque de nervios* in Puerto Rico are more likely to be female, over the age of 45, with less than a high school education, formerly married (i.e., divorced, widowed, or separated), and out of the labor force. However, 10% of the men in the sample reported an *ataque de nervios*, which indicates that some men express their distress through this cultural syndrome. Among Latinos in the United States—and like other psychiatric disorders—*ataque* is positively correlated with higher acculturation (e.g., U.S. birth and English proficiency), suggesting higher psychiatric vulnerability in this postmigration population. The level of neighborhood violence is also a risk factor for *ataque*. Risk factors among Puerto Rican youth differ somewhat by the site (New York vs. Puerto Rico) and by study; they include older age (especially adolescence in girls), single-parent household status, exposure to violence, stressful life events in the past year, and higher perceived poverty. In one of the community-based studies in Puerto Rico, multiple regression analysis also revealed an independent positive association between *ataque* status in the youth and a family history of the syndrome, suggesting the possible influence of intergenerational behavioral modeling.

Lewis-Fernández and colleagues estimated the lifetime prevalence of *ataque de nervios* in two clinical settings serving adult Puerto Rican psychiatric outpatients. The prevalence rate of *ataque* was 55.1% among immigrant Puerto Ricans (*N* = 89) in an outpatient Latino mental health clinic in New England and 51.5% among outpatient referrals to psychiatry (*N* = 97) in three rural Puerto Rico primary care clinics. In both sites, the gender distribution of *ataque* sufferers was nearly equivalent: 56.3% female in New England and

Telegram: @medical_k

www.konkur.in

54.8% female in Puerto Rico. However, women were twice as likely to seek mental health care in both settings. Finally, in these rural clinics for low-income residents in Puerto Rico, *ataque* rates also did not differ by age cohort or level of education. All social groupings among this disenfranchised sector of the population appeared equally at risk for *ataque* episodes. Two large opportunity samples of Puerto Rican or Latino primary care patients in the Northeastern United States separately found a lifetime *ataque* prevalence of 26% to 28%, confirming the elevated prevalence of the syndrome in clinical populations. An elevated clinical prevalence was also observed among youth: lifetime prevalence of *ataque* was 25.5% in a representative sample of youth utilizing the mental health system in Puerto Rico (N = 767).

Precipitants/Etiology. Prototypically, *ataque de nervios* was linked by sufferers to an acute precipitating event or to the summation of many life episodes of suffering brought to a head by a trigger that overwhelmed the person's coping ability. In the Puerto Rico community sample studied by Guarnaccia and Canino, the first experience of an *ataque* was closely tied to a precipitating event. In 92% of cases, the *ataque* was directly provoked by a distressing situation, and 73% of the time, it began within minutes or hours of the event. A majority of first *ataques* (81%) occurred in the presence of others, as opposed to when the sufferer was alone and led to the person receiving help (67%). Finally, unlike the typical experience of persons with panic disorder, most respondents reported feeling better (71%) or feeling relieved (81%) after their first *ataque*. These findings suggest that first episodes of *ataque de nervios* are closely tied to the interpersonal world of the sufferer and that they result in an unburdening (*desahogarse*) of one's life problems, at least temporarily. One function of the *ataque* may be to rally the person's social network, including reversing the current interpersonal arrangement in favor of the sufferer. In one primary care study of 508 Latino adults in the Northeastern United States, partner support was associated with significantly lower odds of *ataque de nervios*, while

Telegram: @medical_k

www.konkur.in

emotional strain from one's partner, family, or friends was each associated with higher lifetime prevalence.

Specific precipitants were varied but typically consisted of acutely stressful experiences resulting in feelings of loss, grief, anger, or fear. In general, the most frequent triggers identified by the Puerto Rico epidemiologic study included arguments with a spouse or other close relatives, the drunkenness of a family member, an accident that threatened the life of a person close to the subject, death of a close family member, natural disaster, or the passing of a fright (*susto*) through a person. Certain precipitants were obviously traumatic and were correlated with globally elevated prevalence rates in exposed subpopulations. For example, this survey showed a higher prevalence of *ataques* among those severely affected by a recent natural disaster (19%) than among nonexposed individuals (14%), and intermediate rates among subjects only moderately affected (16%). However, *ataques* have been reported after apparently minor stressors, such as family squabbles, adolescent romantic disappointments, or peer razzing. In these cases, the presence of underlying interpersonal or sociocultural conflicts of longer duration—such as a marital argument or abuse, migration, poverty, discrimination, precarious employment/source of income, or family discord—has been invoked by investigators to explain the enhanced *ataque*-producing power of superficially mild triggering experiences.

Studies in psychiatric outpatient samples of the relationship between childhood trauma exposure and the presence of *ataques* have yielded conflicting results. Daniel Schechter and colleagues found a positive association, whereas Lewis-Fernández and colleagues did not. In this latter study, childhood traumatic exposure was high across Puerto Rican psychiatric outpatients regardless of *ataque* status, suggesting that, in a clinical sample, factors in addition to childhood trauma accounted for this condition. In a different psychiatric outpatient sample of diverse Latino subethnicities with a history of traumatic exposure (N = 202), greater trauma severity was not associated with a higher frequency of *ataques*. More research is needed in samples with and without traumatic exposure to clarify the association between this risk factor and *ataque*.

Telegram: @medical_k

www.konkur.in

Relationship to Psychiatric Diagnoses. Psychiatric evaluations of *ataque* sufferers have usually revealed the presence of some form of psychopathology. In the Puerto Rico adult epidemiologic survey, 63% of respondents who reported an *ataque de nervios* met diagnostic criteria for one or more psychiatric disorders measured in the DIS. This suggests that rather than being an expression of nonpathologic distress, most *ataques* are associated with a psychiatric disorder. Overall, *ataque* sufferers had 4.35 times the odds of meeting criteria for a psychiatric diagnosis than those who did not report the cultural syndrome. At the same time, 37% of *ataque* sufferers did not fulfill DIS criteria. This suggests that a substantial minority of respondents with this syndrome are describing milder levels of distress using the idiom of the cultural syndrome; alternatively, they may be reporting psychiatric disorders not assessed by the study instrument.

It is important to note that *ataques* do not correlate exclusively with one psychiatric diagnosis and cannot be treated as simply a culturally shaped version of a specific psychiatric disorder. The combined research findings support a strong relationship between *ataques de nervios* and mood and anxiety disorders in youth and adults, as well as disruptive disorders in youth and dissociative disorders in adults. Of particular concern is the strong relationship between *ataque* and suicidal ideation (odds ratio [OR] = 6.2) and attempts (OR = 8.1). In a U.S. nationally representative community sample of diverse Latino subethnicities (N = 2,554), lifetime history of *ataque de nervios* was independently associated with suicidal ideation (OR = 2.4) after adjusting for multiple covariates, suggesting that the cultural syndrome conveys additional risk beyond recognized risk factors such as psychiatric diagnosis and traumatic exposure. During *ataque* episodes, sufferers may make goal-directed or ill-formed attempts at self-harm, increasing the morbidity (and occasional mortality) of the syndrome.

While early speculation by psychiatrists focused on whether an *ataque* constitutes a culturally shaped version of a panic attack, Lewis-Fernández and colleagues systematically demonstrated that only 36% of best-remembered *ataques* met DSM-IV-TR criteria for

Telegram: @medical_k

www.konkur.in

panic attacks and 17% met criteria for panic disorder. What mainly distinguished *ataques* that did not fulfill panic disorder criteria from those that did include the cuing of episodes by precipitants, symptom crescendo longer than 10 minutes, and feeling relieved rather than frightened after an episode. However, features that were common to both *ataque* and panic disorder included recurrence of attacks, the experience of fear or nervousness during an episode, and anticipatory or behavioral sequelae afterward. Patients who described feeling relieved after their *ataque* also reported significantly fewer panic symptoms than those without this feeling.

Specific characteristics of *ataque* profiles may be associated with distinct psychiatric diagnoses. A study by Ester Salmán and Michael Liebowitz of a sample of Puerto Ricans and Dominicans (N = 156) attending a Manhattan research clinic that was enriched with individuals suffering from *ataque de nervios* (N = 109) found a link between *ataque* features and specific psychiatric disorders. Among those participants in the study whose *ataques de nervios* were characterized by intense fearfulness and feelings of asphyxia and chest tightness, diagnoses of panic disorder were more common. Those whose *ataques* were more dominated by the emotion of anger and aggressive behavior, such as breaking things, were more likely to meet the criteria for co-occurring mood disorders.

Ataque is strongly associated with dissociative experiences. The severity of *ataques*, assessed as lifetime number of episodes, is positively and independently related to self-reported dissociative symptoms, measured with the Dissociative Experiences Scale (DES), and to clinician-diagnosed dissociative disorders, assessed with the Structured Clinical Interview for DSM-IV. Further evidence of the relationship between *ataque de nervios* and dissociation comes from the significant correlation between *ataque* and other Latino cultural concepts that are also related to higher dissociative capacity on the DES. One of these idioms is characterized by “pseudohallucinations” in several sensory modalities—hearing voices or noises, seeing shadows (*celajes*), and feeling presences when alone—that are popularly attributed to spiritual influences. In an outpatient U.S. Latino sample with high traumatic exposure (N =

Telegram: @medical_k

www.konkur.in

202), *ataque de nervios*, pseudohallucinations, and a third Latino folk illness, “being currently ill with nerves,” were all significantly associated with each other and with elevated DES scores, forming a nexus of “nerves”-related cultural concepts linked to dissociative capacity.

In youth, *ataques de nervios* are associated with research diagnoses of mood, anxiety, and disruptive disorders. In a Puerto Rico community-based survey, youth aged 4 to 17 years with *ataques* had ORs of 7.6 for any mood disorder, 5.0 for any anxiety disorder, and 3.1 for any disruptive disorder, compared to youth who did not report an *ataque*. In the clinical sample of the same study, the equivalent ORs were 5.8, 3.5, and 2.0, respectively. Youth with *ataques de nervios* had 4.3 times the odds of meeting criteria for any psychiatric diagnosis in the community and 2.3 times the odds of doing so in the clinical setting. Moreover, impairment was likewise elevated among youth with *ataques* compared to those without, with an OR = 5.6 in the community and OR = 2.1 in the clinical sample. In another study, after adjusting for demographic characteristics and the level of psychosocial stressors, children aged 5 to 13 years with *ataques* in San Juan and the South Bronx had nearly 3 times higher odds of meeting criteria for an anxiety or a depressive disorder, nearly 2 times the odds of a disruptive disorder, and 1.4 times higher odds of global impairment.

Additional Clinical Features. Assessment of the phenomenologic features of *ataques de nervios* experienced by the 77 respondents in the Puerto Rico epidemiologic study with at least one lifetime *ataque* who were reinterviewed by Guarnaccia revealed that the largest number (28%) had suffered only one such episode over the course of their life. Thirteen percent had two *ataques*, 8% experienced three, 9% had four, and 4% had five. The second-largest number (23%) comprised those who had more than five lifetime *ataques*, while 15% were unsure about the total. The bimodal distribution of *ataque* frequency (one vs. six or more) suggests that persons with frequent episodes constitute a minority of *ataque* sufferers. This raises the question of whether having an isolated *ataque* in response to a

Telegram: @medical_k

www.konkur.in

markedly stressful event—as opposed to recurrent *ataques*—represents a relatively normal expression of distress in Latino communities. However, the lifetime presence of one or more *ataques* is associated with disability and outpatient mental health service use among U.S. Latinos, even after adjusting for demographic characteristics, traumatic exposure, psychiatric diagnoses, and chronic health conditions. This suggests that experiencing an overwhelming reaction such as *ataque* may not be without clinical consequences.

The association between *ataque* and a sense of loss of control and of being overwhelmed highlights the importance of the relationship between the cultural syndrome and other behaviors associated with acute emotional dysregulation. Most concerning among these is the strong association noted earlier between *ataques* and suicidal ideation and attempts. Other behaviors related to this acute dysregulation include loss of aggression control, expressed as attacks on people or property, and dissociative experiences, both of which are related to the acute *ataque* experience.

Specific Cultural Factors. The complex relationship between *ataque de nervios* and psychiatric diagnosis may be further clarified by placing *ataque* within a broader Latin American popular nosology of *nervios* (nerves) of which it is part. Experiences of adversity are linked in this nosology to ensuing “alterations” of the nervous system, which result in its impaired functioning, including the peripheral nerves. This quasi-anatomical damage is evidenced in emotional symptoms, including interpersonal susceptibility, anxiety, and irritability, as well as in physically mediated symptoms, such as trembling, palpitations, and decreased concentration. Certain people are considered at greater risk for *nervios* when confronted with adversity, such as those with an inherited predisposition or with stressful perinatal experiences (e.g., mother’s alcoholism). But in all cases, the possibility that sufficient adversity will result in an alteration of the nervous system leads to the popular view that persons faced with experiences of suffering should “control” their reactions to avoid nervous system damage. This usually takes the

Telegram: @medical_k

www.konkur.in

form of dampening the emotional impact of the experience so that the nerves will not be substantially “altered.”

Clinical and popular discussions about *nervios* and *ataques* in Latino communities thus typically reference cultural views about the importance of remaining in control and of facing adversity with *tranquilidad* (equanimity) regardless of the severity of a stressor. *Ataque de nervios* can therefore be understood as a behavioral syndrome stemming from general notions and practices about how to behave, rather than a peculiar cultural expression of a particular diagnosis. As a marker of being overwhelmed, *ataques* are associated with various forms of psychopathology, but the *ataque* itself cannot be reduced to just the psychiatric disorder; rather, it is a marker of the severity of the stressor, of the person’s reaction style, of their level of support, and of the resulting distress and pathology.

Aspects of Caribbean Latino cultural contexts may promote the observed association between *ataque de nervios* and dissociation since the appearance of dissociation during the *ataque* may be enhanced by the cultural perception that a mature social actor needs to be always in control. Dissociation may be particularly promoted by the popular view that when out of control, the person is no longer “themself” (“*ése no era yo* [that was not me]”). The uncontrolled behavior is disavowed as not being part of the self. This may facilitate the emergence of dissociative splits that allows the person to distance themself from the moral consequences of the *ataque* episode. Similarly, prevalent cultural concerns about the psychological and social dangerousness of strong emotions may reinforce the role of anxiety sensitivity in *ataque*. Individuals with high anxiety sensitivity appear to be at elevated risk for *ataque* prevalence and severity, possibly due to positive (adverse) feedback effects on *ataque* onset or persistence.

Community rates of *ataque* in adults are significantly higher in women than in men. The female-to-male ratio is 2:1 in Puerto Rico and 3:2 among U.S. Latinos. The gender difference may appear during adolescence since it is absent in both South Bronx- and San Juan-based representative samples of Puerto Rican children aged 5 to 13 years but is found in a Puerto Rico-wide representative sample

Telegram: @medical_k

www.konkur.in

of youth aged 4 to 17 years. The gendered nature of *ataque* in adults has been attributed in part to traditional gender roles pressuring Latina women to restrict some emotions in social situations, especially around sexual, aggressive, or assertive needs. The gender-specific cultural directive to remain "in control" may predispose women to express suppressed feelings in situations of interpersonal conflict as acute paroxysms of emotionality and uncontrolled behavior, which can later be disavowed as unwilled or even ego-alien.

Treatment. No treatment studies of *ataque de nervios* have been conducted. Typical treatment in community settings involves, first, ensuring the safety of the person and those around them, given the association between *ataque*, suicidality, and uncontrolled aggressivity. "Talking the person down" is usually helpful, accompanied by expressions of support from relatives and other loved ones; the use of rubbing alcohol (*alcoholado*) to help calm the person is a culturally prescribed way of expressing this support.

"Telling the story" of what led to the *ataque* usually constitutes the principal therapeutic approach in subsequent stages of treatment. Since one of the main functions of the attack is to communicate a feeling of being overwhelmed, indicating receipt of the message and the desire to offer support are usually perceived as therapeutic. The person should be allowed to set the pace of disclosure and to give enough details and circumstances to feel "unburdened" (*desahogado[a]*).

In the case of single or occasional *ataques* in the absence of a psychiatric diagnosis, brief follow-up is usually sufficient. This may be discussed with the patient and the family as a way of ensuring a full return to the previous healthy state. For recurrent *ataques*, treatment depends on the associated psychopathology, the nature of the precipitants—including traumatic exposure—the degree of family conflict or support, the social context, the previous treatment experiences, and the patients' and family's expectations, among other factors.

Telegram: @medical_k

www.konkur.in

Psychotherapy is typically the mainstay of treatment, usually with a family focus, given the usual source of the overwhelmed behavior in the interpersonal milieu. A social activism stance by the therapist that acknowledges the origins of adversity among low-income Latinos in socioeconomic disenfranchisement and ethnoracial discrimination is helpful in addressing the sociocultural roots of *ataque de nervios.* Pharmacotherapy may also be useful in the treatment of *ataque*-related psychopathology; the primary emphasis should be placed on treating the underlying disorder. Given the slow crescendo of many *ataques*, judicious use of short-acting benzodiazepines also has a role in helping abort an impending episode. However, this should not be the main form of treatment for recurrent *ataques* since it only forestalls the principal function of the syndrome as a mode of communication.

Possession Syndrome

Involuntary possession trance states are very common presentations of emotional distress around the world. Cognate experiences have been reported in very diverse cultural settings, including India, Sri Lanka, China, Japan, Malaysia, Niger, Uganda, Southern Africa, Turkey, the United States, Canada, Haiti, Puerto Rico, and Brazil among others. *Possession syndrome* is an umbrella English-language term used in the clinical and anthropologic literature on South Asian presentations of involuntary possession trance that encompasses conditions with many different names in regional languages and dialects of India and Sri Lanka. These presentations are seen as a severe affliction by the person's cultural group because they are involuntary, cause distress, and do not occur as a normal part of a broadly accepted collective cultural or religious ritual or performance.

DSM-IV-TR did not list possession syndrome or any other pathologic possession trance condition as a "culture-bound syndrome." Instead, this class of clinical presentations was included in Appendix B of DSM-IV and DSM-IV-TR under the proposed category of dissociative trance disorder (DTD), one of the "criteria

Telegram: @medical_k

www.konkur.in

sets and axes provided for further study." Categories in this section of the manual fell short of full inclusion in DSM-IV as specified diagnoses but were included in the appendix to stimulate research for possible incorporation in DSM-5. Beyond its global prevalence, another reason why involuntary possession trance was given a special status in DSM-IV was its inclusion in ICD-10 as a subtype of trance and possession disorders (F44.3), a specified diagnosis under the dissociative (conversion) disorders in the section on neurotic, stress-related and somatoform disorders. The goal of making the ICD and DSM nosologies more compatible helped to promote consideration of involuntary possession trance in DSM-IV and DSM-5. In ICD-11, the main characteristics of possession trance disorder include the following:

A disorder characterized by a trance state in which there is a marked alteration in the individual's state of consciousness resulting in significant distress or impairment. During the trance episode, the individual's normal sense of personal identity is replaced by another identity attributed to an external "possessing" spirit, power, deity, or another spiritual entity, and the individual engages in behaviors or movements that are experienced as being controlled by the external agent. The trance episodes must be recurrent or, if single, last for at least several days and be involuntary, unwanted, and not accepted as a part of a collective cultural or religious practice. The episodes must also not be due to the effects of a substance or medication or be better explained by another disorder of the nervous system and must result in clinically significant distress or impairment.

In DSM-5 and DSM-5-TR, pathologic possession trance was included under dissociative identity disorder, leading to its redefinition as two variants: possession form and nonpossession form. This incorporation was due largely to the phenomenologic similarity between pathologic possession trance and dissociative identity disorder. Both are disorders of identity alteration that occur during a dissociative state of consciousness and are characterized by involuntary stereotyped and culturally determined behaviors or movements that are experienced as being under the control of an alternate identity. Among 119 possessed patients who visited

Telegram: @medical_k

www.konkur.in

traditional healers in Uganda, for example, Marjolein Van Duijl and colleagues observed involuntary shaking of the head or parts of the body (attributed to spirits), talking in a different voice—which others recognized as the voice of a specific spirit—and feeling influenced by unidentified forces that cause unusual behavior. Nearly half of the possessed patients mentioned something holding the body, so they were unable to move or speak. Among traditional healers and local health workers in these villages, case vignettes of dissociative identity disorder were always attributed to spirit possession. In many healing traditions, patients or practitioners learn how to become possessed to serve as a vehicle for a healing deity or spirit, which then is able to diagnose and treat a wide range of health conditions and life predicaments. Such deliberately sought and socially regulated "executive possession" should not be seen as pathologic.

In both possession and nonpossession types of pathologic identity alteration, sufferers can report full or partial amnesia for the events of the dissociative state. Moreover, a history of exposure to traumatic experiences is common in both conditions. In the Uganda study, for example, individuals with pathologic possession scored higher on the Harvard Trauma Questionnaire and the Traumatic Experiences Checklist than 71 randomly selected healthy inhabitants of the same villages, and scores on both trauma scales were strongly correlated with symptoms of dissociation (r = 0.64 − 0.69) and pathologic possession (r = 0.51 − 0.64). To rule out the misdiagnosis of nonpathologic possession states, dissociative identity disorder requires the presence of amnesia, as well as the fact that the identity alteration states (a) be associated with clinically significant distress or impairment (criterion C) and (b) not be a normal part of a broadly accepted cultural or religious practice (criterion D). In addition, the text states that the pathologic possession episodes "present recurrently [and] are unwanted and involuntary."

Possession trance can occur in epidemic form. For example, in recent years, there have been many episodes of groups of school children in Nepal experiencing possession episodes characterized by involuntary movements and speech. Individuals who are affected in

Telegram: @medical_k

www.konkur.in

these epidemics may be high on measures of hypnotizability and more likely to have a past history of peritraumatic dissociation.

The possession-form and nonpossession-form variants of dissociative identity disorder are not mutually exclusive: individuals in one cultural setting may experience either form, and a single individual may experience both forms. Typically, in nonpossession-form dissociative identity disorder, the alternate identities are experienced as *internal* aspects of the person, as other identity states. In possession-form dissociative identity disorder, by contrast, the alternate identities are typically experienced as *external* possessing agents, usually of supernatural or spiritual origin (e.g., demons and spirits). The main contrast between these two forms of dissociative identity disorder appears to be shaped by the patient's sociocultural milieu. That is, possession-form dissociative identity disorder arises in contexts where possessing agents are considered ontologically "real" (e.g., some fundamentalist religions in the United States or traditional South Asian cultures), as opposed to nonpossession-form dissociative identity disorder, which draws its alternate identities from individualistically focused experiences, such as stages of life (e.g., childhood) or biographical roles in the patient's life (e.g., protector and perpetrator).

The decision to subsume pathologic possession trance states under dissociative identity disorder is not without controversy, however. It is an open empirical question, for example, what proportion of pathologic possession states meets dissociative identity disorder criteria, which include substantial amnestic gaps in addition to identity alteration. The nonpossession form of the disorder is typically a chronic condition arising in childhood in the wake of prolonged and severe trauma. Some pathologic possession trance states follow this pattern, but others are triggered by nontraumatic stressors, such as romantic disappointments and work or religious conflicts, and present as single or recurrent episodes rather than persistent conditions. However, the absence of systematic assessment of childhood trauma precludes excluding this exposure from the genesis of dissociative disorders in these populations. With accumulating evidence, the placement of pathologic possession in

Telegram: @medical_k

www.konkur.in

psychiatric nosology will be further clarified. Dissociative identity disorder may prove to be a heterogeneous condition, encompassing a gamut of identity alteration symptoms, courses, and precipitants across cultural contexts. Alternatively, the evidence may favor the inclusion of pathologic possession trance as a separate diagnostic entity in DSM, as in ICD-11.

Pathologic possession trance states thus constitute local presentations that are farther along the process of incorporation into Western psychiatric classification systems than the usual cultural concepts of distress. Their truly global prevalence makes them candidates for “universalistic” disorders, even though they are considered uncommon in modern Euro-American and European societies. Their status is still unresolved, however, given their inclusion as a variant of dissociative identity disorder in DSM-5 and as a distinct disorder in ICD-11. Moreover, since local presentations of pathologic possession trance vary substantially across cultural settings, possession syndrome is discussed here as a cultural concept of distress, focusing on its specific characteristics in South Asia.

Phenomenology. It is important to distinguish at the outset between possession syndrome, as an instance of possession trance, and the broader category of possession. The latter term refers to a general ideology describing the full range of direct spirit influences on human affairs, including effects on physical, psychological, spiritual, social, and ecologic realms. By contrast, as a subset of general possession experience, “possession trance” refers to specific alterations in consciousness, memory, behavior, and identity attributed to direct spirit influence. In addition to pathologic possession trance states, South Asian cultures authorize multiple examples of normal possession and possession trance in religious, healing, and other ritual contexts. When voluntary and normative, these states are typically seen as instances of religious devotion, mystical ecstasy, social commentary, asceticism, interpersonal relations, existential reflection, and the study of consciousness. This chapter discusses possession syndrome as a pathologic entity with

Telegram: @medical_k

www.konkur.in

an established phenomenology, that is, as a special case in the general continuum of etiologic ideas regarding possession illnesses. A prototypical episode is composed of the elements in Table 29.1–3.

Data on the epidemiology, precipitants, and associated psychopathology of subjects with possession syndrome in South Asia is limited by methodologic considerations. These include a lack of representative community samples and nonsystematic definitions of the syndrome, which shows considerable regional variation.

Epidemiology. Period-prevalence rates among psychiatric cohorts in India conducted mostly via chart review have been variously reported as 0.2% over 1 year, 0.06% over 7 years, and 0.93% over 12 years. Patients with dissociative disorder accounted for 0.15% to 1.5% of outpatients and 0.15% to 1.2% of inpatients at a major psychiatric facility in India between 1999 and 2008; of these, 11.5% of outpatients and 5.4% of inpatients met ICD-10 criteria for trance and possession disorder.

Community-based surveys have yielded higher rates. In 1972, Morris Carstairs and Ravi Kapur found a 6-month period prevalence of 0.97% for involuntary possession syndrome in a South Indian village, using a symptom checklist in a 50% sample of all village adults (N = 1,233). They also reported a 6-month period prevalence of an additional 1.8% for voluntary possession states. V. Venkataramaiah and colleagues surveyed the total population (N = 1,158) of a school catchment area in another South Indian village during an epidemic of possession syndrome in 1979. They found a 1-year period prevalence of 3.5% for involuntary attacks, as well as a prevalence of 0.2% for voluntary possession trance episodes.

Anthropologic accounts of widespread occurrence and cultural barriers to discussing the supernatural features of the syndrome have suggested that the actual prevalence is likely higher than that reported in public surveys. The clients of indigenous healers currently provide the main source of comparative data. For example, 17% of those patients seen by one traditional healer during a 4-month period who met research criteria for psychiatric ailments (N = 30) received an indigenous label of possession syndrome. Finally, the periodic

Telegram: @medical_k

www.konkur.in

occurrence of syndrome epidemics complicates the epidemiologic picture.

Possession syndrome is more common in women, with a female-to-male ratio of 2 to 3:1 in most community and psychiatric cohorts. The 1999 to 2008 cohort showed much higher female-to-male ratios among outpatients (4.7:1) than inpatients (1.3:1), suggesting that women with trance and possession disorder were significantly less likely to be hospitalized. Sex distribution may also vary historically, according to evolving cultural gender attributions, and show geographical or possibly idiosyncratic variation. Various studies conducted in India suggest that women experience considerable social disadvantage related to the typically patriarchal social system, including early marriage, childbearing as the primary social function, family and spousal violence, lack of social integration, poor social support from family members, and limited autonomy. These factors may contribute to the higher prevalence of possession syndrome among women. The age of onset is usually between 15 and 35, but many cases reportedly begin in childhood. Attacks may persist well into middle age, and geriatric cases have also been reported. The syndrome has been identified in all Hindu castes, as well as in Muslims, Christians, and tribal peoples; however, it is more commonly described among Hindus.

Telegram: @medical_k

www.konkur.in

Table 29.1–3.
Phenomenology of Possession Syndrome

Telegram: @medical_k

www.konkur.in

a. Onset occurs typically due to subacute conflict or stress and shows considerable variation. It may be gradual and nonspecific —e.g., diverse somatic complaints, such as dizziness, headaches, abdominal discomfort, hot–cold flashes, listlessness, or difficulty breathing—or sudden and specific, in the form of an abrupt transition to an altered state of consciousness. Onset may also vary by geographical region, presenting in certain areas of the country (e.g., parts of Uttar Pradesh) as a mounting series of rage attacks. If presentation is gradual and nonspecific, transition to the altered state may occur spontaneously or after contact with an indigenous healer specializing in the treatment of the syndrome.
b. Behavior during the altered state consists of some or all of the following:
   i. Dramatic, semipurposeful movements—such as head bobbing, bodily shaking, thrashing, gyrating, or falling to the ground—accompanied by guttural, incoherent verbalizations such as mumbling, moaning, or shrieking.
   ii. Aggressive or violent actions directed at self or at others, including spitting, striking, and impulsive suicidal or homicidal gestures. Verbalizations may be coherent, and consist of derogatory comments or threats of violence directed against significant others or against the subject (in the third person) and typically considered by observers to be uncharacteristic of the subject's usual behavior.
   iii. Specific gestures, comments, or requests denoting the appearance of a known possessing personality by (1) reference to standard attributes of culturally recognizable figures or (2) the name and degree of relation of deceased family members or acquaintances.
c. The altered state is marked by the emergence of one or several secondary identities distinct from that of the subject. Their specific identities, which may remain undisclosed for some time, typically adhere to cultural norms regulating permissible agents of possession, which vary by religion, region, and caste.

Telegram: @medical_k

www.konkur.in

Acceptable agents include spirits of deceased family members, in-law relations, or known village acquaintances who died under specific conditions of distress, and minor supernatural figures of the Hindu pantheon (rarely major deities) and the Islamic spiritual world. They do not include the identities of alternate, living persons, nor apparently alternation of co-conscious multiple identities, as in nonpossession-form dissociative identity disorder, though consecutive possession by two or three agents is not rare, and one case of 21 successive possessions has been reported. On occasion, a single agent may possess several members of a family over time, or in succeeding generations.

d. Possession by the secondary identity(ies) is episodic, resulting in alternation between the usual personality of the subject and the altered state. The subject in their usual identity appears in a daze, exhausted, distressed, or confused about the situation and may report visual or auditory perceptual disturbances regarding the possessing agent, as well as “unconsciousness” and partial or total amnesia for the altered state. States of consciousness may alternate continuously within one episode over hours to weeks, with each state lasting minutes to hours. This pattern may persist intermittently over months or years.
e. Frequently, the specific identities of possessing agents remain undisclosed for some time, requiring the active ministrations of family members and the intervention of specialized indigenous practitioners. The process of disclosure is conceived as a struggle between the family members and the beneficent agents possessing the healer on the one side, and the troublesome possessing identities on the other. It is characterized by remarkable reactivity on the part of the subject to environmental cues, including direct questioning, strategic neglect, and aggressive manipulation. Often, this kind of ritualized intervention elicits the withheld disclosure, and leads to a process of negotiation between the family, the healer, and the possessing agent regarding the propitiatory treatment necessary for the resolution of the episode. Examples of this treatment typically consist of ritual offerings, admission to a possession

Telegram: @medical_k

www.konkur.in

cult, resolution of family conflicts, cessation of abuse, and the postponement or precipitation of marriage.

f. Outcome is variable. Total recovery is often reported at the cessation of a single acute episode, which may be of several weeks' duration. Alternatively, prolonged morbidity may result, or even, rarely, death. The subject may seek exorcism treatment with multiple healers, or undertake a pilgrimage to a regional healing temple. At times, they are prescribed entrance into a ritual devotion cult offering programmed periodic possessions.

Caste distribution may fluctuate historically and respond to sociocultural determinants of the appropriateness and desirability of possession syndrome as an idiom of distress. It has been reported more frequently among disadvantaged castes, of low income and education, and rural residence. Nevertheless, some case studies revealed the prevalence of the syndrome among more advantaged groups, such as Brahmins, despite the cultural proscriptions against it. Case reports suggest higher rates among widowed persons, but a systematic study did not confirm this association. The presence of possession syndrome in other family members (or in ancestors) may be a risk factor, but this relationship has not been investigated systematically.

Precipitants/Etiology. Precipitants of possession syndrome are varied but typically include social or family conflicts and stressful life transitions that elicit strong feelings of vulnerability in persons without firm emotional support. Examples encountered in the literature include marital conflict, abuse, and neglect, at times associated with alcoholism; the arrival of a new bride to the home of her husband's family; delay in arranging a marriage, or in consummating it; forced marriage; widowhood; postpartum status; loss of family social standing; death of a family member; difficulty finding employment and financial difficulties; alienation from family support; and subordination to other family members and in-laws. These precipitants were identified in 67% and 73% of separate mental health cohorts.

Telegram: @medical_k

www.konkur.in

Some older clinical studies stressed the pathogenic role of hysterical and histrionic ego defenses in possession syndrome. However, this ignores the fact that pathologic possession commonly occurs in settings where nonpathologic possession is a positive, socially mandated experience. What may distinguish pathologic episodes is the importance of traumatic precipitants—deaths of children, murder of husband, sexual abuse of a close friend, measles epidemic, physical abuse, the revelation of husband's incest with daughter. Social scientists such as Richard Castillo have emphasized the underlying context of violence against women in India—including selective abortion, infanticide, murder due to discovered premarital relations, rape, sale into prostitution, "dowry death" (the new bride is killed if dowry is considered insufficient), marital abuse, witch killings, and *sati* (widow burning). These data suggest that many instances of possession syndrome may arise not from intrapsychic vulnerability but from widespread undisclosed early trauma, an exposure that has been insufficiently investigated. Some researchers agreed on the etiologic role of childhood stress as a risk factor for possession syndrome but differed on the specific contributions of physical and sexual abuse as opposed to emotional or physical neglect. Alternatively, anthropologic investigators have argued that individual biographical data was insufficient to explain the specific association of spirit possession with marginal persons and transitional life phases, such as birth, menarche, marriage, pregnancy, widowhood, and death. They located the etiology of attacks in caste-specific cultural expectations linking social and spiritual vulnerability. Additional collectively defined precipitants of possession syndrome include certain acts and settings, such as crossing physical boundaries (e.g., the village limit, an empty field at night), which invite the attention of possessing spirits.

Relationship to Psychiatric Diagnoses. Psychoanalytically based evaluations of subjects with possession syndrome often reported evidence of hysterical traits predisposing to dissociative psychopathology in otherwise normal subjects. Others distinguished the intrapsychic origin of the acute behavioral syndrome—which they

Telegram: @medical_k

www.konkur.in

attributed to hysterical processes—from the underlying personality formation and psychic vulnerability. These authors argued that attacks could arise in subjects with diverse personality structures and biologic propensities. Some research reported a substantial proportion of attacks among patients with a primary diagnosis of schizophrenia (40% to 59%) and manic depressive illness (11% to 13%), in whom the possession symptoms took longer to resolve, compared to patients without these disorders.

As noted earlier, DSM-5-TR includes most cases of possession syndrome under dissociative identity disorder. However, cases that do not fulfill the amnesia criterion should receive other DSM diagnoses, including other specified dissociative disorder. As with all cultural concepts of distress, there is no one-to-one overlap between the cultural label and any DSM disorder; psychiatric evaluation must proceed at the level of the individual. In ICD-11, possession syndrome cases would fulfill criteria for trance and possession disorders. Prior to the inclusion of possession phenomenology in dissociative identity disorder, possession syndrome did not have a diagnostic home in DSM: a study conducted in 1987 in a New Delhi outpatient psychiatric clinic (N = 1,517) found that 10% of cases with dissociative pathology received an ICD-10 diagnosis of trance and possession disorders, whereas none met DSM-III-R criteria for multiple personality disorder.

Additional Clinical Features. Rates of relapse are unknown, although anecdotal reports suggest it is not uncommon. Relapse within 15 years was not infrequent and has been recorded after two to three decades. Four of 15 subjects in one study were found to have suffered previous episodes, and 1 subject in another series reported three consecutive postpartum attacks. Entry into a ritual possession cult may reduce or eliminate relapse.

Specific Cultural Factors. Possession syndrome constitutes a folk illness category throughout India and Sri Lanka. It may present initially in a variety of forms, linked by the attribution of spirit etiology. When it presents in a nonspecific fashion, indigenous diagnosis is

Telegram: @medical_k

www.konkur.in

confirmed by the appearance of the altered state during the therapeutic ritual. It is considered an affliction by its painful, involuntary nature and attributed to the intervention of specific spiritual agencies acting independently or at the behest of a witch. Certain castes and persons in transitional states (e.g., puerperium) are considered most vulnerable to spirit attacks, especially when deprived of emotional and material support. The degree of pathology ascribed to the sufferer, the therapy chosen, and the outcome attained depend on the interaction of several factors: psychological (e.g., traumatized ego), biologic (e.g., psychosis), sociocultural (e.g., caste status), and situational (e.g., family dynamics). For instance, when it presents in some Moger women of South India, possession syndrome may be seen as an affliction opening the door to a sacred practice in a possession cult. In some Havik Brahmin women, however, it may constitute the last step in a series of symptomatic expressions of acute distress instead, leading directly to exorcism and incomplete conflict resolution.

Treatment. Specialized indigenous practitioners and ritual therapies are generally available and widely utilized, but psychiatric treatment is typically avoided. Indigenous treatments include neutralization of the conflict or stress via the communal rituals involved in exorcism, as well as the reformulation of the suffering into beneficent individual and communal practice via initiation into a spirit devotion cult—such as the Siri cult of South India—or education into the roles of oracle (diviner), exorcist, or, rarely, avatar (divine incarnation).

Shenjing Shuairuo

Shenjing shuairuo (“weakness of the nervous system” in Mandarin Chinese) is a translation and cultural adaptation of the term “neurasthenia” (from Greek roots for “lack of nerve strength”), which was introduced to China from Russia in the early 1900s. As formulated by the American neurologist George Beard in 1868, neurasthenia denoted a heterogeneous syndrome of lassitude, pain, poor concentration, headache, irritability, dizziness, insomnia, and

Telegram: @medical_k

www.konkur.in

over 50 other symptoms. At first, neurasthenia was considered an "American disease" resulting from the "pressures" of a rapidly modernizing society but was later adopted by European diagnosticians. Its pathophysiology was thought to derive from a lowering of nervous system function through a physical process due to excessive use, especially among the educated and wealthier classes. In Soviet psychiatry, buttressed by Pavlovian research, neurasthenia was a central component of mental health nosology, which became especially influential in Chinese psychiatry after the communist revolution of 1949.

While neurasthenia declined in importance in Western psychiatric nosology and practice during the 20th century, *shenjing shuairuo* underwent marked popular and professional development in mainland China, Taiwan, Hong Kong, in Chinese migrant communities, and in Japan, where a similar syndrome was labeled *shinkei suijaku*. From a peak in about 1980, when it constituted up to 80% of all "neurotic" diagnoses in Chinese societies, *shenjing shuairuo* has become less common. The diagnosis was included in the *Chinese Classification of Mental Disorders, Second Edition, Revised* (CCMD-2-R; 1993), under the section on "Other Neuroses." The CCMD-2-R diagnosis required three symptoms out of five nonhierarchical symptom clusters, organized as weakness, emotional, excitement, and nervous symptoms, as well as a fifth category of sleep disturbances. Like other neurotic disorders in the Chinese manual, the condition had to last at least 3 months and (a) lower the efficiency of work, study, or social function; (b) cause mental distress; or (c) lead to treatment seeking. Depressive and anxiety symptoms, which used to be central in previous professional definitions of *shenjing shuairuo*, became exclusionary in CCMD-2-R, probably due to the growing influence of Western nosologies. Physical weakness and mental fatigue, which are prominent elements of some neurasthenic presentations in other parts of the world, are not prioritized in the Chinese classification. The third edition of the CCMD (2001) retained *shenjing shuairuo* in the section on the Neuroses as a diagnosis of exclusion. This decision was

Telegram: @medical_k

www.konkur.in

based on multicenter field trials in China on the discriminant validity and clinical utility of the neurosis subtypes.

The general category of “neurasthenia” included in ICD-10 (F48.0) emphasized the components of weakness and fatigue and relegated other possible symptoms to secondary characteristics. Although the evolving CCMD nosology has not emphasized these symptoms in its definitions of *shenjing shuairuo*, some controversy remains over the proper status of fatigue and weakness in the Chinese classification. Some investigators considered the centrality of fatigue in the ICD-10 definition of neurasthenia a misleading alignment of the international classification with the Western diagnoses of somatoform disorders and chronic fatigue syndrome. For example, Sing Lee estimated that the ICD-10 definition excluded over 80% of Chinese patients with *shenjing shuairuo* who reported prominent symptoms other than fatigue. ICD-11 no longer includes an entry for neurasthenia, apparently due to decreasing official support internationally for the category. The DSM-5-TR chapter on culture and psychiatric diagnosis includes an entry for *shenjing shuairuo*, as an example of a cultural syndrome, which follows the CCMD-3 definition and does not prioritize the fatigue component.

Phenomenology. Given the evolution of diagnostic practice regarding *shenjing shuairuo* in Chinese societies over the last decades, the phenomenologic description in this chapter is based instead on clinical histories of self-identified sufferers—or the “illness” aspect of the syndrome. The elements in Table 29.1–4 are prototypical.

Epidemiology. The changing professional definitions of ICD neurasthenia and CCMD *shenjing shuairuo* complicate the interpretation of the epidemiologic reports, which are in any case limited in European languages. Most studies have used ICD definitions, which in turn have evolved over time, or else refer to rates of “neurasthenia” without distinguishing between ICD and CCMD diagnoses. Therefore, the relationship between these reports

Telegram: @medical_k

www.konkur.in

of neurasthenia prevalence and the folk presentation of *shenjing shuairuo* remains unclear.

Table 29.1–4.
Phenomenology of *Shenjing Shuairuo* (Weakness of the Nervous System)

Telegram: @medical_k

www.konkur.in

a. Onset is usually gradual, sometimes spanning several years, and typically emerges out of a conflictive, frustrating, or worrying situation that involves work, family, and other social settings, or their combination. A sense of powerlessness in changing the precipitating situation appears central to most illness accounts of the syndrome.
b. Symptoms show substantial individual variation, but usually involve at least some of the following spontaneous complaints: insomnia, affective dysphoria, headache, bodily pains and distortions (e.g., “swelling” of the head), dizziness, difficulty concentrating, tension and anxiety, worry, fatigue, weakness, gastrointestinal problems, and “troubled vexation” (*fan nao*). This last emotion has been described as a form of irritability mixed with worry and distress over “conflicting thoughts and unfulfilled desires,” that may be partially concealed in Chinese communities for the sake of preserving social harmony.
c. The sufferer frequently seeks the sick role, attributing his/her difficulties in meeting work, school, or other social expectations to the syndrome. Sources of treatment vary substantially across Chinese communities, depending on the availability of formal and traditional service sectors. Typically, physical health services, such as general health or neurology clinics, or traditional Chinese medicine providers are preferred to psychiatric services, though this may be less pronounced among school-related presentations, especially in more Westernized settings such as Hong Kong.
d. Course is variable, and may respond closely to changing interpersonal and social circumstances. Amelioration of the precipitating stressor(s) typically brings about substantial improvement, although residual symptoms appear common.
e. Response to treatment may be strongly mediated by the illness role and its relationship to the intractability of precipitating stressors.

Telegram: @medical_k

www.konkur.in

Several community studies have been conducted, but most are available only in Chinese. One community-based study conducted in 1959 in Chengdu City (*N* = 10,830) found a point prevalence of 5.9% for unspecified "neurasthenia" of greater than 3 months' duration. Prevalence rates from other community surveys prior to 1980 have been reported as between 6% and 10%. Several investigators noted a rise in presentations of *shenjing shuairuo* to medical services in the aftermath of the Cultural Revolution (1966 to 1976) when social space was opened for a public accounting of the traumas associated with this period. However, epidemiologic documentation of this likely upswing in community and clinical prevalence is limited. One nationwide community-based study from 1986 found a prevalence rate of 1.3% in the general population. Prevalence rates among students have typically been high, given the association of school-based stressors with *shenjing shuairuo*. In 1993, 5.1% of Chinese college students in Anhui, China, fulfilled the CCMD-2 criteria for the syndrome. Lee and colleagues reported a 6.3% prevalence of moderate or severe *shenjing shuairuo* among Hong Kong undergraduates in 1995. A 2014 household survey in Guangzhou by Brian Hall and colleagues, using the Patient Health Questionnaire (PHQ-9) and the neurasthenia criteria from ICD-10, found a prevalence of depression of 5.3% and of neurasthenia of 15.4%. The prevalence of neurasthenia alone or with depression did not differ significantly by any demographic characteristic studied, including age, gender, education, and income.

Clinical epidemiology studies have varied markedly over time. By numerous anecdotal reports, between about 1950 and 1980, neurasthenia, either in the ICD or the CCMD formulation, constituted probably the most common psychiatric diagnosis in China. The narrowing of the psychiatric definition of neurasthenia since 1980—such as by the exclusion of primary affective presentations—and its reduced application in diagnostic practice likely decreased prevalence rates in clinical epidemiology. Yet the prevalence of *shenjing shuairuo* in medical clinics remained high. A 1983 clinical epidemiologic study in a county general hospital in Sichuan province (*N* = 1,401) found a prevalence of 3.9% for ICD-9–defined

Telegram: @medical_k

www.konkur.in

neurasthenia. From 1997 to 1998, 5.3% of adult outpatients using internal medicine, neurology, and traditional Chinese medicine clinics in a referral hospital in Hunan province met CCMD-2-R criteria for *shenjing shuairuo*. Rates of up to 6.3% have been reported in other general clinical settings. Psychiatric inpatients appear to have much lower rates, probably reflecting the outpatient nature of most neurasthenia care. In 1990, the prevalence of neurasthenia among 2,275 inpatients discharged from the Shanghai Institute of Mental Health was only 0.26. Due to the growing official acceptance of the ICD classification in China, the removal of neurasthenia from ICD-11 may lead to less use of the diagnosis of *shenjing shuairuo* in official clinical documentation.

The 12-month prevalence of ICD-10 neurasthenia among Chinese Americans in Los Angeles County was studied by Yan-Ping Zheng and colleagues. The prevalence of all neurasthenia diagnoses, regardless of diagnostic exclusions, was 6.4%. The rate of “pure” neurasthenia—those without any lifetime comorbid DSM-III-R diagnoses—was 3.6%, higher than any other DSM-III-R disorder. These “pure” neurasthenia sufferers did not differ on most sociodemographic characteristics from respondents without a psychiatric diagnosis, with “pure” depression, or with “pure” anxiety disorder. Further analysis of the study subsample (95%) who were foreign-born revealed that those with higher neurasthenic symptom counts were older, had less education, and were more likely to be formerly married (separated, widowed, or divorced). Lower acculturation increased the risk of neurasthenia, but only in the presence of financial stress (as an interaction term). Participants with lower acculturation were more likely than those with higher acculturation to express the syndrome when confronted with financial stress. The authors concluded that “neurasthenia is a unique form of expressing distress among low acculturated groups of Chinese Americans.”

Precipitants/Etiology. An empirical assessment of the precipitants of *shenjing shuairuo* has found high rates of work-related stressors, which were made more intractable by the centrally directed

Telegram: @medical_k

www.konkur.in

nature of mainland Chinese society. These included unwelcome work assignments, job postings that caused family separations, harsh criticism at work, excessive workloads, monotonous tasks, and feelings of inadequacy or incompatibility of skills and responsibilities. Students usually described somewhat less severe study-related precipitants, particularly school failure or anxiety over the mismatch between personal or family aspirations and performance. Other interpersonal and family-related stressors included romantic disappointments, marital conflict, and the death of a spouse or other relative. The work of Arthur Kleinman has emphasized the political nature of many precipitants of *shenjing shuairuo*, especially during the 1980s and 1990s as a result of the vicissitudes of the Cultural Revolution. This societal upheaval involved traumatic changes in social circumstances, family separations, acute humiliations, social ostracism, demoralization, and exposure to violence and deprivation.

A common theme to most precipitants of *shenjing shuairuo* involved frustration of a keenly held aspiration, glossed as “troubled vexation,” to which social circumstances allowed no or insufficient solution. Loss of face (*mianzi, lianzi*), a key social value in Chinese communities, was also frequently noted as a trigger of *shenjing shuairuo*.

Chinese etiologic understandings of the syndrome commonly invert the Western view of “psychosomatic” presentations, whereby social–interpersonal precipitants cause psychological distress that is displaced onto bodily experience. In what Kleinman described as “somatopsychic” interpretations, many sufferers of *shenjing shuairuo* located the pathologic impact of external stressors directly onto physical functioning, producing somatic symptoms that only secondarily caused psychological distress. This schema permits sufferers to acknowledge a psychological contribution to their illness while yet locating the nexus of pathology on physical processes.

Relationship to Psychiatric Diagnoses. Several studies in Chinese communities found a strong relationship between *shenjing shuairuo* and mood, anxiety, and somatoform disorders. Kleinman found considerable overlap between *shenjing shuairuo* and these

Telegram: @medical_k

www.konkur.in

disorder clusters in his studies in both mainland China and Taiwan. In the People's Republic, his study of 100 Chinese patients diagnosed with *shenjing shuairuo* found that 93 also had a depression diagnosis, with 87 meeting the criteria for major depressive disorder. Sixty-nine patients were also diagnosed with an anxiety disorder and 25 with a somatoform disorder. In Taiwan, 22 of 51 patients with *shenjing shuairuo* also met the criteria for major depressive disorder, which was the most common psychiatric diagnosis in this group of patients.

Subsequent investigations confirmed these associations, with rates of depressive disorders ranging from 30% to 70% in cases of *shenjing shuairuo*. The association with somatoform and anxiety disorders was also found repeatedly. The exact correlations with these disorders depended on whether the subjects came from community or clinical settings; in clinical studies, the correlations varied between general medicine and psychiatric clinics. Outpatient primary care settings tended to yield associations between *shenjing shuairuo* and the somatoform disorders. One study by Sing Lee and colleagues with 100 primary care patients in Hong Kong with unexplained fatigue of at least 6 months' duration that excluded patients already in treatment for a depressive disorder found that 72% endorsed a self-label of *shenjing shuairuo*. In the full sample, the most common diagnoses on the Structured Clinical Interview for DSM-III-R were somatoform pain disorder (47 percent) and undifferentiated somatoform disorder (35 percent). Fourteen patients met the criteria for depressive disorders, with the other diagnoses mostly in the anxiety spectrum.

A study conducted from 1997 to 1998 by Doris Chang and colleagues in three general medicine clinics in Hunan also found similar correlations. The study included 139 patients, mostly of rural origin, who presented with unexplained somatic complaints. Only 55 percent received any diagnosis on the Structured Clinical Interview for DSM-IV, all in the somatoform disorder spectrum. Undifferentiated somatoform disorder was the closest counterpart to *shenjing shuairuo* in DSM-IV, with a diagnostic concordance of kappa = 0.24 ($p < .001$). The fact that 45% of subjects with the CCMD-2 syndrome

Telegram: @medical_k

www.konkur.in

did not meet the criteria for any DSM-IV disorder, however, suggested to the authors that *shenjing shuairuo* is a distinct clinical condition with only partial comorbidity with DSM diagnoses.

A similar conclusion was reached by Hall and colleagues in their 2014 community-based epidemiologic study in Guangzhou (*N* = 751). This study did not use the CCMD definition of *shenjing shuairuo*, however, relying instead on the ICD-10 criteria for neurasthenia, which had only a partial overlap with CCMD-3. The comorbidity between neurasthenia and PHQ-9-based depression was only 2.5%, but people with depression had nearly six times higher odds of having neurasthenia. Sleep latency was highest among individuals with neurasthenia and specific to this disorder, possibly linked to higher levels of worry. Zheng and colleagues, in their 1997 community-based epidemiologic study among Chinese Americans in Los Angeles County (*N* = 1,747), likewise used the ICD-10 criteria for neurasthenia. They identified 112 (6.4%) subjects with ICD-10 neurasthenia in the community. Over half (*N* = 63; 56%) did not meet the criteria for a DSM-III-R diagnosis. Compared with those with depression and anxiety diagnoses, these respondents reported fewer psychological symptoms on the SCL-90-R but similar levels of somatization symptoms.

The overlap with ICD definitions of neurasthenia has been assessed in a few studies. Chang and colleagues found an overlap of 53% between the CCMD-2 *shenjing shuairuo* category and ICD-10 neurasthenia. An even more limited overlap with the international classification was found in a 1989 study conducted at the Shanghai Psychiatric Hospital. Clinical diagnoses of *shenjing shuairuo* obtained by two senior Chinese psychiatrists yielded only a 22.5% overlap with the ICD-9 neurasthenia category.

Additional Clinical Features. The clinical course of the syndrome may depend on the associated psychiatric comorbidity and on the degree of persistence of the precipitating stressors. One longitudinal study found complete resolution of *shenjing shuairuo* symptoms and good social adjustment 20 years after the index diagnosis in 83 out of 89 cases. Only one case was receiving continued treatment, and

Telegram: @medical_k

www.konkur.in

no subjects reported the onset of depressive disorder subsequent to the *shenjing shuairuo* diagnosis.

Chinese psychiatrists have carried out numerous studies of neurophysiologic and cognitive function in *shenjing shuairuo* patients since the 1950s. Most have reported abnormalities compared to normal controls, including in tests of polysomnography, EEG, psychogalvanic reflex, gastric function, and memory function. These findings need to be replicated with well-controlled samples using contemporary diagnostic instruments.

Specific Cultural Factors. The evolving definitions of *shenjing shuairuo* have emerged out of a tradition of syncretism in Chinese medicine between indigenous illness understandings and international contributions. Nineteenth-century Western notions of a weakened nervous system due to overuse (neurasthenia) found an ancient cognate expression in Chinese concepts of bodily meridians or channels (*jing*) binding vital organs in balanced networks along which forces (e.g., *qi*, vital energy, in *yin* and *yang* forms) could be disrupted from their normal, harmonious flow. This gave rise to *shenjing shuairuo*, an illness whereby the *jing* that carries *shen*—spirit or vitality, the capacity of the mind to form ideas, and the desire of the personality to live life—have become *shuai* (degenerate) and *ruo* (weak) following undue nervous excitement.

As noted by Kleinman, this Chinese conception is much more relational and contextual than the typical Western medical view. Bodies are seen as acting in the midst of specific contexts and social relationships rather than abstractly or individually. Physical networks are thus metaphorical representations of interpersonal and societal connections, with emotions acting as mediating channels. These social networks, just like bodies, “can be vitalized or devitalized, demoralized or remoralized. Indeed, bodies are networked, networks embodied.”

The result is an illness form, *shenjing shuairuo*, that tightly links social and interpersonal situations with bodily afflictions, such as the metaphorical linkage described earlier between dizziness and social dislocation due to revolutionary upheavals. Other contributors to the

Telegram: @medical_k

www.konkur.in

persistence of this illness form include elevated stigma against mental illness in Chinese communities, which is forestalled by the primarily physical nature of *shenjing shuairuo*; the contributions of Pavlovian psychiatry and Japanese research to Chinese nosology, which emphasized neurasthenia beyond its role in Western psychiatry; the prominent use of the syndrome by the communist authorities as a health-based, treatable cause of reduced productivity during the 1950s and 1960s; and its popular acceptability as a veiled complaint against social deprivation and oppression at a time when direct confrontation would be harshly suppressed.

Treatment. Kleinman noted a discrepancy in treatment patterns between Taiwanese and Chinese *shenjing shuairuo* patients, with those in Taiwan more frequently resorting initially to self-help remedies, which included special foods, tonics, and dietary changes. He attributed this discrepancy to the availability of inexpensive care in the People's Republic.

When accessing formal sectors of care, most patients used both Western-trained physicians and practitioners of traditional Chinese medicine. Nonpsychiatric medical settings were preferred, including neurology and general medicine clinics, in concert with cultural understandings of the somatopsychic etiology of *shenjing shuairuo*, which emphasize its physical mediation. The modality of treatment was usually traditional Chinese medicines, which were prescribed by both Western-trained and traditional Chinese medicine practitioners. This conformed to the balanced status ascribed to both types of training among Chinese physicians. Polypharmacy was common, combining sedatives, traditional herbs, antianxiety agents, vitamins, and other tonics. In spite of active suppression of religious healing in China, almost a quarter of patients were also engaged in such treatment in the early 1980s.

ONGOING WORK ON THE RELATIONSHIP BETWEEN CULTURAL CONCEPTS OF DISTRESS AND PSYCHIATRIC NOSOLOGY

Telegram: @medical_k

www.konkur.in

Research

In 1969, Yap challenged the field to learn more about “culture-bound syndromes” so that their relationship to psychiatric disorder could be resolved, yet much research still needs to be done. Without a more systematic and wide-ranging program of research on a broader range of cultural concepts of distress, current approaches that only focus on classificatory exercises are unlikely to further the current understanding. The strategy of trying to find the right classificatory scheme by basing it on the similarity between one or two symptoms of a cultural syndrome and of the psychiatric disorder is limited. It is particularly problematic when researchers privilege the DSM categories as the main organizing structure of relevance to the cultural concepts of distress. This approach is unlikely to produce new insights into these concepts on their own terms or in relation to psychiatric diagnosis. It ignores, for example, that many cultural concepts are not organized syndromically so that classifying them on the basis of prototypical symptoms is incompatible with their organizational structure. Comparing etiologic categories with symptom-based diagnoses on the nature of their symptoms is not only useless but counterproductive.

A simple, symptom-based comparison further ignores the function of cultural concepts as idioms or modes of expressing distress. Comparison of cultural concepts and psychiatric disorders as idioms should focus on the mutual compatibility of their intended communications (do they deliver the same message?) and the cultural fit between the idiom—whether indigenous or professional—and the situation in which it arises (is the message equally appropriate?). An idiom of distress intended as a sign of anger that is misinterpreted by the diagnostician as a sign of severe mental illness (e.g., psychosis) is not being accurately translated from the idiomatic perspective. Similarly, an idiom that is considered culturally appropriate to the situation (e.g., anger as a comprehensible reaction) would be well matched by a diagnosis that idiomatically conveys a similar sense of appropriateness.

Telegram: @medical_k

www.konkur.in

In order to resolve the cognitive dissonance created by the complex relationship between the cultural concepts and psychiatric disorders, cross-cultural mental health researchers need to carry out an intensive research that illuminates these concepts rather than simply attempting to subsume them into psychiatric categories and obliterating them. Peter Guarnaccia and his colleague Lloyd Rogler proposed a research program on cultural concepts of distress to bring their study into the mainstream of mental health research. This framework is faithful to the holistic nature of the cultural concepts while at the same time applying current research approaches from several fields. It comprises a series of key questions that need to be answered in order to understand these concepts from the cultural as well as the psychiatric perspectives.

Guarnaccia Rogler's questions are organized into the following five broad dimensions:

1. **Nature of the phenomenon:** How is the folk category characterized within its cultural context? What are the defining features of the phenomenon? Is the folk illness organized syndromically? Does it refer primarily to an etiologic construct? What is the message it attempts to convey as an idiom of distress? How salient is the concept, defined as the rapidity and extent of its recognition within a cultural context?
2. **Location in the social context:** Who are the people who report the folk category, and what is their location in the social structure? What are the situational factors that provoke these conditions?
3. **Relationship to psychiatric disorder:** How is the folk illness empirically related to psychiatric disorder(s)? Does it cut across diagnostic groupings? What is the range of its overlap with psychiatric categories?
4. **Social/psychiatric history of the cultural concept:** When the onset and offset of the cultural concept and the associated psychiatric disorder(s) do not coincide, what is the sequence of onset? How does the life history of the sufferer, particularly the experience of traumatic events, affect the sequence? How many

Telegram: @medical_k

www.konkur.in

episodes of the folk illness has the person experienced? How severe have they been?

5. **Treatments and outcomes:** Holistically, how should be person's suffering be addressed? If the folk illness is effectively treated, does the sufferer also experience relief of the associated psychiatric disorder(s)? And vice-versa, if the psychiatric disorder is resolved with psychotherapy or pharmacotherapy, does the folk illness resolve as well?

Clinical Application

Medical anthropology and cultural psychiatry, and psychology have developed tools and perspectives that are useful in assessing cultural concepts of distress in clinical work and in negotiating between the concepts and psychiatric diagnoses. One such model is the Explanatory Model Questions developed by Kleinman. Another model is the Outline for Cultural Formulation, included in DSM-5-TR along with its operationalization as a set of semistructured questionnaires known collectively as the Cultural Formulation Interview. These frameworks are designed to help clinicians inquire about and better understand the cultural dimensions of their patients' presentations of their mental health problems.

The key area of the Outline for Cultural Formulation is the section on cultural explanations of the individual's illness. The major elements of inquiry include the predominant idioms of distress through which symptoms are communicated; the meaning and perceived severity of the individual's symptoms in relation to the norms of the cultural reference group; local illness categories used by the individual's family and community to identify the condition; the perceived causes or explanatory models that the individual and reference group use to explain the illness; and past and current experiences with popular and professional sources of care. These areas can serve as a support for clinicians who seek to better understand their patients' perspectives on the symptoms, expressions, and difficulties they present.

In DSM-5, the Outline was rendered more operational for routine clinical practice by standardizing its implementation as the Cultural

Telegram: @medical_k

www.konkur.in

Formulation Interview. This is composed of three types of semistructured interviews that offer clinicians concrete ways to carry out the cultural assessment of patients and their entourages. The three components of the Cultural Formulation Interview are a core 16-item questionnaire, an informant version of the core interview to obtain information from caregivers, and 12 supplementary modules that expand on these basic assessments. If used routinely to frame the intake evaluation, the Cultural Formulation Interview can help establish a foundation of person-centered information on the patient's context and perspective, and a working alliance, on which to build the rest of the diagnostic interview and treatment negotiation process.

There are several resources that clinicians can turn to for further guidance and examples using this formulation technique. The cultural formulation has been elaborated by the Cultural Committee of the Group for the Advancement of Psychiatry in their 2002 publication Cultural Assessment in Clinical Psychiatry. Illustrative cases using the cultural formulation and discussing the implications of cultural understanding of mental health problems have been available in select issues of *Culture, Medicine, and Psychiatry* starting in 1996. Key writings on the cultural formulation approach were assembled in *Cultural Formulation: A Reader for Psychiatric Diagnosis* (2008). The McGill Cultural Consultation Service published *Cultural Consultation: Encountering the Other in Mental Health Care* in 2014, describing the cultural assessment of over 400 cases with an expanded cultural formulation approach. Finally, the *DSM-5 Handbook on the Cultural Formulation Interview* (2016) describes in detail the components of the Cultural Formulation Interview, presents multiple clinical vignettes to illustrate its use, and suggests strategies for incorporating the interview into clinical training and routine practice.

Once the information is elicited, the next key step is for clinicians to lead a negotiation process whereby they and their patients come to understand each other's perspectives on the mental health problem and come to an agreement on how to proceed. Kleinman described this approach in *The Illness Narratives* (1988). The process that Kleinman developed is for the provider to first elicit and understand the patient's explanatory model and then to make clear the provider's

Telegram: @medical_k

www.konkur.in

explanatory model. The process then focuses on developing a treatment plan based on negotiation between the patient and provider models. It may be useful to include the patient's cultural terms and explanations in case formulations and treatment plans, as they may help clarify symptoms and etiologic attributions that could otherwise be confusing. This approach has been further elaborated in a variety of cultural competence training programs for physicians to aid them in this negotiation process. The impact on the quality of mental health care from these approaches for assessing cultural understandings of cultural concepts of distress and for clinician–patient negotiation are pressing areas for research.

USING CULTURAL CONCEPTS OF DISTRESS TO IMPROVE MENTAL HEALTH SERVICE DESIGN AND IMPLEMENTATION

In the previous section, we discussed the added value of incorporating cultural concepts of distress into clinical assessment using the Cultural Formulation Interview. In this section, we discuss how attention to cultural concepts of distress can play an important role in culturally appropriate and effective mental health care more broadly. As we have emphasized, cultural concepts of distress are not simply placeholders for psychiatric categories—they have their own meanings and both personal and social consequences that may interact with many different clinical conditions and social predicaments. In many instances, cultural concepts of distress may be more meaningful to patients and families than psychiatric diagnostic terms because they represent shared experiences and expectations.

Many of the cultural concepts of distress previously described in this chapter have been used to improve mental health services. In this section, we will illustrate the clinical uses of cultural concepts of distress by focusing on the example of "thinking too much"—a cultural concept of distress characterized by both worry about future events and rumination about past events that has been observed in

Telegram: @medical_k

www.konkur.in

various forms across many cultures and contexts. The qualification "too much" refers to the intrusive quality of these thoughts and difficulty controlling them once they have begun. "Thinking too much" may also be associated with sleep problems and negative perceptions of self. In some cultural contexts, experiencing "thinking too much" for a prolonged period is associated with a risk of more severe psychopathology such as delusions or hallucinations or a lack of self-control (e.g., an inability to abide by social norms). Coping with "thinking too much" varies cross-culturally, but it often includes strategies to control the intrusive thoughts such as by sharing them with others, engaging in prayer or other religious practices, using behavioral distractions, and seeking treatment from a variety of practitioners of traditional medicine as well as biomedical health workers. Local examples of "thinking too much" include *kufungisisa*, a Shona term in Zimbabwe; *reflechi twòp*, a Kreyòl term in Haiti; *pensando mucho*, a Spanish term in Latin America; *man maa kura khelne*, a Nepali term in South Asia; and *kut careen*, a Khmer term in Cambodia.

Cultural Concepts of Distress and Engagement with Mental Health Services

Challenges in mental health services are often categorized as *supply side* or *demand side*. "Supply side" refers to the availability of mental health services for a particular population and setting. "Demand side" refers to help-seeking behaviors to engage the available services. For many minority populations in high-income countries and for most residents of low- and middle-income countries, there are both supply-side and demand-side barriers. Culturally and contextually sensitive care is often lacking, and when services are available, there is a hesitance to engage such services because of lack of awareness about care, difficulties trusting providers due to prior experiences with poor-quality care, lack of recognition of a psychiatric illness, and stigma associated with using mental health services. The utilization of cultural concepts of distress can help to reduce demand-side barriers. For example, in Zimbabwe, although the label of depression

Telegram: @medical_k

www.konkur.in

carries mental illness stigma, framing psychological treatment as care for *kufungisisa* makes it more acceptable and appealing. Similarly, in Haiti, describing psychosocial and psychological support as an approach to help with *reflechi twòp* helped lay community counselors encourage persons with psychological distress to participate in care. In Peru and other Latin American countries, cognitive behavioral therapy has been a treatment for *pensando mucho* in programs for women with perinatal depression.

Cultural concepts of distress can also be added to mental health screening tools or used to develop new screening instruments to identify persons who would benefit from services. Standard biomedical screening tools such as the PHQ-9 often lead to high numbers of false positives when adapted for use in a new cultural context. Adding a question about a cultural concept of distress can help identify individuals with forms of distress for which it may be appropriate to seek help. In Nepal, for example, adding a question about problems in the “heart–mind” (*man*) as a required symptom reduced false positives on the PHQ-9. Moreover, patients referred based on both heart–mind problems, and high PHQ-9 scores had the shared understanding that they all experienced a similar type of distress.

Another approach to using cultural concepts of distress to promote engagement with different types of mental health services is through proactive case detection. This approach uses consultation with community members to identify persons in the community who may need mental health services. For example, teachers can be consulted to refer students with distress. Health workers can refer persons they encounter when delivering vaccinations or reproductive health services. Religious leaders and traditional healers can refer members of their congregations and communities. Cultural concepts of distress can be an effective way to explain who would benefit from referrals when communicating with these community members who are not mental health professionals. For example, in Haiti, Vodou priests (*Hougan*) have been trained to refer persons suffering from ongoing *reflechi twòp* to be evaluated for mental health services. Similarly, in the Democratic Republic of Congo, community members

Telegram: @medical_k

www.konkur.in

referred mothers who had *maladi ya souci* (a sickness of worry) to participate in a culturally adapted version of cognitive behavioral therapy. Recently, the World Health Organization has adopted the Community Informant Detection Tool (CIDT), which was developed by Mark Jordans and colleagues as a way of using cultural concepts of distress in a prototype narrative to train community members to identify persons with distress and link them with mental health services.

Once people are engaged through acknowledging their cultural concepts of distress, it is important to consider how these concepts may align with the available types of service. Traditional medicine systems or religious healers may recognize the same terms, and the cultural concept then may help direct the individual toward appropriate support. For biomedical services, it is important to further evaluate how the individual's cultural concepts of distress may map onto, modify, or obscure diagnostic criteria for specific psychiatric conditions. However, the increasing availability of transdiagnostic treatments means that individuals with specific symptoms or behavioral problems included in cultural concepts of distress may benefit from psychological interventions that target these symptoms or problems. Cultural concepts can also be incorporated into stepped-care services, as has been done in global mental health programs in low- and middle-income countries. In stepped-care services, patients who present with distress framed in terms of a cultural concept associated with limited functional impairment may be treated with a brief psychological intervention, such as training in stress management or problem-solving techniques. However, the presence of more severe impairment or urgent symptoms such as suicidal thoughts or behavior indicates the need for a higher tier of services, or potentially, emergency care. Similarly, endorsement of a cultural concept of distress among patients who also met criteria for a specific psychiatric diagnosis may require a disorder-specific pharmacologic and/or psychological intervention.

Cultural Concepts of Distress and Promotion of Collaborative Care

Telegram: @medical_k

www.konkur.in

The efficacy of indigenous interventions may stem in part from their fit with local cultural explanations and expectations. Including elements of local concepts of distress in both the explanation of the treatment plan and in specific interventions may then increase effectiveness. For example, Tibetan, Mongolian, Chinese, and other related medical traditions have developed treatments for worry and rumination associated with “wind”-based and *qi*-based conditions, such as *rlung, yadargaa*, and *shenjing shuairou*. By understanding the healing theories associated with these cultural concepts of distress, biomedical mental health practitioners can better understand who may benefit from these healing practices. This runs counter to assumptions that traditional healing practices will have universal benefits for all types of patients and any type of depressive or anxiety disorder. Rather, the greatest benefit may be among those individuals who experience specific aspects of depression or anxiety but also endorse relevant aspects of the cultural concept of distress. Moreover, cultural concepts of distress can serve as a communication bridge among different types of care providers and support referrals when needed from one type of care system to another. In Haiti, persons suffering from *reflechi twòp* with suicidality report greater benefits when receiving care from a *Hougan* (Vodou priest). This suggests that care for suicidality may be optimal when both mental health specialists and *Hougan* are involved if that is the preference of the patient and family. While such cultural information can guide the development of collaborative care systems and services, in each case, it is crucial to move beyond cultural stereotypes and generalizations to determine individual patients’ experiences, expectations, and preferences.

Cultural Concepts of Distress and Monitoring and Evaluation of Mental Health Services

Another role that cultural concepts of distress can play is in monitoring the progress and outcomes of treatment. When biomedical interventions are evaluated, DSM and ICD symptoms are typically used to determine if treatment is progressing and deemed to

Telegram: @medical_k

www.konkur.in

be successful. However, this may miss aspects of distress that are most salient to the person receiving care. Monitoring progress with measures that track culturally salient symptoms and outcomes can provide a more accurate assessment. For example, if a major concern of a patient is “thinking too much,” then this can be tracked during care to see if the individual feels that the distress is improving by monitoring the relevant local cultural concept. As described above in relation to the Cultural Formulation Interview, when clinicians prioritize the concerns of the patient, this will help promote patient engagement and guide decisions about what treatment will be most beneficial. At a systems level, an intervention or a whole system of care can be evaluated by monitoring changes in cultural concepts of distress. For example, in Haiti, *reflechi twòp* has been included in the Kreyòl Distress Inventory as an outcome measure. Similarly, in Zimbabwe, the Shona Symptom Questionnaire includes *kufungisisa* as one of the symptoms to evaluate the outcome of mental health interventions. For treatments of Cambodian refugees, the Cambodian Somatic Symptom and Syndrome Inventory (CSSI) was developed and used to determine the effectiveness of both medications and culturally adapted psychotherapy.

When evaluating interventions using cultural concepts of distress, it is important that results be transparently communicated. For example, in a study in East Africa of a group psychological treatment, the depression symptom measure was validated against a cultural concept for traumatic grief. However, when the study was published, it was reported as establishing evidence for treating depression. It would have been more accurate to describe the intervention as having local evidence for resolution of traumatic grief, as it was described in the local context because that construct is closer to the cultural concept of distress used to locally adapt the symptom–outcome measure. Again, the broad issue is that local cultural concepts should not simply be assimilated to standard psychiatric concepts and categories because they provide additional information about the personal and social meaning and consequences of distress.

Telegram: @medical_k

www.konkur.in

Cultural Concepts of Distress and Adaptation and the Development of Mental Health Interventions

Finally, cultural concepts of distress can play an important role in the development and adaptation of clinical interventions, especially psychological and interpersonal or social interventions. One of the best predictors of effective cultural adaptation is when the adaptation addresses the explanatory models of participants. Eva Heim and Brandon Kohrt developed a cultural adaptation framework for psychological interventions centered around cultural concepts of distress as the core of the adaptation process. They suggest focusing the beginning of the intervention on cultural concepts of distress to present the intervention in ways that are readily understood by patients. The pathways by which the intervention alleviates psychological distress should consider the potential causes identified in cultural concepts of distress to the extent possible.

The Friendship Bench study in Zimbabwe provides a clear example of how a local cultural concept of distress for "thinking too much," *kufungisisa,* was central in developing, implementing, and evaluating a psychological intervention. The Zimbabwean psychiatrist Dixon Chibanda developed the Friendship Bench psychological intervention based on principles of problem-solving therapy, but the intervention is framed according to the concept of how to manage "thinking too much" (*kufungisisa*). In the intervention, problem solving is explained as an activity to reduce *kufungisisa*. Moreover, *kufungisisa* is not simply used as a substitute for depression but is linked to other aspects of Shona ethnopsychology in Zimbabwe. In particular, *kufungisisa* is ameliorated through the practices of *kuvhura pfungwa* ("opening of the mind"), *kusimudzira* ("uplifting"), and *kusimbisa* ("strengthening"). The intervention also makes use of cultural notions of social space and interpersonal interaction. The intervention is delivered on a bench outside the hospital. The person delivering the intervention is thought of as a "helpful grandmother-type" figure who listens closely to one's needs and provides sage advice. Discussing excessive thoughts with a trusted family member or other confidant is what one would typically do when experiencing

Telegram: @medical_k

www.konkur.in

kufungisisa. Parts of the Friendship Bench intervention are delivered in groups. In this context, it is easy to explain the purpose of the group to all participants because they typically have a shared experience and understanding of *kufungisisa*. This focus is more comprehensible and less stigmatizing than framing the group as depression treatment. In a randomized controlled trial comparing the Friendship Bench with a waitlist control, participants in the Friendship Bench showed a greater reduction on the Shona Symptom Questionnaire, which includes *kufungisisa*. In addition, they showed improvement in depression symptoms. Six months after receiving the Friendship Bench psychological intervention, only 13% of patients were depressed, compared with 50% of persons in a basic treatment comparison group, which included a nurse-led evaluation, brief support counseling, option for medication, education, and support for common mental disorders, and referral to a psychiatric facility if appropriate. The Friendship Bench thus illustrates the power of framing a psychological intervention according to local concepts and the benefit this has both for reducing the cultural concept of distress as well as symptoms of a psychiatric disorder. There are similar examples of adapting interventions based on *pensando mucho* among Latin American populations, *kut careen* and other Khmer idioms for Cambodian refugees, and concepts of worries in the heart–mind and tension in South Asia.

CONCLUSION

Integrating cultural concepts of distress into mental health services is essential to culturally informed care. It is a deliberate process that uses information about the relationship between professional classification systems and local traditions of distress to accurately translate the person's experience into clinically useful formulations and diagnoses. Integrating this local information into clinical practice can also help identify individuals with psychological distress; enhance their engagement in mental health services; provide effective psychoeducation; facilitate collaboration among biomedical mental health specialists and traditional healers and helpers; monitor

Telegram: @medical_k

www.konkur.in

individual patient-level and service-level outcomes; and guide the cultural adaptation and implementation of mental health interventions. This chapter has outlined key areas for this translation and implementation process.

29.2 Cultural Assessments in Psychiatry

Neil Krishan Aggarwal, M.D., M.B.A., M.A., and Roberto Lewis-Fernández, M.D., M.T.S.

Cultural psychiatry has been the medical subspecialty most involved in developing clinical, research, and educational methods for patient cultural assessments. Cultural psychiatry—also known as cross-cultural, transcultural, or anthropologic psychiatry—has typically focused on three areas: (1) the extent to which manifestations of psychopathology are similar or different across societies, (2) the provision of mental health services for underserved ethnoracial groups in multicultural societies, and (3) the cultural bases of psychiatric knowledge and practice to reveal how mental health systems reflect underlying societal concerns and values. Cultural assessments play a fundamental role in each area, clarifying the relative biologic and environmental contributions of symptom manifestations; patient preferences on how, where, when, and with whom to receive care; and cultural assumptions within the patient–clinician relationship such as communication and relational styles. The inclusion of the Outline for Cultural Formulation (OCF) in *DSM-IV* and the Cultural Formulation Interview (CFI) in *DSM-5* indicated

Telegram: @medical_k

www.konkur.in

growing acceptance of cultural assessments within psychiatry, not just for underserved ethnoracial groups, but for *all* people, including those whose identities are defined through gender, sexual orientation, migration, and veteran status.

HISTORICAL OVERVIEW

Cultural assessments in psychiatry have evolved alongside changing definitions of culture, especially within disciplines such as anthropology and psychology. In 1904, the renowned psychiatrist Emil Kraepelin—one of the first to differentiate *dementia praecox* (schizophrenia) from manic-depressive illness—sailed to Java, Indonesia, and investigated symptom manifestations in 100 European, 100 indigenous, and 25 Chinese patients at the Buitenzorg mental hospital. Kraepelin found that Javanese patients with psychosis experienced fewer hallucinations and delusions than European patients. He concluded that “the Javanese mind” was more primitive than “the European mind.” Kraepelin carefully recorded patient symptoms to examine similarities and differences between both groups, assuming that the definition and expression of psychotic illness would be identical in both populations. Although his assumptions and interpretations were based on racist intellectual trends from 19th-century physical anthropology that posited hierarchical relationships among races based on supposed biologic differences, Kraepelin inaugurated the field of comparative psychiatry and was among the first psychiatrists to use interpreters.

Another landmark movement emerged in the 1920s and 1930s with the Culture and Personality School. Social anthropologists such as Gregory Bateson, Ruth Benedict, Margaret Mead, and Ralph Linton collaborated with psychoanalysts such as Abram Kardiner and drew from Sigmund Freud’s theories on personality structure and organization. Many researchers tried to apply psychoanalytical theories to ethnographic data. This school contended that culture molds personality types, especially during child development, and that different cultural contexts produce different personality types based on socialization practices. For this reason, its theorists held

Telegram: @medical_k

www.konkur.in

that studies of individual personalities could lead to insights into general characteristics of prototypical national cultures. The school gained prominence during World War II with the American government using “National Character Studies” to understand the character and strategies of the Axis Powers, as exemplified by Benedict’s classic work on the Japanese, *The Chrysanthemum and the Sword*. Postwar, the school lost influence for suggesting that all members in a society act similarly through a prototypical personality, for assuming that culture is static rather than dynamically created and debated by society’s members, and for insufficiently demonstrating robust links between child development practices and adult personality traits.

These examples demonstrate how the process of conducting cultural assessments has changed based on contemporary understandings of culture.

Current trends in cultural assessments can be traced to the extensive collaboration among cultural mental health experts and interpretive medical anthropologists since the 1970s. A substantial scholarship has grown from this collaboration, which is based on the following principles: (1) formal psychiatric diagnoses may not be translatable across all societies, and empirical data must demonstrate their applicability in each society to avoid a “category fallacy,” the assumption that constructs (such as those related to mental health and illness) developed in one cultural setting are equally valid in other settings; (2) the clinician’s interview bears a resemblance to the anthropologist’s ethnography in attempting to reconcile personal lived experience with scientific theory; and (3) a clinical interview can approximate ethnography by understanding the patient’s explanatory model (EM) of mental illness, such as its causes, onset, mechanism, treatments, course, and severity. This orientation acknowledges that individuals belong and contribute to their cultural groups without assuming the homogeneity of cultural experience. In addition, this orientation acknowledges that professional biomedical theories and practices are also cultural products and that successful treatment requires negotiation between patient and clinician EMs. These principles have laid the foundation

Telegram: @medical_k

www.konkur.in

for four main ethnographic interviews used in patient cultural assessments: psychiatrist-anthropologist Arthur Kleinman's EM framework (1980), the Explanatory Model Interview Catalogue (EMIC) (1992), the Short Explanatory Model Interview (SEMI) (1998), and the McGill Illness Narrative Interview (MINI) (2006). These cultural assessments identify key domains that can be used in evaluating all patients irrespective of their cultural background.

Kleinman's Explanatory Model Framework

Arthur Kleinman's work in medical anthropology and cultural psychiatry during the 1970s centered on EMs, the culturally based understandings of sickness and treatment that patients and practitioners use. Kleinman contended that the study of interactions among patient and practitioner EMs could introduce a method to understand cultural influences in clinical communication. He identified five themes in illness EMs: (1) etiology; (2) time and mode of onset of symptoms; (3) pathophysiology; (4) course of sickness, including the degree of severity; and (5) treatment. Differences in patient–practitioner EMs could be analyzed as the differences between illness and disease, the former referring to the patient's lived experience of sickness and the latter referring to the practitioner's professional knowledge. Kleinman believed that analyzing patient EMs could illuminate the personal meanings of sickness and help-seeking preferences. His framework was influential in cultural psychiatry, primary care, and medical anthropology as a form of readily applied ethnography in clinical settings throughout the 1980s and 1990s. Subsequent patient cultural assessment interviews have variously engaged with Kleinman's EM framework to expand in other directions.

The Explanatory Model Interview Catalogue

Psychiatrist-epidemiologist Mitchell Weiss and his colleagues developed the EMIC as a method for cross-cultural research in psychiatric epidemiology based on the EM framework. The abbreviation EMIC invokes the anthropologic distinction between

Telegram: @medical_k

www.konkur.in

emic cultural knowledge rooted in local communities and *etic* theoretical knowledge of outside professionals, as in the illness/disease distinction mentioned earlier. Kleinman warned against a mechanical use of EMs that could reduce a patient's culture to decontextualized clinical information such as a lab result or physical examination finding; this may have prevented him from elaborating a research methodology beyond unstructured in-depth interviews. In contrast, Weiss designed the EMIC to operationalize the EM framework with a clear methodology, enable systematic comparisons across sites, and enhance diagnostic epidemiology with cultural epidemiology to analyze the relationships of illness understandings and practices with clinical outcomes. Based on research with patients having mental illness and leprosy in India, Weiss also created the EMIC to quantitatively rate narrative differences among patients; for example, noting whether a patient answered about a perceived illness cause in direct response to a question or in passing during a response to another question. EMIC instruments follow a tailored question format and set of domains rather than reproducing a single, unvarying interview; therefore, an EMIC instrument is customized for every research question. Starting from general introductory questions for each domain—which may be similar across EMICs—each iteration of the interview progresses to specific questions targeting a range of local illness experiences and interpretations. EMICs include assessment domains such as (1) patterns of distress, (2) perceived illness causes, (3) help seeking and treatment, (4) general illness beliefs, and (5) disease-specific queries. In addition to operationalizing Kleinman's EM framework, the EMIC introduces this final domain to assess the patient's general understanding of a specific disease. This domain is intended to ascertain the extent to which the patient's individual illness explanations resemble or differ from other explanations in the patient's cultural background to which the individual is exposed. This domain addresses a criticism of Kleinman's EM framework that it relies too heavily on individual explanations of illness without considering their degree of representativeness within a particular cultural grouping.

Telegram: @medical_k

www.konkur.in

The Short Explanatory Model Interview

Criticisms emerged that the EM framework was underspecified and that the EMIC was too detailed and time-consuming. Psychiatric researchers in England developed the SEMI as a standardized, valid tool to assess common mental disorders in large-scale fieldwork and primary care settings. The SEMI covers five sections: (1) the patient's individual and social background; (2) the nature of the presenting problem; (3) help-seeking behavior, including contact with nonmedical healers; (4) interactions with the clinician/healer to clarify roles and expectations for promoting satisfaction; and (5) illness understandings, covered through a presentation of three vignettes for common mental disorders—depression, phobia, and somatization—followed by open-ended questions to capture the respondent's attitudes to the vignettes. The interview was tested in four primary care sites in England and Zimbabwe. In addition to assessing patient EMs and general views on mental illness, the SEMI expands cultural assessment to inquire about the patient's background and expectations of care to inform current treatment.

The McGill Illness Narrative Interview

The final ethnographic interview comes from researchers at McGill University in Canada, who raised concerns that the EM framework may be too unstructured and incomplete for systematic comparison and that the EMIC and SEMI may be too structured for narrative spontaneity. The MINI incorporates medical anthropologist Allan Young's critique that the EM framework assumes logical, coherent accounts of an illness experience. Young's work demonstrated that individuals use multiple representations and modes of reasoning to produce narratives of illness that can be complex, internally inconsistent, and even self-contradictory. Many patients may not be able to stipulate the causes of an illness, preferring explanations based on illness prototypes common to people in their communities (e.g., learned through popular myths or media accounts) or based on chain complexes in which people reason by association, such as through a chain of events (e.g., that a symptom and a potential cause

Telegram: @medical_k

www.konkur.in

are related because they happened close together). The elicitation of illness prototypes recognizes broad social influences on an individual's meanings of illness, whereas chain complexes acknowledge reasoning based on categories salient to the patient rather than predetermined EM domains. To capture such variation, the MINI consists of open- and closed-ended interview components.

The *DSM-IV* Outline for Cultural Formulation

These four assessment interviews generated significant interest among mental health experts conducting cultural assessments in clinical practice. Anthropologists developed a related but independent scholarship demonstrating that the health care system can be analyzed as a cultural system and that psychiatric diagnosis is a form of clinical interpretation influenced by social networks and institutions. Throughout the 1980s, a consensus emerged among mental health clinicians and anthropologists that patients and providers—independently and together—routinely create and debate meanings of health, illness, and treatment. Psychiatrists and anthropologists have agreed that such acts of meaning making merit attention to close gaps between patient and provider understandings during any sickness. Mental health clinicians have found patient cultural assessments helpful to clarify mismatches between symptom manifestations and official diagnostic criteria or to engage patients in treatment based on their preferences for care; anthropologists have concentrated on the extent to which illness narratives reflect local patient worlds coming into contact with the biomedical system.

For the *DSM-IV* revision process, the U.S. National Institute of Mental Health (NIMH) convened a conference in April 1991 at the University of Pittsburgh among cultural experts, the *DSM-IV* task force, and workgroup representatives to enhance the new Manual's cultural validity. Cultural experts included cultural psychiatrists and psychologists, medical anthropologists, and members of underserved ethnic and racialized groups within the American Psychiatric Association (APA) leadership. Following this conference, the NIMH Group on Culture and Diagnosis developed recommendations for

Telegram: @medical_k

www.konkur.in

DSM-IV, such as an introduction to the upcoming manual on the importance of culture, a section on cultural considerations for each diagnosis, a glossary of "cultural syndromes and idioms of distress," a cultural commentary on *DSM-IV's* multiaxial evaluation format, and guidelines for a cultural formulation. The NIMH group based the elements of its OCF on a literature review, demonstrating four domains that were common across patient cultural assessments: (1) cultural identity of the individual, (2) cultural explanations of the individual's illness, (3) cultural factors related to the psychosocial environment and levels of functioning, and (4) cultural elements of the patient–clinician relationship. A final domain was included to record how cultural information could influence diagnosis and care. Clinicians could use the OCF to supplement the multiaxial diagnostic assessment and to describe the patient's cultural and social reference groups in clinically relevant ways. Table 29.2–1 lists OCF domains for assessment.

www.konkur.in

Table 29.2–1.
The DSM-IV Outline for Cultural Formulation

Telegram: @medical_k

www.konkur.in

Cultural Formulation Domain	Subtopics for Assessment
Cultural identity of the individual	▶ Individual's demographic and other socially and culturally defined characteristics ▶ Aspects of identity that are prioritized by the individual and how they interact (intersectionality) ▶ Degree of involvement with the cultural contexts of origin and the new cultural contexts (for immigrants and ethnic minorities) ▶ Degree of interaction and identification with own group and other segments of society (for those who identify with racialized and ethnic groups) ▶ Language abilities, use, and preference (including multilingualism) and their impact on access to and processes of care
Cultural concepts of distress	▶ Cultural constructs (idioms of distress, explanations, and syndromes) that influence how symptoms or problems are communicated ▶ Meaning and perceived severity of individual's distressing experience in relation to cultural norms

Telegram: @medical_k

www.konkur.in

	▶ Priority symptoms, perceived seriousness of the illness, level of associated stigma, and anticipated outcomes ▶ Current preferences for and past experiences with professional and popular sources of care
Psychosocial stressors and cultural features of vulnerability and resilience	▶ Culturally relevant interpretations of social stressors, challenges, supports, and levels of functioning and disability ▶ Social determinants of mental health, including access to resources and opportunities, exposure to racism, discrimination, systemic institutional stigmatization, and social marginalization or exclusion (structural violence) ▶ Role of religion and interpersonal networks in causing stress or providing support
Cultural features of the relationship between the individual and the clinician, treatment team, and institution	▶ Individual differences in cultural background and identity between the individual and the clinician, treatment team, or institution ▶ Problems that these differences may cause in diagnosis and treatment (e.g., difficulties in eliciting symptoms and understanding their cultural significance, in determining whether a behavior is normal or pathologic, or in establishing rapport)

Telegram: @medical_k

www.konkur.in

Overall cultural assessment	▶ Discussion of how cultural considerations specifically influence comprehensive diagnosis and care

The OCF's inclusion in *DSM-IV* provided an institutional mechanism for mental health experts and anthropologists around the world to appraise the current state of knowledge, harmonize efforts at patient cultural assessments, and suggest future directions. In contrast to the multiaxial evaluation with its standardized codes, the OCF was designed for clinicians to narratively describe the patient's account of suffering from an *emic* perspective rich with contextual details. The use of the word "formulation" was an attempt to stimulate the type of narrative analysis already familiar to psychiatrists trained in psychodynamic formulations who assess details of a patient's psychological conflicts in the context of life experiences. The formulation was also designed to standardize a methodology for cultural assessment and produce outcome studies in mental health services research. Field trials with various American ethnicities validated its utility and offered tangible clinical examples.

However, the OCF faced challenges right from its inclusion. Although the NIMH group recommended its placement at the beginning of the Manual, the OCF was placed in the ninth appendix. It was also combined with the *Glossary of Cultural Syndromes and Idioms of Distress* and renamed by the *DSM-IV* leadership as the *Glossary of Culture-Bound Syndromes*, a decision that tended to exoticize the OCF as if it should be used only with unusual cultural presentations rather than with every patient. Despite these obstacles, the OCF has been used worldwide since its publication in 1994. While much of this work has found the OCF a useful clinical tool, problems have been identified. Its format as a description of domains to be assessed, lack of implementation guidelines, and brevity—which required that clinicians already be familiar with cultural topics or social science theories—hindered widespread clinical use. Nonetheless, the OCF remains the most widely taught method of

Telegram: @medical_k

www.konkur.in

cultural assessment in U.S. psychiatric residency programs. In addition, psychiatrists and psychologists in Canada, Denmark, England, the Netherlands, Sweden, and the United States have independently operationalized the OCF's implementation. These efforts range from brief semistructured interviews for individual clinicians to use with every patient to cultural consultation services that receive referrals from other health professionals and utilize cultural and linguistic brokers. A major contribution of the OCF has been to organize subsequent research along with its four domains of cultural assessment, facilitating its operationalization into the CFI in *DSM-5*.

KEY DOMAINS IN PATIENT CULTURAL ASSESSMENTS

Cultural Identity of the Individual

Cultural psychiatrists assume that understanding a patient's identity is indispensable to a thorough clinical evaluation. Early OCF guidelines suggested that cultural identity assessments be conducted through an "interpersonal grid" to record potentially relevant variables such as ethnicity, race, geographical origin, language, acculturation, gender, age, sexual orientation, religious or spiritual beliefs, socioeconomic class, and education. This suggestion can be seen as a precursor to contemporary understandings of intersectionality, the idea that individuals belong to multiple groups through which identities are ascribed and self-selected. However, the recommendation for an interpersonal grid faced criticism. The group raised concerns about stereotyping patients or minimizing sociocultural phenomena based on a clinician's determination of the patient's identity. Others have advocated a broader approach that accounts for changes in self-reported identity based on context (i.e., interviewer, setting), and that includes the patient's perception of the clinician's identity. Assessments of cultural identity can help clinicians discern whether forms of social belonging, stigma, and language

Telegram: @medical_k

www.konkur.in

fluency impact symptom experience, expression, and interpretation in certain cultural contexts and settings.

Studies show that many psychiatric trainees may feel uncomfortable and invasive in asking patients about their identities without prior training. Nearly all OCF-inspired interviews include common elements to assess identity, such as the cultural groups with which a patient identifies; the levels of importance and meaning ascribed by the patient to these identifications; evaluations of language fluency and preferences; and assessments of patients' involvement in their cultural contexts of origin and the new cultural contexts in the case of immigrants, especially, including positive and negative experiences with involvement in both contexts. Aspects of identity in some OCF-based interviews included evaluations of whether patients experience multiple identities simultaneously or over time and how cultural identity impacts the clinical problem. Several OCF-based interviews also included detailed migration histories. All OCF-based interviews have used open-ended questions to encourage interaction and discussion, rather than closed-ended checklists. All authors have also warned against an oversimplification of cultural factors in which social processes such as adverse experiences associated with migration and discrimination are mistakenly understood as inherent and representative of the cultural group itself rather than as time-limited and context-driven reactions to social predicaments.

Studies published since the OCF have highlighted unique challenges for certain populations. Some refugees may be suspicious of questions about identity, and many migrants may not know how to discuss their backgrounds in new societies. Children and adolescents may have different cultural identities than their parents, depending on mixed parentage, adoption, and socialization or acculturation. The cultural identity of older patients may be shaped by cultural meanings of old age based on their social roles and status. For all patients, cultural identity should be explored with reference to social context, developmental phase, and the possibility of change over time. Clinicians should especially endeavor to clarify

Telegram: @medical_k

www.konkur.in

which aspects of identity patients consider to be ascribed by others and chosen for themselves.

Cultural Concepts of Distress

EMs of illness have underpinned most studies on patient cultural assessments in mental health and anthropology. Compared to the original assumption of EMs as cognitively linear, later research has shown that EMs can exhibit metaphorical thinking, no clear causes, sequences of events linked by patients based on contiguity or metonymy in ways that may be unclear to others, and images or examples of illness used analogically to understand the current illness episode. EMs can change based on context, including the language, interviewer, and setting in which they are elicited; interactions with close associates, the community, or the health care system; acculturation status for immigrants and refugees; and experiences of discrimination within the health care system. Attempts to code illness narratives from patients with medically unexplained symptoms revealed three types of EMs: *nominal*, in which a condition was named without elaborating on causal attribution or mechanism; *causal attributions*, in which a symptom or illness was linked to a cause; and *process or mechanism explanations*, in which mechanistic or metaphorical devices linked cause and symptom.

Culture and context influence EMs. Clinical narratives reflect broader cultural norms affecting communications with mental health care providers, family, and friends. Access to the illness representations of crucial members in the person's extended social network (either directly or as reported by the patient) provides a range of possible views influencing the person's experience. The organization of health care services in a society may also determine patients' attitudes toward disease, diagnosis, and treatment based on familiarity with the health care system. For this reason, mental health clinicians should evaluate culture and context when working with *all* patients since the act of diagnosis still relies on linguistic communication within psychiatry.

Telegram: @medical_k

www.konkur.in

Eliciting past treatment experiences and current treatment expectations are also important components of EMs. Cultural scripts associate a patient's illness representations with patterns of self-coping and help seeking, including perceived relevance, the efficacy of mental health treatments, and their potential dangerousness. Cultural adaptations of evidence-based therapies that take account of cultural scripts may improve patient engagement and response, highlighting the value of identifying cultural interpretations prior to treatment planning. Nonmedical forms of self-coping and help seeking are common, diverse, and merit clinical attention because they may complement or conflict with biomedical care. Barriers to utilizing mental health services are also determined by cultural priorities for care, family values and interactions, and local health system and socioeconomic factors affecting access to mental health services. A sound cultural assessment strives to situate EMs against the relevant social and health contexts of the patient.

Early theoretical guidelines on the OCF included the *culture-bound syndromes* in this section. *DSM-5-TR* substitutes the term "culture-bound syndrome" with three other terms: *cultural idioms of distress, cultural explanations,* and *cultural syndromes*. These terms denote the ways that suffering, behavioral problems, and troubling thoughts and emotions are experienced, understood, and communicated, either as symptom clusters, ways of expressing distress that may not involve specific symptoms, and/or as explanations or attributions. Key aspects of patients' clinical presentations may be patterned by such cultural concepts.

Nearly all OCF-based interviews include questions on illness-related idioms, the meaning and severity of symptoms, causes, expected course of illness, experiences with care, and treatment expectations. Nearly all interviews ask the patient to describe the views of close associates such as family and friends to situate the individual's perspective in the community context. This line of questioning attempts to operationalize the understanding of culture as shared and interpersonal. OCF-based instruments vary in assessing how the patient describes the clinical problem to close associates, the most troubling aspects of the clinical problem, the

Telegram: @medical_k

www.konkur.in

contribution of illness prototypes within a given cultural context to the patient's understandings, the most useful treatments received, treatment recommendations of close associates, and the patient's use of traditional healers and alternative services.

Psychosocial Stressors and Cultural Features of Vulnerability and Resilience

This domain encourages clinicians to clarify the context of a patient's illness—especially cultural interpretations of the stressors and supports associated with onset and course—and fears and hopes affecting levels of functioning. OCF-based interviews have used open-ended questions, with some interviews asking questions directly of the patient and others instructing clinicians to identify these data based on patient responses. In all cases, the goal is to obtain a description of the life context in which illness emerges and to elicit responses from the patient, the family, and the community. The subjective, lived experience of the patient's and social network's response is crucial because culture shapes the perceived centrality, magnitude, and treatability of the problem as well as forms of stress and support. This approach synthesizes the person's subjective experience of risk, resilience, and protective factors and the clinician's analysis of the patient's social and cultural context. For example, the subjective–objective approach might rely on a functional assessment of key activities of daily living that the clinician conducts alongside the patient's and social network's cultural interpretations of normative functioning.

The OCF was partly developed to address the adverse experiences of disadvantaged ethnoracial groups. Since its publication, studies have elaborated on additional social stressors. A recurrent finding has been the effect of migration status on the mental health of refugees as a social determinant of health independent of premigratory trauma. The factors most associated with risk for psychopathology include low socioeconomic status, poor housing, unemployment or underemployment, lack of official residency status, linguistic barriers, limited social networks, racial or

Telegram: @medical_k

www.konkur.in

ethnic discrimination, role strain, family conflict, status loss, acculturative stress, nostalgia, and bicultural tension. Acculturation issues may affect disempowered or marginalized ethnoracial groups, not just immigrants. Discrimination-related stress affects members of other social groups, such as religious minorities, lesbian–gay–bisexual–transgender–queer persons, those with lower socioeconomic status, and individuals who are differentially abled.

In clinical assessment, family, friends, and other close associates can provide valuable information about cultural context. Collateral information from relevant members of the patient's social network is critical for children and adolescents, older adults, and those with conditions affecting cognitive functioning such as dementia or psychosis that could interfere with the clinical interview. OCF-based interviews have varied in the extent to which they seek collateral forms of information, with some protocols for children and adolescents identifying multiple sources of information and perspectives. Although patient cultural assessments such as the OCF and its related interviews can accommodate the use of medical interpreters and cultural brokers, there is little guidance on how to operationalize this process in practice.

Finally, psychiatrists have reported that patients frequently turn to religion, spirituality, and secular moral traditions in understanding and responding to mental illness. A "religiosity gap" may exist among clinicians trained in empirical/positivistic scientific methods and patients searching for holistic treatments, especially within complementary and alternative systems. Cultural assessments should attend to the meanings of religion and other moral systems in crafting illness assumptions and beliefs, especially when a religious community provides emotional, social, and material support. Clinicians may be able to mobilize such information with patients to support recovery through groups and organizations aligned with these traditions.

OCF-based interviews have assessed stressors, supports, and levels of functioning differently. Variations include focusing on the impact of stressors, the views of the social network, the role of the person's partner, forms of religious/spiritual or moral support, barriers

Telegram: @medical_k

www.konkur.in

to receiving help, and the views of the social network on subsequent levels of functioning.

Cultural Features of the Relationship between the Individual and the Clinician, Treatment Team, and Institution

Many OCF case studies have illustrated the challenges confronting clinicians who provide cross-cultural care. These include tensions between biomedical forms of treatment and other forms of healing, the failure of health systems to provide interpreters, and difficulties in cross-cultural communication. Clinicians have discussed their reactions to consider the patient as an individual and a member of a social group. Sincere clinicians may encounter obstacles in addressing discrimination, racism, and subtle forms of cross-cultural bias during the medical interview. This domain of the OCF provides an opportunity to consider how such experiences affect patients' perceptions of care and promote clinician self-reflection on the challenges of delivering culturally sensitive health care.

Existing OCF-based interviews address this domain differently. Some provide queries to the clinician in the form of introspection, such as questions on mutual perceptions of power and the social positions of the patient and clinician, including the history of relationships between their respective cultural groups. This work operationalizes the concepts of "cultural transference" and "cultural countertransference" to analyze patient–physician relationships. Other instruments suggest questions that can be directly posed to the patient, such as the quality of communication during the interview, the need for interpreters, important topics missed by the interview, the perceived impact of ethnic or cultural matching with the clinician or lack thereof, and the role of the patient during the interview. Although this is a sensitive topic, early, open inquiry into past negative experiences of care and potential miscommunications with clinicians may facilitate rapport, engagement, and a commitment to overcome treatment barriers.

Future Directions for the OCF

Telegram: @medical_k

www.konkur.in

DSM-5 included the OCF as it was published in *DSM-IV* with only minor edits. Since then, mixed-methods (qualitative–quantitative) analyses of patient cultural assessments and debriefing interviews have suggested revisions to the OCF that would (1) combine the current third and fourth domains into a single domain on key social relationships and (2) create a new domain to cover the social, cultural, political, and economic contexts of care. This suggestion comes from one clinical site, particularly in response to growing calls throughout academic medicine for greater attention to the structural contexts of care, such as the social determinants of health and systemic racism. Further studies are needed to validate these findings with data from other settings. This work indicates the ongoing relevance of the OCF to contemporary research and practice in cultural psychiatry.

The Cultural Formulation Interview in *DSM-5* and *DSM-5-TR*

Nearly 20 years of experience with the OCF and its related interviews since 1994 led to the *DSM-5* revision. The *DSM-5* Cross-Cultural Issues Subgroup (DCCIS) developed corresponding semistructured interviews to operationalize the OCF for clinicians. This set of interviews is known collectively as the CFI and consists of a core questionnaire of 16 items, an informant version of the core CFI to obtain collateral material from caregivers, and 12 supplementary modules that expand the core cultural assessment based on topics of interest (i.e., explanatory models) or populations with specific needs (i.e., children and adolescents, immigrants and refugees). The APA has made these instruments available for free at http://www.psych.org/practice/dsm/dsm5/online-assessment-measures.

The DCCIS was part of the larger *DSM-5* Gender and Cross-Cultural Issues Study Group and included experts in culture and mental health from diverse countries and cultural groups. One goal of the DCCIS was to improve cultural assessment within psychiatric

Telegram: @medical_k

www.konkur.in

diagnoses. The subgroup was charged by the *DSM-5* task force with making recommendations on ethnoracial, cultural, and contextual issues to the *DSM-5* workgroups, such as differences in risk factors, precipitants, symptom presentations, prevalence, symptom severity, and course of illness for each diagnosis. These recommendations have appeared within the text of *DSM-5* and were further expanded in *DSM-5-TR*.

In addition, the DCCIS undertook a critical review of the *DSM-IV* OCF. DCCIS participants prepared literature reviews on the OCF as a whole, each of its four domains, and key implementation questions raised by the use of the OCF in clinical care. Such topics included recommended guidelines for use, special populations in need of attention such as children, the older adults, or immigrants and refugees, and the format and content of previously developed interviews, protocols, and questionnaires operationalizing the OCF. DCCIS members provided recommendations on revising the OCF, including how to facilitate implementation through the CFI.

Based on these literature reviews and previous experiences of DCCIS members developing and using OCF-based cultural assessments, the OCF was revised slightly for *DSM-5*, mostly by making the *DSM-IV* text more explicit in places. Examples of this clarification process include the incorporation of elements of cultural identity not mentioned in *DSM-IV,* such as religious affiliation and sexual orientation, among others; clinician instructions to identify stressors and supports in the patient's social environment; and mention of the impact of racism and discrimination on the clinician–patient relationship. These clarifications were expanded in *DSM-5-TR:* for example, by referring under cultural identity to intersectionality, the interaction of various aspects of the person's identity, and by guiding clinicians to elicit the level of interaction and identification by individuals who identify with racialized and ethnic groups both with their own group and with other segments of society.

Other changes made the OCF more operational. An initial 14-item interview was developed largely from previous question lists, interview protocols, and interviews that operationalized the OCF; most of the authors of the OCF-based approaches were members of

Telegram: @medical_k

www.konkur.in

the DCCIS. The content of the questions was formulated, discussed, and debated in 2010 and 2011 during biweekly conference calls, supported by the *DSM-5* development process. The resulting 14-item version of the CFI was tested in a field trial from November 2011 to November 2012 at 12 clinical sites in the United States, Canada, Peru, the Netherlands, Kenya, and India. This trial utilized a standardized training format (http://www.ucl.ac.uk/ccs/specialist-services/#cfi) and research design to evaluate the CFI's acceptability, feasibility, and clinical utility among patients and clinicians. Field trial results were used to finalize the 16-item version in *DSM-5*. An informant version of the CFI was prepared to elicit collateral information from parents, caregivers, and other close associates. Supplementary modules were also developed for a more comprehensive assessment. Some modules expand various sections of the core CFI, as mentioned above.

Definition of Culture

To facilitate the application of the interview, a definition of *culture* was included in *DSM-5* and updated in *DSM-5-TR*. *Culture* is defined as (1) the processes through which people assign meaning to experience, drawing from the values, orientations, knowledge, and practices of the diverse social groups (e.g., ethnic, faith, occupational, and veterans groups) in which they participate; (2) aspects of an individual's background, developmental experiences, and current social contexts and position that may affect their perspective, such as age, gender, social class, geographic origin, migration, language, religion, sexual orientation, disability, or ethnic or racialized background; (3) the influence of family, friends, and other community members (the individual's social network) on the individual's illness experience; and (4) the cultural background of the health care providers, and the values and assumptions embedded in the organization and practices of health care systems and institutions, that affect the clinical interaction.

This definition appears in the text of *DSM-5-TR* and emphasizes the all-encompassing effects of culture on individual subjective

Telegram: @medical_k

www.konkur.in

experience, as well as the fundamental role of family and close associates in shaping conceptions of illness and help-seeking expectations. In the United States, culture is frequently conflated with ethnic and racialized categories, which may unintentionally stereotype patients. Other components of culture—for example, age cohort, occupation, and sexual orientation—are often not part of a cultural assessment. By contrast, the CFI encourages clinicians to elicit the contextual frame of each patient's experience—seeking to use information about the collective to understand an individual's perspective and to clarify how local environments influence the person's situation, including how sociocultural contingencies help pattern a set of events. In addition, the CFI focuses the cultural formulation on the patient's self-identified group rather than on visible group markers of identity that may inadvertently lead to stereotyping. Finally, the updated definition focuses attention on the cultural background of the clinician and the cultural assumptions that organize health care delivery as important cultural contributors to the clinical environment.

Supplementary modules used to expand each CFI subtopic are noted in parentheses.

GUIDE TO INTERVIEWER	INSTRUCTIONS TO THE INTERVIEWER ARE ***ITALICIZED.***
The following questions aim to clarify key aspects of the presenting clinical problem from the point of view of the individual and other members of the individual's social network (i.e., family, friends, or others involved in current problem). This includes the problem's meaning, potential sources of help, and expectations for services.	*INTRODUCTION FOR THE INDIVIDUAL:* I would like to understand the problems that bring you here so that I can help you more effectively. I want to know about ***your*** experience and ideas. I will ask some questions about what is going on and how you are dealing with it. Please remember there are no right or wrong answers.

CULTURAL DEFINITION OF THE PROBLEM

CULTURAL DEFINITION OF THE PROBLEM

(Explanatory Model, Level of Functioning)

Elicit the individual's view of core problems and key concerns. *Focus on the individual's own way of understanding the problem.* *Use the term, expression, or brief description elicited in question 1 to identify the problem in subsequent questions (e.g., "your conflict with your son").*	1. What brings you here today? *IF INDIVIDUAL GIVES FEW DETAILS OR ONLY MENTIONS SYMPTOMS OR A MEDICAL DIAGNOSIS, PROBE:* People often understand their problems in their own way, which may be similar to or different from how doctors describe the problem. How would *you* describe your problem?

Telegram: @medical_k

www.konkur.in

Ask how individual frames the problem for members of the social network.	2. Sometimes people have different ways of describing their problem to their family, friends, or others in their community. How would you describe your problem to them?
Focus on the aspects of the problem that matter most to the individual.	3. What troubles you most about your problem?

CULTURAL PERCEPTIONS OF CAUSE, CONTEXT, AND SUPPORT

CAUSES

(Explanatory Model, Social Network, Older Adults)

This question indicates the meaning of the condition for the individual, which may be relevant for clinical care.	4. Why do you think this is happening to you? What do you think are the causes of your [PROBLEM]?
Note that individuals may identify multiple causes, depending on the facet of the problem they are considering.	*PROMPT FURTHER IF REQUIRED:* Some people may explain their problem as the result of bad things that happen in their life, problems with others, a physical illness, a spiritual reason, or many other causes.
Focus on the views of members of the individual's social network. These may be diverse and vary from the individual's.	5. What do others in your family, your friends, or others in your community think is causing your [PROBLEM]?

STRESSORS AND SUPPORTS

Telegram: @medical_k

www.konkur.in

(Social Network, Caregivers, Psychosocial Stressors, Religion and Spirituality, Immigrants and Refugees, Cultural Identity, Older Adults, Coping and Help Seeking)

Elicit information on the individual's life context, focusing on resources, social supports, and resilience. May also probe other supports (e.g., from co-workers, from participation in religion or spirituality).	6. Are there any kinds of support that make your [PROBLEM] better, such as support from family, friends, or others?
Focus on stressful aspects of the individual's environment. Can also probe, e.g., relationship problems, difficulties at work or school, or discrimination.	7. Are there any kinds of stresses that make your [PROBLEM] worse, such as difficulties with money, or family problems?

ROLE OF CULTURAL IDENTITY

(Cultural Identity, Psychosocial Stressors, Religion and Spirituality, Immigrants and Refugees, Older Adults, Children and Adolescents)

	Sometimes, aspects of people's background or identity can make their [PROBLEM] better or worse. By ***background*** or ***identity,*** I mean, for example, the communities you belong to, the languages you speak, where you or your family are from, your race or ethnic background, your gender or sexual orientation, or your faith or religion.
	8. For you, what are the most

Telegram: @medical_k

www.konkur.in

Ask the individual to reflect on the most salient elements of his or her cultural identity. Use this information to tailor questions 9–10 as needed.	important aspects of your background or identity?
Elicit aspects of identity that make the problem better or worse. *Probe as needed (e.g., clinical worsening as a result of discrimination due to migration status, race/ethnicity, or sexual orientation).*	9. Are there any aspects of your background or identity that make a difference to your [PROBLEM]?
Probe as needed (e.g., migration-related problems; conflict across generations or due to gender roles).	10. Are there any aspects of your background or identity that are causing other concerns or difficulties for you?

CULTURAL FACTORS AFFECTING SELF-COPING AND PAST HELP SEEKING

SELF-COPING

(Coping and Help Seeking, Religion and Spirituality, Older Adults, Caregivers, Psychosocial Stressors)

Clarify self-coping for the problem.	11. Sometimes people have various ways of dealing with problems like [PROBLEM]. What have you done on your own to cope with your [PROBLEM]?

PAST HELP SEEKING

(Coping and Help Seeking, Religion and Spirituality, Older Adults, Caregivers, Psychosocial Stressors, Immigrants and Refugees, Social Network, Clinician-Patient Relationship)

Telegram: @medical_k

www.konkur.in

Elicit various sources of help (e.g., medical care, mental health treatment, support groups, work-based counseling, folk healing, religious or spiritual counseling, other forms of traditional or alternative healing). *Probe as needed (e.g., "What other sources of help have you used?").* *Clarify the individual's experience and regard for previous help.*	12. Often, people look for help from many different sources, including different kinds of doctors, helpers, or healers. In the past, what kinds of treatment, help, advice, or healing have you sought for your [PROBLEM]? *PROBE IF DOES NOT DESCRIBE USEFULNESS OF HELP RECEIVED:* What types of help or treatment were most useful? Not useful?

BARRIERS

(Coping and Help Seeking, Religion and Spirituality, Older Adults, Psychosocial Stressors, Immigrants and Refugees, Social Network, Clinician-Patient Relationship)

Clarify the role of social barriers to help seeking, access to care, and problems engaging in previous treatment. *Probe details as needed (e.g., "What got in the way?").*	13. Has anything prevented you from getting the help you need? *PROBE AS NEEDED:* For example, money, work or family commitments, stigma or discrimination, or lack of services that understand your language or background?

CULTURAL FACTORS AFFECTING CURRENT HELP SEEKING

PREFERENCES

(Social Network, Caregivers, Religion and Spirituality, Older Adults, Coping and Help Seeking)

Clarify individual's current	Now let's talk some more

Telegram: @medical_k

www.konkur.in

perceived needs and expectations of help, broadly defined.	about the help you need.
Probe if individual lists only one source of help (e.g., "What other kinds of help would be useful to you at this time?").	14. What kinds of help do you think would be most useful to you at this time for your [PROBLEM]?
Focus on the views of the social network regarding help seeking.	15. Are there other kinds of help that your family, friends, or other people have suggested would be helpful for you now?

CLINICIAN-PATIENT RELATIONSHIP

(Clinician-Patient Relationship, Older Adults)

Elicit possible concerns about the clinic or the clinician-patient relationship, including perceived racism, language barriers, or cultural differences that may undermine goodwill, communication, or care delivery.	Sometimes doctors and patients misunderstand each other because they come from different backgrounds or have different expectations.
Probe details as needed (e.g., "In what way?").	16. Have you been concerned about this and is there anything that we can do to provide you with the care you need?
Address possible barriers to care or concerns about the clinic and the clinician-patient relationship raised previously.

The Core CFI

Table 29.2–2 presents the core CFI interview. The interview has been designed like other semistructured interviews, such as the Structured

Telegram: @medical_k

www.konkur.in

Clinical Interview for DSM Disorders (SCID), in which instructions to clinicians appear next to questions for patients. As emphasized in *DSM-5-TR*, the CFI follows a person-centered approach to cultural assessment by asking the patient about their views and those of close associates to avoid stereotyping by ethnoracial background or clinical expectations for a given illness. Clinicians are encouraged to voice the questions in their own style and ask probes as necessary to understand patient answers completely. The CFI is designed for use in the initial assessment of patients in all clinical settings, regardless of the cultural backgrounds of the patient or the clinician. Even patients and clinicians who seem to share the same cultural background may differ in ways that are critical to care, such as by educational level, socioeconomic status, or role expectations. The CFI may be used in its entirety or incorporated piecemeal; however, its developers recommend obtaining the person's narrative as an unbroken flow before proceeding to the rest of the clinical interview. The CFI may be especially helpful when there is difficulty in diagnostic assessment due to differences in the cultural, religious, or socioeconomic backgrounds of the clinician and the patient; when there is uncertainty about the fit between patient symptoms and diagnostic criteria; when it is difficult to judge illness severity or impairment; when patients hold views of symptoms or expectations of care that differ from clinicians' based on their experience with other cultural systems of healing and health care; when patients and clinicians disagree on the course of care; when there is mistrust of mainstream services and institutions by individuals with collective histories of trauma and oppression; or in cases of suboptimal treatment engagement and adherence. In response to criticisms about the absence of guidelines for the OCF, the DCCIS specifies instructions to clinicians to facilitate cultural assessments.

The core CFI is divided into four main domains. The first domain is the *Cultural Definition of the Problem* and consists of the first three questions. Question no. 1 is a broad, open-ended inquiry about the patient's presenting concerns. The prompt invites patients to describe their problems and emphasizes an understanding of the patient's illness, even if these descriptions are "similar to or different

Telegram: @medical_k

www.konkur.in

from how doctors describe the problem." Question no. 2 clarifies the patient's description of the problem as would be discussed with close associates, in recognition that culture influences information sharing according to the audience and social context. At this point in the interview, patients may be reticent to describe the problem in nonbiomedical ways that the clinician could find unusual and may therefore censor such descriptions. By framing the question in relation to the person's social network, the goal is to facilitate the patient's report of descriptions that are salient in the social environment. Question no. 3 on what troubles the patient most about the problem asks about what is most at stake for the individual during the illness.

Questions no. 4 to 10 belong to the second domain of the core CFI, *Cultural Perceptions of Cause, Context, and Support*. Questions no. 4, 6, and 7 focus the interview on the patient's EMs for the causes, social stressors, and social supports of the illness. Question no. 4 includes the placeholder "[PROBLEM]" to solicit the patient's preferred terms and phrases for how a problem is framed, known as *idioms of distress*. Once obtained, the patient's vocabulary can be substituted for the placeholder throughout the interview to build rapport and bridge patient–clinician linguistic differences in understanding the illness. In some cases, the patient may use biomedical vocabulary such as "I might have depression," but in other cases, terms referencing social determinants of health may be evident, such as "I worry about my rent, electricity, and phone bill." Terms communicating the presenting problem may vary greatly, and the CFI can reveal how patients frame issues so that clinicians can tailor treatment strategies.

Question no. 5 asks the patient to consider what close associates may understand as the cause of illness in response to the *DSM-5-TR* understanding of culture as the meanings and viewpoints transmitted within social groups. In this instance, the meanings being transmitted are the understandings of illness, and the social group is the patient's close associates. As with question no. 2 on the definition of the problem, framing the inquiry through members of the social network

Telegram: @medical_k

www.konkur.in

encourages a fuller range of responses that may influence the individual's EMs.

Questions no. 8, 9, and 10 also belong to this second domain but orient the interview toward the patient's cultural identity. Question no. 8 begins with a brief introduction that clinicians can use to clarify the meaning of *cultural background or identity* as relevant to health care. The introduction provides examples of identities that may be important for the patient, such as language, ethnicity, religion, and sexual orientation. These examples are meant to be representative in order to stimulate thought, not a fixed set of identities from which the patient must choose. Question no. 8 then asks the patient directly about the most important aspects of background or identity. This method of allowing the patient to name the preferred cultural identity departs from previous models of cultural competence that have made assumptions about patient identities based on a group affiliation such as ethnoracial background without accounting for their importance to the individual. For example, one patient in the *DSM-5* field trial initially named his identity as "Cuban" but then explained that identifying as a Christian was more helpful in understanding his suffering existentially. A model of cultural competence that assumed ethnicity was the most important group affiliation—without accounting for the patient's self-ascribed identity—could have overlooked the role of religion in providing meaning to the illness experience. Question no. 9 asks the patient how this identity may impact the current illness experience or patient-centered definition of the clinical problem. Question no. 10 asks the patient to consider how identity may cause other problems in life that may not be as obviously related to the illness but may be nonetheless important, such as problems with migration, gender roles, or intergenerational conflict.

Questions no. 11, 12, and 13 form the third domain known as *Cultural Factors Affecting Self-Coping and Past Help Seeking*. This domain encourages patients to share past forms of self-coping and help seeking in recognition that most forms of help are sought outside of the biomedical health care system. Question no. 11 addresses the patient's coping practices, and question no. 12 considers help seeking broadly to include help inside and outside of

Telegram: @medical_k

www.konkur.in

the biomedical system (i.e., religion-based support and support groups). An additional prompt for question no. 12 clarifies the types of help that have been most and least helpful. This information may aid the clinician in developing a treatment plan for the current illness episode. Question no. 13 asks about past barriers to treatment to help devise the current treatment plan around available resources.

The final three questions constitute the last domain of the CFI, *Cultural Factors Affecting Current Help Seeking*. Question no. 14 asks the patient about current treatment preferences, and question no. 15 explores treatment preferences recommended by close associates. As with questions on patient terms and causes for the presenting problem, this question is examined at the individual and social levels to explore how patients fashion cultural meanings within social groups. Question no. 16 begins with an open-ended statement to help the patient anticipate how perceived differences with the clinician can adversely affect care. By asking the patient about this potential barrier, the clinician can work to resolve such differences. Even if the question is not answered during the initial visit, the clinician's openness may empower the patient to raise concerns in future visits. The core CFI adopts an ecologic approach to culture by asking the patient about the illness, moving outward to views of the social network and the role of social supports and stressors, and then finishing with the illness in relation to the health care system.

The Informant CFI

The informant CFI (I-CFI) guides clinicians in conducting a cultural assessment of the patient's clinical problem from the perspective of a key informant such as a spouse, relative, or friend who may be present during the clinical encounter. Patients are often accompanied by relatives or other potential informants during clinic visits, providing clinicians with the opportunity to include them during diagnosis and treatment planning. Social relationships can have profound effects—positive and negative—on pathways to and through mental health treatment, including decisions about when or whether to seek care, participation in clinic visits, and implementation of treatment plans in

Telegram: @medical_k

www.konkur.in

the home, such as adherence to medication. The roles of close associates and their perspectives on illness and treatment are informed by cultural meanings and practices.

Clinical care often requires consultation with family members, other kin, or friends. Certain aspects of culture may be shared among patients and others within the social network, but there may be differences within families. For example, an older immigrant man who is depressed and most comfortable speaking his native language may be accompanied by an adult child who speaks English and has different cultural values. In such cases, the patient and the informant may have different EMs for the patient's depression or view of treatment. In such situations, the I-CFI can assist clinicians with eliciting the perspectives of key informants through the lens of culture, enabling a deeper understanding of the patient's illness and the interpersonal dimensions of care. This can create opportunities for clinical negotiation and the development of shared understandings of illness and goals for treatment.

The I-CFI can play an especially important role in several situations when an informant is available. In some instances, the informant may be the primary or sole source of information to assess the role of cultural factors in diagnosis and treatment. This may occur when a patient is unable to give a meaningful or coherent history because of conditions such as severe cognitive impairment (i.e., from Alzheimer disease or a head injury), catatonia, severe paranoia, agitation, or substance intoxication. Alternatively, the patient may be a young child, and a cultural assessment of the parent or other caregiver's perspective may be helpful. In other cases, the clinician may seek clarification from the informant when the patient's responses to the CFI are ambiguous or partial (as when asking the patient about how others in their cultural group would view the symptoms). The clinician may also administer the I-CFI if there is a family member or friend who is influential in the patient's clinical care and decision making. Finally, the I-CFI may be useful when treatment hits an impasse, and an assessment of the social context may identify underlying causes.

Telegram: @medical_k

www.konkur.in

In choosing whether to use the I-CFI, the clinician should consider several issues. First, the clinician should discuss the involvement of the informant with the patient while respecting all desires for autonomy and privacy. Patients may not want a relative involved due to concerns about burdening family members, shame about certain aspects of the problem, or discomfort in discussing conflicts with the informant. In these situations, the clinician may decide not to involve the informant or opt to negotiate family involvement over time after the patient and clinician have established rapport. In other situations, as when the patient insists on having relatives present during the clinical encounter and defers to them, the clinician may need to negotiate time during the visit to meet individually with the patient to allow discussion of sensitive issues that may involve family members (i.e., cases of conflict or abuse). After the informant interview, the clinician may decide whether to interview the relative (or another informant) in the presence of the patient and vice versa. Clinicians should balance patient preferences with medicolegal requirements related to patient confidentiality that are operational in their practice settings.

A related issue is that the clinician may find important differences in the views of patients and informants (i.e., in their illness EMs or the extent to which behavior is viewed as normative in their cultural context). One approach to such situations is to present the different perspectives in a nonjudgmental way, together with the biomedical view of illness, to try and negotiate a partially shared understanding of illness and treatment. When multiple perspectives cannot be resolved in this way, documenting differences may assist the clinician in seeking additional information to clarify diagnostic issues or in anticipating obstacles to implementing the treatment plan.

The clinician has flexibility in the timing and administration of the I-CFI. For example, the I-CFI could be used at the initial visit or later. The clinician may use all of the I-CFI or only the parts most apparently relevant to clinical care. With multiple family members or caregivers, pragmatic decisions must be made about whom to interview based on patient preferences and the informant's involvement in the patient's life. Finally, the supplementary modules

Telegram: @medical_k

www.konkur.in

may be useful with the I-CFI, particularly the caregiver module, which further explores the role of cultural factors in caregiving. The I-CFI can be accessed in *DSM-5-TR* and at the website noted earlier.

The CFI Supplementary Modules

The final set of CFI assessments is the supplementary modules, listed in Table 29.2–3. The core CFI operationalizes a basic cultural assessment, but the need for supplementary modules may arise when certain cultural domains are not addressed or assessed without requisite depth during the initial clinical encounter. In other circumstances, the core CFI may not be needed as much as a specific supplementary module. Supplementary modules that are based on special populations such as children and adolescents, immigrants, and older adults include questions tailored for their cultural needs. Alternatively, a clinician can administer the EM module to learn more about the patient's understanding of the problem or the spirituality, religion, and moral traditions module to better grasp the meanings of suffering. These examples suggest how 12 supplementary modules can be utilized with the core CFI and the informant version or as part of a stand-alone interview.

All supplementary modules possess a common format. They begin by noting common questions with the core CFI. Instructions for administering the module are provided, followed by an introduction for the clinician to the patient. Most modules are organized by a specific subdomain, further assessed through several questions. For example, in the cultural identity module, the subdomains include language ability and migration history, assessed by 6 and 9 questions, respectively. Like the core CFI, the supplementary modules are mostly problem focused, attempting to elicit how the module topic relates to the presenting problem. Some, like the cultural identity module, focus more on aspects of the patient's identity than the presenting problem. Other modules are focused on the presenting problem, such as the EM and coping and help-seeking modules. In some cases, questions in one module are assessed in another based on topical interrelationships. Investigators

Telegram: @medical_k

www.konkur.in

continue to develop new supplementary modules, such as for the cultural assessment of grief and bereavement.

Table 29.2–3.
The CFI Supplementary Modules

Number	Module
1	Explanatory model
2	Level of functioning
3	Social network
4	Psychosocial stressors
5	Spirituality, religion, and moral traditions
6	Cultural identity
7	Coping and help seeking
8	Patient–clinician relationship
9	School-aged children and adolescents
10	Older adults
11	Immigrants and refugees
12	Caregivers

Research on the CFI Since *DSM-5's* Publication

By 2020, a substantial evidence base emerged on the CFI. One systematic review article identified 25 studies on the CFI, with sample sizes ranging from 1 to 460 participants. Studies were divided into two types: those that used the pilot CFI from the *DSM-5* field trial, which collectively enrolled 960 subjects, and those that used the final version of the CFI in *DSM-5,* which enrolled 739 subjects. The studies covered three broad themes: how the CFI (1) affects a clinician's practice; (2) relates to existing theories in medical communication, implementation science, and family psychiatry; and (3) is used within cultural competence training programs. Most studies reported that patients and clinicians viewed the CFI as

Telegram: @medical_k

www.konkur.in

improving clinical rapport, though no study has examined longer-term clinical outcomes such as improvements in symptoms of functioning.

FUTURE DIRECTIONS

This chapter has presented a historical overview of patient cultural assessments, from Kraepelin's initial attempts at cross-cultural comparative psychiatry over a century ago to the CFI in *DSM-5-TR*. Common themes in patient cultural assessments since the 1970s have included a focus on the patient's cultural background and identity, explanations of illness, levels of psychosocial support and functioning, and experiences with help seeking, including with the biomedical system. The CFI represents the most international attempt at standardizing a pertinent set of questions for patients and clinicians in all clinical encounters with the assumption that culture constantly frames understandings and practices related to sickness and care.

Members of the DCCIS have continued to expand their work on cultural assessments beyond *DSM-5-TR*. The CFI presents a brief list of questions designed to elicit clinically relevant cultural information within practice constraints. Research is currently underway on the comparative effectiveness of the CFI with other forms of resource-intense cultural assessments such as cultural consultation services in changing diagnosis and recommended treatment modalities. The CFI also reflects an attempt to mobilize contemporary notions of culture from anthropology and the interpretive social sciences, but further work is needed to clarify if these notions apply in all clinical settings and how best to elicit this information through simple and succinct probes. Ongoing partnership with collaborators from anthropology, psychology, and sociology may illustrate new domains necessary for thorough cultural assessments that can be incorporated in future revisions. For example, ongoing work focuses on the best ways to assess the impact on a patient's illness experience and access to care of social determinants of health, including societal–structural disparities by ethnoracial background and social position. Studies on CFI implementation in

Telegram: @medical_k

www.konkur.in

educational and clinical settings are needed to understand how trainees learn the CFI, which questions obtain the most pertinent cultural information applicable to diagnostic and treatment planning, and how patients perceive differences with nonculturally informed care. Outcome studies measuring the CFI's effects on patient symptoms, quality of life, and functional assessment are needed to examine potential mechanisms of action. Finally, research must continue to identify the most successful strategies for implementing the CFI during routine practice, including in team-based care.

Special Areas of Interest

30.1 Psychiatry and Reproductive Medicine

HELEN BRADSHAW, M.D., MARIKA TOSCANO, M.D., AND LAUREN M. OSBORNE, M.D.

Reproductive events and processes have both physiologic and psychological consequences—and psychological states affect reproductive physiology and modulate reproductive events. This section examines these bidirectional relationships, intending to introduce fundamental concepts related to the classic reproductive events, such as menarche, the menstrual cycle, pregnancy, delivery, postpartum, and the menopausal transition. Both psychiatry and reproductive medicine have defined distinct diagnoses that include the functioning of both systems. For instance, premenstrual dysphoric disorder (PMDD)—mood, cognitive, and behavioral changes that can occur in association with the menstrual cycle—exemplifies a somatopsychic disorder, in which biologic changes occurring in the soma trigger changes in psychological state. In contrast, functional forms of hypothalamic anovulation represent psychosomatic illness that originates in the brain but alters somatic functioning. Medicine

Telegram: @medical_k

www.konkur.in

has traditionally separated the treatment of reproductive events from that of psychological functioning. However, increasing awareness of a false dichotomy between mind and body is beginning to shape new systems and approaches to care that place greater attention on addressing mental health needs in medical settings. The field of reproductive psychiatry has blossomed in recent years, with distinct residency training tracks and postdoctoral fellowship training for both psychiatrists and obstetricians—making this a crucial and distinctive subspecialty field of psychiatry.

Since its inception, most of this field's research, policy, and clinical activities have applied exclusively to women. Men's reproductive health, and the perinatal mental health of fathers, have only recently been recognized as worthy of study and attention. Similarly, the unique reproductive mental health needs of people who have female reproductive organs but do not identify as women are now being recognized—but evidence to support these unique needs at this time is limited. Therefore, we need to note that we speak to the interplay of reproductive and psychiatric systems on the health of all people with ovaries. Not all individuals that possess ovaries identify as women, and not all women have ovaries. An individual's genetic/chromosomal sex, either assigned female at birth (AFAB) or assigned male at birth (AMAB), does not necessarily correspond with that individual's experienced gender throughout life. Here, as we open the chapter, we remind the reader of this distinction between genetic/chromosomal sex and expressed gender. Emerging research may in the future allow us to make distinctions about the reproductive mental health of people of different genders, but as most research currently has been done on women, we will continue to use that term in this edition of this textbook.

REPRODUCTIVE DEVELOPMENT

Fetal and Neonatal Development

A fetus's genetic/chromosomal sex is defined by sex chromosome composition (XX vs. XY), which subsequently directs gonadal

Telegram: @medical_k

www.konkur.in

differentiation into ovaries or testes. This, in turn, directs the hormonal patterns that determine phenotypic sex, defined as the appearance of external genitalia and secondary sex characteristics that arise during puberty. The genetic/chromosomal sex of an embryo is determined during the fertilization process, with an oocyte (egg) contributing an X chromosome and a sperm contributing either an X or a Y chromosome. Subsequent gonadal differentiation does not occur until approximately 6 to 8 weeks of gestation, and prior to this developmental phase, the embryo contains both male and female undifferentiated gonads (both the Wolffian duct and Müllerian duct systems). Phenotypic sex is bidirectional until about 8 to 10 weeks of gestation, with undifferentiated external genitalia consisting of the genital tubercle and genital folds and swellings. The default developmental pathway occurs in the absence of a Y chromosome and testosterone when the Müllerian duct system develops into fallopian tubes, the uterus, and the upper vagina; the genital tubercle becomes the clitoris, and the genital folds and swellings become the labia. In the presence of a Y chromosome containing the SRY gene region, which codes for testis-determining factor, the undifferentiated gonads are converted to testes. The fetal testes begin to secrete testosterone and anti-Müllerian hormone (AMH), leading to regression of the Müllerian duct system and development of the Wolffian duct system to produce male internal genitalia. Testosterone's enzymatic conversion to dihydrotestosterone (DHT) by 5-alpha–reductase results in masculinization of the external fetal genitalia. The urogenital tubercle becomes the glans, the urogenital folds become the penis and male urethra, and the labioscrotal swellings in the midline become the scrotum. Male differentiation occurs between 8 and 10 weeks of gestation, with external genitalia recognizable by 14 to 16 weeks. If testosterone synthesis is absent or compromised, if enzymatic conversion of testosterone to DHT does not occur, or if the fetal tissues contain androgen receptor defects, rendering them insensitive, a spectrum of incomplete masculinization ensues, including microphallus, hypospadias, cryptorchidism, or partial vagina. In female fetuses, excess androgen exposure from 8 to 12 weeks of development from maternal or fetal sources, such as occurs in fetal

Telegram: @medical_k

www.konkur.in

congenital adrenal hyperplasia or maternal virilizing tumors, can partially masculinize a female fetus, leading to findings such as clitoromegaly or labial fusion.

Sexual differentiation of the central nervous system (CNS) is mainly dependent on the effect of testosterone on target areas within the developing brain. In response to placental human chorionic gonadotropin (hCG), the fetal testes secrete testosterone in the mid-first trimester. Fetal testicular function peaks between 15 and 18 weeks, then declines, with the maintenance of in-utero testosterone production assumed by the fetal pituitary gonadotropins. In contrast, the fetal ovary does not develop functional follicles until the third trimester. The estrogens produced by the fetal gonads and placenta do not cross the blood–brain barrier because of circulating binding proteins, and thus circulating estrogens do not have access to and cannot imprint the developing CNS in utero. In late pregnancy, gonadotropin secretion is restrained in male and female fetuses due to the negative feedback effects of increasing placental estrogen and progesterone production. At the time of birth, when maternal estrogen and hCG circulating in the neonate decrease sharply compared to fetal life, the newborn's hypothalamic–pituitary–gonadal axis escapes from this suppressive effect and gonadotropin secretion rises dramatically in both sexes.

Similarly, follicle-stimulating hormone (FSH) rises to a greater extent in girls, and luteinizing hormone (LH) rises to a greater extent in boys. In boys, the gonadotropin rise is followed by an elevation of testosterone concentrations to adult levels, with a peak at 3 to 6 months postnatally, followed by a steady decline to prepubertal levels by 9 to 12 months of age. Girls have a more marked and sustained postnatal rise in gonadotropins than boys, with FSH reaching levels greater than during a normal adult menstrual cycle and LH levels equivalent to adult levels. In girls, this gonadotropin rise peaks at 12 to 18 months and falls to prepubertal levels by 24 to 36 months. Thus, between birth and 3 years of age, the brains and bodies of girls and boys have been exposed to dramatically different patterns, durations, and doses of sex-steroid secretion.

Telegram: @medical_k

www.konkur.in

The organizational effects of testosterone on the developing CNS are thought to depend primarily on in situ aromatization (the conversion of androgens to estrogens by the enzyme aromatase) of testosterone to estradiol. In addition, testosterone may bind directly (without conversion to estradiol) to androgen receptors in the CNS. Therefore, sexual dimorphism of brain structure may reflect androgen exposure and central dimorphism in crucial brain areas that are responding to high aromatase activity (which, thus, can convert testosterone to estradiol) and the presence of androgen receptors. In the nonhuman primate brain, androgen receptors are in the hypothalamus, amygdala, and prefrontal visual and somatosensory cortices, whereas estrogen receptors (ERs) are more highly concentrated in the female hippocampus than in the male. The degree to which gender-related behavioral asymmetries are accounted for by differences in fetal/infant-steroid hormone exposure is open to debate, but clearly, a mechanism for inducing differences exists.

Morphometric studies of the developing and adult brain support the sex-steroid theory of CNS sexual dimorphism. Sex differences cluster in brain regions with developmentally rich sex–steroid-receptor distribution. Sexual dimorphism is prominent in the cortex, which may result from rapid postnatal decreases in sex–steroid-receptor concentrations. By the age of 6 years, brain volume is 95% of that of an adult; however, boys and girls follow different trajectories in brain tissue changes between the age of 6 years and adulthood. By adulthood, men have 10% larger brain volumes relative to women, larger corpus callosum genu and overall white matter volume, and increased ventricular size. By adulthood, women have larger cortical volume relative to men, higher cortical gray matter volume, and larger volumes in Broca's area, the superior temporal cortex, hippocampus, caudate, thalamus, anterior cingulate gyrus, dorsolateral prefrontal cortex, and interhemispheric white matter connections.

Ongoing and future research will clarify how sex-chromosome genes, independent of gonadal hormones, contribute to the sexual differentiation of brain cells. This concept has already been substantiated from research on embryonic tissues studied before

Telegram: @medical_k

www.konkur.in

gonadal development and through animals engineered to be discordant for genotypic and phenotypic sex. For example, sex-chromosome determination of the midbrain dopamine system has been described. Magnetic resonance imaging (MRI) studies have further clarified the contributions of sex chromosomes and gonadal hormones to the sexual differentiation of the brain. More recent research has identified early sex differences in microglia, the immune system of the CNS, as a possible explanation for discrepancies in the incidence of neurologic diseases and response to treatment across the sexes. Many questions remain that will inform future directions in research on the sexual differentiation of the brain, such as the permanence versus transience of the effects and the role of animal models in understanding environmental factors.

Puberty

Gonadotropin-releasing hormone (GnRH) neurons in the hypothalamus are endogenously pulsatile and active during fetal and neonatal life, making the hypothalamic–pituitary–gonadal axis fully functional before birth. However, between infancy and puberty, the hypothalamic–pituitary–gonadal axis enters a dormant period, with a mechanism proposed to be related to the effects of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). In humans, this postnatal gonadal hiatus involves desynchronizing and suppressing the hypothalamic GnRH pulse generator by undetermined central mechanisms that are largely gonad independent. Although pulsatile GnRH activity remains during this time of dormancy, the frequency and amplitude are low and irregular. Puberty—the resumption of gonadal activity—is also a centrally initiated process that depends on synchronizing the pulsatile release of hypothalamic GnRH. The character of gonadotropin secretion pulses changes around puberty, with a 10-fold increase in LH levels compared to a 2-fold increase in FSH levels and, to a lesser extent, an increase in pulse frequency. LH levels further increase to 20 to 40 times greater than prepubertal levels, particularly during nocturnal pulses. These changes are likely triggered at least in part by expression of the *KiSS1* gene (a gene that encodes a family of neuropeptides called kisspeptins), the excitatory

Telegram: @medical_k

www.konkur.in

neurotransmitter glutamate, and possible contributions from neuropeptide Y. Although prenatal exposure to sex steroids has organizational effects on the developing brain, the reinitiation of gonadal activity during puberty exerts primarily activational influences on the brain and behavior The stimulus for the onset of puberty remains unknown. However, genetics, environment, social factors, and overall health all influence the transition.

Gender

The phenotypic sex of an individual depends on chromosomal sex and exposure and responsiveness of target tissues to endogenous and exogenous sex steroids. *Gender* differs from biologic sex in that it refers to a person's self-image and sex-role identity. Although the development of gender identity is not entirely understood, it is likely influenced not only by exposure and responsiveness to sex steroids but also by expectations and behavioral patterns learned in early childhood from parental, familial, and societal models. Notions of gender direct mannerisms, marital, career, and other behavioral choices that may depart from biologic options. Consider the following example: a child born with a penis and testes identifies as female from a young age and undergoes therapy to prevent masculinization at the time of puberty, followed by feminization with hormones, and later pursues breast construction and vaginoplasty as an adult, with life-long persistence of her female identity. Consider a second example: a female-identifying individual with *Müllerian agenesis*, a condition with ovaries present but uterus and vagina absent, pursues a heterosexual relationship and motherhood via surgical and technologic advances, despite the biologic constraints of her disorder.

While the two examples in the paragraph above offer distinct situations with few similarities, the first describing the experience of a male-to-female transgender individual and the second an example of a person with a disorder of sexual development (DSD), much of our understanding of the development of gender identity is drawn from the literature on DSD. The understanding of gender as two separate categories, either male or female, often referred to as the gender binary, has predominated throughout history and has heavily

Telegram: @medical_k

www.konkur.in

influenced concepts of mental experience. However, recent literature and social activism have challenged the accuracy of understanding individuals as either male or female based upon phenotypic sex. While transgender individuals identify with their nonphenotypic sex, many identify outside of the gender binary and describe themselves as queer, agender, gender fluid, demi- or pan-gender. Our understanding of the biologic and environmental factors that contribute to an individual's development of gender identity remains limited. Available research suggests that the development of gender identity is not simply a psychological process and implicates an array of biologic mechanisms, including genetics, neuroanatomical gender differences, and prenatal and postnatal androgen exposure, in the development of gender identity.

Early Sexuality

Children's behavior can be understood by acknowledging the sexual motivations that, until Sigmund Freud's time, had been assumed to be quiescent until adolescence. The fact that incest, sexual abuse, and other sexual taboos that may occur in childhood have powerful aftereffects, even in adult life, bespeaks the importance of childhood sexuality in establishing healthy relationships.

In puberty, the overriding influence on sexuality is the dramatic change in the hypothalamic–pituitary–gonadal axis that occurs in both sexes. Major hormonal changes, combined with the issue of identity diffusion, contribute to the characteristic tension in relationships, particularly between male and female peers and between adolescents and their parents.

In adulthood, one of the major maturity indicators is establishing healthy sexual relationships. When it is in harmony with other components of the self and with others, sexuality is an integral component of the adult character.

Adolescence

Carol Gilligan observed that preadolescent girls exhibit a sense of self-confidence and a belief that they can influence the course of events in their lives, whereas, during adolescence, that self-esteem

Telegram: @medical_k

www.konkur.in

and belief in their efficacy appear to diminish. Before puberty, boys are more vulnerable than girls are to depressive illness. Girls display a precipitous rise in depression rates throughout adolescence that outpaces adolescent boys. Compared to boys, by age 15 years, girls are twice as likely to have experienced a lifetime episode of major depression. This gender difference has been linked to the onset of puberty rather than to chronologic age and persists for the next 35 to 40 years, spanning the female reproductive years. The predominance of depression in women and the adolescent-onset of this gender difference have been replicated cross-nationally and represent one of the most robust findings in the field of psychiatric epidemiology. In addition, LGBTQ+ youth have higher rates of depression than their non-LGBTQ+ peers.

Negative life events and chronic psychosocial stressors place individuals at risk for major depressive episodes. Several theories about the sex difference in depression point out that women are more likely than men to experience certain traumatic life events. These include physical or sexual abuse and chronic life stressors, such as single parenthood, gender discrimination in the workplace, or financial adversity. Growing evidence indicates that puberty may sensitize girls to the depressogenic effects of life stress. Because women tend to develop a strong affiliative style in their social relationships and a sense of self in connection with others, social stressors, such as conflicts, breaches, or losses within interpersonal relationships, contribute to their depression risk. Men, in contrast, tend to focus on issues of individuation and assertiveness within social relationships and develop an agenic and autonomous sense of self.

Early menarche is associated with an increased risk of depressive symptoms. However, additional research is needed to clarify the causality and biologic mechanisms responsible for this relationship. Results of the 2005 to 2016 National Health and Nutrition Examination Survey (NHANES) demonstrated that women with early menarche had 1.25 (95% CI of 1.16 to 1.61) times the odds of depressive symptoms at the time of the survey compared to women who experienced normal or late menarche. More than 15,000 reproductive-age women completed the survey, and comparisons

Telegram: @medical_k

www.konkur.in

were made after controlling for the likely confounders of age, race, educational attainment, income, and marital status. While the association between early menarche and depressive symptoms has been well-replicated, few studies have addressed the causality of this relationship. A longitudinal study assessing the relationship between a genetic risk score for early menarche and depressive symptoms at four time points during adolescence demonstrated a causal relationship until age 14. Hypothesis surrounding the possible mechanisms linking early menarche to depressive symptoms include dysregulation of the HPA axis and an incongruity between biologic and cognitive maturation.

Recent theories have implicated the hypothalamic neurohormone oxytocin in facilitating such affiliative behaviors as maternal caregiving and adult pair-bond formation in female mammals. Shelley Taylor and coworkers proposed the existence of a uniquely female response to stress, which they termed the *tend-and-befriend response*, based on the oxytocin-mediated caregiving system, which, for women, serves to decrease sympathetic and hypothalamic–pituitary–adrenal (HPA) responses to stress while simultaneously promoting affiliative responses. This stands in contrast to the prototypic model fight-or-flight human stress response. Instead of fighting or fleeing, quieting and tending to offspring's needs when under stress and affiliating with other adults to promote the protection of oneself and one's offspring may represent a more adaptive female response to environmental threats.

Although gender role socialization may begin well before puberty, social pressures to conform to stereotypically feminine versus masculine gender roles likely intensify during the adolescent transition, as the development of secondary sex characteristics make adolescents look more like adults, and they begin to engage in greater levels of cross-sex interaction and dating. Of importance, hormonal changes in the reproductive neuroendocrine axis at puberty may potentiate and interact with this socialization process to promote an adolescent intensification of gender-based behaviors. Some have speculated that the increase in testosterone in boys and the attendant

Telegram: @medical_k

www.konkur.in

aggressiveness, often directed at girls, contribute to a change in girls' behavior during adolescence.

MENSTRUAL CYCLES

Menstrual Physiology

Menstrual cyclicity results directly from ovarian cyclicity (Fig. 30.1–1). Each ovarian cycle starts with recruiting a group of follicles in response to FSH, with subsequent follicular development and maturation, and finally "selection" of one, which becomes the dominant follicle (also called a mature oocyte) that proceeds toward ovulation. As the follicle follows this progression, hormonally active theca and granulosa cells proliferate and synthesize steroid hormones, estrogen more than androgen or progesterone.

Follicular development is initiated by the hypothalamic release of GnRH at a pulse frequency of approximately one pulse every 90 minutes. GnRH stimulates the release of the pituitary gonadotropins LH and FSH. In turn, LH stimulates ovarian theca cells to synthesize and secrete androgens; FSH induces granulosa cell development, including the enzyme aromatase, which converts the thecally produced androgens to estrogens. In the presence of a constant GnRH pulse frequency of one pulse every 90 minutes, the secretion of LH and FSH in the follicular phase is regulated primarily by estradiol feedback at the pituitary level. Rising estradiol concentrations suppress FSH, limiting the number of follicles that become mature oocytes capable of ovulating. When estradiol concentrations rise exponentially to exceed a critical threshold and remain elevated for at least 36 hours, which is the pattern one fully mature follicle produces, an LH surge is triggered, and ovulation (release of the ovum from the follicle sac) ensues approximately 36 hours later. Thereafter, granulosa cells transform into progesterone-secreting luteal cells, and the ovulated follicle is then referred to as the *corpus luteum,* which secretes progesterone.

FIGURE 30.1–1. Changes during reproductive and menstrual cycles **(Top)**. Chart illustrating plasma hormone concentrations in the normal female reproductive cycle **(Bottom)**. FSH, follicle-stimulating hormone; LH, luteinizing hormone. (See eBook for color images.) (Illustration depicting the ovarian events and uterine changes during the menstrual cycle. LifeART image copyright © 2024 Lippincott Williams & Wilkins. All rights reserved.)

The target tissues for ovarian steroids include the endometrium and the hypothalamic GnRH pulse generator, whose frequency is slowed dramatically by the combination of estrogen and progesterone secreted during the postovulatory or luteal phase of the menstrual cycle. This inhibition of GnRH is followed by decreased secretion of LH and FSH so that new follicular development is prevented until the corpus luteum regresses. As progesterone concentrations decline, GnRH pulsatility increases, and secretion of gonadotropin, especially FSH, rises. The menstrual cycle phases can be termed *follicular* and *luteal* in reference to ovarian events or *proliferative* and *secretory* in reference to endometrial events.

The typical menstrual cycle is 21 to 35 days in adults but may range from 21 to 45 days due to differences in luteal phase length. It is generally assumed that regular menstrual cyclicity signals ovarian cyclicity and ovulation, but that assumption is erroneous. Menses and menstrual cycle interval cannot be used to determine whether a woman is or is not ovulatory or if the luteal phase was normal. The clinician who links a psychological state to a reproductive event must know how to determine the presence or absence of gonadal activity. Ovarian activity can be estimated by using several different methods. At-home urine test kits to measure LH levels (over-the-counter "ovulation predictor kits" at drug stores) can demonstrate LH surge and presence of ovulation, which usually occurs on postmenstrual days 13 to 15 for women with 28-day cycles. Urine testing with these kits should be timed to begin on postmenstrual day 11 and continued until ovulation is detected.

Similarly, blood tests may be used to detect ovulation. A blood test to measure serum progesterone can be performed about one week before the anticipated onset of the next menstrual period, and an

Telegram: @medical_k

www.konkur.in

elevated level is usually associated with ovulation. Estrogen and LH levels may also be measured in blood just prior to ovulation. Basal body temperature monitoring with an increase of 0.5 degrees Fahrenheit for several days can indicate that ovulation has occurred. Similar changes in cervical mucous (increased, thin, slippery, and stretchy) can provide at-home clues to determine the presence of ovulation. Women may also be queried regarding the presence or absence of molimina, a group of characteristic symptoms which occur after ovulation, including breast discomfort, increased mucoid vaginal discharge, or premenstrual cramping and bloating. Menstrual cycles can be expected to become more regular with advancing gynecologic age (time since first menses), and, in the absence of pathology, they generally remain regular until 5 to 10 years before the menopausal transition. Ovarian function is characterized by higher estradiol and lower progesterone secretion during the perimenopausal years. Ovarian function does not gradually decline but rather becomes erratic and unpredictable, potentially exposing the brain and soma to large fluctuations in hormone concentrations.

Ovulatory Dysfunction

Ovulatory dysfunction (i.e., oligo-ovulation, anovulation) is identified in 3.4% to 18.6% of menstruating women. Oligo- or anovulation refers to the failure of the ovary to release an ovum during the typical menstrual cycle period of 21 to 45 days. This can sometimes be confused with oligomenorrhea (bleeding that occurs less frequently than every 35 days) or amenorrhea (absence of bleeding over three typical cycles), which are menstrual cycle changes that fall under the term “abnormal uterine bleeding” (previously termed dysfunctional uterine bleeding). While ovulatory dysfunction can sometimes be the etiology of oligo- or amenorrhea, some women with ovulatory dysfunction demonstrate normal menstrual cycle bleeding patterns despite a lack of ovulation. Additionally, many women with oligo- or amenorrhea will have alternative etiologies causing changes in their bleeding patterns unrelated to ovulation.

The physiologic causes of ovulatory dysfunction include adolescence (due to immaturity of the HPA axis), perimenopause,

Telegram: @medical_k

www.konkur.in

lactation, and pregnancy. Pathologic ovulatory dysfunction can arise from hyperandrogenic states (such as polycystic ovarian syndrome, congenital adrenal hyperplasia, or androgen-secreting tumors), endocrinopathies (hyperprolactinemia, thyroid disease), premature ovarian failure, iatrogenic causes (radiation, chemotherapy, or medications including antipsychotics and antidepressants), health conditions (obesity, diabetes), eating disorders/excessive exercise, or hypothalamic dysfunction, which is discussed further below.

Functional Hypothalamic Amenorrhea

Functional hypothalamic amenorrhea (i.e., hypogonadotropic hypogonadism), defined as menstrual cycle interval persistently exceeding 45 days and/or amenorrhea for 3 months or more for which there is no organic or pathologic cause, is a consequence of a nonorganic reduction in GnRH secretion that results in reduced pituitary secretion of gonadotropins and subsequent chronic anovulation. Previously referred to as *idiopathic* or *psychogenic amenorrhea* in the psychiatric literature, functional hypothalamic anovulation is a diagnosis of exclusion. The term “functional” indicates that correcting the underlying causal behavioral factors can reverse ovulatory dysfunction. This implies that the ovaries can respond to appropriate gonadotropin input of either endogenous or exogenous origin; that there are no structural abnormalities of the thyroid, adrenal, pituitary, or brain; that the use of drugs, including antipsychotic medications, does not account for the suppression of GnRH; and that the patient is not pregnant. Neuroimaging may be needed to establish no significant anatomical lesions of the brain or pituitary. Two major questions concerning the pathogenesis of functional hypothalamic amenorrhea remain unresolved. First, the peripheral and central signals that disrupt GnRH pulsatility are poorly understood. Second, how do behavioral, cognitive, and personality variables activate the neural systems to disrupt GnRH secretion? Physicians and patients alike wonder what lifestyle variables provoke or contribute to this type of ovulatory dysfunction and what pharmacologic and nonpharmacologic treatment interventions should be considered.

Telegram: @medical_k

www.konkur.in

The idea that psychogenic stress can induce reproductive dysfunction in women was formally introduced in 1946. The best biochemical evidence supporting the concept that stress impairs GnRH release in women with functional hypothalamic amenorrhea is the consistent demonstration that the activity of the HPA axis is increased. For instance, a prospective study found that young U.S. women who developed transient amenorrhea while studying in Israel had higher urinary cortisol concentrations on arrival than did those whose menses remained regular. There appears to be a dose–response relationship between the type, severity, and number of stresses on one hand and the proportion of women who develop anovulation on the other. Biological and psychological predispositions may confer resistance or sensitivity to various stressors. Exercise, low weight, weight loss, affective and eating disorders, various personality characteristics such as perfectionism and unrealistic expectations, drug use, and a variety of external and intrapersonal stresses have been linked to the development of anovulation. Most women with functional hypothalamic anovulation, when carefully evaluated, display more than one of these traits or behaviors. Recent evidence suggests synergism between metabolic stressors that suppress the hypothalamic–pituitary–thyroidal axis, such as excessive exercise and nutritional restriction, and psychosocial challenges that activate the HPA axis. Thus, multiple chronic stressors are more likely to induce functional hypothalamic anovulation than is a single, larger-magnitude stressor

While further research is necessary to elucidate the mechanisms involved in the tight regulation of ovulation, eating disorder literature demonstrates that nutritional deficits or significant caloric fluctuations (through either restriction or overexercise) commonly result in decreased LH pulsatility, leading to hypogonadotropic hypogonadism and resulting amenorrhea. Amenorrhea occurs in 66% to 84% of patients with anorexia nervosa. Excessive exercising resulting in the female athlete triad (i.e., relative energy deficiency) can also disrupt the hypothalamic–pituitary–gonadal axis. It is thought that endorphin release, central stress (from elevated cortisol), and energy deprivation in these athletes leads to slowing of the GnRH pulsatility amplitude

Telegram: @medical_k

www.konkur.in

and frequency, resulting in hypogonadotropic hypogonadism and amenorrhea. Women with functional hypothalamic anovulation are more likely to require fertility treatments than women in the general population. Furthermore, untreated and protracted illness, especially in women with low BMI, increases the risk of miscarriage and preterm labor.

Recovery is possible if response patterns to ongoing psychosocial demands are developed that are less likely to activate the central and metabolic processes that disrupt pulsatile GnRH release. The current standard of practice, other than observation, is to offer pharmacologic interventions, such as oral contraceptives or hormonal replacement if fertility is not desired, and pharmacologic ovulation induction if fertility is sought. However, pharmacologic intervention alone does not lead to spontaneous recovery and cannot be expected to ameliorate stress-induced alterations in central neurotransmission and hypothalamic function or to reverse ongoing metabolic derangements secondary to exercise or weight loss. For instance, bone accretion does not proceed apace in the face of metabolic compromise, even if exogenous hormone replacement is given in supraphysiologic doses. Although women with functional hypothalamic anovulation frequently do not meet DSM-V criteria for eating disorders or depressive disorders, all these states are characterized by increased cortisol secretion, which alone can alter thyroid hormone secretion and action and alter metabolism and attendant central signals. Thus, it is not surprising that women with amenorrhea due to decreased GnRH drive, regardless of cause, have lower bone mineral density.

Furthermore, pharmacologic intervention alone may mask the recognition of psychological dysfunction and forestall the development of more effective response patterns. In addition, ovulation induction may place low-weight women with functional hypothalamic amenorrhea who conceive at risk for premature labor and intrauterine growth retardation. Fetal neuropsychological development may be compromised by the concomitant presence of hypothalamic hypothyroidism (euthyroid sick syndrome) or hypercortisolemia if ovulation is pharmacologically induced. If women’s parenting skills with functional hypothalamic amenorrhea

Telegram: @medical_k

www.konkur.in

are impaired by ongoing stress, their children may be at risk for poor psychosocial development. Clearly, treatment strategies need to consider that stress and mild psychological dysfunction can play an important role in the genesis of this form of anovulation. If an eating disorder is recognized, specialized psychiatric treatment is indicated.

Psychobiological characteristics can predispose a woman to chronic activation of central neural processes in response to commonplace events. Global hypothalamic dysfunction, including inhibition of GnRH pulsatility, can result. Although identifying the neuromodulators that mediate the development and maintenance of the disruption of GnRH is of academic interest, clinicians must make sure that all other possible causes of anovulation and amenorrhea have been excluded before recommending psychological, psychiatric, or behavioral interventions.

REPRODUCTION

Pregnancy, parturition (childbirth or delivery), and the postpartum period involve a series of tightly orchestrated hormonal events that create the potential for unique psychological states. As pregnancy advances, estrogen and progesterone concentrations rise, and a host of placentally elaborated polypeptide hormones induce metabolic adaptations. Parturition is an intense biologic event that eventuates in the abrupt withdrawal of estrogens, progesterone, and other placental hormones. Parturition is also accompanied by a large-magnitude release of oxytocin and the initiation of the neuroendocrine cascade that establishes lactation. The metabolic demands of pregnancy, parturition, and lactation, the need to deliver infant care across the usual circadian rest-activity cycle, and the hypoestrogenism accompanying lactational amenorrhea present unique physiologic challenges. Menses (and ovulation) generally resume in 6 to 12 weeks if the mother declines to nurse or when lactational frequency declines (usually after 4 to 6 months) if she does nurse. Breastfeeding, and eventual weaning, have implications for maternal mental health, as discussed later in the text in the Breastfeeding and Perinatal Depression sections, respectively.

www.konkur.in

SEXUALITY AND SEXUAL DYSFUNCTION

It has been said that the most important sexual organ is the brain. This truism emphasizes the essential role of desire and comfort in mediating sexual awareness and expression. Brain centers mediate libido in a general way. Other brain centers influence the selection of sexual partners and the circumstances under which sexual longings are expressed. Hormones made by the ovaries and testes, such as estrogens and androgens, bind in certain brain centers and increase sexual interest. Whether and how this sexual interest gets expressed as behavior depends on several factors, including general health and well-being, the availability of a partner, a sense of what is appropriate, and prioritization of this interest above other interests and obligations. One of the major aims of social and cultural institutions is to channel or direct sexual interest to minimize negative outcomes, such as sexually transmitted diseases (STDs), while ensuring that children will be born and thrive. Sexual interest can be inhibited by any number of negative emotions, including anger, fear, worry, and dislike, and by a marked decline in health or hormones. Like other personality factors, sexual interest, or libido, has a spectrum, with some people having more and others less. As discussed earlier in the Gender section, a person's expression of sexuality and sexual behavior is not necessarily dictated by expressed gender or natal sex. The sexual response cycle and the dysfunctions are covered in a separate section in this textbook on Human Sexuality.

FERTILITY AND INFERTILITY

Gametogenesis

Gametogenesis, the production of oocytes and sperm, occurs because of puberty. Gametogenesis is the minimum physiologic requirement for fertility. In women, the ovary must have oocytes that respond appropriately to gonadotropin input with the maturation of an ovulated oocyte. In men, the testes must manufacture normal sperm capable of penetrating the layer of granulosa cells surrounding the oocyte and then fusing with the outer oocyte cell wall, the zona

Telegram: @medical_k

www.konkur.in

pellucida. The fallopian tube must be capable of oocyte capture, and the density of sperm in the fallopian tube must be such that there is a juxtaposition of sperm and oocyte. The sperm must negotiate the layers of granulosa cells surrounding the oocyte (cumulus) and fuse with the outer cell membrane of the oocyte (zona pellucida) to release the paternal DNA into the oocyte cytoplasm. Thereafter, the tube must be capable of timely transfer of the fertilized oocyte or zygote to the primed endometrium of the uterus. Implantation must occur, and normal fetal development must ensue for the pregnancy to continue. In the absence of medical intervention, the customary way ovulated oocytes are fertilized is via coitus or sexual intercourse.

Infertility

Infertility is defined as failure to achieve pregnancy within 12 months of unprotected intercourse or therapeutic donor insemination in women younger than 35 years or within 6 months in women older than 35 years. Infertility is estimated to affect 15% of all couples and may arise from female factors, male factors, or a combination of male and female factors, or may be unexplained. Common causes of female factor infertility include diminished ovarian reserve, ovulatory dysfunction, tubal factors (endometriosis, history of pelvic inflammatory disease [PID], or other scarring of the fallopian tubes), uterine factors (Müllerian anomalies, endometrial polyps, or intracavitary fibroids), or abnormalities of cervical mucus. Common causes of male factor infertility include abnormal semen quality or sperm functional parameters; anatomical, endocrine, genetic, functional, or immunologic abnormalities of the male reproductive system (including chronic illness); or sexual conditions incompatible with the ability to deposit the sperm in the female genital tract. Unexplained infertility is a term used when no apparent cause of infertility can be determined after testing excludes the common male and female factors listed above. The basic infertility evaluation can involve a semen analysis, hysterosalpingogram or sonohysterogram, hormonal studies, and tests of ovarian reserve to define possible contributing or causal factors. Ovulation and ovulatory adequacy can be monitored by obtaining a luteal phase serum progesterone level

Telegram: @medical_k

www.konkur.in

(with repeated levels <3 ng/mL indicative of anovulation). Ovarian reserve testing can involve measurement of serum antimüllerian hormone level (<1 ng/dL indicates diminished reserve), antral follicle count by transvaginal ultrasound (<5 to 7 indicates diminished reserve), or postmenstrual days 2 to 5 estradiol and FSH levels (FSH > 10 IU/L with estradiol >60 to 80 pg/mL indicates diminished reserve). Semen analysis involves quantitative microscopic evaluation of sperm parameters such as semen volume, sperm concentration, morphology, and motility. However, spermatogenesis is difficult to assess because the process takes 70 to 90 days to complete, and the morphologic features of sperm that a standard semen analysis can assess do not always correlate well with function (i.e., ability to fertilize a human oocyte). Diagnostic uncertainty and a seemingly endless array of treatment approaches can easily provoke tension, indecision, and disagreement in the couple with infertility.

The sense that the window of opportunity is narrow can engender panic; a woman's age correlates well with fecundity, and treatment success declines sharply after age 35 years, even when ovulation occurs regularly. Although fertility declines with age in men, the decline is gradual until age 50, and fertility may persist beyond age 60. The offspring of older mothers have an increased risk of chromosomal aneuploidies, particularly trisomy 21. An increase in autosomal dominant conditions has been reported in the offspring of older fathers. Of the identifiable causes of infertility, approximately 20% are thought to be due solely to male factors, 40% to female factors, and 20% to both. Anovulation is the most common cause of infertility in women. Approximately 20% of men with suboptimal semen parameters have microdeletions of the long arm of the Y chromosome in a region thought to play a critical role in spermatogenesis. Approximately 30% of infertile couples have unexplained infertility, which means no identifiable cause.

Table 30.1–1.
Lifestyle Factors That Affect Infertility

Factor	Impact on Fertility	Study
Obesity (BMI > 35)	Time to conception increased 2-fold	Clark et al.
Underweight (BMI < 19)	Time to conception increased 4-fold	Clark et al.
Smoking	RR of infertility increased 60%	Augood et al.
Alcohol (>2 drinks/day)	RR of infertility increased 60%	Eggert et al.
Caffeine (>250 mg/day)	Fecundability decreased 45%	Wilcox et al.
Substance abuse	RR of infertility increased 70%	Mueller et al.
Toxins/solvents	RR of infertility increased 40%	Hruska et al.

RR, relative risk.

Data from Practice Committee of the American Society for Reproductive Medicine and the Practice Committee of the Society for Reproductive Endocrinology and Infertility. Optimizing natural fertility: a committee opinion. *Fertil Steril*. 2022;117(1):53–63. doi:10.1016/j.fertnstert.2021.10.007.

The degree to which psychogenic or lifestyle factors play a role in infertility is controversial. Because lifestyle variables, such as tobacco exposure, alcohol consumption, caffeine exposure, drug use, excessive exercise, weight loss or gain, exposure to environmental pollutants or toxicants, and psychogenic stress, can compromise reproduction, it is worth reviewing lifestyle factors with the couple and informing them of the potential adverse consequences of these factors in a supportive manner. However, the literature surrounding the contributions of many modifiable lifestyle factors demonstrates inconsistent effects on fertility (see Table 30.1–1). Psychogenic

Telegram: @medical_k

www.konkur.in

variables can interfere with coital frequency, reduce the likelihood of conception, suppress the central hypothalamic-pituitary drive to the gonad, and compromise the quality and quantity of gametes produced. In addition, a diagnosis of infertility, and the therapeutic interventions available to support conception, can result in significant psychological distress for both partners, and discussions should be approached with sensitivity. Given limited evidence surrounding the role of lifestyle factors, coupled with the psychological impact of infertility, we caution providers against ascribing causality between any given lifestyle factor and a couple's fertility challenges.

Standard interventions for family building in infertile couples include a variety of assisted reproductive techniques (ART), including ovulation stimulation (via selective ER modulator, aromatase inhibitor), ovulation induction (via injectable exogenous gonadotropins), intrauterine insemination, in vitro fertilization with fresh or frozen embryo transfer (IVF-ET), and intracytoplasmic sperm injection (ICSI), as well as assisted cycle monitoring/optimization of natural fertility, gestational surrogacy, or adoption. In in vitro fertilization techniques, the ovaries are generally hyperstimulated using injectable exogenous gonadotropins to produce at least three or four mature follicles from which the oocytes can be retrieved using a transvaginal procedure. Fertilization can then occur in two ways: (1) Sperm and oocytes are mixed in a laboratory and supported in vitro, or (2) a single sperm can be injected into each egg (ICSI) to promote fertilization. If fertilization occurs, the fertilized embryo or blastocyst is transferred to the recipient's uterus after the endometrial lining has been optimized for implantation. ART carries a substantially increased risk of multifetal gestation. Because of the increased maternal perinatal and neonatal morbidity/mortality of twin or higher-order multiples, professional societies recommend the transfer of a single embryo regardless of patient age. However, the transfer of more than one embryo may be appropriate in select patients over 37. More than 1.5% of all live-born infants in the United States are conceived via ART. However, approximately 25% of implantations (as evidenced by a transiently elevated serum β-hCG concentration) are not sustained. The likelihood of a successful full-term pregnancy increases

Telegram: @medical_k

www.konkur.in

dramatically if fetal cardiac activity is observed approximately 2 weeks after missed menses (i.e., 4 weeks after the gamete or embryo transfer). Gamete intrafallopian transfer (GIFT) is a form of assisted reproduction with similar rates of success, in which three or four oocytes are mixed with sperm and placed into the fallopian tube during a laparoscopy. Fertilization occurs in the tube and, thus, is not observed. IVF-ET has largely supplanted this procedure because GIFT requires a laparoscopy and general anesthesia and because pregnancy results are not better than with IVF-ET.

When it is not possible to correct underlying causes, substitutions are possible. Not only are donor sperm available, so too are donor oocytes, gestational surrogates, and uterine transplants. Embryos can be cryopreserved indefinitely and potentially transferred to a biologically unrelated recipient or the woman herself years after the menopausal transition. Oocyte retrieval and cryopreservation are now available outside of investigational protocols for fertility preservation in patients undergoing gonadotoxic therapy or gonadectomy (often in the setting of malignancy) or in women with a genetic predisposition for ovarian failure (such as fragile X-associated primary ovarian insufficiency). Although not yet endorsed by professional societies, this technology is being marketed for fertility preservation in healthy women who choose to delay childbearing and considered in people seeking biomedical gender transition. The most recent advances in ART focus on optimizing IVF live birth rates, fertility preservation, preimplantation screening for aneuploidy, and mitochondrial replacement to prevent certain diseases.

Infertility treatments are expensive and consume much time and energy. A sense of psychological and physical invasion is common. Infertile men and women may feel angry, damaged, or guilty. Studies suggest an association between women with infertility and increased risks of invasive ovarian, endometrial, and breast cancers, further increasing anxiety and psychological turmoil. The potential for husbands and wives to respond differently to the experience of infertility and its treatments, particularly any of the ARTs, can overwhelm customary adaptation patterns and lead to psychological decompensation. Even successful infertility treatment poses

Telegram: @medical_k

www.konkur.in

challenges. Singleton pregnancies achieved through ART have higher odds of perinatal mortality, preterm delivery, low birth weight or very low birth weight, Cesarean delivery, placental abruption, pre-eclampsia, placenta previa, vasa previa, and stillbirth. ART is also associated with increased risks of multifetal gestation. In 2011, the proportion of twin pregnancies arising from ART was 36% (17% attributed to IVF and 19% attributed to ovulation induction or stimulation) and 77% of all triplet pregnancies (32% attributed to IVF and 45% attributed to ovulation induction or stimulation). In higher-order multiple gestations, the couple must grapple with the option of selective reduction to optimize maternal and fetal outcomes of the pregnancy. ART is associated with an increased chance of monozygotic twinning among twin pregnancies, bringing the additional risk of intrauterine growth abnormalities, congenital anomalies, and twin-to-twin transfusion syndrome leading to perinatal complications. A multiple pregnancy also increases overall preterm labor and delivery risks, with associated neonatal sequelae of prematurity, pre-eclampsia, gestational diabetes, and Cesarean delivery.

Furthermore, multiple gestation complicates postpartum adjustment and carries a lifelong parenting challenge. There is some evidence that children born to previously infertile parents are viewed by their parents as special. These parents may have trouble setting limits or may be overly protective.

Whether or not it is treated, infertility can produce a variety of psychological reactions. Responses depend on personality attributes, including adaptability, cultural expectations, support systems, knowledge about reproductive processes, and the attitudes of the involved clinicians. Infertility can damage self-image and impair a sense of health and integrity. Some individuals feel that they are being made to suffer for past wrongs; others blame the medical profession for being inadequate or inattentive; some regret decisions surrounding delayed childbearing. A sense of panic, helplessness, and loss of control may compromise self-esteem. Women and men alike are generally overwhelmed by the complexity, cost, invasiveness, and uncertainty associated with medical intervention or

Telegram: @medical_k

www.konkur.in

adoption. Almost all patients who undergo infertility treatment (Table 30.1–2) experience a loss of privacy as they cope with physicians, nurses, insurance carriers, psychologists, hospitals, and laboratory personnel. The sense of intimacy that reinforces marriage and mutuality may be challenged when sex and procreation are separated by technology (Table 30.1–3). Ultimately, infertility presents the specter of psychological death. Thus, it is not surprising that patients with infertility report as much anguish and distress as patients newly diagnosed with acquired immunodeficiency syndrome (AIDS).

Same-sex and transgender couples often seek these same medicalized assisted reproduction techniques to build families and may also experience the challenges of infertility superimposed on the need for assisted reproduction. Lesbian and transgender couples often seek fertility-industry–assisted intrauterine insemination via donor sperm or pursue oocyte retrieval and in vitro fertilization from one partner followed by embryo transfer and pregnancy carried by the other partner. Same-sex male or transgender couples have increasingly sought in vitro fertilization and gestational surrogacy. Compounding the psychological stresses and potential complications of seeking these assisted forms of reproduction for family building, LGBTQ+ parents must also navigate complex legal systems with differing state-by-state regulations surrounding assisted reproduction that restrict their parenthood and parental rights.

Ideally, psychological support services should be available for all individuals and couples undergoing active evaluation and biomedical fertility interventions. Unlike the traditional medical model, in which diagnostic testing precedes and directs the course of treatment, empirical therapy may precede more-invasive diagnostic testing in infertility. Cause and effect can be difficult to identify, and magical or superstitious thought processes are common in patients and practitioners. Fertility treatments can threaten interpersonal relationships and romantic relationship adjustment, particularly if the partners react differently to the challenges. Although fertility is an attribute of a couple, blame may be prematurely or incorrectly assigned to one person in the dyad. In addition to individual or

Telegram: @medical_k

www.konkur.in

couples counseling, groups, such as Resolve, can offer support and information. When donor sperm, oocytes, embryos, or gestational surrogacy are being considered, a thorough psychological evaluation is recommended before treatment to ensure that all parties agree to the treatment plan and understand the potential implications and ramifications.

Dysfunctional attitudes and disharmony constantly threaten persons seeking fertility treatments. Prophylactic evaluation is preferred in all treatment settings, but specialized services may not always be immediately available. Stress can compromise gametogenesis and libido, and fertility treatment alone can be stressful enough to activate the central mechanisms that compromise reproductive function. Psychological support is intended to lessen the likelihood of this effect and reverse it if it is already occurring.

Pharmacologic agents used to treat ovulation disorders or hyperstimulate the ovaries in preparation for oocyte retrieval may alter mood and cognition. These agents include clomiphene citrate (Clomid, a selective estrogen receptor modulator [SERM]), Letrozole (an aromatase inhibitor), GnRH analogs, human gonadotropins, hCG, estrogen and progesterone, and bromocriptine (Parlodel). Danazol (Danocrine, a synthetic androgen) or leuprolide (a gonadotropin hormone-releasing agonist) may be used to arrest the growth of endometriosis (greater than stage I/II) as an adjunct to later fertility therapy. Most of the agents alter estradiol and progesterone levels, and the resultant hormonal fluctuations may trigger mood lability and depression in sensitive individuals. Agents such as clomiphene, danazol, and bromocriptine may also directly affect the brain. The current understanding of the effects of ovarian hormones on cognitive function is largely drawn from studies of postmenopausal women receiving hormone replacement therapy (HRT). While some observational studies have suggested that estrogen exposure may affect cognition, randomized control trials have not demonstrated cognitive benefit from HRT initiated after natural menopause. The Women's Health Initiative Memory Study (WHIMS) and The Women's Health Initiative Study of Cognitive Aging (WHISCA) are randomized, placebo-controlled clinical trials of 7,429 and 2,302 women,

Telegram: @medical_k

www.konkur.in

respectively. Neither found an association between HRT and cognitive improvements, nor between HRT and a decreased risk of dementia. However, cognitive decline has been associated with surgical menopause in women undergoing elective oophorectomy at the time of hysterectomy; therefore, data remain inconclusive.

Table 30.1–2.
Tests in the Infertility Workup

Telegram: @medical_k

www.konkur.in

Possible Cause	Test	Comments
Ovulatory dysfunction	Basal body temperature chart	Patient must do each morning
	Endometrial biopsy	Infrequently used office procedure in the late luteal phase used to determine if the endometrium has been adequately stimulated with progesterone
	Serum hormone testing	Serum progesterone can be measured 1 week prior to expected menses; LH and estrogen can be measured just prior to expected ovulation
	Urinary ovulation detection kit	Home test kits that show changes in the level of LH in a woman's urine preceding ovulation
	Transvaginal ultrasound	Visualizes ovarian follicles and their size (ovulation generally occurs when the follicle measures about 1.8–2.5 cm)
Anatomic disorder	Hysterosalpingography	X-ray done in the proliferative phase, in which a radio-opaque dye is introduced through the cervix into the uterus to define

Telegram: @medical_k

www.konkur.in

		intrauterine contours and tubal patency
	Sonohysterography	Transvaginal ultrasound examination with instillation of saline into the uterine cavity to define contours
	Diagnostic laparoscopy	Infrequently used surgical procedure to view external surfaces of internal female reproductive structures for evidence of endometriosis or scarring
	Hysteroscopy	Visualizes endometrial cavity directly
Diminished ovarian reserve	Antral follicle count	A transvaginal ultrasound done in the early part of the menstrual cycle to count the number of small (2–10 mm) follicles in the ovary
	Serum hormone levels	High FSH and estradiol on postmenstrual day 3 or low antimüllerian hormone levels may indicate diminished ovarian reserve
Abnormal spermatogenesis	Semen analysis	Normal value >20 million/mL, 2 mL volume, 60% motility
	Postcoital test	Midcycle timing to look

Telegram: @medical_k

www.konkur.in

		at sperm–cervical mucus interaction
Immunologic disorder	Antisperm antibodies	Male semen test
Azoospermia	Testicular biopsy	Determines eligibility for intracytoplasmic sperm injection
	Semen analysis for fructose	Determines if the vas deferens are patent

Table 30.1–3.
Assisted Reproduction Techniques

Telegram: @medical_k

www.konkur.in

Method	Comments
Ovulation induction or augmentation (multiple agents, particularly recombinant or highly purified gonadotropins)	Stimulates multifollicular development and ovulation; may produce multiple births; used in anovulation, luteal phase deficiency, unexplained infertility, and assisted reproduction
Induction of spermatogenesis	Used in men with idiopathic hypothalamic hypogonadism of functional or organic nature
Intrauterine insemination	Donor sperm is injected into the uterine cavity or the fallopian tubes; the sperm of the male partner may be used if healthy
Gamete intrafallopian transfer	Transfer of collected oocytes and sperm into the fallopian tubes; zygote may also be transferred; used for infertility from endometriosis and unexplained infertility
In vitro fertilization and embryo transfer	Transfer of developing embryos into the uterus after extracorporeal incubation of collected sperm with oocytes retrieved by laparoscopic surgery or by ultrasound-guided transvaginal aspiration; used with occlusion of the fallopian tubes or significant sperm dysfunction; permits preimplantation genetic diagnosis
Intracytoplasmic sperm injection	Injection in vitro of sperm head or sperm DNA to cause fertilization and production of embryos for transfer to receptive endometrium;

Telegram: @medical_k

www.konkur.in

	may be used even if sperm are barely viable; genetic causes of male infertility may be transmitted to offspring
Gamete donors	Donation of sperm or oocytes to another couple; can include oocytes only, oocyte cytoplasm only to restore reproductive competence to aged oocyte, donor sperm alone, or any combination; cytoplasmic transfer considered unethical and is illegal in some states
Gestational surrogacy	An arrangement where a woman carries and delivers a child for another couple or person. Laws vary for each state in the United States and contracts are involved.
Embryo donor	Donation of a fertilized embryo in order to help an intended parent(s) have a child. No genetic link between embryo and intended parent(s), however the intended parents are able to experience pregnancy and birth

Data from Susman V. *Pregnancy in Behavioral Sciences for Medical Students*. Williams & Wilkins; 1993.

The first systematic review on the psychopathological effects of infertility treatments was recently published. Nine clinical trials were included in the review. One study demonstrated fewer mood symptoms associated with gonadotropin-releasing hormone (GnRH) antagonists than GnRH agonists. Two studies compared GnRH agonists/antagonists to natural cycle protocols and found fewer symptoms associated with the protocols that avoid gonadotropin

Telegram: @medical_k

www.konkur.in

stimulation. The National Institute on Aging (NIA) is currently conducting a study on the effects of hormonal infertility treatment on cognition in premenopausal women. This and future work may better characterize fertility treatments' potential affective and cognitive implications.

Treatment of infertility itself is anxiety-provoking because of the uncertainty and sense of expectation. A further concern of infertile couples is whether ARTs increase the risk of neurodevelopmental or other abnormalities, including childhood cancers. The uncertainty about whether there is a link between infertility treatments and poor health outcomes in the mother or child only exacerbates anxiety and guilt. Infertility is a far more devastating disorder than most laypersons and physicians realize.

Early Pregnancy Loss and Stillbirth

Unlike infertility, which can continue indefinitely, pregnancy loss is often a defined event. *Early pregnancy loss* (i.e., miscarriage, spontaneous abortion) is defined as a nonviable, intrauterine pregnancy with either an empty gestational sac or a gestational sac containing an embryo or fetus without fetal heart activity within the first 12 6/7 weeks of gestation. Early pregnancy loss is a common occurrence. Eighty percent of pregnancy losses occur in the first trimester, and an estimated 10% of all clinically recognized pregnancies result in early pregnancy loss. This rate is an underestimation, given that many women who experience early miscarriages are unaware that they were pregnant. Because the most common reason for early pregnancy loss is a cytogenetic abnormality, it follows that the frequency of clinically recognized early pregnancy loss is highly dependent on age, with rates 9% to 17% in women ages 20 to 30 years, 20% at age 35 years, 40% at age 40 years, and 80% at age 45 years. A single miscarriage does not predict poor future reproductive performance. *Recurrent pregnancy loss* is inconsistently described but is most commonly defined as two or more clinical pregnancy losses. Fewer than 5% of women will experience two consecutive miscarriages, and only 1% will experience three or more. An etiology for recurrent pregnancy loss is made in about 50% of

Telegram: @medical_k

www.konkur.in

patients and includes factors related to genetics, age, antiphospholipid syndrome, uterine anomalies, thrombophilias, hormonal or metabolic disorders, infection, autoimmunity, sperm quality, and lifestyle issues. Therefore, recurrent pregnancy loss can more closely resemble infertility in its chronicity and sense of lost potential than a defined event. The term *stillbirth* (i.e., fetal death or perinatal loss) refers to fetal death after 20 weeks gestation and is estimated to be around 6 per 1,000 live births, though it is less frequent at later gestational ages (about 3 per 1,000 live births after 28 weeks).

Acute reactions to an isolated miscarriage or stillbirth, such as shock, blame, guilt, numbness or anger, and denial, can gradually decline and lead to acceptance and resolution. However, a minority of parents continue to experience more persistent and impairing symptoms, diagnosed as complicated grief. Parents are at an increased risk for complicated grief developing when the death occurs suddenly or traumatically. Though there is no strict timeline for the grief process, diagnosing a parent with complicated grief 6 months following a fetal loss would be inappropriate. Each parent may experience grief differently, and the event can have a lasting impact on the relationship. When a patient experiences stillbirth, bereavement care should be individualized to personal, cultural, or religious needs. It should include recognition of parenthood, acknowledgment of partners' and families' grief, an acknowledgment that grief is individual, awareness of burial cremation, and funeral rituals. Although it is uncommon to identify an exact etiology of stillbirth, good communication of test results related to a fetal autopsy, placental examination, or genetic testing and the diagnoses excluded may relieve feelings of parental guilt or anger. Individual bereavement counseling and peer support groups can also benefit symptoms of anxiety or depression after a stillbirth. Although it might be assumed that grief and emotional turmoil would be related to gestational age, observations do not support this assumption. Women who miscarry have more than twice the relative risk of major depression than community women. More than half of women with a history of major depression experience a recurrence after miscarriage. Because of the

Telegram: @medical_k

www.konkur.in

significant risk of depression, acute intervention is recommended for all women and couples who experience a miscarriage or stillbirth; services should be extended beyond the acute event when indicated.

Pseudocyesis

Pseudocyesis is the development of the classic symptoms of pregnancy—amenorrhea, nausea, breast enlargement and pigmentation, abdominal distention, and labor pains—in a nonpregnant woman. Pseudocyesis demonstrates the ability of the psyche to dominate the soma, probably via central input at the level of the hypothalamus. Predisposing psychological processes are thought to include a pathologic wish for and fear of pregnancy; ambivalence or conflict regarding gender, sexuality, or childbearing; and a grief reaction to lost potential after a miscarriage, tubal ligation, or hysterectomy. The patient may have a true somatic delusion that is not subject to reality testing, but a negative pregnancy test result or pelvic ultrasound scan often leads to resolution. Psychotherapy is recommended during or after a presentation of pseudocyesis to evaluate and treat the underlying psychological dysfunction. A related event, couvade, in which the child's father undergoes simulated labor as if he were giving birth, occurs in some cultures.

Fertility Control

Voluntary Termination of Pregnancy. Voluntary termination of pregnancy (VTOP) is distinct from spontaneous abortion (i.e., miscarriage) (Table 30.1–4). VTOP is the planned termination of a pregnancy. In 2017, approximately 862,000 abortions were performed in the United States—13.5 abortions per 1,000 reproductive-aged women (15 to 44 years). This correlates with 18.4% of all U.S. pregnancies in 2017 ending in VTOP. Abortion rates in the United States have been steadily declining and reached the lowest rates since the passage of Roe V. Wade in most recent statistics, perhaps related to increasing abortion restrictions such as counseling and ultrasound requirements, waiting periods, and clinic closures. As in the past, in the United States in 2014, a disproportionately higher

Telegram: @medical_k

www.konkur.in

number of abortions were obtained by heterosexual women (94%), white women (39%), multiparous women (59%), women using contraception the month they became pregnant (51%), poor or low-income women (75%), and women younger than age 30 years (61%).

www.konkur.in

Table 30.1–4.
Types of Pregnancy Loss and Termination

Telegram: @medical_k

www.konkur.in

Spontaneous abortion	Spontaneous expulsion of the products of conception before 20 weeks of gestation
Recurrent spontaneous abortion	Two or more spontaneous abortions
Missed abortion	A pregnancy in which there is a fetal demise (usually for a number of weeks) but no uterine activity to expel the products of conception
Threatened abortion	An ongoing pregnancy complicated by bleeding (+/– cramping) before 20 weeks of gestation
Incomplete abortion	Some, but not all, of the products of conception have been passed; retained products may be part of the fetus, placenta, or membranes
Septic abortion	A spontaneous abortion that is complicated by intrauterine infection
Inevitable abortion	The cervix has dilated, but the products of conception have not been expelled
Complete abortion	All products of conception have been passed without the need for surgical or medical intervention
Induced abortion (voluntary termination of pregnancy)	Using medication or a surgical procedure to end a pregnancy as a means of fertility control, or when pregnancy poses a high risk of morbidity/mortality to the mother, or in cases of life-limiting fetal anomalies; medication abortion can be performed up to 70 days

Telegram: @medical_k

www.konkur.in

	gestation and includes use of mifepristone (RU-486, an anti-progestin) with or without misoprostol (prostaglandin analog) or methotrexate. Surgical procedures include manual vacuum aspiration or suction curettage in the first trimester, and dilation and evaluation (D&E) in the second trimester (up to ~24 weeks). Labor induction termination may also be used in the second trimester. “Partial birth abortion” is not a medical term but refers to a ban on intact D&E wherein a fetal demise does not occur before surgery.

In the United States in 2016, 65.4% of legally induced abortions were performed at or before 8 weeks of gestation, 14.7% between 9 and 10 weeks, 8.2% between 11 and 12 weeks, 6.3% between 13 and 15 weeks, 4.1% between 16 and 20 weeks, and 1.3% over 21 weeks. Medication abortion (used up to 10 weeks of gestation) accounted for 39% of all VTOP. Of concern are statistics reporting that up to 18% of abortion clinics in 2017 reported seeing patients who had attempted self-induced abortion. Table 30.1–5 summarizes the most common abortion techniques.

In contrast to prior discourse, there is no high-quality evidence showing significant untoward psychological effects of VTOP on women’s mental health. In fact, there is high-quality evidence demonstrating that rates of mental health problems for women with an unplanned/undesired pregnancy are the same whether they continue to live birth or proceed with a first-trimester abortion. In one study comparing the outcomes of women who sought treatment in a clinic because they thought they were pregnant, women who were pregnant and chose to abort were reported later to be doing better emotionally

Telegram: @medical_k

www.konkur.in

and in pursuing personal, educational, and work endeavors than were either those who were not pregnant or those who chose to continue the pregnancy. Another study suggested untoward consequences on women's mental health and well-being who were denied the option to abort and, thus, were required unwillingly to carry the pregnancy to term and then raise an undesired child. This study suggested untoward consequences on the mental health and well-being of the child as well. However, termination of a wanted pregnancy because of an abnormal karyotype or fetal anomalies can be traumatic, and supportive intervention is recommended.

Techniques for inducing abortion (Table 30.1–5) have been used for at least 5,000 years. Given the considerable risks associated with childbearing and the physical, emotional, and financial demands of child-rearing, VTOP was viewed historically as a means of modulating the maternal and societal risks of unrestrained reproduction. Historically, the concept of therapeutic abortion before *quickening,* which is generally defined as the time at which the mother perceives fetal movements, was well accepted. In the United States, legislation regulating VTOP was introduced in the early 1800s, with the intent to protect women from sepsis and other complications associated with the procedures. However, VTOP, whether by surgical or chemical means, now entails minimal medical risk and is safer than carrying a pregnancy to term. Furthermore, there is no high-quality evidence to support the suggestion that VTOP increases risks of breast cancer, adverse future pregnancy outcomes, or infertility, as some misinformation exists on this.

Medication abortion, which can be used in selected patients under 70 days gestation, is commonly achieved using two medications: mifepristone (previously called RU-486) and misoprostol. In cases where regulations prohibit the use of mifepristone, misoprostol-only regimens are also validated. Mifepristone is a selective progesterone receptor modulator that binds to the progesterone receptor with a higher affinity than progesterone. However, it blocks its action, leading to decidual necrosis and softening of the cervix, sensitization to prostaglandins, and subsequent increased uterine contractility. Misoprostol is a prostaglandin E1 analog that stimulates uterine

Telegram: @medical_k

www.konkur.in

contractions and softens the cervix. Uterine aspiration is a surgical procedure used to induce abortions in the first trimester, and dilation with evacuation (or D&E) is used for second-trimester abortion. For pregnancies with lethal fetal anomalies or maternal medical indications for termination of pregnancy beyond 24 weeks, induction of labor and vaginal delivery (termed “induction termination”) is recommended.

The medical risks of both surgical and medical VTOP are few, but all procedures require physician input. Medically induced VTOP, however, requires less physician input than do surgical techniques, although medical VTOP requires careful monitoring to ensure that the termination occurs in a timely fashion. Rarely hemorrhage can occur and require surgical intervention or a transfusion. Studies indicate that women who choose to terminate their pregnancies do at least as well as women who continue their pregnancies to term or were never pregnant concerning physical and mental health and educational, occupational, and marital functioning. Diana Greene Foster, a demographer with an area of focus on family planning, directed a 10-year prospective longitudinal study, entitled the Turnaway Study, that assessed the psychological, physical, and financial impact of electing a VTOP versus continuing an unwanted pregnancy to term. The study, which resulted in more than 50 peer-reviewed papers, found no evidence that pregnancy termination increases a woman’s risk of psychiatric illness, neither in the short- nor long-term. In fact, the study demonstrated that being denied a VTOP was associated with a greater risk of psychiatric illness than undergoing a VTOP in the short term.

Table 30.1–5. Abortion Techniques

Telegram: @medical_k

www.konkur.in

Timing	Type	Benefits	Risks
First trimester	Manual vacuum aspiration or suction curettage	Manual vacuum aspiration may be performed in an office setting (avoiding anesthesia), may be performed after 70 days gestation, immediate examination of tissue aspirate can confirm complete procedure, slightly increased efficacy compared to medication abortion	Rare complications of hemorrhage, cervical laceration, retained products of conception, infection, or uterine perforation
	Medication abortion (use of medications such as mifepristone, prostaglandin analogs, and methotrexate to induce an abortion up to 70 days gestation)	Avoids risks and costs of procedural intervention, perception of privacy	Takes longer to complete than uterine aspiration, requires active patient participation, incomplete medication abortion or ongoing pregnancy, may be contraindicated

Telegram: @medical_k

www.konkur.in

			in some patients
Second trimester	Dilation and evacuation (cervical preparation with osmotic dilators and/or medications [mifepristone, prostaglandin analogs] followed by surgical dilation and evacuation of uterine contents using suction and grasping forceps)	Fewer complications than medication abortion, less pain reported, may be considered less emotionally challenging by patients	Rare complications of hemorrhage, cervical laceration, retained products of conception, infection, or uterine perforation
	Induction of labor termination (use of pharmacologic uterotonic medications such as mifepristone, prostaglandin analogs, oxytocin, with or without osmotic	May be preferred by some patients/providers for termination of pregnancies complicated by fetal anomalies or genetic disorders (when preservation of fetal anatomy is desired), or maternal health issues; may be	Compared with D&E, less cost-effective, greater risk of complications (such retained products of conception requiring surgical procedure), and may be prolonged

Telegram: @medical_k

www.konkur.in

cervical dilators or transcervical Foley catheter. May sometimes be combined with an intraamniotic procedure to stop the fetal heartbeat prior to induction of labor).	necessary if a D&E trained physician is not available	
Abdominal surgery (hysterotomy or hysterectomy)	Should only be performed in rare instances when D&E or medication abortion have failed or are contraindicated	Much higher risks of complications than D&E or medication abortion

Data from ACOG Practice Bulletin #135. June 2013. https://www.acog.org/clinical/clinical-guidance/practice-bulletin/articles/2013/06/second-trimester-abortion#:~:text=The%20proportion%20of%20abortions%20performed,the%20past%20two%20decades%204; ACOG Practice Bulletin #225, October 2020, https://www.acog.org/clinical/clinical-guidance/practice-bulletin/articles/2020/10/medication-abortion-up-to-70-days-of-gestation.

Current legislative attention has shifted from safeguarding maternal health to the ethics of abortion and the right of women to exercise control over their bodily functions. Traditionally, ethical deliberations regarding VTOP were reserved for religions. Given the diversity of religious perspectives on the role of women and procreation, a consensus is neither likely nor necessarily desirable. Nonetheless, the current legislative debate centers on who has the authority to

Telegram: @medical_k

www.konkur.in

regulate induced abortion and to what degree. The 1992 Supreme Court ruling in *Planned Parenthood of Southeastern Pennsylvania v. Casey* upheld the basic right of women to elect pregnancy termination before fetal viability. However, it also upheld the right of the state to regulate and restrict abortion and define viability. Furthermore, in some states (e.g., Pennsylvania), pregnant women do not have the right to select whether they wish to receive advanced life support in life-threatening situations. The Freedom of Choice Act put before the U.S. Congress recognized the right of states to regulate the strictly medical aspects of abortion to safeguard maternal health. It restricts a woman's freedom to terminate a pregnancy after, but not before, fetal viability. This legislative effort represented a compromise between those who argued against any medical mediation of the process and those who would grant women complete autonomy. Application of this law would hinge on the interpretation of the phrase *fetal viability,* a concept that is not easily defined. Making the option of induced abortion contingent on fetal viability reveals continuing ambivalence about allowing women the autonomy to make decisions about physiologic processes that directly shape their lives. A recent example is the Texas Heartbeat Act which was passed in May 2021 and took effect in September 2021. The new legislation bans abortions following the detection of cardiac activity, which typically occurs as early as six weeks gestation when many women are not yet aware of the pregnancy. The act restricts abortion in the country's second-largest state to an extent not seen in fifty years, without exceptions for rape, sexual abuse, or incest. Various reproductive rights groups requested an injunction from the U.S. Supreme Court to prevent the law from being enacted. The Court denied the preliminary injunction and later remanded the case back to the Fifth Circuit. In December 2021, a state district judge ruled that portions of the statute's enforcement mechanism violated the Texas constitution but did not enjoin the law's enforcement. In the summer of 2022, the Supreme Court ruled in Dobbs v. Jackson that the constitution does not protect the right to abortion, and 27 states now have at least some restrictions.

Telegram: @medical_k

www.konkur.in

Contraception. In 2018, there were 72.7 million reproductive-age women, of which 46 million were sexually active and not seeking to become pregnant. Unfortunately, 49% of pregnancies in the United States are unintended, higher than rates in most developed countries. Lack of knowledge, misperceptions of contraceptive methods as abortifacients, exaggerated safety concerns about contraceptives, and emphasis on abstinence-only sexual education all contribute as barriers to contraceptive use, and thus to family planning and pregnancy intendedness. Despite this, 99% of sexually active American women have used a contraceptive method other than natural family planning during their lifetime, and in 2018, 65% of women ages 15 to 49 were currently using a contraceptive method. Methods of contraception fall into five main categories: barrier methods (such as condoms or diaphragms), hormonal agents (including oral contraceptive pills/patch/vaginal ring, depot injection, and emergency contraception), long-acting reversible contraceptives (LARCs; such as intrauterine devices or implant), surgical sterilization procedures, and fertility-awareness methods (natural family-planning) that require abstinence around the time of ovulation (Table 30.1–6). Most women utilizing contraception use a combined hormonal (estrogen/progesterone) contraceptive (CHC), such as a pill, patch, or ring. However, LARCs are gaining popularity due to their higher efficacy. In fact, from 2002 to 2012, LARC use increased from 2% to 12% in the United States. The perfect contraceptive would be completely reversible, free of adverse effects, and completely efficacious with typical use. Because no perfect contraceptive is available, people must select a method that best meets their needs, and this involves assessing personal preferences, reproductive goals, method efficacy, acceptability, and availability. Decisions regarding contraceptive methods must also consider underlying medical conditions, which may change the balance of potential risks of certain contraceptive methods while also acknowledging the potential risks of unintended pregnancy. Frequently, the responsibility for choosing and using a contraceptive falls primarily on the woman within a heterosexual relationship. This can lead to resentment, lack of

Telegram: @medical_k

www.konkur.in

compliance, and marital disharmony. For those in a stable relationship, contraceptive counseling can include both partners.

Given the high prevalence of both mental illnesses and contraceptive use, providers should remain cognizant of potential drug-drug interactions when caring for women of reproductive age. CHC may alter the efficacy of certain psychotropics, and vice versa, through pharmacokinetic and/or pharmacodynamic interactions. Carbamazepine and St. John's Wort may decrease CHC efficacy by increasing the metabolism of hormones, thereby effectively reducing the dose of the CHC and, in turn, the effectiveness of the contraceptive. Concurrent use of CHC and lamotrigine may reduce the serum concentration of lamotrigine, possibly requiring an increase in lamotrigine dose to maintain a therapeutic effect. However, CHC can have the opposite effect on clozapine dose: The estrogen in CHC may impair clozapine metabolism, resulting in an increase in serum clozapine level and possibly requiring a halving of the clozapine dose. Regarding anxiolytic use, CHC will increase the effect of benzodiazepines, while barbiturates reduce the efficacy of CHC. CHC use does not modify the effectiveness of fluoxetine, and conversely, selective serotonin reuptake inhibitors (SSRIs)/serotonin-norepinephrine reuptake inhibitors (SNRIs) do not appear to interact with CHC metabolism.

The assessment of the risks and benefits of a given contraceptive strategy should not be limited to considering the biologic risks alone but must consider the mindset of each party, particularly regarding gender issues and cultural perspectives. If significant discord exists within a couple, counseling may be indicated. Counseling can also be considered for the person or couple who feels guilty about the idea of interfering with natural bodily functions for this purpose.

Clinicians must be mindful of the difference between actual and perceived risk. Concerns of current and later bodily harm from the use of contraception are common, and the risks of childbearing and child-rearing frequently are underestimated. The mortality associated with childbearing is estimated to be 10 per 100,000 live births between the ages of 20 and 24 years, 44 per 100,000 between the ages of 35 and 39 years, and 71 per 100,000 after age 40 years. However,

Telegram: @medical_k

www.konkur.in

comparable mortality in nonsmoking women on oral contraceptives is 1.2 per 100,000 live births, 3.9 per 100,000 live births, and 6.6 per 100,000 live births, respectively. The potential risks of child-rearing are difficult to quantify, including role strain and stress, interrupted education or career advancement, depression, loss of independence, and compromise of the psychosexual relationship with one's partner. This misperception of risk is particularly prevalent among adolescents, who may be uninformed and have unrealistic ideas about the rewards of pregnancy and the risks of STDs. In addition, a teenager's aptitude for listening and making decisions may be limited by impulsivity or ambivalence.

In short, despite the availability and relative affordability of contraceptive means, their use is constrained by the discrepancy between actual and imagined risk.

A few recent studies report a correlation between oral contraceptives and a diagnosis of depression among adolescents. However, possible confounders and the causality of the relationship remain an active area of study with ongoing debate. A prospective study conducted in Denmark demonstrated an association between oral contraceptive use and suicide, with 2 months following the initiation of oral contraceptive identified as the time of highest risk for an attempt. A prospective cohort study followed 800,000 Swedish women over the year following initiation of a hormonal contraceptive. Adolescents taking hormonal contraceptives were more likely to be prescribed a psychotropic medication during the year of follow-up than were women naive to hormonal contraceptives. This relationship was not demonstrated among adult women. The GABA pathway, which has demonstrated sensitivity to neurosteroid changes, is possibly implicated in the relationship between hormonal contraceptives and the subsequent development of depression, though mechanisms have not yet been elucidated. However, the causality of the relationship remains in question. A confounder may be responsible for the association between hormonal contraception and depression; hormonal contraception use might serve as a marker for another characteristic directly responsible for the increased risk of depression among adolescents. A more recent study analyzing data

Telegram: @medical_k

www.konkur.in

from Swedish national registers found considerable heterogeneity in the association between hormonal contraceptive use and depressive illness, identifying the relationship to be strongest among adolescents, immigrants, and low-income earners. The association remains an active topic of study and continues to be debated. Current professional guidelines state that women with depressive disorders can safely use all hormonal contraception methods.

Because coitus is not always anticipated, there is a need for postcoital or the so-called emergency contraceptives. No clinical examination or pregnancy testing is required prior to using emergency contraception, and treatment should be initiated as soon as possible after unprotected intercourse to improve efficacy. Available methods include high doses of levonorgestrel, high doses of combined hormonal contraceptive (CHC) pills, antiprogestins, and intrauterine device (IUD) insertion. Insertion of the Copper IUD (and most recently the Levonorgestrel IUD) within 120 hours of unprotected intercourse remains the most effective method of emergency contraception but can be logistically challenging for patients to access. The use of levonorgestrel 1.5 mg pill (Plan B) within 72 hours of intercourse has greater efficacy and is associated with less severe adverse effects than a high dose of combined oral contraceptives (the Yuzpe method). In the United States, Plan B is available without a prescription to women 18 years or older. Selective progesterone receptor modulators (ulipristal acetate) require a prescription. However, they can be effective up to 120 hours after unprotected intercourse, and in a recent meta-analysis, ulipristal acetate demonstrated greater efficacy than levonorgestrel in preventing pregnancy (pregnancy rates were 1.4% in users of ulipristal, compared to 2.2% in users of levonorgestrel). Emergency contraception should not be confused with medical abortion. In general, pharmacologic emergency contraception inhibits or delays ovulation but does not prevent the implantation of a fertilized oocyte. The IUD prevents fertilization by affecting sperm viability and function. None of these methods confers risk to an established pregnancy or teratogenicity to a developing embryo.

www.konkur.in

Table 30.1–6. Current Methods of Contraception

Type	Efficacy (as % of women who will become pregnant in a typical year of use)	Advantages	Disadvantages	Risks
Barrier (chemical or mechanical)				
Spermicidal agents	28%	Readily available and easy to use	Messy; loss of spontaneity; requires forethought	Allergic reactions
Diaphragm, cervical cap	12% (diaphragm), 17–23% (cervical cap)	Inexpensive; does not interfere with menstrual cycle	User familiarity required; prescription and fitting required; may interfere with spontaneity; requires forethought	Recurrent urinary tract infections with diaphragm; allergic reactions to latex or spermicide
Male condom	18%	Readily available and easy to use; protects against sexually transmitted infections	May interfere with spontaneity; requires forethought	Allergic reactions to latex or spermicide
Female condom	21%	Inconvenient to use; protects against sexually transmitted infections	May interfere with spontaneity; requires forethought	Allergic reactions to latex or spermicide
Hormonal (suppresses ovulation and/or impairs endometrial development)				
Combined hormonal contraceptives	9%	Includes pills, patches, and intravaginal rings. Can reduce menstrual cramps, make periods lighter or shorter, can improve acne or reduced unwanted hair growth, can decrease risks of cancer of the uterus, ovary, or colon	Side effects including headache, nausea, breast tenderness, breakthrough bleeding; require daily or weekly use, regardless of frequency of sex; must be prescribed and monitored by health care professional	Associated with a small increased risk of deep vein thrombosis, heart attack, and stroke. Should not be used by women with certain risk factors or who are within the postpartum period. Can be taken continuously to achieve ovarian suppression and amenorrhea and to treat medical conditions such as endometriosis or dysmenorrhea
Postcoital steroids (emergency contraception)	2% (pregnancy rate after use)	Can be used after unprotected intercourse or contraceptive failure to prevent a pregnancy. Methods include oral estrogen-progestin, progestin only, selective progesterone receptor modulators, or insertion of a copper IUD	Must be initiated as soon as possible (within 72–150 hours after unprotected intercourse) to maximize efficacy. Side effects can include nausea, headache, irregular bleeding	Not effective for long-term contraception, body weight can influence effectiveness of oral emergency contraceptive methods
Contraceptive implants (rods)	0.05%	Long-acting and reversible contraceptive implant (approved for 3 years, effective up to 5 years); once in place, no forethought required, few medical contraindications to use, one of the most effective forms of contraception available	Irregular bleeding and spotting due to endometrial effects and suppression of ovarian function; requires office procedure for placement and removal. Side effects such as unpredictable vaginal bleeding, headaches, breast pain, weight gain, acne	Problems with insertion or removal of the implant, slightly increased risk of ectopic pregnancy if pregnancy occurs while implant is in place
Progestin-only contraceptives	6% for injectable; 9% for oral pill	Includes progestin-only pills and depot injection. Can make periods lighter or stop periods altogether. Can be used safely in the postpartum period or while breastfeeding, and in women who have contraindications to using estrogen in combined hormonal contraception. Depot formulation can be administered every 13 weeks which improves user efficacy and it has been shown to reduce risks of uterine cancer and reduce pelvic pain caused by endometriosis	May lead to unpredictable spotting or bleeding in some women. Other side effects include headaches, nausea, breast tenderness. Depot formulation can cause weight gain in some women (about 5 lb), may not be reversed if pregnancy is desired prior to 3-month window, and can be also be associated with slow return of ovarian function (on average, 10 months to become pregnant after stopping the injection)	After prolonged use, depot formulation can be associated with bone loss and increased fracture risk later in life (though this is partially or completely reversible). Women with cardiovascular disease risk factors may have increased risk of developing cardiovascular disease while using the depot formulation

Telegram: @medical_k

www.konkur.in

Intrauterine device	0.1–0.8%	Long-acting and reversible. Copper IUD is effective for 10 years, hormonal IUD is effective for 5 years. Once in place, no forethought required, few medical contraindications to use, one of the most effective forms of contraception available. Hormonal IUD can be used to decrease menstrual pain and heavy menstrual bleeding. There is immediate return to fertility once IUD is removed.	Requires office procedure for insertion/removal. Copper IUD can be associated with increases in menstrual bleeding and painful periods during the first months of use. Hormonal IUDs can cause frequent spotting, more days of bleeding, or heavier bleeding during first months of use, however over time length of period and amount of menstrual bleeding usually decreases or may stop completely.	In a small number of women, the IUD may spontaneously expel. During placement, the IUD could cause uterine perforation. Rarely, pregnancy can occur with IUD in place and if this occurs there is a higher chance of an ectopic pregnancy. Rarely, pelvic inflammatory disease can occur after IUD insertion.
Sterilization				
Male sterilization (vasectomy)	0.15–0.5%	Failure very rare; 20-minute office procedure; does not affect male sexual function. Safer, more effective, and less expensive than tubal occlusion procedures.	Can take 3–6 months to reach azoospermia	Can be reversed in only 80% of cases; Procedural complications include infection, bleeding, hematoma formation, granuloma formation, epididymitis
Female sterilization	0.15–0.5%	No impairment of sexual function or pleasure; total salpingectomy for tubal sterilization can reduce risks of ovarian cancer. Can be used safely by women with medical contraindications to hormonal contraception, can be performed in the immediate postpartum period, no alterations to menstrual cycles, not user dependent for efficacy and very low failure rates.	More complex procedure than vasectomy; reversal of tubal ligation is costly and very rarely successful.	Surgical morbidity; risk of post-tubal sterilization regret, increased risks of ectopic pregnancy (though lower than noncontraceptive users)
Other				
Fertility awareness-based methods	24%	Readily available	User must monitor cervical mucus and body temperature closely; imposed coital timing	None
Lactational amenorrhea method	8%	Temporary method of contraception can be used for the first ~6 months after giving birth by women who exclusively breastfeed	Can have breakthrough ovulation prior to first menses resulting in unintended pregnancy	None
Withdrawal, coitus interruptus	22%	Readily available	Difficult to implement	None

Data based on https://www.acog.org/womens-health/faqs/birth-control; https://www.cochranelibrary.com/cdsr/doi/10.1002/14651858.CD001329/full.

The mental and physical health risks of contraceptive use are significantly lower than are those associated with pregnancy, parturition, and parenthood. However, contraception often gives an unwarranted illusion of control over bodily processes. No method is perfect, and unintended pregnancy can occur despite responsible use. In addition, if a couple or person intends to have children, childbearing should not be postponed indefinitely hoping that the perfect time will arrive. It can be difficult to conceive on demand.

Sterilization. In women, sterilization can be accomplished by several methods of tubal occlusion, ligation, or excision as a primary surgical procedure, or may be effected through hysterectomy (with or

Telegram: @medical_k

www.konkur.in

without oophorectomy) for other medical indications. Hysterectomy for sterilization alone is associated with more morbidity and mortality than any other method of female sterilization and is therefore not primarily performed for this purpose. In men, vasectomy can be performed as an outpatient procedure with local anesthesia and is safer than any of the present female sterilization methods, with the lowest failure rate of any method of permanent sterilization (0.15% in the first year). Approximately 600,000 tubal occlusions and 200,000 vasectomies are performed each year in the United States. Postpartum partial salpingectomy has the lowest failure rate of any female sterilization method (7.5 per 1,000 procedures over 10 years), followed by silicone band method (17.7 per 1,000 procedures/10 years), bipolar coagulation (24.8 per 1,000 procedures/10 years), and titanium spring clip (36.5 per 1,000 procedures/10 years). Although uncommon, another risk of female sterilization procedures is ectopic pregnancy (7.3 per 1,000 procedures/10 years); overall, those who have undergone sterilization procedures have a much lower ectopic pregnancy risk than non-users of contraceptives. Sterilization procedures have not been shown to affect female or male sexual function or the menstrual cycle, and multiple observational studies report an association of tubal procedures with decreased incidence of ovarian cancer, particularly in women with BRCA1 or 2 mutations.

Comprehensive preoperative counseling is an important step in determining candidacy for sterilization. The permanence of the procedure, risks of failure, regret, alternatives (i.e., LARC and vasectomy), and prohibitive expenses of reversal procedures should be discussed with the patient who is deciding on permanent sterilization. In a well-informed and counseled patient, age and parity should not be barriers to accessing permanent sterilization.

It is difficult to determine how often a reversal of sterilization is sought or performed, and it is even more difficult to estimate the frequency of regret that the sterilization was performed. No formula can predict who will seek reversal, but factors such as remarriage, age <30 at time of sterilization, death of a child, and sterilization performance during the postpartum period seem to play roles. Regret is high when sterilization is undertaken to stabilize a marriage. The

Telegram: @medical_k

www.konkur.in

success of reversal depends on various factors, including the method of sterilization, the ages of the partners, and the elapsed time since the sterilization procedure. Clinicians need to make couples and individuals aware of these considerations but should not use them as reasons to deny the planned procedure. Again, when a couple is involved, the mutuality of the decision should be discussed to avoid later resentment. Voluntary sterilization, especially vasectomy, has become the most popular birth control in couples married for more than 10 years.

SEXUALLY TRANSMITTED INFECTIONS

An STI is a contagious disease acquired because of physical, sexual interaction. While STIs have coexisted throughout human history, treatments became more available in the 1950s for many previously life-threatening STIs. AIDS, caused by infection with human immunodeficiency virus (HIV), remains incurable, life-threatening, and transmissible from mother to fetus.

Trichomoniasis is the most-prevalent nonviral STI (2.1% among females, 0.5% among males in the United States). Most trichomonas infections have minimal or no symptoms, leading to untreated infection and passage between sex partners. Reproductive morbidity related to trichomoniasis is reported to be a 1.4 times greater likelihood of preterm birth and small for gestational age infants and a twofold increased risk for cervical cancer. Reproductive sequelae of STIs such as *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are infertility, chronic pelvic pain (CPP), or ectopic pregnancy because of tubal scarring. Because asymptomatic infection is common among both men and women, many women diagnosed with these bacterial cervical infections already have a subclinical or clinical PID. PID is a spectrum of inflammation and infection of the upper female genital tract, including any combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. PID is attributed to *N. gonorrhoeae* and *C. trachomatis* in about 50% of cases, but it can also arise from other nonsexually transmitted vaginal microorganisms. *C. trachomatis* infection has the additional reproductive morbidity

Telegram: @medical_k

www.konkur.in

leading to congenital chlamydial pneumonia or ophthalmia neonatorum during pregnancy and delivery. *N. gonorrhoeae* during pregnancy and delivery can similarly lead to ophthalmia neonatorum, as well as disseminated gonococcal infection among neonates. In men, *N. gonorrhoeae* and *C. trachomatis* can also obstruct the vas deferens and chronic prostatitis in men and subsequent male infertility.

Another STI that can have serious consequences is venereal warts or human papillomavirus (HPV) infection. Genital infections with certain subtypes of HPV can lead to premalignant changes of the penis, vulva, vagina, and cervix and are thought to cause cervical cancer. An HPV vaccine is recommended for young men and women to be administered prior to the onset of sexual activity. Risk assessment with education and counseling, consistent use of primary prevention methods (such as condoms), pre- and postexposure prophylaxis or vaccination for preventable STIs, screening for asymptomatically infected persons, expedited partner therapy, effective diagnosis/treatment/and follow-up of infected persons, mutual sexual monogamy, and abstinence are advocated as public health measures for STI prevention. However, abstinence-only education results in more unintended pregnancies than holistic approaches to sexual education, including education on contraception. Therefore, we encourage clinicians to engage in open and supportive discussions with patients surrounding individual sexual practices, risks, and preferences in family planning.

PELVIC PAIN

CPP is an emerging diagnosis within women's health care, with evolving treatment approaches. CPP is pain lasting for more than 6 months and is perceived in the pelvis or lower abdomen. It is associated with central sensitization symptoms such as multiple pain sites, sleep disturbance, anxiety, depression, rumination, catastrophizing, hyperalgesia, allodynia, or failure to respond to treatment. It is two times more common in women than men and affects approximately 15% in the United States. In women with CPP,

Telegram: @medical_k

www.konkur.in

etiologies are thought to be related to lower urinary tract, sexual, bowel, myofascial, or gynecologic dysfunction, and diagnoses include interstitial cystitis, irritable bowel syndrome, pelvic congestion syndrome, pelvic floor dysfunction, endometriosis, pudendal neuropathy, and vulvodynia.

The pathophysiologic mechanisms for CPP are complex. Theories include viscero-viscero cross-sensitization (in which pathology or injury in one organ, such as the uterus, can hypersensitize another adjacent organ, such as the bowel or bladder) and viscerosomatic convergence (in which persistent visceral nociceptive stimuli lead to noxious somatic stimulation via shared neural pathways). Some common triggers for the onset of visceral nociceptive stimuli include malfunctioning pelvic floor muscles, injury, or surgery.

CPP is often associated with negative cognitive, behavioral, sexual, and emotional consequences, and multiple pelvic pain syndromes often coexist in the same patients. These patients often have compounding nonpelvic coexisting pain syndromes, including fibromyalgia, chronic low back pain, temporomandibular joint disorder, and chronic fatigue. There is a complex relationship among trauma, abuse, mental health history, social stressors, and CPP, with a controversy of cause and effect. Catastrophizing, feelings of helplessness, and posttraumatic stress disorder (PTSD) increase the intensity of CPP and affect the quality of life. Historically, treatment of pelvic pain focused on uterine or ovarian pathology and surgical intervention; this approach, however, does not provide meaningful pain relief in CPP patients. In fact, data demonstrate that 50% to 90% of the women evaluated in CPP specialty centers have pain originating from musculoskeletal structures and not pelvic organs themselves. Treatment of CPP can include pharmacotherapy with anticonvulsants or antidepressants (particularly SSRIs/SNRIs or tricyclic antidepressants [TCAs]) and gabapentin/pregabalin.

In some cases, when pain is cyclic, hormonal therapies (HTs) such as progestins or gonadotropin-releasing hormone agonists or antagonists may be used to suppress the menstrual cycle. Recommended lifestyle modifications include pain education, elimination of dietary triggers, stress management, mindfulness and

Telegram: @medical_k

www.konkur.in

meditation, physical therapy, and exercise. Cognitive behavioral therapy (CBT) can help patients develop pain coping strategies and should be integrated into treatment plans. Adjuvant therapies addressing psychosocial modulators of pain, anxiety, depression, sleep, fatigue, cognitive impairment, and sexual dysfunction using a multidisciplinary approach are important treatment components.

PREMENSTRUAL MOOD SYNDROMES

Women commonly experience both physical and psychological symptoms in the days or weeks prior to the onset of menses. The label to give those symptoms depends on their pattern and severity, particularly their impact on functioning. While some women's symptoms are mild, transient, and nonimpairing, others may experience more serious symptoms that qualify for one of three possible syndromes.

Premenstrual syndrome, affecting up to 80% of women, is the least severe of these three syndromes and is defined by the American College of Obstetrics and Gynecology (ACOG) as the following:

- AFFECTIVE SYMPTOMS: depression, angry outbursts, irritability, anxiety, confusion, social withdrawal
- SOMATIC SYMPTOMS: breast tenderness, abdominal bloating, headache, swelling of extremities
- At least one affective and somatic symptom in the three prior menstrual cycles during 5 days before menses.
- Symptoms resolve within 4 days of onset of menses do not recur until day 12.
- Symptoms present in two cycles by prospective recording.
- Symptoms adversely affect social or work-related activities.

By definition, women with PMS do not have symptoms at other times of the menstrual cycle. Women with Premenstrual Exacerbation of an Underlying Mood Disorder (PME), by contrast, experience premenstrual symptoms but also have psychiatric symptoms at other times. The premenstrual symptoms typically represent a worsening of the symptoms present at other times rather than a qualitative change.

Telegram: @medical_k

www.konkur.in

Among women with psychiatric illness, more than half experience a worsening of psychiatric symptoms during the luteal phase of their menstrual cycle. Individuals with personality vulnerabilities, such as borderline personality disorder, are also likely to be at an increased risk of worsening symptoms during the luteal phase. While women can sometimes have PMDD alongside an underlying mood disorder, it is likely that most women with mood disorders and luteal phase symptoms, in fact, have PME.

Neither PMS nor PME is a recognized psychiatric disorder. PME in particular needs considerably more research, as it affects such a large proportion of women with psychiatric illness and details of both etiology and optimal treatment are unknown. For example, some research indicates that women with PME do not respond to treatment with CHC, while women with PMDD do (see below).

Premenstrual Dysphoric Disorder

PMDD was recognized as a diagnosis in 2013, with the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), and is categorized as a depressive disorder. PMDD affects 2% to 8% of women during the reproductive years and is associated with emotional and physical symptoms that occur in the week prior to menses, resolve within days following onset of menses, and result in marked functional impairment. To meet the criteria for PMDD, a woman must experience at least five symptoms, including a mood symptom, that begin during the week prior to menses and resolve following the onset of menstruation. In women with another mood disorder, PMDD should be diagnosed only if the luteal phase symptoms differ in quality (not just quantity) from follicular phase symptoms. Before a diagnosis can be made, a physical examination and thyroid studies must be completed. Given the distinct pattern of symptoms characterized by PMDD, careful prospective daily symptom charting throughout two menstrual cycles is also necessary for diagnosis. PMDD occurs much less frequently than PME or PMS. Risk factors for PMDD include a high potassium diet, metabolic syndromes, increased BMI, nicotine and alcohol use, childhood

Telegram: @medical_k

www.konkur.in

trauma, low socioeconomic status, white race as compared to Black, and family history of PMDD.

Research into PMDD comorbid with other disorders is often difficult to parse, as many studies have included both women with PMS and those with PMDD and have often not considered the concept of PME. Some research suggests that bipolar disorder comorbid with PMDD is associated with worse prognosis, including earlier age of onset of bipolar disorder, more rapid cycling, increased frequency of affective episodes, and additional psychiatric comorbidities including anxiety, PTSD, bulimia nervosa, adult attention-deficit hyperactivity disorder (ADHD), and substance use disorders.

While the pathogenesis of PMDD is not entirely understood, evidence supports both hormonal and serotonergic mediators. Absolute concentrations of hormones do not predict PMDD. Rather, the disorder appears related to increased sensitivity to hormonal fluctuations. Recent literature supports allopregnanolone's role in the pathogenesis of PMDD. Allopregnanolone acts as a positive allosteric modulator of the $GABA_A$ receptor. In rodent and human studies, impairment in the interaction between allopregnanolone and $GABA_A$ results in increased sensitivity to stress during the luteal phase of the menstrual cycle, leading to a heightened susceptibility to affective symptoms. Paradoxically, the administration of allopregnanolone has demonstrated efficacy in managing PMDD. Neuroimaging research has provided empirical evidence of hormonal effects on emotion processing–related activity in orbitofrontal, amygdala-hippocampal, anterior cingulate cortices, and brain reward circuits in monetary reward paradigms.

First-line treatments for PMDD include exercise, adoption of a complex carbohydrate diet during the luteal phase of the menstrual cycle, cognitive-behavioral therapy (CBT), SRIs, and CHCs. Second-line treatments include an increased dose of SRI and hormonal supplementation, including estradiol patches and oral or vaginal progesterone. The third-line treatment utilizes GnRH analogs to prevent menstrual cycling with concurrent continuous hormonal replacement. A recent study comparing ulipristal acetate, a selective progesterone receptor modulator, to placebo in women with PMDD

Telegram: @medical_k

www.konkur.in

found a significant increase in remission of symptoms for the drug. Symptom relief was especially noted in the mood (as opposed to physical) symptoms, holding out the promise of a potential hormonal treatment for PMDD if these results can be replicated.

PERINATAL PSYCHIATRIC DISORDERS

Baby Blues

The baby blues is the most common constellation of mood symptoms experienced by women (occurring in up to 80% of women) in the immediate postpartum period. The baby blues include transient symptoms and rapid mood shifts, including tearfulness, irritability, anxiety, insomnia, lack of energy, loss of appetite, and the general experience of feeling overwhelmed—particularly about newborn caregiving tasks. By definition, the baby blues are transient. Onset typically occurs after the third postpartum day, after the mother has left the hospital after delivery. Symptoms typically peak by day 5 and spontaneously resolve by day 10 postpartum. While the presence of the blues is unrelated to psychiatric history, it has been estimated that 20% to 25% of women who experience symptoms of baby blues will experience baby major depression. Treatment of the baby blues should include psychoeducation, validation of the mother's experience, and careful monitoring for a worsening or prolongation of symptoms.

Perinatal Depression

As perinatal mental health has gained increasing public health and scientific attention, there is a greater appreciation that many affective disorders (not just postpartum depression [PPD]) emerge both during pregnancy and postpartum. A change in the conceptualization of PPD occurred with the revision of the time specifier in DSM-5, published 2013, in which "postpartum onset" was changed to "perinatal onset." "Perinatal onset" recognizes new symptom onset anytime in pregnancy through 1-month postpartum, based on data that many postpartum affective episodes either have their onset in or predate

Telegram: @medical_k

www.konkur.in

pregnancy. However, diagnosing women who experience *either* prenatal or postpartum symptoms with a single “perinatal depression” may muddle key distinctions in the development and response to treatment of affective episodes during the perinatal period. Pregnancy and postpartum are biologically distinct states, and symptom onset during these two states may represent biologically distinct entities. For women without a history of depression, the onset of symptoms is most common during the first month postpartum and increases the risk for an eventual diagnosis of bipolar disorder. Depressive episodes that occur only postpartum are more likely to be associated with obsessive-compulsive and psychotic symptoms. Onset during pregnancy is more likely in women with a history of depression. It remains unclear whether depressive symptoms with prenatal versus postpartum onset demonstrate distinct responses to treatment. It will serve physicians and investigators to take note of the timing of symptom onset to capture potentially important distinctions between affective illnesses that frequently occur during the perinatal period.

Although pregnancy was once considered a time of mental wellness, minor or major depression affects up to 25% of pregnant women, similar to nonpregnant women. Postpartum depressive syndromes affect 15% of mothers, with rates that triple among inner-city and adolescent mothers. Completed suicide is a leading cause of death in new mothers. Infanticide, more commonly associated with postpartum psychosis (PPP) than PPD, is another devastating outcome that has brought the field of postpartum mental illness frequent media attention. Several studies have examined the course of unipolar depression in pregnancy. In a specialized perinatal psychiatry clinic, the rate of depression relapse was 68% in women who discontinued antidepressants prior to pregnancy, compared to 26% in women who maintained their medication during pregnancy.

In contrast, in a community sample with less severe illness, only 16% of the cohort stopping their medication in early pregnancy experienced a recurrence. In both studies, 50% to 75% of relapses occurred in the first trimester, which, in addition to considerable literature supporting the compatibility of antidepressants with pregnancy, further argues against delaying medication until the

Telegram: @medical_k

www.konkur.in

second trimester. Also, both studies reported that the duration of the depressive episode, a history of more recurrences, and a major depressive episode in the 6 months prior to pregnancy were associated with an increased likelihood of pregnancy relapse. A recent meta-analysis found that women with a history of severe and/or recurrent depression demonstrated more than a twofold risk of depression relapse during pregnancy with discontinuation of their psychotropic, compared to women who continued medications throughout pregnancy. Medication reduction without discontinuation resulted in a 35% risk of relapse, supporting a dose-response. A randomized control trial found that Preventative Cognitive Therapy (PCT) was ineffective in preventing relapse of depression among women who gradually tapered pharmacologic treatment during pregnancy.

While the psychosocial adjustment to motherhood lasts longer than 1 month, the DSM-5 time specifier ends at 1-month postpartum to denote a syndrome with the greatest biologic link to the hormonal shifts of pregnancy and delivery. Heightened biologic sensitivity for PPD at 1 month comes from familial studies, wherein PPD onset within 30 days was concordant among parous sisters, and postpartum mood symptoms within 30 days was associated with strong genome-wide linkage signals. From linkage studies of large obstetric and psychiatric databases based upon hospitalization and outpatient contacts, there was a two- to threefold increased risk of PPD in primiparous women evenly distributed across the first 5 months postpartum, with risk remaining elevated out to 2 years postpartum in one study.

Postpartum episodes are sometimes characterized by obsessive-compulsive, particularly intrusive violent thoughts, psychotic symptoms, and anxiety. See additional details described in the OCD section below. Risk factors for PPD include a personal or family history of depression and a personal history of previous depressions related to reproductive events (such as PMDD or previous PPDs). As with non-PPDs, women facing multiple or severe psychosocial problems, trauma, or chronic interpersonal difficulties are at increased risk of experiencing a major depressive episode during the

Telegram: @medical_k

www.konkur.in

postpartum period. One study revealed a 50% rate of childhood sexual abuse history in women hospitalized for PPD. Current theories surrounding the biologic etiology of PPD are addressed in the Mechanisms section later in the text.

A subgroup of women experiences late-onset PPD when weaning from breastfeeding. A recent review of current literature supports the hypothesis that fluctuation and dysregulation of allopregnanolone, an agent known to act on inhibitory GABA neurons, likely plays a role in late-onset PPD. Further research may serve to identify markers to identify a subgroup of women susceptible to the onset of a mood episode at the time of weaning.

Evidence-Based Treatments for Postpartum Depression. A few placebo-controlled trials for the treatment of PPD have been conducted. The SSRI fluoxetine was compared with CBT, combination treatment, and placebo. Fluoxetine and CBT were similarly effective, and fluoxetine was significantly more effective than placebo. Sertraline failed to significantly differ from placebo as an add-on treatment to brief dynamic psychotherapy. In a pragmatic trial of SSRI versus supportive care listening visits, the SSRI proved superior by 4 weeks of treatment. Paroxetine was associated with greater remission rates than placebo in an 8-week trial. For PPD with comorbid anxiety, antidepressants and CBT were efficacious; however, there was no added benefit of combining modalities. In small, open trials, sertraline, venlafaxine, escitalopram, paroxetine, and bupropion SR were effective for the treatment of PPD. In studies of the prevention of PPD, the TCA nortriptyline did not confer protection compared with placebo, but a randomized pilot trial of sertraline given immediately after birth for 17 weeks had greater benefit than placebo (93% vs. 50% remained healthy, respectively) in conferring preventive efficacy.

PPD treatment or prophylaxis with the reproductive hormones estrogen and progesterone has been examined as a means of compensating for the abrupt hormonal withdrawal that accompanies delivery. Numerous studies have attempted to parse out the contributing roles of estrogen and progesterone in the development of

Telegram: @medical_k

www.konkur.in

PPD. In an RCT of transdermal 17β-estradiol 200 mg per day versus placebo, the estradiol-treated group had a significant reduction in depression scores beginning 4 weeks after treatment initiation that was maintained at 3 months. An open trial of sublingual estradiol (mean dose of 4.8 mg/day) in women with severe depression resulted in rapid response within 1 week and an 83% remission rate by 2 weeks of treatment. However, a more recent double-blind, placebo-controlled trial including 12 women with PPD demonstrated no significant improvement with transdermal estradiol administration.

For new-onset depression, an SSRI may be tried initially because such agents are well tolerated and are associated with a low risk of toxic effects in patients taking an overdose. However, if the patient previously had a positive response to a specific drug from any class of antidepressants, resumption of the prior agent should be strongly considered. Women may be more likely to have a response to serotonergic agents, such as the SSRIs and venlafaxine, than to non-serotonergic TCAs, yet safety and efficacy data for TCAs such as nortriptyline and desipramine are generally good, given that they have been in use for a relatively long time.

Slow increases in the dose help manage side effects. Women who have recently given birth are often sensitive to medication side effects, possibly related to elevated anxiety, which is common early in the postpartum course. Treatment should be initiated at half of the recommended starting dose (e.g., 25 mg of sertraline per day or 10 mg of paroxetine per day) for 4 days, and small increments should increase doses (e.g., 25 mg of sertraline per week or 10 mg of paroxetine per week) as tolerated until full remission is achieved. If the patient responds to an initial trial of medication lasting 6 to 8 weeks, the same dose should be continued for a minimum of 6 months after a full remission has been achieved to prevent a relapse. If there is no improvement after 6 weeks of drug therapy or if the patient has a response but then has a relapse, a medication change (within-class or different class) is recommended. Drug doses may need to be increased in the third trimester during the period of increased hepatic metabolism and expansion of blood volume. Antidepressant trials are often initiated in primary care and

Telegram: @medical_k

www.konkur.in

obstetrician-gynecology offices, and consultation with psychiatrists can facilitate optimal dose titration to achieve remission, address treatment resistance, and treat psychiatric comorbidities. Long-term maintenance treatment to prevent recurrence should be considered for women who have had three or more episodes of severe depression.

BREXANOLONE AND RELATED COMPOUNDS. The utility of compounds derived from progesterone in the treatment of PPD has gained momentum in recent years, culminating in FDA approval of a novel agent for the treatment of PPD, brexanolone, in March 2019. Brexanolone is structurally identical to allopregnanolone, an endogenous neuroactive steroid and a progesterone metabolite. Three randomized, double-blind, placebo-controlled studies demonstrated significant improvement in depression following a 60-hour continuous infusion of brexanolone. While there is significant ongoing enthusiasm for brexanolone, and it is now available at sites across the country, it remains expensive and time prohibitive for many, costing $34,000 per infusion and requiring at least a 2.5-day inpatient admission, and many have noted the strong placebo response of the clinical trials. The current understanding of brexanolone's mechanism of action is discussed in the Mechanisms section later in the text. A related oral compound, zuranolone, was granted FDA approval for the treatment of PPD in August 2023. A double-blind RCT including 151 women meeting criteria for PPD demonstrated significant improvement in depressive symptoms at day 3, with persistence to day 45, among those receiving zuranolone compared to the placebo group.

NONPHARMACOLOGIC TREATMENTS FOR POSTPARTUM DEPRESSION. Complementary and alternative medicine therapies suggest potential benefits as monotherapy or in conjunction with pharmacologic treatments. Psychosocial interventions for individuals and groups, delivered in-home, clinic, or by phone, compared to usual care, are associated with symptom reduction, reduced psychosocial stress, increased mental wellness, and prevention of PPD in an increasing

Telegram: @medical_k

www.konkur.in

number of studies. Promising modalities include brief interpersonal psychotherapy, CBT, mindfulness, computerized resources, in-home nurse visits, and peer-based telephone support. Light therapy and supplements may also provide relief. Five-week morning 7,000 lx bright light therapy was associated with a significant improvement in depressive symptoms in an RCT compared to red, dim light. A meta-analysis of 18 RCTs examining the use of omega-3 polyunsaturated fatty acids (PUFAs) in treating perinatal depression found a small beneficial effect. The result was of statistical significance, but the response appeared to be so small and inconsistent that the authors advised against prescribing omega-3 PUFAs to prevent or treat mood episodes during pregnancy. However, it might be beneficial as an adjunct therapy in treating PPD. There is strong evidence for the effectiveness of cognitive-behavioral and interpersonal therapy in managing PPD. Research is too limited to draw conclusions surrounding the effectiveness of exercise, yoga, massage, acupuncture, light therapy, and supplements.

Postpartum Psychosis

The most severe perinatal mood disorder, PPP, is rare, affecting approximately 0.1% to 0.2% (1 to 2 in 1,000) of postpartum women. The disorder was recognized as early as 400 BC by Hippocrates. PPP typically presents within the first few weeks following delivery. Depersonalization, delirium, agitation and insomnia, and delusions are characteristic of the disorder. Affective symptoms—including depression, irritability, anxiety, mixed episodes, and, most often, mania—are also present, and are an important reminder that the syndrome is an affective psychosis. (A woman with an underlying primary psychotic illness who experiences an exacerbation in the postpartum is NOT the same as a woman with PPP, see below for nonaffective psychoses.) A clinical cohort study assessing the phenotype of PPP found abnormal thought content among 75% of cases, disorganization among 25%, disturbed consciousness in 10%, and catatonia in 5%. It is important to recognize that the clinical presentation of PPP can include waxing and waning of consciousness, similar to delirium; therefore, it is imperative to obtain

Telegram: @medical_k

www.konkur.in

collateral information about symptoms as a presentation at any moment may not reveal the full extent of symptoms.

Women with pre-existing bipolar disorder are at very high risk of PPP. In addition, women with new-onset PPP are eventually diagnosed with bipolar disorder in 50% to 80% of cases. PPP is a medical emergency because of the potential risk for infanticide or suicide, and therefore imminent referral to a psychiatrist, hospitalization, and initiation of lithium is typically indicated. PPP has been associated with a 70-fold increased risk of suicide in the first 12-month postpartum, with peak rates within a few days to a few weeks after discharge. Although being a mother is protective against suicide, this narrow time interval postpartum for very ill women constitutes an exception and warrants greater vigilance. Infanticide risk is also greatly increased in this patient population. In a classification of maternal filicides, 24% occurred within the context of acute maternal psychosis and another 56% due to altruistic beliefs about alleviating suffering in the infant, which was often accompanied by maternal suicide. If recognized early and treated aggressively, PPP can have a good prognosis. Lithium is the gold standard for managing the disorder, with 98% of patients in one longitudinal study responding to lithium treatment. Benzodiazepines and antipsychotics can be useful for symptomatic management but should not take the place of lithium.

Bipolar Disorder

Although an important proportion of PPP cases will be attributable to bipolar disorder, it is critically important to recognize that the mothers with bipolar illness also have a higher risk of experiencing a nonpsychotic, nonmanic episode in the perinatal period. A birth register study found a relative risk of 37.2 for relapse in the postpartum period for women with bipolar disorder (approximately 10-fold greater than the risk for women with other psychiatric disorders). While some of these women will have PPP, most will have depressive episodes. Episodes were notable for short postpartum latency and increased postpartum duration relative to pregnancy incidence. Mothers with bipolar II disorder demonstrated more widely distributed timing of mood episodes, both during pregnancy and at 1-month

Telegram: @medical_k

www.konkur.in

postpartum. Clinicians should maintain a high suspicion for bipolarity, given some indication that this diagnosis might be missed in as many as 50% of cases presenting with unipolar PPD.

Pharmacologic treatments are the first-line therapy for the treatment of bipolar disorder; however, close clinical monitoring and efforts to enlist the aid of social supports to prevent sleep disruption and stabilize social rhythms in the new mother with a history of bipolar disorder may be particularly important. Illness recurrence occurs in most women who discontinue psychotropic management, and women are particularly vulnerable to illness during the postpartum period. In a retrospective cohort study including 101 women with bipolar disorder (some followed through pregnancy and postpartum, others nonperinatal), the risk of recurrence after discontinuing mood stabilizer therapy in pregnant women was similar to that in nonperinatal women. In contrast, postpartum recurrences were 2.9 times more frequent than those in nonperinatal women. Among the perinatal women, 85% of women who discontinued mood stabilizer therapy relapsed, while only 33% of those who continued mood stabilizer treatment relapsed (all those relapses occurred postpartum).

Lithium prophylaxis in late pregnancy or 24 hours postbirth has been associated with a nearly 10-fold decrease in the rate of postpartum illness recurrence. Sustained remission out to 9 months postpartum was optimized with lithium maintenance therapy. For unresponsive illnesses, benzodiazepines, antipsychotics, and ECT also have an important role. A low-dose, mid-potency antipsychotic, such as perphenazine, can be added as a PRN agent for prodromal or breakthrough symptoms.

Nonaffective Psychosis

This category includes diagnoses of schizophrenia, delusional disorder, and brief and unspecified psychosis. While first-generation antipsychotics (FGAs) are associated with diminished fertility rate via hyperprolactinemia and anovulation, second-generation antipsychotics (SGAs) are associated with normal fertility rates, and there is a high rate of unwanted pregnancies and repeated VTOPs in

Telegram: @medical_k

www.konkur.in

this population. These are often high-risk pregnancies due to low rates of prenatal care, high rates of poverty, homelessness, poor social support, poor nutrition, and high use of prescribed medications, alcohol, drugs, and tobacco. These women also have increased rates of sexual abuse prepregnancy and physical abuse in pregnancy. Often these mothers are less aware of signs of labor and delivery and are at greater risk of obstetric complications. Women with nonaffective psychosis represent the minority (15%) of hospitalizations of perinatal women due to psychosis, which are largely accounted for by affective psychosis. In women with schizophrenia, the relative risk of hospitalization in the first 30 days postpartum compared to 6 months postpartum is 5.7. Common delusional themes include ideas that the birth did not occur or that the baby is dead or defective; there can also be command hallucinations to harm the baby. Fifty percent of these mothers are separated from infants at discharge from the obstetric hospital due to incapacity to provide for the child's minimal needs for physical sustenance. There is a 75% puerperal recurrence rate in schizophrenia and a 100% readmission rate 10-year post index postpartum admission due to schizophrenia relapse.

This is a diagnostic group for whom severe and persistent mental illness is convincing for medication needs. Psychotic illness confers the greatest increase in the risk of poor fetal outcomes. Evidence from standard guidelines is currently used to guide treatment with no knowledge that treatment efficacy differs between postpartum and nonpostpartum populations. Although there is a tendency for physicians to discontinue or avoid initiating long-acting injectable antipsychotics (LAIs) during pregnancy and postpartum, given concern for the possible risk in exposing a fetus to such agents, the utility of these medications is supported by the literature. There are no clear contraindications to pregnancy identified, and there is a role for the judicious use of LAIs in pregnant women, especially for women at risk of relapse or where there is a concern for medication adherence. Women with psychiatric illness who discontinue antipsychotics during the first trimester of pregnancy are twice as likely to experience a return of their illness compared to those who continue on medication.

Infants of women with untreated psychosis are more likely to have congenital malformations than healthy women. As it is not feasible to conduct RCTs assessing the risks of LAI exposure to the fetus during pregnancy, we must rely on limited information, largely drawn from case studies. Based upon case reports, LAIs appear to be well tolerated by women and offspring during pregnancy, and rates of premature birth, spontaneous abortion, and congenital anomalies do not appear to differ from the general population. Theoretically, LAIs likely carry risks similar to orally administered antipsychotics, for which data are also limited. Prescribers should carefully weigh the known and unknown risks of the medication against the substantial risks associated with psychiatric decompensation for both the woman and baby. Adjunct psychosocial treatments include individual cognitive treatments, family support, and rehabilitation programs to facilitate mother-infant caregiving and bonding. Close collaboration among health professionals is necessary during the perinatal period in these women.

Perinatal Anxiety

Anxiety disorders are the most prevalent of psychiatric disorders, and women, compared to men, have a greater overall lifetime prevalence of anxiety disorders and increased peak prevalence during the childbearing years. Thus, both gynecologists and primary care practitioners need to have a basic familiarity with anxiety disorders to promote early detection and treatment. A recent systematic review and meta-analysis found prevalence rates for self-reported anxiety symptoms ranging from 18.2% to 24.6% during pregnancy and 15% postpartum. Rates of diagnosed disorders are lower (15.2% and 9.9%, respectively). Rates of anxiety comorbidity in women with perinatal depression reach 50%. Medical diagnoses such as hypo/hyperthyroidism, anemia, and hypertension have a similar phenotype and should be ruled out.

Prenatal pregnancy-specific anxiety (along with the less clearly defined stress) has been associated with increased glucocorticoid concentrations in the mother–fetus dyad, pregnancy complications, earlier delivery timing, prematurity, and low birth weight. Risk factors

Telegram: @medical_k

www.konkur.in

in pregnancy include young adulthood, single motherhood, pregnancy complications, stressful life events, poor physical health, and past year victimization. Therefore, assertive screening in pregnancy is warranted, and affective symptoms shouldn't be assumed to be normative responses to pregnancy. Both antenatal anxiety and depression are highly predictive of PPD, which is important in framing the decision-making process for treatment choices in pregnancy.

Perinatal Obsessive-Compulsive Disorder (OCD)

Subsyndromal obsessive-compulsive disorder (OCD) symptoms may reach a 25% prevalence in perinatal women. A recent longitudinal study followed 763 women from the third trimester of pregnancy to 9 months postpartum and found 7.8% of women to meet criteria for OCD during pregnancy and 16.9% of women to meet criteria during the postpartum period. Prevalence slowly increased throughout pregnancy and into the postpartum period, peaking at 2 months postpartum. OCD has a prevalence of 1% to 1.5% in the general population. It has been hypothesized that the symptoms of postpartum OCD may be an exaggeration of adaptive maternal behavior. Postpartum OCD is more likely than OCD occurring outside the postpartum period to be characterized by obsessions involving contamination, aggression, and compulsions around cleaning and checking. More specifically, women with postpartum OCD commonly experience unwanted, recurrent, and intrusive thoughts and images of unintentionally or intentionally harming the infant. Ego-dystonic aggressive obsessions toward the infant, usually regarded as highly distressing by new mothers, must be distinguished from ego-syntonic aggressive ideation, which may accompany psychosis. However, these distressing symptoms are frequently missed by practitioners at rates as high as 70%, and it is therefore imperative that clinicians ask specifically about intrusive violent thoughts and images. Subsyndromal aggressive obsessions are significantly more common in postpartum compared with nonpostpartum women. OCD and depression are highly comorbid in postpartum women, with 40% of women with OCD also meeting the criteria for MDD. Risk factors for postpartum OCD include primiparity, history of psychiatric illness,

Telegram: @medical_k

www.konkur.in

obstetric complications, and sleep deprivation. SRIs are the first-line in the treatment of OCD. CBT, in addition to pharmacologic management, is helpful for many women. As doubt of self and guilt surrounding symptoms are common features of perinatal OCD, a strong therapeutic alliance with the treating clinician is important.

Evidenced-Based Treatment for Anxiety and Related Disorders. Standard guidelines for treating GAD, PTSD, and panic disorder should inform the treatment of postpartum women with these disorders, using specific psychotherapeutic interventions when available. Medication management described in standard guidelines includes SSRIs as a first-line treatment. There is also considerable evidence for the benefit of TCAs, such as clomipramine for OCD and imipramine for panic disorder. Nightmares of PTSD can be effectively treated with the alpha-1 adrenergic receptor antagonist prazosin and could benefit this population. The use of benzodiazepines to promote sleep and/or treat residual anxiety symptoms not addressed by the primary behavioral or antidepressant medication is a common clinical practice.

Nonpharmacologic Treatments for Postpartum Anxiety and Related Disorders. An array of nonpharmacologic treatments, including yoga, tai chi, self-guided workbook with weekly telephone support, relaxation therapies, acupuncture, exercise, and massage, have demonstrated promise in reducing antenatal anxiety in several studies with variable degrees of rigor. Prevention of postpartum anxiety has been successful in prenatal educational formats that deliver CBT for postpartum OCD symptom reduction and parenting communication for reducing postpartum generalized anxiety and improving overall postpartum adjustment and marital satisfaction. However, results remain mixed, as there was no benefit seen with 12-session group CBT when added to paroxetine in women with comorbid depression and anxiety. For women who meet full criteria for OCD, CBT with Exposure and Response Prevention (ERP) is the gold standard, as it is for nonperinatal women.

Theorized Mechanisms in the Pathogenesis of Perinatal Psychiatric Illness

Scientific investigation is beginning to clarify the pathogenesis of PPD and, to a limited extent, postpartum psychosis. Little research has been conducted on the etiology of other perinatal psychiatric disorders. Therefore, this section presents the evidence pertinent to our current understanding of the pathophysiology of PPD and offers a brief review of the literature investigating the etiology of postpartum psychosis. Future research will be necessary to inform discussions on the pathophysiology of other psychiatric perinatal disorders.

What constitutes the “hormonal trigger” prompting postpartum depressive symptoms has been a topic of significant scientific curiosity. Well appreciated are the hormonal excursions of the perinatal period, whereby late gestational increased concentrations of CRH (1,000-fold), cortisol (3-fold), estradiol (100-fold), and progesterone (10-fold) are followed by different rates of decline after delivery. Postpartum withdrawal of estradiol and progesterone, which occurs rapidly within the first 2 to 7 days postpartum, when studied under simulated conditions, induced depressive relapse in women with a history of PPD but not in women without such history. Other experimental simulations of this kind indicate that reproductive hormonal fluctuations are associated with disruptions in CNS corticolimbic connectivity that promotes healthy emotion processing. While studies have found no relationship between estradiol and PPD, numerous recent studies have implicated the dysregulation of allopregnanolone, a progesterone metabolite, in the development of PPD. Lower serum levels of allopregnanolone and reduced sensitivity of allopregnanolone to stress during pregnancy have been associated with depressive episodes during pregnancy and postpartum.

Other hormones may additionally contribute to the pathogenesis of PPD. The hormones CRH, cortisol, oxytocin, and prolactin, which fluctuate across the perinatal period and demonstrate interindividual differences, may confer differential risk for mood disorders and are implicated in stress response, emotion processing, and social cognition functions. Although there are no peripheral hormone biomarkers for perinatal mood disorders, gestationally elevated CRH

Telegram: @medical_k

www.konkur.in

and reduced oxytocin, as well as prolonged blunting of the postpartum HPA axis, have been associated with perinatal depression in as yet unreplicated studies. Subclinical hyperthyroidism poses a risk for antenatal depression, whereas thyroid hypofunction or increased antibodies was associated with PPD.

The immune system is another likely contributor to the development of PPD. The literature supports an association between immune dysfunction and MDD; additional research is necessary to elucidate the mechanisms and population implicated in the association. Given that pregnancy and postpartum are periods of significant immune dysregulation and that autoimmune disorders are associated with MDD in the general population, it would be reasonable to consider a role for dysregulation of the immune system in the pathogenesis of PPD. Early studies attempting to clarify the role of the immune system in PPD focused on the activity of proinflammatory cytokines, with mixed results, finding both elevated and reduced levels of proinflammatory cytokines to be associated with depressive episodes. The immune system's role in the development of depressive illness is an ongoing and active field of research; numerous groups are working to examine various potential regulators, including acute phase reactants, B- and T-cells, microglia, toll-like receptors, immune cell populations, and extracellular vesicles.

Functional MRI of healthy mothers in the early puerperium as they attend to visual and auditory cues of their baby reveal activation of brain regions involved in reward (striatum, midbrain, orbitofrontal cortex), empathy (superior temporal sulcus), emotional appraisal (insula and amygdala), and emotion–cognition integration centers (anterior cingulate gyrus) with transitions to the maternal role. Depressed mothers activate this circuitry to a lower extent. Genetic mechanisms research assumes a general vulnerability for mood disorders and a specific hormonal sensitivity. PPD risk increases in mothers with a personal and/or family history of depression. Within 30 days of delivery, postpartum mood disorder was concordant among parous sisters and was associated with strong genome-wide linkage signals. Several monoamine and steroid hormone gene

Telegram: @medical_k

www.konkur.in

polymorphisms and hormone-sensitive epigenetic signals have been described, all of which require further investigation.

Psychological and sleep-related mechanisms have a critical place in understanding postpartum disorders. Maternal sleep deprivation is a common, if not universal, consequence of the infant's lack of a circadian rest-activity cycle and a significant risk factor for developing PPD. Therefore, therapies supporting sleep are critical to psychiatric care in the postpartum period. The average time an infant develops a recognizable nocturnal sleep pattern is 12 weeks. Currently, infants display a clear nychthemeral pattern of melatonin secretion, indicating maturation of the master clock, the suprachiasmatic nucleus. Becoming a mother represents an unparalleled identity transition and a disruption of life's routine, including relationships, work, sleep, exercise, nutrition, and finances. High social stress, marital discord, minority status, adolescence, and neuroticism are all associated with increased perinatal mood disorders. Women with a history of attachment insecurity or trauma might have particular struggles when faced with an infant to protect from abuse or neglect.

The current understanding of the pathogenesis of PPP is limited. Like the suspected etiology of PPD, increased sensitivity to hormonal fluctuations around the time of delivery likely plays a role in developing PPP. Disruption in the physiologic reconstitution of the immune system following parturition is another plausible explanation. Immune dysfunction is more common among women with PPP; women with PPP are more likely to experience co-occurring autoimmune thyroiditis, encephalitis, and pre-eclampsia than those without PPP. In fact, a study including 23 women with PPP and 117 unaffected controls matched by primiparity demonstrated significantly elevated rates of both autoimmune thyroid disease and clinical thyroid failure. Women with PPP experienced thyroid disease at a rate of 19%, while only 5% of women in the control group demonstrated disease.

Furthermore, women with PPP progressed to thyroid failure at a rate of 67%, as compared to 20% of controls. Therefore, it is recommended that clinicians test for serum thyroperoxidase antibodies among women with PPP. The above observations

Telegram: @medical_k

www.konkur.in

surrounding the elevated rates of an array of autoimmune disorders among women with PPP have prompted an early investigation into possible mechanisms underlying immune dysfunction leading to PPP. Differences in inflammatory cells between women with and without PPP have also been observed. Elevated levels of monocytes, lower naïve CD4 and CD8 count but higher activated CD8 and memory T cells and decreased natural killer cells have been observed in women with PPP, compared to healthy controls. A recently postulated theory implicates dysfunction in immune-mediated myelination in the pathogenesis of PPP. More specifically, impairment in regulatory T cells and CCN proteins involved in CNS remyelination has been proposed. Additional investigation is necessary to explain the mechanisms involved in the pathogenesis of PPP and to develop more targeted treatments for this rare but highly morbid disorder.

Breastfeeding. Breastfeeding is the continuation of the reproductive cycle, both through providing neonatal and early childhood nourishment and through the normalization of maternal pregnancy physiology. In the United States in 2014, 83% of infants were breastfed at any point, 55.3% were breastfeeding at 6 months, and 33.7% were breastfeeding at 1 year. Breastfeeding is associated with maternal benefits such as decreased risks of breast and ovarian cancer, diabetes, and hypertensive heart disease, and infant benefits such as timely neuronal development, passive immunity, and reduction of food allergies. There are additional psychological benefits for both mother and infant. Optimally, breastfeeding should be exclusive for 6 months, and continue as complementary feeding for 1 to 2 years.

Lactation occurs because of a complex psychoneuroendocrine cascade triggered by the abrupt decline in estrogen and progesterone concentrations at parturition. Lactation becomes established in response to the neurologic stimulation transmitted by suckling. The composition and amount of breast milk change as the infant grows. In mother–infant dyads with breastfeeding difficulties, steps should be taken toward managing challenges to preserve or improve maternal mental health. When milk production or latch are suboptimal, feeding

Telegram: @medical_k

www.konkur.in

plans should be simplified to promote bonding. If demands of nighttime breastfeeding and sleep disturbance trigger mood changes, another caregiver should provide infant feedings to allow for 5 to 6 hours of uninterrupted sleep. A mother's perception of insufficient or inadequate ability to breastfeed can undermine confidence in her ability to meet her infant's needs and leave her vulnerable to symptoms of PPD. Cluster-feeding (several short feeds close together), constantly feeding for several hours, or a fussy infant awake all night should be evaluated for feeding difficulties to prevent extreme fatigue in the mother and allow for optimal infant nutrition and maternal rest. If for some reason, however, the mother cannot breastfeed, reassurance that the child can be well cared for and adequately fed with current formulas should be provided to minimize the attendant guilt that may occur. PPD and breastfeeding difficulties can often co-present. There is a theoretical argument that depression and lactation difficulties have a common neuroendocrinologic basis, perhaps mediated by disrupted oxytocin, prolactin, or stress neuroendocrine circuitries. Studies evaluating the protective or aversive effects of breastfeeding on mental illness have demonstrated inconsistent results. A recent cross-sectional study found breastfeeding to be protective against the development of PPD, with a dose–response relationship. The study attempted to control for many likely confounders (including demographics, depression severity, desire for pregnancy, reproductive and abuse history, birth complications, and substance use). Mothers with anxiety or depression history should be encouraged to obtain lactational education and support early to optimize success. The fostering of skin-to-skin contact between mother and infant during lactation has important emotion-regulatory influences for both members of the dyad and facilitates mother-infant socioemotional bonding.

Screening

Given that numerous risk factors are predictive of mental illness during the postpartum period, assertive screening in pregnancy is warranted, and affective symptoms should not be assumed to be normative responses to pregnancy. Western European countries and

Telegram: @medical_k

www.konkur.in

Australia have been international leaders in establishing nationwide surveillance programs to detect postpartum mood disorders. Legislation at the national and state-level in the United States over the past decade reflects increased recognition of the seriousness of maternal mood disorders, with the 2010 Melanie Blocker Stokes MOTHERS Act and the recent Bringing Postpartum Depression Out of the Shadows Act, which was passed as part of the 21st Century Cures Act. The postpartum bill authorized the Secretary of Health and Human Services to provide federal grants to states for screening, assessing, and treating PPD. An increasing number of U.S. states mandate health care providers and facilities to screen newly delivered mothers for PPD. The U.S. Preventive Services Task Force (USPSTF) made a formal recommendation that all women be screened for depression during pregnancy and the postpartum period in 2019. The American Psychiatric Association (APA) also published a position statement in 2018, declaring “all pregnant and postpartum women should be assessed for both the presence of and risks for a psychiatric disorder” and continues “all perinatal patients should be evaluated for depressive, anxiety, and psychotic disorders throughout the pregnancy and postpartum period.” The statement specifies that screening be conducted with “a validated screening tool twice during pregnancy, once in early pregnancy for pre-existing psychiatric disorders and once later in the pregnancy,” and again postpartum at pediatric visits, as recommended by the American Academy of Pediatrics (AAP). The American College of Obstetricians and Gynecologists (ACOG) additionally supports screening women during pregnancy and postpartum.

As in other medical conditions, screening for perinatal psychiatric disorders has caveats and must be responsibly implemented so that cases identified can be referred to treatment promptly. Careful planning for the choice of instrument, the setting, clinical cut-off scores, and the timing of administration must be appropriate to individual settings. Screening offers little hope for symptom improvement if referrals for treatment cannot be made. The assessment of perinatal disorders can be confounded by somatic complaints common to the postpartum period, such as sleep and

Telegram: @medical_k

www.konkur.in

eating disturbances, decreased sexual interest, weight gain, and fatigue. As a result, the Edinburgh Postnatal Depression Scale (EPDS), which de-emphasizes such symptoms, has become a common instrument utilized by obstetricians, family doctors, psychiatrists, and pediatricians. The ten-question scale is available in 70 languages, has been validated cross-culturally, and is easily completed by the patient or care provider in a few minutes. Sensitivity and specificity range from 70% to 88% and studies evaluating the accuracy of the EPDS demonstrate that it identifies ill individuals more effectively than a clinician's assessment. EPDS includes a question about suicidal thoughts, which is especially important in this high-risk population. Moreover, a three-question mini-anxiety screener is embedded within the EPDS, making it possible to screen for both depressive and anxiety disorders at once. Antenatal presence of anxiety and depression is highly predictive of PPD and, therefore, important to consider in the decision-making process surrounding treatment during pregnancy.

Psychiatric Treatment Decision Making During Pregnancy and Postpartum

Structured Clinical Decision Making. Because of the temporal coincidence of mood disorders during women's reproductive years, and because pregnancy is unplanned in 50% of cases, psychiatrists must routinely ask about contraception and family planning during pharmacologic management visits. The family planning period is ideal for a structured preconceptual counseling discussion regarding perinatal treatment with prospective parents. Decision making in the treatment of pregnant women should be structured to include patient education regarding the natural history of her psychiatric disorder, the identification and review of likely risks and benefits associated both with the disorder and available somatic treatments, and frank discussion of available treatment options. This decision-making process must be tailored to address the severity of the patient's current illness and psychiatric history and the experiences, values, and concerns of the patient. Clinical decision making must balance

Telegram: @medical_k

www.konkur.in

the known and unknown risks of medication treatment with the known and unknown risks of untreated psychiatric illness.

Providers must engage patients in a comprehensive discussion of risks associated with treatment versus the considerable risks associated with an untreated mood disorder. Discussions supporting open communication with patients in a comprehensible format, respecting the patient's concerns and value structure, are critical to optimizing treatment decisions and obtaining fully informed consent for treatment. Such conversations iteratively take place. Some women will desire a withdrawal of psychotropic medications under close supervision prior to pregnancy, with iterative decisions about medication resumption over time in the event of symptom recurrence or if there is a recommendation for postpartum prophylaxis. When pregnancy is discovered during a pharmacologic treatment course, an analysis of the risks associated with medication continuation and the risks associated with illness relapse must be carefully evaluated.

Clinical decision making is complicated for pregnant and breastfeeding women because of the exponential growth in reports about psychotropic use in pregnancy that can be difficult to interpret and are often conflicting. Furthermore, clinicians in psychiatry and obstetrics may lack experience or comfort in this domain, and thus the perinatal patient may lack access to a useful decision-making process. Perinatal psychiatrists are skilled in this area and should be consulted when needed. Updated data about the risks of psychotropic use during pregnancy and lactation can be found at a variety of free websites, including the U.S. National Library of Medicine http://www.toxnet.nlm.nih.gov/Developmental and Reproductive Toxicology Database or Drugs and Lactation Database, the Organization of Teratology Information Specialists http://www.otispregnancy.org/, Thomas Hale's website on lactation http://www.infantrisk.com/, and the Massachusetts General website http://www.womensmentalhealth.org/. Subscribers to Micromedex Solutions can also access Reprotox, TERIS, and Shepard's databases. The National Curriculum in Reproductive Psychiatry (NCRP), available at https://ncrptraining.org/, is a free, online, interactive curriculum that offers up-to-date learning and teaching

Telegram: @medical_k

www.konkur.in

materials on the pathophysiology, epidemiology, diagnosis, and treatment of psychiatric disorders that occur throughout the reproductive lifespan. Notably, the U.S. Food and Drug Administration published a new Pregnancy and Lactation Labeling Rule that went into effect June 30, 2015, to improve access to a summary of all pertinent studies that bear upon perinatal use of individual medications.

This update replaces the older system of pregnancy letter categories A, B, C, D, and X, in use since 1992. Instead it "requires that labeling include a summary of the risks of using a drug during pregnancy and lactation, a discussion of the data supporting that summary, and relevant information to help health care providers make prescribing decisions and counsel women about the use of drugs during pregnancy and lactation (https://www.fda.gov/drugs/labeling-information-drug-products/pregnancy-and-lactation-labeling-drugs-final-rule)." The prior letter categorization system was oversimplified, confusing, and poorly conveyed the information available surrounding the use of medications during pregnancy. For example, sertraline, regularly used in pregnant and breastfeeding women, belongs to category C as "Animal reproduction studies have shown an adverse effect on the fetus, or there are no animal reproduction studies and no well-controlled studies in humans." When very little information is available on a drug, it gains category B classification – meaning that there is less information available than that for category C drugs. Clinicians, however, often misinterpreted this system as a simple gradation from A to and thought category B was necessarily safer than category C. These categories did little to guide clinicians and patients in navigating risk-risk discussions. Since 2018, all drugs, regardless of the date submitted to FDA, are required to use the new format.

In the absence of specialized perinatal treatment guidelines, the APA guidelines apply generally. The Centers for Disease Control "Treating for Two" initiative draws attention to the fact that, in some cases, avoiding or stopping medication use during pregnancy may be more harmful than taking a medication. The use of medication is increasingly common for women with moderate-to-severe psychiatric

Telegram: @medical_k

www.konkur.in

disorders, for whom removal of treatment would increase the likelihood of neurovegetative symptoms, incapacitating anxiety, functional impairment, drug and alcohol abuse, suicidality, or psychosis.

Risks of Psychiatric Illness During Pregnancy

IMPACT ON MOTHER. Untreated illness can lead to clinical deterioration, with concomitant psychological distress, social and occupational dysfunction, financial hardship, an inability to plan for and successfully cope with the impending life transition of motherhood, and possible suicidal ideation and self-harm. Recently acquired data from nearly 600,000 American women of reproductive age demonstrates a dramatic risk in suicidal ideation and self-harm behaviors over the last 12 years. Suicidal ideation increased from 0.1% per 100 women in 2006 to 0.5% per 100 women in 2017, and self-harm behaviors were reported by 0.1% per 100 women in 2006, subsequently doubling to 0.2% per 100 women in 2017. With many psychiatric disorders, functional impairment results in sleep disturbance, poor nutrition, lower use of prenatal vitamins, weight loss, and increased risk of cigarette, alcohol, and drug use. Poor rates of prenatal care can fail to detect gestational anemia, diabetes, hypertension, and hypothyroidism, which can harm both mother and fetus. Close attention must be paid to the host of behaviors that accompany psychiatric relapse in framing the risk-benefit discussion. As an example, cigarette smoking is associated with increased rates of miscarriage, intrauterine and perinatal death, preterm birth, and intrauterine growth restriction, outcomes that may be worse than any risk of psychotropic medications.

IMPACT ON OFFSPRING. Untreated mental illness carries significant independent risks for pregnancy outcomes. Increasingly appreciated is the impact of the prenatal milieu on fetal and infant health. The maternal HPA axis can have fetal programming effects that increase offspring risk for subsequent adult-onset medical and psychiatric disorders. Severe prenatal maternal stress during the first trimester of

Telegram: @medical_k

www.konkur.in

pregnancy has been associated with congenital anomalies. Furthermore, prenatal anxiety, pregnancy-specific anxiety, depression, and maternal stress hormones have all been associated with preterm birth, increased rates of obstetrical interventions during labor and delivery, small-for-gestational-age, low birth weight, impaired neonatal stress regulation, infant fearful temperament, adverse cognitive outcomes, and reduced gray matter brain volumes. Novel tests of fetal cardiovascular reactivity during maternally stressful tasks are associated with altered nervous system function in utero in fetuses of depressed and anxious mothers.

Fetal neurodevelopment is an active field of research. More recent neuroimaging studies demonstrate altered structure and function in infants of mothers with depression. Changes in connectivity between the amygdala and the prefrontal cortex, decreased hippocampal growth, less cortical thickening, and increased amygdala volume have been identified in women with prenatal depression.

The potential negative impact of psychiatric illness on maternal caregiving functions is well demonstrated. Mentally ill mothers have an increased likelihood of having intrusive or withdrawn interactional styles with their infants and may lack sensitivity and attunement to infant cues. These maternal behaviors have been associated with offspring vulnerability for poor self-regulation, low self-esteem, insecure attachments, behavioral problems, and motor and cognitive development delays. Ultimately, the complex multifactorial nature of the fetal environment, postbirth environment, and shared parental–infant genetic factors make unitary explanations of infant development overly simplistic. Yet, awareness of these distinct levels of infant developmental origins empowers newly pregnant women to optimize conditions for their offspring.

Nonsomatic Treatments for Perinatal Mood Disorders. Treatment options should be presented according to a hierarchy from least to most somatically invasive. Nonpharmacologic depression treatments, such as outpatient psychotherapy or mindfulness-based stress reduction, can be advantageous for mild to moderately depressed or anxious women by providing emotional support and

Telegram: @medical_k

www.konkur.in

instrumental skill development needed to facilitate coping through this life transition. Maintenance of ongoing clinic visits and psychiatric monitoring and optimizing general health and social behaviors are all important strategies that promote primary prevention or early intervention as needed, thus conferring the best prognosis and preventing the untoward consequences and refractory course that otherwise might develop.

Chronobiologic treatments were developed because depression results from a desynchronization of circadian rhythms. Treatment implications are to resynchronize the biologic rhythms of sleep and activity with those of other underlying circadian rhythms, such as melatonin, cortisol, thyroid-stimulating hormone (TSH), or prolactin. This end may be achieved by administering bright light (greater than 2,500 to 10,000 lx) or wake therapy (sleep deprivation) at critical times of the day. Although still in its experimental stages, the use of bright light or wake therapy in women with pregnancy or PPD has had promising results in pilot studies. Further studies in this area would be worthwhile, given the relatively short onset of action of these treatments and the avoidance of risks associated with pharmacologic interventions.

The benefits of social and material support that is not delivered in traditional clinics and promotes the organic routine of a mother caring for her children in her home cannot be understated for new mothers. Models for treatment delivery continue to change over the years. In the United Kingdom, Australia, and several European countries, home health care providers have had a major effect on improving recognition and management and reducing the adverse consequences of these disorders. In the United States and elsewhere internet-based intervention, health coaches by phone and support groups are increasing. For women with severe mental illness, mother-baby inpatient units (in Europe, Australia, and India) enable mothers to undergo the necessary treatment while breastfeeding and developing a relationship with their baby. In the United States, there are several mother–baby day hospitals and three Inpatient Perinatal Psychiatry Units, located at the University of North Carolina at Chapel Hill, Zucker Hillside Hospital in Queens, New York, and El Camino

Telegram: @medical_k

www.konkur.in

Health in Mountain View, California. However, none of these options allow the baby to stay with the mother.

Safety of Psychopharmacology During Pregnancy and Lactation

MAKING SENSE OF THE LITERATURE. Although ethical considerations limit performing randomized, prospective medication studies with pregnant women, improved methods for naturalistic studies (large samples, propensity score matching) and ongoing collection of observational data in registries have increased the information available to women facing perinatal treatment decisions. Increasingly sophisticated study designs and statistical methods have been important for reducing sources of bias, such as confounding by indication, which refers to the host of demographic, behavioral, and health-related characteristics associated with the illness itself (i.e., increased smoking, poor prenatal care) or use of medication (i.e., potentially more severe illness). Both medication exposure and maternal mental illness contribute to the outcomes of interest, and thus the most informative studies can measure and control for each. A true teratogen is associated with a consistent birth defect across studies; therefore, inconsistent findings of disparate defects are harder to interpret, especially in view that the psychiatric disorder itself is not always accounted for. Additionally, well-powered studies that properly control for confounding are needed to detect rare infant malformations. The multifactorial nature of infant development suggests that large studies are needed to control for numerous contributory variables. Greater outcomes standardization and data pooling across research centers will facilitate advances in this domain.

Pharmacotherapy is an important modality for women with illnesses unresponsive to alternative treatments and for those with moderate-to-severe symptoms. The psychiatrist plays an important role in supporting the patient to make an informed decision and providing education to and fostering communication with the obstetrician and pediatrician. A guiding principle in treating pregnant women is

Telegram: @medical_k

www.konkur.in

minimizing fetal exposures both to the untreated illness and to psychotropics. The medication to which a mother has responded in the past is often the best choice, even absent substantial data, given the known risk of severe, untreated illness. Most drugs cross the placenta, albeit to a varied extent. Psychotropic transfer to the baby via lactation is much lower than placental transfer due to incomplete psychotropic absorption into breast milk and first-pass metabolism effects in the infant. If fetal exposure to a particular psychotropic has already occurred, this agent would be reasonable to continue during lactation rather than switching to one with theoretically lower exposure. If the drug was started postpartum, observing the infant's behavior before the mother is treated permits clinicians to avoid misinterpreting typical behavior as potentially drug-related. For each psychotropic class below, the available evidence is summarized in order of reproductive domain: congenital teratogenicity, late gestation effects, neonatal withdrawal/toxicity, developmental (neurobehavioral) teratogenicity, and lactation.

It is also crucial to consider the timing of making decisions about medication use in pregnancy. Ideally, pregnancy should be considered when prescribing medications for any reproductive-aged woman, regardless of her plans (as nearly 50% of pregnancies are unplanned). Ideally, a thorough conversation of the risks of untreated illness versus the risks of medication use should be conducted with each woman well before a planned pregnancy to allow time to observe the effects of any suggested modifications. Because limiting exposure to both medication and illness is the goal, women taking small doses of numerous medications might be able to pare down to fewer medications at larger doses if planning a pregnancy. Similarly, women taking a newer drug with less evidence for compatibility with pregnancy, and a history that does not include lack of response or tolerance to older drugs, might trial a drug with more evidence if planning a pregnancy. But if the same woman were to present already pregnant, the calculation is different; switching to another drug is another exposure for the fetus, and unknown efficacy for the mother may mean even more exposures down the line. Timing within the pregnancy itself also matters. While few drugs are associated with

Telegram: @medical_k

www.konkur.in

congenital teratogenicity, for those that are, it is important to remember when the period of organ formation occurs; if a pregnancy has already advanced beyond that point at presentation, there is no utility to stopping the drug (and possibly considerable potential for harm).

Finally, it is crucial to take into account pregnancy changes to metabolism and volume of distribution and their effects on serum concentration of drugs. Many clinicians are tempted to reduce medication doses in pregnancy (on the theory that this will pose less risk to the fetus). In fact, there is no evidence to support this practice, and we know that serum concentrations of many drugs will be 40% to 50% lower at the end of pregnancy—meaning that many women will require higher rather than lower doses of drugs to maintain their mental health. There are unfortunately as yet no guidelines to inform prophylactic dose changes in pregnancy, but clinicians would be wise to monitor symptoms carefully and react to relapses quickly. For those drugs that have commercially available tests for blood level (such as lithium, lamotrigine, and the TCAs), incorporating frequent levels across pregnancy can inform decisions about dose changes.

SEROTONIN REUPTAKE INHIBITORS (SRIS = SSRIS AND SNRIS). All SRIs are generally considered compatible with pregnancy. Some studies, largely those with inappropriate control groups, have demonstrated a statistically significant, though arguably not clinically relevant, relationship between SRI use and congenital teratogenicity. There was significant concern about the association of paroxetine with cardiac septal defects, resulting in the FDA revising its label to category D in 2005. However, subsequent meta-analyses failed to reproduce the relationship, challenging the conclusion that paroxetine is a cardiac teratogen. More recently, several large, methodologically rigorous studies have demonstrated no significant relationship between cardiac malformations and SRI use in the first trimester. The possible link between late pregnancy (after 20 weeks of gestation) exposure to SRIs and persistent pulmonary hypertension of the newborn (PPHN) also created public alarm and FDA label changes warning of risk in 2006, which was then rescinded in 2011. An

Telegram: @medical_k

www.konkur.in

increasing number of studies and meta-analyses draw contrasting conclusions and do not adequately control for confounders such as maternal depression severity, preterm birth, and mode of delivery. Current information, therefore, does not support SRI discontinuation due to PPHN risk.

Spontaneous abortion rates were initially estimated to be higher among women taking antidepressants. Significant limitations of this early research include lack of control for psychiatric status; lack of control for a history of prior miscarriage; and the possibility that therapeutic abortions were misrepresented as miscarriages due to stigma. Several analyses in a large cohort found no increased risk attributable to SRIs when controlling for depression status. Additionally, SRI use was not associated with an increased risk of stillbirth, neonatal death, or postneonatal death in a second well-controlled, large study.

Antidepressant exposure in late pregnancy has been significantly associated with lower gestational age and lower APGAR scores at 1 and 5 minutes, even with proper controls for psychiatric status. SRI exposure was associated with lower infant birth weight only when maternal psychiatric status was unaccounted for. Importantly, these effects are quite low and of questionable clinical significance. A 1.2- to 2-fold increased risk of preterm delivery, defined as birth prior to 37 weeks of gestation, was associated with in utero SRI exposure in a meta-analysis that controlled for illness exposure; however other characteristics of women who maintain meds through pregnancy could confer residual confounding. Depression has also been associated with preterm birth, but additional research is needed.

A neonatal adaptation syndrome affects approximately 30% of late pregnancy, SRI-exposed newborns, and substantially more preterm infants are affected. Features of poor neonatal adaptation include respiratory difficulty, hypoglycemia, hypertonia, jitteriness, vomiting, seizures, and sleep disturbances. The syndrome appears to be time-limited, with the greatest incidence in the first 48 hours postbirth but potentially extending to 2 weeks postbirth. While one study provided evidence for similar rates of neonatal signs in the absence of SRI exposure 2 weeks prior to delivery, thus implicating maternal or other

Telegram: @medical_k

www.konkur.in

neonatal factors in this syndrome, another study found increased adaptation syndrome risk even after control for maternal characteristics. Long-term sequelae of this syndrome have not been adequately studied; one study found continued differences in response to visual and auditory stimuli in SRI-exposed babies compared to unexposed at 30 days postdelivery.

Several prospective studies have found no impact of SRIs or TCAs on temperament, mood, arousability, activity level, distractibility, global intelligence quotient (IQ), or language development in children followed to 7 years of age. The concern that in utero SRI exposure is associated with a delay in motor skills and milestone achievement development has been lessened by evidence that development was still in the normative range in these studies and that no effects of in utero exposure were noted at evaluations beyond 1.5 years of age. Similarly, studies that suggest that diagnoses of autism spectrum disorders (ASDs) and ADHD as related to in utero SRI exposure inconsistently control for confounding factors such as underlying maternal diagnosis/illness severity, other exposures such as tobacco and alcohol, as well as family history of these behavioral disorders. With better control for these variables, more recent studies find no association between SRI exposure and ASD or ADHD.

Sertraline and paroxetine are the SRIs with the largest evidence base of use in breastfeeding and negligible concentrations detected in infants. Relative infant doses from breast milk are often less than 2% of adjusted maternal dose or have milk/plasma ratios less than one. Citalopram, fluoxetine, and venlafaxine are more commonly associated with infant concentrations greater than 10% of the adjusted maternal dose. In general, there are low rates of adverse effects, which are short-lived, in breast-fed infants whose mothers were treated with SRIs. With fluoxetine, in case reports, breast-fed infants of fluoxetine-treated mothers gained less weight after birth, although adverse behavioral effects were not observed. Colic was reported in three infants who were breastfed by mothers taking fluoxetine.

It is important to remember that both breastfeeding and infant metabolism change over time. The full-term neonatal cytochrome

Telegram: @medical_k

www.konkur.in

P450 activity is approximately one-half of that found in adults. The collective data on serum levels suggest that infants older than 10 weeks are at low risk for adverse effects from antidepressants. Premature infants, and those with immature liver function, may have an increased risk of adverse effects initially. As the baby matures, those risks lessen. As the baby grows, the quantity of milk ingested will increase—but so will the intake of other food sources, leaving breast milk as a smaller proportion of nutrient intake.

In summary, there is no evidence to support stopping or failing to start SRI treatment in pregnant or lactating mothers. One caveat applies to the newer SRIs, including vortioxetine, vilazodone, and levominalcipran. Because these drugs' mechanisms of action are like other SRIs, there is no theoretical reason for risks to be different—but they have not been studied. It is, therefore, wiser to choose an older drug when possible.

TRICYCLIC ANTIDEPRESSANTS. The data show no evidence of increased incidence of congenital malformations in fetuses exposed to TCAs, although evidence is less extensive than that for the SRIs, and most reported exposures have been to clomipramine. Increased likelihood of preterm birth and low birth weight at an OR of ~1.5 mirrors the findings of SRI-exposed pregnancies, and like SRIs, there have also been reports of PPHN and cardiac septal defects related to TCA exposure. Secondary TCAs (i.e., nortriptyline, desipramine) may be preferred in pregnancy based upon fewer hypotensive and anticholinergic effects. A poor neonatal adaptation syndrome has been described with SRI exposure, and some evidence suggests it could be more severe and include anticholinergic symptoms of urinary retention and bowel obstruction. TCAs are not typically found in measurable amounts in nursing infants. Respiratory depression and sedation, the only adverse outcomes reported with any TCA, occurred in an infant whose mother took doxepin. Of the drugs in this class, nortriptyline has been studied the most as a treatment for breastfeeding women. Children exposed to TCAs both in utero and through breast milk have been followed through preschool and compared with children who were not exposed to these drugs, and no

Telegram: @medical_k

www.konkur.in

developmental problems were found. Due to increasing preferences for SRI treatment, fewer long-term studies are available following in utero TCA exposure.

MONOAMINE OXIDASE INHIBITORS. The use of monoamine oxidase inhibitors (MAOIs) is less optimal than many other agents in pregnancy for several reasons. First, studies have found growth restriction in animals receiving doses more than the maximum human recommended dose. Second, pregnancy-induced hypertension is a common complication of pregnancy that often has an insidious onset; further exacerbation of that condition using MAOIs may lead to placental hypoperfusion and have serious fetal consequences. Third, if premature labor occurs, tocolysis with β-mimetics may be obstetrically indicated but not possible because of potential interaction with the MAOI. Fourth, anesthetic management in labor may be complicated by the relative contraindication of opioids in patients taking MAOIs. If pregnancy occurs while the patient takes MAOIs, a gradual cross-taper to a more evidence-based drug is the preferred strategy. Guidelines have been suggested for appropriate obstetrical anesthesia and analgesia for women treated with MAOIs.

BUPROPION. Bupropion's dopaminergic mechanism of action and role in smoking cessation gives it an important place in the treatment armamentarium, and it is preferred by many reproductive-aged women concerned about SRI-associated weight gain. Data on bupropion are growing but still scant compared to those available for SRIs. Some small studies raised concerns about an increased risk of ventricular septal defects and left outflow tract heart defects among exposed infants, but numerous recent studies have not supported these concerns. A recent systematic review and meta-analysis including more than 5 million pregnancies reported an odds ratio of 1.23 (95% CI 1.01 to 1.49) for the use of bupropion during the first trimester and occurrence of cardiac malformations in the offspring, a statistically significant but likely not clinically significant association. The challenge of adequately powering studies to look at rare heart defects remains, and the studies to date have not consistently

Telegram: @medical_k

www.konkur.in

controlled for important confounding effects of maternal illness. A recent review on the management of ADHD during pregnancy recommends bupropion as the preferred therapy and notes that the drug appears to be compatible with pregnancy. No associations have been found between bupropion use and late gestation effects, neonatal withdrawal/toxicity, or developmental (neurobehavioral) teratogenicity, but data are limited at this point. A few small studies have assessed the degree to which bupropion passes to breastmilk. One study, conducted on two breastfed infants of mothers currently taking bupropion, was unable to detect bupropion, and its active metabolite, hydroxybupropion, in the blood of either infant. Infant exposure has been measured at 0.14% of the standard adult dose of bupropion and is therefore very small.

MIRTAZAPINE. Mirtazapine is a novel antidepressant with noradrenergic and selective serotonin effects. It can be extremely useful for women with sleep issues or nausea and vomiting of pregnancy, but there is far less evidence about the use of mirtazapine in pregnancy than is available for SRIs. The case literature showed effectiveness in rapid alleviation of hyperemesis gravidarum, based on serotonin 3 receptor blockade. Treatment benefits were obtained at doses of 7.5 to 45 mg/day, and in some cases, mirtazapine was administered initially through intravenous fluids, and the treatment course was concluded after 10 days. In a study of first-trimester mirtazapine exposure, there was no increased rate of malformations and similar rates of spontaneous abortion and preterm birth compared to pregnancies with other antidepressant exposures. The estimated infant dose through breast milk is about 1.8% to 4.4% of the maternal dose.

FIRST-GENERATION ANTIPSYCHOTICS. Although FGAs have been utilized in pregnancy for decades and are historically offered to manage hyperemesis gravidarum, our understanding remains limited to observational studies and case reports. As with any study on a gravid population, our research questions remain limited by the safety of subjects and human research ethics. The available data are

Telegram: @medical_k

www.konkur.in

reassuring, supporting that FGAs are unlikely to be major teratogens. However, an association between haloperidol exposure during the first trimester and limb abnormalities has been inconsistently demonstrated. Some studies have associated FGA use with major malformations, but the study designs failed to control for confounders. For example, in a meta-analysis of nearly 75,000 births among women treated with a low-potency antipsychotic (chlorpromazine), there was a 0.4% increased risk of malformations compared to the general population. Another systematic review found that the high-potency antipsychotic haloperidol was not associated with increased risks of malformation. Furthermore, in a meta-analysis of studies of parents with schizophrenia, the rate of malformations and perinatal death did not differ from the general population. Preterm birth and small-for-gestational-age births may be more common with FGA than SGA exposure.

Use of these agents in the second and third trimester is associated with slightly increased rates of perinatal complications, low birth weight, and transient perinatal syndromes (withdrawal symptoms, extrapyramidal symptoms, difficulty with feeding, and possible neonatal jaundice and functional bowel obstruction) that generally resolve within days but may last for up to 10 months after birth. Again, these studies failed to control for likely confounders, such as severe mental illness. Lactation studies of FGAs consistently report infant to maternal plasma concentrations at less than 10%. There may be an increased risk of gross motor skills delay among exposed infants at 6 months. However, this appears to be transient, with no difference between exposed and unexposed infants at 1 to 2 years. Continued treatment is recommended, given the high risk to the mother and offspring during a recurrence of psychosis and the minimal risks of treatment. The use of such agents as augmentation or adjunctive agents (in combination with antidepressants or mood stabilizers) in treating mood and anxiety disorders must be weighed against the severity of illness. Lower-potency FGAs have a greater risk of hypotension, while higher-potency agents confer risk for extrapyramidal symptoms. Intermediate-potency agents such as perphenazine constitute a useful compromise in this drug category.

Telegram: @medical_k

www.konkur.in

SECOND-GENERATION ANTIPSYCHOTICS. Our understanding of the safety profile of SGA use in pregnancy has made significant strides in recent years. A recent report on data belonging to the National Pregnancy Registry for Atypical Antipsychotics confirms that SGAs are unlikely to have a major teratogenic effect, with an odds ratio comparing exposed to unexposed infants of 1.48 (95% CI, 0.625 to 3.517). A review including data on 14,000 women utilizing SGAs during pregnancy found no association between congenital malformations and the use of either aripiprazole, olanzapine, or quetiapine. However, there was a statistically significant, though of questionable clinical significance, increased risk for malformations among users of risperidone and paliperidone. Authors could not comment on the safety of ziprasidone, clozapine, amisulpride, asenapine, lurasidone, and sertindole use during pregnancy due to limited data. Another study of over 1 million Finnish women, with data collected from 1996 to 2016, demonstrated an increased risk of pregnancy complications related to glucose metabolism, including gestational diabetes, Cesarean section, large-for-gestational-age infant, and preterm birth, among women taking either an FGA or SGA. However, controls were pregnant women without any history of antipsychotic use during pregnancy. Of note, maternal mental illness was not assessed nor controlled for and therefore a likely confounder in the study. A systematic review published in 2017 supports continuing women on the minimum effective dose of SGA throughout pregnancy, recognizing that discontinuation during pregnancy results in a high risk of relapse of mental illness, with weighty repercussions for both mother and offspring.

SGAs confer less risk for extrapyramidal side effects in the mother than FGAs, and the same is likely true for neonates exposed in utero. In a study of 142 pregnancies with exposure to SGAs, the antipsychotic dose was inversely related to gestational age at birth and positively related to the likelihood of NICU admission. Higher rates of respiratory distress were reported when SGAs were combined with mood stabilizers. Intake of SGA through milk leads to 0.1% to 10% maternal dose, and most are considered compatible with lactation. (There are theoretical concerns about the effect of

Telegram: @medical_k

www.konkur.in

aripiprazole on milk production, however, and this should be considered for women who are having difficulty establishing breastfeeding.) The National Pregnancy Registry for Atypical Antipsychotics continues to accept eligible subjects to further our understanding of the benefits and risks of SGA use during pregnancy (http://womensmentalhealth.org/clinical-and-research-programs/pregnancyregistry/).

While the above demonstrates that most FGAs and SGAs are compatible with both pregnancy and breastfeeding, there is one that should be used only with caution. Clozapine has the rare but serious possible side effect of inducing fatal agranulocytosis in adults, and therefore particular caution should be demonstrated with use in pregnancy and lactation.

LITHIUM. Decisions surrounding lithium use in pregnancy and lactation should be taken with care. Women being treated with lithium are likely to have a severe illness, with potentially devastating consequences for both mother and child associated with discontinuation. This considerable known risk must be weighed against the known risks of treatment, which are less substantial than previously believed. The scientific community continues to assess the risk of Ebstein cardiac anomaly following first-trimester lithium exposure. While the risk was originally cited as 400-fold, this risk was later revised to 10- to 20-fold (0.5–1 per 1,000). Some argue the risk may be even lower due to methodologic limitations in extant studies. A recent study analyzing data from more than 1 million pregnancies found a slightly increased and dose-dependent risk of cardiac anomalies, on the order of one additional case per one hundred live births. Despite this dramatic reduction in perceived risk, fetal echocardiography is recommended to rule out the presence of cardiac malformations as a precaution. There may be other risks associated with the use of lithium in pregnancy, but thus far, there is a lack of consensus regarding gestational size increases and preterm delivery. While many clinicians are daunted by the risks posed by lithium use, it should be remembered that approximately 85% of women with bipolar disorder who discontinue mood stabilizers for

Telegram: @medical_k

www.konkur.in

pregnancy will relapse. Continuation of lithium throughout pregnancy will therefore be the choice that best minimizes risk for many patients with bipolar disorder.

Neonatal signs of lithium toxicity have been described to include muscle flaccidity, inhibition of normal neonatal reflexes, lethargy, cyanosis, and cardiovascular effects, including atrial flutter, tricuspid regurgitation, and congestive heart failure. Careful monitoring of maternal lithium concentration in pregnancy is required because of the dramatic shifts in fluid volume during pregnancy. A higher glomerular filtration rate, coupled with the increased plasma volume, often requires higher doses in the gravid woman to achieve comparable serum lithium concentrations. Lithium crosses the placenta freely, and maternal and fetal plasma concentrations are similar. Maternal serum lithium should be closely monitored as delivery approaches. Although lithium is commonly held for 24 to 48 hours prior to delivery to reduce infant exposure, there is no scientific evidence to demonstrate that this practice reduces the risk of adverse outcomes.

Furthermore, missed doses of lithium place the mother at significant risk of relapse following delivery. Because of possible dehydration during labor, rapid loss of fluid volume after delivery, and potentially elevated gestational lithium doses, reinstatement of lithium therapy in the recently delivered mother should be gradual to approximate pregravid doses. Early postpartum measurement of lithium concentrations and maternal side effects is required.

Reports of successful breastfeeding and healthy infants of well-informed and clinically stable mothers treated with lithium have shifted perceptions surrounding the use of lithium in lactating women. The mean concentration of lithium in breast milk is approximately half that of the maternal serum concentration, ranging from 20% to 70%. Lithium concentrations in the serum of breastfeeding infants were, on average, one-third of the level found in maternal serum, but with considerable variability, with infant-to-maternal serum concentration ratios ranging from 5% to 67%. However, given the large range in concentrations observed, laboratory monitoring of infant serum lithium, TSH, blood urea nitrogen, and creatinine immediately

Telegram: @medical_k

www.konkur.in

postpartum and up to 6 weeks of age is recommended, with ongoing monitoring every 2 to 3 months thereafter for the duration of breastfeeding. Long-term neurobehavioral assessments have found no difference in exposure relative to nonexposed siblings in the two studies. Recent literature suggests that lithium presents less risk to the breastfed infant than previously thought. Women who are will be well served by clinicians that engage them in personalized discussions surrounding the risks and benefits of breastfeeding while taking lithium.

ANTIEPILEPTIC DRUGS (AEDS). Our understanding of the safety and risks associated with the use of antiepileptic drugs (AEDs) during pregnancy and breastfeeding is largely drawn from neurology literature. Convergent studies from numerous AED registries associate first-trimester use of carbamazepine and valproate with neural tube defects in 0.5% to 5% and major malformation in up to 16% of exposed offspring, with valproate conferring a greater risk than carbamazepine. Valproate was also associated with greater fetal death rates than other AEDs. This finding led to the recommendation that women taking AEDs take an increased dose of daily folate (4 mg/day), thereby mitigating some of the risk of neural tube defects. Other than neural tube defects, reported malformations include heart defects, urogenital defects, and oral clefts. Oxcarbazepine, while related to and like carbamazepine, has been little studied. Experimental animal studies indicate that risks are similar to those of carbamazepine, but human data are lacking.

Lamotrigine has gained attention as a therapy for bipolar depression in pregnant women, as registry data have demonstrated no difference in rates of neural tube and cardiac malformations compared to the general population. Initial studies of comparably small population size found a small increase in the incidence of oral clefts among infants of mothers taking lamotrigine. More recent, larger studies have found no increased risk of facial malformations. A case-control study in 2016 further supported the favorable profile of lamotrigine, showing no difference in orofacial cleft or cleft palate rates among infants exposed and unexposed during pregnancy. Of

Telegram: @medical_k

www.konkur.in

note, lamotrigine carries FDA approval for the treatment of bipolar depression. However, it has not demonstrated efficacy in managing acute mania. It should also be remembered that estrogen has a major effect on glucuronidation, thus substantially increasing clearance of lamotrigine across pregnancy and likely necessitating higher doses. While there are, regrettably, no clear guidelines for psychiatry on prophylactic dose changes of lamotrigine in pregnancy, clinicians can be guided by the guidelines for neurology.

Lamotrigine, carbamazepine, and valproate all demonstrate compatibility with breastfeeding. The dose excreted in breastmilk, divided by the maternal dose, ranges from 9% to 18% for lamotrigine, 1% to 6% for valproate, and 4% to 6% for carbamazepine. Rare cases of lamotrigine-associated adverse events have been reported, including thrombocytosis and rash. Maternal levels should be monitored, and infant levels can be monitored when there is a concern for toxicity in the infant, possibly suggested by difficulty breathing, rash, poor feeding, or drowsiness. There have been no reports of adverse events clearly attributable to valproate; however, thrombocytopenia was reported in one case of a breastfed child whose mother was taking valproate, and hepatotoxicity remains a theoretical risk. While carbamazepine is generally well tolerated by the breastfed infant, some infants have demonstrated transient mild hepatic toxicity, poor feeding, and sedation associated with carbamazepine exposure. Infants should be monitored for jaundice, poor weight gain, and drowsiness. If there is a concern for elevated levels of carbamazepine, infant serum liver enzymes, blood counts, and a carbamazepine level can be assessed. When AED exposure is limited to breast milk, there is no evidence for adverse impact on IQ, verbal and nonverbal memory, or executive function by age 6.

In summary, while all antiepileptics are considered compatible with lactation, there are significant concerns about the use of carbamazepine and especially valproate in pregnancy, and they should be discontinued if possible. If used, folic acid supplementation (4 mg daily) is essential. A wise course of action is to prescribe these drugs in reproductive-aged women only when all other possible treatments have failed, thus answering in advance the question of

Telegram: @medical_k

www.konkur.in

whether it will be possible to discontinue. More information on these drugs is needed, and pregnancy registries have been established both in the United States (North American Antiepileptic Drug (AED) Pregnancy Registry: 1-888-AED-AED4 (1-888-233-2334) http://www.massgeneral.org/aed/) and in Europe (EURAP Registry (International Registry of Antiepileptic Drugs and Pregnancy): http://www.eurapinternational.org/registry/index.php).

REPRODUCTIVE SENESCENCE

The Menopausal Transition

Menopause—the cessation of ovulation and absence of menses for 1 year—is due to the depletion of responsive ovarian oocytes and generally occurs between 47 and 53 years, with an average age of 51 in the United States. Perimenopause describes the period of hormone fluctuation leading up to amenorrhea and can begin as early as ten years prior to the menopausal transition. Women frequently experience somatic and psychological symptoms during this period, and ovulation and menses typically become more erratic. On average, women experience symptoms associated with the menopausal transition for 4 to 8 years.

An effort to operationalize the stages of reproductive aging resulted in The Stages of Reproductive Aging Workshop (STRAW), a seven-stage system anchored by the final menstrual period. Menstrual cyclicity and FSH measurement are indices used to determine one's reproductive stage. However, psychiatric symptoms do not correlate with hormonal measurements, so treatment is determined based on clinical assessment alone. While the staging system may offer a helpful index for gynecologists tracking a woman's progress through perimenopause and following the menopausal transition, psychiatrists do not utilize it.

Surgical menopause occurs when the ovaries are removed. Surgical menopause differs from natural menopause in the abrupt decrease in estrogen levels and abrupt rise in FSH levels, compared to variable fluctuations in hormone levels occurring over the natural

Telegram: @medical_k

www.konkur.in

menopausal transition. In natural menopause, the ovaries remain intact and secrete androgens, including testosterone and androstenedione, which can be converted in many tissues to estrone, a weak estrogen. Elective bilateral oophorectomy at the time of hysterectomy (surgical removal of the uterus) was historically performed in women in their 40s or older undergoing hysterectomy for benign disease, with the rationale that removal reduced risks of ovarian cancer, and avoided the potential for re-operation for additional ovarian surgery. Because women in this age range were approaching natural menopause, the advantages of ovarian preservation were thought to be outweighed by the risks. This paradigm has drastically shifted in recent years, with ovarian preservation now recommended for women undergoing hysterectomy for benign disease until age 51 or even older in selected cases. This shift arose with accumulating evidence that surgical oophorectomy is associated with serious long-term health consequences, particularly in women of younger ages. In particular, elective oophorectomy was associated with increased risks of all-cause mortality, cardiovascular disease, chronic kidney disease, cognitive impairment/dementia/parkinsonism, depression, anxiety, glaucoma, sexual dysfunction, and osteoporosis. However, some of these effects were mitigated by hormone replacement with estrogen during surgical oophorectomy.

Both men and women age and experience an age-related decline in reproductive capacity, but only women experience complete gonadal cessation. Loss of reproductive capacity may present a psychological challenge to those not reconciled to the loss of fertility. However, even with gonadal failure, the availability of donor oocytes and sperm means that pregnancy can be initiated in a menopausal woman with an intact uterus who elects to pursue that option. Some women find these multiple options overwhelming. The menopausal transition is not only a marker of life stage, but it also presents biologic and psychological challenges unique to women.

Physical Symptoms of Menopause. Vasomotor symptoms, or hot flushes, are the hallmark distressing sequela of the menopausal

Telegram: @medical_k

www.konkur.in

transition and consist of sudden episodes of perspiration, flushing, chills, clamminess, anxiety, and a sensation of extreme heat in the upper body (particularly in the face, neck, and chest). Symptoms last, on average, 1 to 5 minutes and occur daily in over 85% of women, and up to 10 times daily in up to one in three women. Lifestyle alterations such as layering clothing, consuming cold beverages, lowering the surrounding environmental temperature, and avoiding consumption of alcohol and caffeine can improve these symptoms in some women. However, pharmacologic interventions are often necessary to manage symptoms and maintain quality of life. HT with estrogen alone or with progesterone is the mainstay of treating vasomotor symptoms, with various formulations including oral pills and transdermal patches, gels, or sprays. Testosterone in combination with HT has also been investigated as a treatment for vasomotor symptoms. However, symptom improvement was not demonstrated, and there were negative consequences on lipid parameters, clitoromegaly, hirsutism, and acne, and testosterone is not currently recommended for the treatment of vasomotor symptoms. Tibolone, a synthetic steroid with tissue-specific estrogen and progesterone action, is another treatment under investigation to treat vasomotor symptoms, but it is not considered first-line therapy. When there are contraindications or intolerances to HT, SSRIs, and SNRIs (one particularly well studied is paroxetine), clonidine, and gabapentin are all effective alternatives to HT for the treatment of vasomotor symptoms. Phytoestrogens (plant-derived substances with estrogenic biologic activity) found in soy and soy-related products have no demonstrated benefit in reducing vasomotor symptoms in numerous placebo-controlled trials. There is also insufficient evidence for the use of herbal remedies such as black cohosh, ginseng, St. John wort, and ginkgo biloba. Similarly, estrogen agonists and antagonists (tamoxifen, raloxifene) are ineffective in treating vasomotor symptoms.

Vaginal atrophy, which results from a hypoestrogenic state, can also lead to distressing symptoms of vaginal dryness, discharge, pruritis, and pain with intercourse. Thinning of vaginal tissue can cause bleeding and fissuring, and loss of elasticity can result in

Telegram: @medical_k

www.konkur.in

narrowing and shortening the vagina. Changes in vaginal pH and vaginal discharge ensue, with increased risks of urogenital infections and sexual dysfunction. Topical administration of estrogen in cream, ring, or tablet formulations is beneficial in reducing these symptoms and has decreased or nonclinically relevant systemic absorption. Ospemifene, an estrogen agonist/antagonist, has evidence of benefit for vaginal atrophy symptoms and is FDA approved for treating moderate-to-severe dyspareunia from menopausal vaginal atrophy. Nonestrogen water-based or silicone-based vaginal lubricants and moisturizers may also be used to treat women who wish to avoid HT.

Menopausal Status and Depression. Depression occurring around the menopausal transition was previously attributable to "empty-nest syndrome," or what was termed "involutional melancholia." Recent acknowledgment that women's roles may encompass more than child-rearing has helped to change this view, and in fact, many women report an enhanced sense of well-being as they can pursue postponed goals. However, there is no question that the menopausal transition does confer a risk for depression. The perimenopausal transition is associated with a two- to fourfold increased risk of depressive symptoms and a twofold increased risk of a depressive disorder in medically and reproductively healthy women *without* prior history of major depressive disorder. These increased risks remained after correction for numerous factors, including hot flashes, poor sleep, and adverse life events, which have challenged the interpretation of earlier studies. Although there is no association between mean hormone levels and mood, one large study found that higher variability of between-visit estradiol concentrations in women relative to their nondepressed, premenopausal baseline was the strongest risk factor for the onset of a depressive disorder. This strongly argues for a mechanistic role of estradiol fluctuations in the onset of perimenopausal depression. Hot flashes were 1.3- to 2.2-fold more likely in women with perimenopausal-onset depressive symptoms and depressive disorder, a factor that argues for a shared neurophysiologic mechanism of perimenopausal depression and vasomotor symptoms.

Telegram: @medical_k

www.konkur.in

Other risk factors for perimenopausal depression include a personal history of mood disorder, previous reproductive-related mood disturbance (such as postpartum and/or premenstrual mood disorder), and psychosocial stress.

Perimenopausal Cognitive Changes

Women commonly report cognitive changes during perimenopause; however, the symptoms are typically mild and develop gradually and are therefore difficult to distinguish from the experience of normal aging. Literature suggests that women may struggle with verbal recall and processing speed during perimenopause, though measurable changes were typically subtle and transient. A 14-year longitudinal study assessing cognitive changes among 400 women demonstrated a significant decline in immediate and delayed recall when comparing pre- and postmenopausal performance. Menopause-related hormonal changes are also correlated with cognitive performance. Limited evidence supports a role for stimulant medications in treating these symptoms.

Treatment of Menopausal Symptoms

Hormone Replacement Therapy. Several health outcomes associated with the use of HT have been studied. Generalizability is made challenging due to differences in study design in the age of initiation, duration of use, dosage, and estrogen or progesterone formulations used in these studies. The most important variable in gauging hormone effect on long-term health is likely the woman's age when hormones are initiated; women who are close to the menopausal transition may benefit from extended exposure to estrogen, whereas initiation many years remote from the menopausal transition is more deleterious than beneficial. The question of whether to initiate or continue this therapy poses a medical, financial, and philosophical challenge. The results of the Women's Health Initiative (WHI) and its secondary analysis suggested that cardiovascular risks and benefits conferred by a standard combination of an oral estrogen plus progestin (conjugated equine estrogens plus

Telegram: @medical_k

www.konkur.in

medroxyprogesterone) or a standard dose of equine estrogen preparation are dictated by the timing of their administration. Oral estrogen or estrogen-progestin protected women from cardiovascular disease if a woman was within 10 years of the menopausal transition but increased risk in women 20 or more years postmenopause. Stroke risk was increased 1.3-fold in women randomized to HRT relative to placebo and did not vary based on age at HRT use. This may be because oral estrogen promotes venous thromboembolism regardless of age. Benefits conferred by HRT in the WHI included protection from bone fracture and reduced colorectal cancer risk

However, because not all estrogens have the same molecular properties, the WHI results are not generalizable to other hormone products. In particular, evidence suggests that more physiologic preparations, such as transdermal estradiol patches, creams, and suppositories, may minimize risks while retaining benefits. A negative effect of synthetic progestins compared to progesterone has also been advanced as an explanation for some of the WHI findings and related epidemiologic studies. Although concern exists that combined oral hormone use after menopause increases the risk of breast cancer and affords minimal, if any, cardioprotection, there is also evidence of benefits. Hormone use retards bone loss and reduces osteoporosis and fracture risk, maintains urogenital integrity, stabilizes mood and other critical brain outputs, including motor abilities, and maintains body habitus and composition. Whether HT protects against dementia also remains controversial. Some experts have suggested that the increased risk of venous thromboembolism and stroke with orally delivered estrogens may have counteracted the trophic effects of estrogens on neurons and glia. It is thought that nonoral routes of delivery of estradiol may prove neuroprotective because there is no increased risk of venous thromboembolism with nonoral formulations. Although women at midlife tend to gain weight, studies have demonstrated that women who use HRT gain less weight and that the weight gained is preferentially deposited in a gynecoid (hips and thighs) rather than android (abdominal) pattern.

Of note, recent, prospectively collected population data showed that rates of dementia increase in both men and women after age 75

Telegram: @medical_k

www.konkur.in

years but that the increase is much greater in women than in men (relative risk, 2.1). However, rates of dementia in women were reduced in proportion to years of hormone use after the menopausal transition. Ongoing estrogen use for longer than 10 years, especially when begun contemporaneously with the onset of the menopausal transition, reduced the risk of dementia in women compared with men. It is not widely appreciated that the brain converts testosterone to estradiol and that men typically have, always in their lives, more estradiol bathing their neurons and glia than women do except when women are pregnant. Because men do not experience gonadal cessation at midlife as women do, their brains continue to be protected by estradiol indefinitely.

Increasing basic research substantiates a role for estrogens in neurotrophic and neuroprotective functions. These are alternatively mediated via classical genomic functions of ERs, which, when ligand-activated, travel to the cell nucleus, where they act as transcription factors. In addition, cell membrane ERs are associated with activation of second messenger cascades and highly amplified gene transcription. SERMs target the same receptors as estrogen—ER subtypes ERα and ERβ—but differ in transcriptional ability based on unique ligand-induced conformational change of the ERs to facilitate the interaction of ERs with coactivators and consequent agonism or antagonism of ER-mediated DNA transcription.

The risks and benefits of using existing SERMS by postmenopausal women are being defined. Antagonism of ERβ may pose a risk for heightened depression and anxiety, given the demonstration of ERβ facilitatory effects on serotonergic activity, social interaction, and positive behaviors in rodent models of depression. Both ER subtypes are involved in neuroprotective functions. The relative density of each receptor subtype in a particular brain region likely underlies the ultimate action of any ER ligand. Although it was postulated that the mixed agonist/antagonist raloxifene would have adverse effects on mood and memory because it is associated with hot flushes, there are no long-term studies that have addressed this in a group of women older than age 70 years when the risk of dementia is sufficient to be able to discern effect.

Telegram: @medical_k

www.konkur.in

Most studies find no increased risk of depressive symptoms in SERM-treated women, and some find SERM-associated amelioration of depressive symptoms. Likewise, raloxifene in doses of 60 or 120 mg was not associated with memory impairment and was recently reported to reduce the risk of mild cognitive impairment in postmenopausal women.

In contrast, tamoxifen was associated with memory impairment when added to standard chemotherapy in breast cancer survivors. Aromatase inhibitors have been shown to have the most deleterious effect on cognitive functioning, which argues for an important role for estrogen in safeguarding neural health. The effect of long-term specific SERM use on cognitive function is an area in need of further study. There is even less information about the long-term risks and benefits of partial estrogen agonists or SERMs than about more conventional estrogen preparations. The same holds for phytoestrogens derived from soy and flaxseed. Direct-to-consumer marketing of hormone preparations means that patients have more questions, concerns, and ambivalence. Although women want more information and guidance, physicians are poorly reimbursed for this type of counseling and often lack sufficient information.

Current evidence does not reveal a strong association between estrogen use and breast cancer. In particular, even in older women, oral contraceptive use is not associated with an increased risk of breast cancer. In terms of quality of life, hypoestrogenism can impair sexual enjoyment and libido and cause hot flushes, night sweats, and profound fatigue. These sequelae can generally be ameliorated or reversed with estrogen use. The trend is to use the smallest dose that relieves these symptoms.

Progestin use is generally recommended for women with a uterus to guard against the development of endometrial hyperplasia and carcinoma; whether or to what degree progestin use compromises the beneficial effects of estrogen use requires clarification. The availability of a progestin-containing IUD may minimize or obviate altogether the risks of systemic progestin exposure. The adverse effects that most limit progestin use are depression and bloating. In animals, including monkeys, progestins increase irritability and diminish sexual

Telegram: @medical_k

www.konkur.in

receptivity, and progesterone has fewer negative side effects than synthetic progestins such as medroxyprogesterone acetate (Provera). Furthermore, concern has been raised that the use of progestins other than progesterone will reverse cardioprotection by promoting vasoconstriction. Progestins may also increase the risk of breast cancer, particularly when used continuously. Women who previously experienced depression or PMS are most prone to mood disturbances with progestin use. To avoid or minimize the effects of progestin exposure, it is prudent to prescribe the smallest amount of progestin necessary to protect the endometrium from hyperplasia or use a progestin-containing IUD. Recent data support the notion that antidepressant and antidementia agents are more efficacious in women when they are estrogen replete. To achieve the best risk–benefit profile, it is worth titrating and individualizing route, dose, type, and regimen to maximize benefits and minimize adverse effects.

The literature has inconsistently supported a role for estradiol in treating depression among postmenopausal women. Women with endocrinologically confirmed perimenopause and a diagnosis of depression in a double-blind placebo-controlled trial experienced a 70% to 80% remission rate during treatment with 50 to 100 μg per day of 17β-estradiol, compared to a 22% rate of response in placebo-treated subjects. However, estradiol was equivalent to a placebo in a postmenopausal trial. Other studies have failed to demonstrate that estradiol has a significant therapeutic effect on mood symptoms during perimenopause. A longitudinal study including 291,709 female Veterans demonstrated a correlation between suicide and estradiol therapy. Women receiving estradiol showed a twofold increased risk of death by suicide compared to women not receiving estradiol. While efforts were made to control for age, race, and medical comorbidities, additional research is necessary to examine potential confounders and clarify causality.

The potential role of progesterone and its derivatives in the modulation of cognitive symptoms associated with the menopausal transition is also an active area of research. However, research has largely been limited to animal models. Inconsistent results surrounding the effects of estrogen and progesterone on affective and

Telegram: @medical_k

www.konkur.in

cognitive symptoms prompted a recent study using a rat model with induced ovarian failure. Rats were administered either estradiol, progesterone, levonorgestrel, estradiol, and progesterone, or estradiol and levonorgestrel and underwent assessments of spatial memory, anxiety-like behaviors, and depressive-like behaviors. Combined estradiol and progesterone treatments offered the most favorable outcomes in the spatial memory task, anxiety-like behaviors, and depression-like behaviors. Another study on ovariectomized rats demonstrated that rats administered exogenous progesterone performed worse on a working memory task than rats that received a control solution. The potential therapeutic applications of progesterone and its derivatives in managing depressive symptoms not exclusive to the menopausal transition have received considerable attention in recent years, as described in the Mechanisms section above.

Alternatives to HRT for Perimenopausal Symptoms. Antidepressant drugs are increasingly prescribed for hot flushes based on clinical trials that show benefit with low-dose SRIs/SNRIs (escitalopram, venlafaxine, and duloxetine, but not sertraline). It is proposed that antidepressants may improve distress tolerance of hot flushes via symptomatic improvement of coexisting mild insomnia, anxiety, dysphoria, and/or irritability. Sleep disturbance affects nearly 50% of perimenopausal women and significantly contributes to reduced quality of life. Perimenopausal insomnia is variably attributed to vasomotor symptoms, night sweats, and mood disturbance but can also be independent of those symptoms. Targeting the sleep symptoms with sleep hygiene interventions may result in sleep and quality-of-life improvement of similar magnitude to that provided by HRT.

Because the evidence does not consistently support the use of HRT for perimenopausal depression, mood symptoms are best targeted with antidepressant treatment. Clinical guidelines for antidepressant treatment in the general population apply. For women who have vasomotor symptoms and/or sleep disturbance, in addition

Telegram: @medical_k

www.konkur.in

to mood symptoms, an antidepressant that can target hot flushes, as well as mood, may be beneficial.

The utility of HRT in supporting cognition also remains questionable, but other treatments show promise. A double-blind, placebo-controlled crossover study of 16 perimenopausal women with cognitive complaints demonstrated significant improvement with atomoxetine. Participants with a history of attention-deficit/hyperactivity disorder (ADHD) were excluded from the study. Another double-blind, placebo-controlled, cross-over study of 32 perimenopausal women demonstrated improvement in delayed verbal recall and subjective memory with the administration of the stimulant lisdexamfetamine. While lisdexamfetamine was largely well tolerated in this study group of healthy women, blood pressure and heart rate increased significantly. Stimulant therapy might be appropriate for some women with impairments in executive function. However, the potential benefits of therapy must be weighed against the significant cardiac risks. An antidepressant may be helpful for cognitive symptoms in women with comorbid depression. Other medications have not shown a clear benefit in addressing cognitive symptoms associated with the menopausal transition.

Aging

Further investigations are required to distinguish the psychological and biologic effects of aging from perimenopause. Aging is associated with diminished resilience and circadian rhythmicity in men and women. Desynchronized or reduced biologic rhythms may compromise sleep, cognition, and mood. While the loss of ovarian estrogen and progesterone associated with the menopausal transition is exclusive to women, men and women experience a gradual decline in adrenal and gonadal androgen production. Androgens help to maintain libido, muscle mass, strength, and energy.

Psychological factors play a role in age-related disability. Disease and disability may present psychological challenges and engender the need for changes in lifestyle and employment. Those who successfully transition to later life can adapt to the medical, biologic, and psychosocial challenges frequently accompany aging. Stress

Telegram: @medical_k

www.konkur.in

may accelerate certain aging processes. In a longitudinal population study of the older adults, women whose cortisol levels remained elevated across the observation interval of 2.5 years displayed progressive cognitive impairment, whereas cognition improved in those whose cortisol levels returned to the normal range. The most common stress was social isolation.

Older adults are at an increased risk for depression compared to younger and middle-aged adults. Most older adults, 80%, experience an episode of depression, and 50% have two or more episodes. Yet, depression remains underrecognized and undertreated among older adults, in part because the presenting signs and symptoms may be confused with dementia or other concomitants of aging. Depression is not a normal aspect of aging. Therefore, clinicians of older adults should maintain vigilance for the signs and symptoms of depression and offer treatment for this common yet highly morbid disorder.

FUTURE DIRECTIONS

Molecular medicine is poised to exponentially expand the understanding of the mechanisms mediating sexual differentiation and reproductive physiology. The therapeutic promise will be greatly expanded as it becomes ever more possible to translate understanding into clinical therapeutics. Concomitantly, given the importance of reproduction to the sense of mortality and immortality, it is likely that even greater anxiety will be aroused by the development of ever-more-clever ways to tinker with reproductive options. The idea that sex steroids imprint the brain in fundamental ways that determine sexual identities, longevity, and aptitudes will make it difficult to think in a polarized manner about gender, families, and aging. Both individual and collective psyche will continue to be even more troubled by the implications for society and self.

Reproductive behavior is extremely personal, but governments and religions often feel compelled to interfere with personal decision making and regulate what is and is not acceptable. A sense of invasion is unavoidable. Offspring may or may not applaud their biologic and social parents' choices and actions. Indeed, concepts of

Telegram: @medical_k

www.konkur.in

belonging and identity will likely be ever more challenged and challenging as more and more reproductive choices are offered to individuals and couples. As the choices burgeon, individuals may feel ever more compelled to seek guidance from authorities and those in the helping fields. This means that the knowledge and scientific expertise needed for those who write laws, interpret supposedly normative teachings, and provide guidance will increase. The medical insurance system is ill-equipped to deal with the reproductive options currently being offered to prospective patients. Insurance companies will likely fail to appreciate the nuances of what constitutes medical necessity or coverage eligibility when reproductive options are perceived as departures from convention. Controlled reproduction has already refined the understanding of reproductive wellness and reproductive rights, but access has not kept pace with the options. It will be interesting to see how various cultures grapple with ideas about the role of women in reproduction and family building in the face of population expansion in some parts of the world and contracture in others. It will also be interesting to see how the expansion of societal concepts of gender affects our understanding of reproductive issues and our research priorities. It will take true societal wisdom to harness the promise of molecular medicine for reproductive and women's health in a manner that protects the vulnerable and satisfies critics and regulatory authorities. Science literacy will continue to be critically necessary, especially for policy development and application.

30.2 Genetic Counseling for Psychiatric Conditions

JEHANNINE AUSTIN, PH.D., M.S., F.C.A.H.S., C.G.C., AND HOLLY L. PEAY, PH.D., M.S.

Historically, healthcare professionals have only infrequently had discussions with patients about the etiology of psychiatric illness and/or familial risk for recurrence. When these topics are addressed with patients, it is often brief and at a high level and/or performed in a group-based context (e.g., psychoeducation). However, discussing the etiology of psychiatric disorders with patients and their families in a deeper manner can be profoundly impactful. These discussions tap into fundamental, existential questions from patients and family members–questions such as, “Why me”?, “Did I do something that caused this”? and “Could I have prevented it”? Some people with psychiatric disorders explicitly ask about the origins of their condition(s), whether genetic or genomic information can provide useful information and the chances of recurrence in the family. But other times, patients and their family members find it difficult to ask these questions because such questions are a challenge to articulate or because they are anxious about the answers. Having an explanation regarding why one developed an illness is critical to the process of adapting to the condition. In the absence of being provided with a comprehensible explanation for the cause of illness, affected individuals will develop their own explanatory model. An explanatory model is important in determining how one behaviorally responds to that illness, including one’s treatment adherence. Studies show that people are more likely to actively participate in treatment if the treatment is seen to directly address what the individual perceives to be the cause of their illness. (See Inglis et al., 2014.)

Genetic counseling about psychiatric conditions has been provided by professional genetic counselors for several decades to address these fundamental questions about why psychiatric disorders develop. Interest

Telegram: @medical_k

www.konkur.in

in the service is widening, perhaps because of strong positive data about patient outcomes of psychiatric genetic counseling, improved understanding of genetic and environmental origins of these conditions, and enhanced focus on risk modification and management. Increasingly, requests for genetic counseling may be made directly to psychiatrists. Many psychiatrists are well placed to initiate discussions about and respond to patient requests for genetics education and to provide counseling around these issues. They may have knowledge of their patients' needs and family histories within ongoing therapeutic relationships. An ideal model, however, involves providing psychiatric genetic counseling in the context of a multidisciplinary team, with collaboration between genetics and mental health professionals. Such collaborative consultation is particularly relevant when there is a need for advanced risk assessment, collection and construction of complicated family histories, and counseling about the appropriateness and clinical utility of genetic and genomic testing.

Advances in knowledge and growth in the clinical use of genomic technologies may also increase inquiries to psychiatric professionals. For example, there is discussion ongoing in the literature regarding whether genetic testing for copy number variants (CNVs) should be performed routinely for all individuals with schizophrenia. Further, people are already able to upload their raw genomic data from direct-to-consumer genetic testing sites like 23andme or ancestry.com into third-party tools that generate polygenic risk scores (a summary variable, which combines many genetic variants of small effect to estimate a person's genetic risk for a given trait or condition) to learn about genetic predisposition to a range of outcomes, including both physical and mental health.

Telegram: @medical_k

www.konkur.in

AR is a 33-year-old client with bipolar disorder. She discusses how much she would like to be a mother, but she is fearful about her mental health during and after pregnancy. She also is haunted by the idea that her child would develop bipolar disorder. She asks for expert advice about the advisability of having children.

BN is a 57-year-old client with recurrent major depression. He has two teenage children and is concerned about their mental health. He asks for advice about how to distinguish between normal teenage moods and a developing mood disorder. He wonders what symptoms to look for and what the appropriate response would be to any emerging symptoms. BN expresses his belief that at least one of his two children is bound to become ill because the illness is so common in his family.

KC is a 20-year-old who requests a consultation. She has no history of psychiatric symptoms. She indicates that she received concerning results about her future risk for a mood disorder from a direct-to-consumer genetic testing company. She would like your advice about how to interpret the results and what she should do to prevent becoming affected.

A couple in their early 30s requests a consultation. One partner has a history of mild social anxiety and has a parent with schizophrenia. The other partner has no contributory history. The couple is planning to become pregnant and asks your advice about embryo selection using polygenic risk scores to ensure a baby does not develop schizophrenia.

Although the situations and queries appear quite different, the underlying issues are similar. Their client's concerns are based on the etiology of psychiatric illness, symptom identification, and risk for occurrence or recurrence in family members. Mental health professionals likely have clients who express such concerns regularly. These questions can lead to discussions about the cause of psychiatric illness, symptom effects during and after pregnancy, teratogen concerns with psychiatric medications, recurrence risks for asymptomatic family members, the utility of genetic and genomic testing, and early intervention and identification efforts—all topics that fall under the umbrella of psychiatric genetic counseling.

Telegram: @medical_k

www.konkur.in

WHAT IS GENETIC COUNSELING?

Genetic counseling is the "process of helping people to understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease." The National Society of Genetic Counseling describes the process as integrating the following factors:

- Interpretation of family and medical histories to assess the chance of disease occurrence or recurrence.
- Education about inheritance, testing, management, strategies for mitigating risk, resources, and research.
- Counseling to promote informed choices and adaptation to the risk or condition.

The process aims to minimize distress and facilitate adaptation, increase one's feeling of personal control, and facilitate informed decision-making and life planning.

Although the term "genetic" counseling suggests a primary focus on the genetic contributions to a condition, in fact–in the context of complex conditions in particular–both genetic and environmental components of the presenting condition are discussed together in a holistic manner. The complex interplay between genes and environment in the etiology of these conditions requires a comprehensive approach to care.

GENETIC COUNSELING FOR PSYCHIATRIC DISORDERS

Many healthcare professionals consider referring to genetic counseling when genetic testing may be an option for a patient. Yet genetic counseling has a long history of meaningful application for a variant of conditions, even *prior to* the development of genetic tests for those conditions. For psychiatric disorders, genetic counseling can be conducted with or without the aid of results from genetic or genomic testing.

Outcomes of psychiatric genetic counseling include:

- a better understanding of etiology and risk in the family,
- psychological support related to familial risk,

Telegram: @medical_k

www.konkur.in

- a discussion of the limited role of parenting in causing or preventing psychiatric disorders (reflecting current scientific knowledge),
- increased empowerment and self-efficacy in terms of managing one's condition,
- early symptom identification and early intervention, and
- facilitated meaning-making and coping.

In our experience, interest in genetic counseling is generally driven by the client's appraisal of psychiatric illness within the family. Several factors that play into a client's evaluation of the illness in the family include the perception of the condition, beliefs about what caused the condition within the family, existing perceptions of risk to family members, and the ability to control risk. With regard to these issues, in the context of psychiatric disorders:

- Affected individuals and family members often describe the disorders as caused by genetic/biologic and environmental factors.
- When considering the risk to family members, many close relatives and individuals with bipolar disorder and schizophrenia overestimate the risk of family recurrence.
- Individuals affected with bipolar disorder and schizophrenia often perceive moderate to high illness burden, and relatives often perceive high burden.
- There is some evidence that a subset of individuals with mood and psychotic disorders, and a subset of their relatives, are less willing or unwilling to have children because of fear of illness in the children.

During a psychiatric genetic counseling consultation, it is helpful to ask the client about these factors because they will likely have a strong effect on how they perceive the information provided and the resulting decisions and life plans that they make.

www.konkur.in

Cassie and her partner, John, sought genetic counseling as a couple to understand more about the causes of mental illness. John said that he wanted to better understand—as he put it: “Why is my sister-in-law’s obsessive-compulsive disorder (OCD) so much more severe than Cassie’s”? In discussion, it emerged that he doubted that Cassie should have been diagnosed with OCD. In exploring the couple’s existing explanations for the cause of illness, it emerged that John perceived environmental factors to be more important in the etiology of OCD. Cassie’s sister had a traumatic event before her symptoms became noticeable to the family, while Cassie had experienced nothing similar. After John repeated several times that he felt that Cassie’s OCD was not as severe as her sister’s, Cassie broke down in tears, saying that she felt John minimized her OCD and that she felt her symptoms were just as severe though not as overt as her sister’s. The clinician was able to help John identify that he was terrified that genetics might be involved because of what this might mean for children that he and Cassie planned to have together. This fear caused him to deny Cassie’s experience. By the end of the session, John and Cassie had come to a better understanding and were developing a plan to work on protective factors together.

Telegram: @medical_k

www.konkur.in

After Anna (12) received a diagnosis of an eating disorder, she and her mother requested a session to discuss the causes of eating disorders. Both Anna and her mom were very distressed about the diagnosis, and both seemed to attribute the disorder entirely to genetic factors. Anna said: “It’s genetic, right? I’m just different…and weird.” Anna’s mom was feeling helpless, watching Anna as she withdrew from her friends. It emerged that Anna’s mom had experienced anorexia as an adolescent and felt profoundly guilty for having “passed on” a condition that she experienced as life-threatening at a similar age. As the clinician discussed the roles of genes and environment in the etiology of eating disorders and relating this back to Anna’s life experiences, both mom and daughter expressed feelings of relief. For the mom, the relief was about feeling that perhaps it was not “all my fault,” and for Anna, it was about feeling less fundamentally different (flawed). As the conversation turned toward protective factors, Anna’s mom began sharing strategies with her daughter that she had found to be helpful in her own recovery. This provided her with a feeling that she was not entirely helpless and seemed to bring the pair closer together.

THE ROLES OF THE GENOME AND ENVIRONMENT IN MENTAL HEALTH

Knowledge about the etiology of psychiatric disorders is improving steadily. These improvements allow more accurate and specific answers about why a disorder has occurred in a particular individual and family. Likewise, it increases our ability to offer more accurate assessments of risk and counseling about environmental modifications.

It is widely accepted that psychiatric illnesses tend to run in families. Disorders can recur in families for several reasons, including shared genomic variation and/or shared environmental exposures. Thus, as described previously, genetic counseling for etiologically complex disorders entails discussions around *both* genetic and environmental risk factors. For example, consider a case in which a father with bipolar disorder has concerns about symptoms developing in his children. Genetic counseling may focus on the following:

Telegram: @medical_k

www.konkur.in

- The family history is indicative of both genetic and shared environmental risk in the family.
- Risk factors for the children, stemming from those genetic and environmental factors.
- Early symptom identification and early intervention (aiming to modify the environment and thus affect the genetically mediated progression of the condition).
- A discussion of the benefits and limitations of environmental modifications aimed at reducing the risk or minimizing emerging symptoms.

The concept of complex disorders accounts for the interplay of the genome and the environment and also includes the broader biologic and physiologic mechanisms of evolution and development that operate within societies and cultures. The onset of most cases of psychiatric conditions, like the onset of other common disorders, is thought to arise when an individual has numerous risk-increasing genomic variants and has experienced one or more environmental or experiential influences that contribute to risk.

The complicated nature of the etiology of psychiatric disorders can be understood by considering an illustrative family history, such as shown in Figure 30.2–1. This pedigree illustrates many different aspects of complex conditions, including the following:

1. Although the variants predisposing to disorders A and B segregate through the family, the disorders in question aggregate in the family.
   a. Individuals may have the necessary genomic susceptibility and never experience any illness because they lack the necessary environmental exposures.
   b. Individuals may have the necessary genomic and environmental susceptibility and never experience any illness due to protective factors (genomic and/or environmental).
2. A different number or complement of susceptibility variants and/or different environmental exposures leads to the existence of two etiologically related disorders in the family, A and B.
3. The typical ages at onset of disorders A and B range from early adolescence through middle adulthood, making it difficult to determine who in the family will remain unaffected throughout their lifespan.

Telegram: @medical_k

www.konkur.in

4. Genomic variants that increase risk are common in a general (unaffected) population.

Genetic Contributions to Psychiatric Disorders

The first evidence that genetic factors were operating in psychiatric disorders came from analysis of families with multiple affected members, twin studies, and adoption studies. Family studies clearly indicated familial etiology, although the relative contributions of genes and environmental factors were unclear. Twin and adoption studies provided insights into the relative contributions of etiologic risk factors, and for all major psychiatric disorders, consistently indicated the importance of genes and environment. Family, twin, and adoption studies also provided insight into the genetic heterogeneity and phenotypic variability of mental disorders. Table 30.2–1 provides a summary of family, twin, and adoption data for schizophrenia.

Thousands of candidate gene, linkage, and genome-wide association studies have provided insight into genetic variants that increase susceptibility to psychiatric illness. Different types of genetic variation can influence vulnerability to psychiatric illness, including single nucleotide and CNVs. These variants do not generally confer vulnerability to a single discrete psychiatric diagnosis. Rather, they confer vulnerability to a range of psychiatric disorders. It is important to remember that many individuals with genomic susceptibility will never develop a psychiatric illness.

Empirical risk for first-degree relatives: ~5–15% Empirical risk for second-degree relatives: ~2–8% Also increased risk for spectrum disorders (schizoaffective disorder, schizotypal personality disorder, and paranoid personality disorder)	Monozygotic twin concordance: 40–60% Dizygotic twin concordance: 10–16% Heritability: ~80%	Support high heritability; unique environmental exposures play a significant role, whereas the influence of shared environmental exposures is more limited

Telegram: @medical_k

www.konkur.in

Single Nucleotide Variants. Many genetic risk variants for psychiatric disorders are of small effect and very common in the general population. For example, the hundreds of individual single nucleotide variants that have been associated with bipolar disorder and schizophrenia in the context of genome-wide association studies typically have odds ratios in the range of 1.01 to 1.3 and are so common in the population that a large percentage of the population will have some of them. While individually, these variations cannot provide much information about the risk of developing a psychiatric disorder, there has been great interest in combining these variants together to generate polygenic risk scores (PRS, as described briefly above). It is important to know that PRSs will not be able to determine who will and will not develop a psychiatric disorder. At present, the best PRS for schizophrenia explains only 11% of the overall liability for developing the condition, and it has been estimated that the upper limit of the liability for schizophrenia that could be explained by a PRS is ~25%. Therefore, the clinical utility of these tests remains in question.

Copy Number Variants. Structural variations like copy number variants (CNVs–missing or extra segments of chromosomes) also contribute to the etiology of psychiatric disorders. Though less common in the population than single nucleotide variants, when present, they have a much larger influence on the risk for psychiatric illness. The best-known example of this phenomenon is 22q11 deletion syndrome, where individuals who have this deletion have a greater chance to develop a variety of psychiatric disorders, including psychotic disorders, with an associated risk of ~25% to 30%.

Epigenetics. New research approaches and a growing understanding of the function of the human genome have opened promising studies of epigenetic phenomena (heritable changes that do not involve alteration to the DNA sequence). A detailed understanding of the causal pathway from any of the identified genomic contributions to disorder susceptibility is not yet clear. It is apparent, however, that changes in the genome do not unequivocally result in major psychiatric disorders. Rather, current knowledge suggests that particular variants may increase the risk of adverse response to an environmental stimulus or may more directly affect a biologic process in a way that facilitates the onset of particular symptoms. As described in the benchmark findings of the Schizophrenia

Telegram: @medical_k

www.konkur.in

Working Group of the Psychiatric Genetics Consortium (2014), most genomic variants exert an effect through altering gene expression rather than through altering protein structures.

Environmental Contributions to Psychiatric Disorders

For disorders like psychiatric disorders that have a complex etiology, environmental factors are typically necessary for the onset of the condition. In this context, “environment” is a catch-all phrase meaning anything outside of the genome that can affect the expression of a gene, including the in-utero environment during development, shared and nonshared family environment, exposures to harmful substances, and medical history.

Adoption studies have indicated that the strongest environmental risk factors are unique or nonshared factors (meaning factors that make siblings less alike). Many misinterpret this to mean that the home environment is not important in the development of psychiatric illness because a shared home environment should make siblings more alike. But home environment and parenting style are not equal for all siblings and may not be stable over time. Outside effects on the home environment, sibling order, sibling relationships, and differences in sibling personality traits (themselves genetically mediated) have effects on the home environment. Even if the home environment is identical, siblings likely perceive differences in their shared environment based on their individual developmental history and personality traits. In some cases, the perception of differences may be as important as actual differences. Thus, the identification of unique factors as the most important environmental contributors does not exclude the relevance of the home environment in the etiology of psychiatric illness. It is important for parents to know, however, that in many cases, the home environment is unlikely to be sufficient to either cause or prevent psychiatric illness in children.

Unique environmental risk factors are unequivocally important in the development of psychiatric illness. Factors that are likely to play a role in schizophrenia and bipolar disorder include the following:

- Obstetrical complications
- Substance use, specifically cannabis and methamphetamine
- Childhood trauma
- Being reared in an urban environment

Telegram: @medical_k

www.konkur.in

- Advanced paternal age
- Immigration
- Maternal prenatal infections
- Season of birth
- Head injury
- Stressful life events
- Viral infection

Unfortunately, many of these factors are pervasive and largely outside of an individual's control.

The interplay between genomic and environmental risk factors is complicated; for example, some cases of depression may be caused through an interaction of genomics and environment, such that susceptibility variants are expressed in an adverse environment but not a supportive one.

PRIORITIES OF PSYCHIATRIC GENETIC COUNSELING

Genetic counseling integrates exploration of psychological and social issues that result from living with a psychiatric condition (personally and/or in the family) with a personal and family medical history (FMH). Increasingly genetic counseling also includes genomic risk information. Genetic counseling takes a person-centered approach that focuses on supporting the client in making autonomous informed health decisions.

Telegram: @medical_k

www.konkur.in

Table 30.2–2.
Steps and Process of Genetic Counseling

Solicit and clarify the client's presenting questions and goals for genetic counseling.
Explore the client's existing explanation for the cause of illness.
Collect and review medical and family medical history.
Identify support systems.
Verify diagnoses in the proband and other affected family members when possible.
Address issues and concerns identified through the genetic counseling process.
Assess the client's emotional and intellectual capacity before proceeding to determine the approach to the provision of education and counseling.
Provide information at cognitively appropriate levels.
Note that the processing of emotional reactions is intertwined with the provision of information.
Assess the personal meaning of the information and the client's willingness to negotiate various risks and burdens.
When applicable, assist the client in arriving at a decision by discussing available options; discuss benefits and limitations of each alternative.
Assist the client with adapting to the risk status in the family.
Assist in formulating a plan that the client is able to carry out.
Provide follow-up counseling and support. Continue to assess the client's and family's understanding of the information and the effect of the information, risks, or decisions.

The basic components of genetic counseling are outlined in Table 30.2–2.

The optimal approach is a two-way exchange of information regarding the client's expectations for the session, understanding of the problem/diagnosis, and future plans or options.

www.konkur.in

A couple in their mid-30s with a 10-year history of infertility had been trying to adopt a child. Recently, the adoption agency told them of a baby being placed for adoption because the biologic mother was affected with bipolar disorder and did not feel she could adequately care for the baby. The FMH collected on the newborn baby did not identify others in his family with psychiatric disorders. The recurrence risk for bipolar disorder in the newborn was, therefore, estimated to be between 5% and 20%, with additional risks for other psychiatric disorders (Table 30.2–3). The couple individually reacted disparately to the estimated risks. When the professional explored factors contributing to their feelings regarding the risks, the husband shared his experience with a childhood neighbor who had "some kind of mental illness" and detailed the "torment and agony" that the child brought to the family. Retorting, the woman shared that her coworker had bipolar disorder and did "just fine" with the help of medication. She, therefore, did not feel that the risks for psychiatric disorders were of concern. The professional facilitated a discussion of the spectrum and meaning of mental illness, along with recurrence risks. Although the couple did not come to an agreement at that meeting over the potential for adopting the child, they did feel that the information and sharing of experiences and perspectives were beneficial. They agreed to return in one week to reach a decision regarding the adoption.

Providing Educating and Counseling about Etiology

By its very nature, genetic information is complex and often technical, with a vocabulary that is not familiar to clients. Traditionally, the professional selects the initial core of information presented to the client. Significant effort should be made to identify and include the information considered most relevant by the client and to identify and address the emotional and psychological issues that discussing this information can raise. The topics that are most often included are a description of the disorder and its natural history, explanation of the possible modes of inheritance and possible implications for family risk, discussion of environmental risk factors, options for early intervention, medical management, prevention or treatment, and (in the cases in which it is applicable) the availability of genomic testing and the associated risks, benefits, and limitations. Owing to the complexity of the information and discrepancies in client learning

Telegram: @medical_k

www.konkur.in

styles, providers may use a variety of means to communicate the information, including written material; graphics that visually present genetic terms, concepts, and modes of inheritance; and a detailed letter summarizing the clinical encounter; as well as other available resources (e.g., support groups and web-based resources).

Discussions about etiology can raise emotional issues related to guilt, shame, and stigma. Thus, the provision of understandable and meaningful information should be coupled with empathy, compassion, and sensitivity to provide a multifaceted genetic counseling encounter. Individuals, couples, and families who experience greater feelings of stigma, higher perceived burden, and higher perceived risk for recurrence in offspring or siblings are likely to require more intensive counseling around family vulnerability. Whereas issues of the stigma associated with mental illness are commonly encountered by the client and addressed by the practitioner within the psychiatric setting, additional efforts to assess stigma pertaining to a genomic etiology seem prudent. Likewise, some clients may experience a higher perceived burden due to the recognition of a genomic contribution and feel that they have less control over preventing or treating their condition.

Periodic follow-up provides opportunities to address emerging issues as they present to the client. The extended nature of such contact provides an optimal opportunity to assist the client or family member in receiving information when it is most relevant, as well as facilitating their use of the information and adaptation to its implications.

In some cases, genomic testing may inform risk, especially in cases with unusual presentation (i.e., highly loaded families; psychiatric symptoms manifesting along with dysmorphic features, birth defects, and/or learning difficulties that are not associated with the psychiatric phenotype). Consideration of genomic testing should include a careful review of potential benefits, limitations, and risks. A genetic counselor with expertise in psychiatric conditions should be consulted to confirm the appropriateness of genomic testing.

Communication of information to interested relatives is appropriate and encouraged within the process of genetic counseling. Invitations to family members to receive information related to the condition in question, the etiologic underpinnings, recurrence risks, and counseling to address the related psychological or emotional issues are encouraged. Summary

Telegram: @medical_k

www.konkur.in

letters describing the consultation can be particularly useful for sharing information with others in the family.

Counseling about Risk Reduction in Children

Clients with children or those considering having children often benefit from counseling specifically focused on the management of uncertainty and the potential for risk reduction. Clients are often keenly interested in information about environmental risk because it may facilitate the placement of blame away from parents while at the same time providing potential interventions that may reduce the risk for their children. Given the nature of risk factors, this counseling often focuses on their limited ability to reduce the risk of the onset of illness in at-risk individuals. There are, however, potential targets for intervention. At-risk individuals have been found to be more vulnerable to certain street drugs (most notably cannabis and methamphetamine) and should be educated about the possibility that such substances may trigger episodes of psychiatric illness. Thinking about the environment more broadly, it may be useful to suggest cognitive-behavioral therapy and the development of strategies for effectively coping with and managing stress. For affected parents with young children, parenting programs, social support, and daycare may be helpful. Providers should discuss the importance of early detection of psychiatric illness because early, and appropriate interventions improve prognosis.

Individuals with psychiatric conditions are often vigilant about monitoring for symptoms in children, though they may have difficulty determining normal behavior from abnormal. Psychiatrists should assist such families in achieving a balance between appropriate vigilance and inappropriate boundary setting or anxiety. Although it may be worrisome to have risk in the family, a family with an affected individual(s) is well placed to recognize early manifestations of symptoms. Encouraging and educating clients about their abilities in this capacity can increase their sense of control.

Risk Assessment

Different clients seek genetic counseling for different reasons, and not all will be interested in discussing chances for themselves or others in the family to be affected. Whether the client is interested in risk assessment should be explored at the beginning of the session, and–if provided–this

Telegram: @medical_k

www.konkur.in

should be done within the contextual framing of what is known about the etiology of these conditions. Therefore, it can be helpful to contract around risk communication twice, once at the beginning of the session and again once this contextual framing discussion has been completed. For clients who are interested in counseling about risk, some may prefer a qualitative discussion of the risk magnitude. These individuals may not welcome or benefit from receiving numerical risk information. For those who prefer a detailed numerical estimation of risk for recurrence, risks based on the family and medical history should be presented as a range to reflect the ambiguity of the estimates. In some cases, based on the family and medical history, it may be possible to suggest that one end of the range is more appropriate for a specific client.

Perceptions of high illness burden and limited control over onset are likely to result in less tolerance for familial risk. Clients often have preconceived ideas about their (or other family members') risk or affected status. These may be influenced by perceptions such as similarities to affected relatives or family and cultural beliefs. As such, risks, as provided, may differ from what is expected, and this should be explored during the consultation.

Individuals also vary in their capability to understand numeric risk. Many people perceive risks from a dichotomous, all-or-nothing perspective (i.e., it is or is not going to happen), and the presentation of risks in a numerical fashion (i.e., 1 person out of 10, or 10%) may be difficult for many clients to process. The baseline for risk provision should be absolute risks. Relative risks may be interpreted incorrectly, especially when the disorder is rare (such as autism). Once clients understand the absolute risk, in some cases, it may be useful to clarify understanding by discussing relative risks.

The majority of families have only one affected family member, and thus empirical risks often are in the range of 10% to 15% or lower. For individuals who do not wish to be given a risk number but instead prefer a qualitative assessment of risk, qualitative communication might be posed as follows: "You are right to think that your children have an increased chance of having (the disorder[s] in question). However, your children have a better chance of *not* having (the disorder[s] in question) than having it." The meaning of descriptive risks is highly subjective, and patients should be consulted about their understanding.

Telegram: @medical_k

www.konkur.in

Finally, it is important to remember that it is the client's perception of risks (perceived or presented) rather than the actual risk that is more likely to affect future decisions and outcomes. A client's perceived estimate of the likelihood that an event will occur is affected by their ability to recall or visualize examples of the occurrence and by their perceptions of the nature of the event (i.e., severity).

The FMH is used to assess the likely etiology of the disorder and estimate risks for recurrence in the family. Confirmation or clarification of the diagnosis or diagnoses in the family is essential to the provision of valid information. Topics that are specific to psychiatric disorders and are important to include in the FMH are listed below.

- Any psychiatric diagnosis, whether childhood, adult, postpartum, or geriatric
  - Age at symptom onset and at diagnosis
  - Subjective assessment of illness severity and treatment response
  - Potentially important environmental exposures (e.g., obstetric complications, cannabis use, head injury)
- Symptomatic, undiagnosed individuals and/or undiagnosed individuals treated with a psychiatric medication
- Developmental history (e.g., has the individual achieved normal milestones for age, such as independent living and employment for adults?)
- Social history
- Substance abuse
- Suicide and self-harm
- Birth defects, intellectual disability or learning disabilities, and unusual medical conditions
- The age and sex of at-risk family members

As mental health providers will be aware, challenges to collecting psychiatric FMH may include guilt and stigma that limit knowledge of diagnoses among family members; the frequency of undiagnosed psychiatric illness; and the dynamic nature of emerging psychiatric symptoms that may result in diagnostic change over time.

Risk Assessment Based on Family and Medical History

In most cases, risk assessment is based on FMH in the absence of meaningful genomic test results. FMH data are used together with empiric

Telegram: @medical_k

www.konkur.in

risks (see Table 30.2–3). It is vital to understand that empiric risks are not specific to any one individual or family but rather are risks obtained from studies that aggregate recurrence risk among large numbers of families. Factors specific to the proband, the family, and at-risk individuals allow for the tailoring of empirical risks. At its most basic, such tailoring requires considering the following series of questions.

Questions about the affected individual(s) in the family:

1. Who will be considered to be affected in the family?
   1. Many individuals who meet the criteria for a major psychiatric disorder are not diagnosed or treated, many are incorrectly diagnosed, or the diagnosis may not be known by the client.
   2. The typical late-teenage/young-adult onset of many major psychiatric disorders confounds pedigree assessment because it is possible that individuals who are genetically susceptible and will become symptomatic have not yet experienced the onset of illness.

2. Are illnesses in the family etiologically related?

Telegram: @medical_k

www.konkur.in

   1. Heterogeneity within diagnostic groups and the occurrence of comorbidity make it more difficult to evaluate which disorders might be etiologically related in a family. The high prevalence of psychiatric disorders confounds the issue because some illnesses might be unrelated to other illnesses in the family.
   2. Generally, disorders that share a spectrum and disorders that are frequently comorbid are considered to be etiologically related. It is difficult to evaluate the relationship between other groups of disorders, although family studies have indicated that, on a research population level, no psychiatric diagnosis occurs in a vacuum; that is, if a relative has one psychiatric illness, family members are empirically increased risk for a range of other disorders as well.
   3. Assortative mating, whether between a couple with concordant or discordant diagnoses, complicates the assessment of the etiologic relationship.
3. What may factors in the family history raise or decrease risk?
   1. Families in which there are multiple affected individuals over several generations, or an unusual clustering of illness in one sibship, likely have the highest chance for recurrence.
4. What factors in the affected individual's psychiatric history may raise or decrease risk?
   1. Age at onset: If age at onset is younger than expected, the risk to relatives may be increased. Relatives likely have an increased risk of experiencing early onset as well.
   2. Severity: More severe illness, and illness that is treatment-resistant, may be associated with increased risk to relatives.
   3. Sex: Depending on the psychiatric disorder in question, the sex of the affected individual may increase or reduce the risk to relatives, although the data are mixed. For example, siblings of females with schizophrenia have been shown in some studies to have a higher risk than siblings of males with schizophrenia.
   4. Environmental exposures: Relatives of affected individuals with known significant environmental exposures may have a reduced risk of the condition if they do not share the same environmental exposure. For example, relatives of an individual with psychosis who has a history of crystal methamphetamine use may have a lower risk of illness (assuming that they are not exposed to the drug). However, consideration of environmental factors is difficult to apply when providing quantitative risk assessment.

Telegram: @medical_k

www.konkur.in

   5. Birth defects or a developmental/medical history suggesting an underlying genetic syndrome potentially increases the risk to family members.
5. What etiology best explains the illness in the family? What are alternate explanations?
   1. Although research suggests that the vast majority of psychiatric disorders are complex in etiology, it is not possible definitively to rule out Mendelian or nontraditional modes of inheritance in any particular family. When family patterns suggest the possible involvement of a genetic variant associated with a major effect, risks often exceed the empirical risk range. In many cases, such “loaded” families do not actually reflect the actions of a genetic variant of major effect, but regardless of cause, such a pattern in the family is indicative of increased risk. Families with multiple affected individuals may benefit from a referral to a genetics professional.

Questions about the at-risk individuals in the family:

1. For what disorder(s) might the individual(s) be at risk?
   1. In the case of psychiatric spectrum disorders, it may be difficult to evaluate *for what specific disorder* family members are at risk. Providers should familiarize themselves with appropriate spectrum disorders based on the at-risk individual’s family history. Family members may be at increased risk for comorbid disorders as well.
2. What factors about the individual may raise or decrease risk?
   1. Current age: At-risk individuals who are young have all of their years of greatest risk for the condition ahead of them, whereas older individuals have “lived through” a portion of their risk. Empirical risks generally reflect lifetime risk and can be qualitatively modified to reflect the at-risk individual’s age.
   2. Past psychiatric and developmental history: Individuals with existing psychiatric symptoms, another psychiatric disorder, or evidence of emerging psychiatric symptoms are at greater risk. Individuals with usual developmental histories (e.g., unusual social relationships; prolonged lack of gainful employment) may have a greater risk.
   3. Environmental exposures: Exposure to known environmental triggers may increase risk, although such exposures are currently difficult to identify and evaluate.

Telegram: @medical_k

www.konkur.in

When evaluating any family history, providers should be aware that the presence of any of the following “red flags” may significantly increase risk. The identification of any of these factors should call into question the use of a standard empirical risk range.

- Learning disabilities or intellectual disability (preceding/unrelated to cognitive deficits due to psychiatric phenotype)
- Birth defects in the client or family members, most notably heart defects or oral clefts
- Dysmorphic facial features
- Unexplained major medical problems
- Neurologic impairment is not explained by the psychiatric diagnosis or medication side effects
- Very early onset of psychiatric symptoms (e.g., schizophrenia during childhood)
- Highly loaded family history (e.g., multiple individuals in several generations affected with psychiatric disorders; diagnoses may vary)

Figure 30.2–2 provides an overview of risk assessment for a family at moderate risk.

The pregnant couple depicted in Figure 30.2–2 presented for risk assessment related to the current pregnancy. There was no relevant family history on the maternal side of the family. Ages at onset and illness severity were typical in the family, and no obvious environmental risk factors were reported. The empirical risk for bipolar disorder for a child born to this couple (reflecting one affected parent) is between 5% and 20%. However, this risk does not incorporate the distantly related paternal cousin who also carries the diagnosis. Therefore, risks at the lower end of the range provided may underestimate the risk for the offspring of this couple. The empirical risk for this child to develop any major affective disorder is between 20% and 30% (again, the family history suggests that the lower end of the range may underestimate risk). The history of depression in the paternal great-aunt is difficult to evaluate because depression may be part of the bipolar disorder spectrum but is very common in females without family liability to bipolar disorder.

Telegram: @medical_k

www.konkur.in

FIGURE 30.2–2. Pedigree of a family at moderate risk for affective disorder.

Families at High Risk (Exceptions). Matters are further complicated by the presence of families in which a combination of etiologic factors for psychiatric illness are skewed in a fashion that mimics a Mendelian pattern of inheritance (autosomal dominant or recessive), with multiple affected individuals in one or more generations. When evaluating such "loaded" families, it is important for the provider to consider the potential causes. Besides presenting unique psychological needs, highly loaded families have higher risks for recurrence, and genomic testing may be considered. Psychiatrists who are not highly experienced in genetics should refer such individuals and families to genetics professionals for evaluation and counseling.

The skewed presentation of psychiatric illness in selected families may be caused by a number of colliding factors that mimic single-gene inheritance. Some examples follow.

Complex Etiology with Unusual Accumulation of Risk Factors

It is possible that families with numerous affected individuals might have an unusual number of susceptibility variants segregating within the family, such that many family members have inherited multiple susceptibility-causing variants. One mechanism for this is "assortative mating," in which individuals with psychiatric illness have children with other individuals with psychiatric illness. Such families may also experience recurrent shared environmental exposures that contribute to the onset of the disorder. In

Telegram: @medical_k

www.konkur.in

these cases, the risk to other family members might be high, although not currently reliably quantifiable.

Genetic Variants of Large Effect. Although overall, they are rare, there are a number of genetic variants that have significant effects on the risk for psychiatric illness and often can involve other features. Examples include Huntington disease, 22q11 deletion syndrome (22qDS), Wilson disease, Wolfram syndrome, late juvenile- or adult-onset metachromatic leukodystrophy, homocystinuria, acute intermittent porphyria, coproporphyria, frontotemporal dementias, and early-onset familial Alzheimer disease. These conditions are examples in which the presence of a genetic variation responsible for the syndrome increases the risk for the development of psychiatric disorders compared to the general population.

22qDS is an example of an inherited disorder with significant variability and increased risks for psychiatric disorders. It is an autosomal dominant microdeletion syndrome localized to the long arm of chromosome 22 (22q11). The clinical spectrum is variable and may include clefting of the soft palate, heart defects (most commonly tetralogy of Fallot, ventricular septal defect or right aortic arch), velopharyngeal incompetence, immune dysfunction, mild intellectual impairment, and psychiatric disorders, although rarely does an individual have all of the symptoms. Approximately 30% of individuals with 22q deletion experience psychotic disorders; risk is also increased for mood disorders. The onset of psychotic symptoms may be earlier than typical. Attention-deficit/hyperactivity disorder (ADHD) is also relatively common.

A FMH from the following case study illustrating the variability of expression of 22q deletion syndrome is shown in Figure 30.2–3.

Telegram: @medical_k

www.konkur.in

A 29-year-old woman contacted a local psychiatrist for genetic counseling regarding her family history of schizophrenia and cognitive impairment. She was concerned that her future children might experience problems similar to those of her sister, nephew, and niece. The psychiatrist collected the FMH and constructed the pedigree. To confirm the diagnoses and to gain further information, the psychiatrist discussed the potential benefits and risks of obtaining medical records. The client decided to pursue this option and obtained permission from her affected sister. The psychiatrist received records on the affected sister and her 13-year-old son, who had mild intellectual disability. The records on the boy indicated that he had undergone genetics evaluation and testing and had been identified as having a microdeletion on the long arm of chromosome 22, consistent with 22q11 deletion syndrome. The records indicated that the client's sister also carried the deletion, although this information had not yet been shared with the family.

The identification of 22qDS in this family offered the option of genetic testing for others in the family. The 22q microdeletion is estimated to arise spontaneously in 80% to 90% of cases. However, this pedigree was suggestive of a hereditary form. Counseling in such situations is difficult owing to the variability of the disorder and the inability to predict the phenotype (e.g., the client may have the deletion and have a very subtle presentation). Genetic testing is warranted to clarify recurrence risks; however, issues regarding confidentiality of the acquired information require attention.

CHALLENGES POSED BY GENOMIC TESTING FOR PSYCHIATRIC DISORDERS

For the vast majority of individuals with psychiatric disorders, available genetic and genomic testing does not achieve clinical utility (A potential caveat is in regard to pharmacogenetic testing). As genomic technologies continue to improve and knowledge about variants that can increase vulnerability for psychiatric illness grows, identification of individuals who are at higher risk for developing psychiatric illness based on (for example) the number of illness-associated single nucleotide variants they carry will become more common. Appropriate applications of such developments

Telegram: @medical_k

www.konkur.in

clearly need careful consideration from both economic and ethical perspectives but may have important clinical uses. For example, at present, it can be very difficult to distinguish between emerging (prodromal) psychosis and normal adolescent behavior in youth who are at higher risk for psychosis (e.g., as a result of close family members who have experienced psychosis). However, some studies of prophylactic strategies to reduce risk among high-risk youth show promise, and for those in whom psychosis does emerge, early intervention is critical to allow for the best possible outcomes. Therefore, genomic technologies could be useful in determining which individuals might benefit most from prophylactic, therapeutic approaches.

FIGURE 30.2–3. High-risk family. ADHD, attention-deficit/hyperactivity disorder.

The clinical implementation of genomic testing for psychiatric illness is and will continue to be the subject of intense debate. Decisions about the initiation of clinical testing will likely hinge on: (1) the demonstration of adequate proof that the identified variants unequivocally increase the risk for psychiatric illness; and (2) affirmation that the information gained from the testing has clinical utility (e.g., informs risk management strategies) and/or demonstration of personal utility, such as testing that aids in coping and adaptation. Conflicting opinions notwithstanding, genomic testing for susceptibility to psychiatric illness is becoming more commonplace. Psychiatrists will be on the front line for receiving requests for genetic

Telegram: @medical_k

www.konkur.in

counseling and testing because of their established relationship with clients and families with psychiatric disorders.

The clinical identification of genomic risks will most likely occur before most individuals have access to preventative options. The option of knowing risks without having access to preventative options raises concerns regarding the effect of such knowledge on the individual's mood, anxiety, distress, self-image, reproductive decisions, and decisions regarding career, family relationships, insurability, employment, and, potentially, other areas.

Across many indications, the majority of persons undergoing genomic testing and receiving their identified risk status have not been shown to experience long-term adverse effects. However, it should be anticipated that those receiving results indicating increased risk for a condition may experience elevated levels of condition-related anxiety and depression soon after receiving results and a small number have prolonged difficulty in adjusting to their results. Supportive counseling should be available to facilitate the adjustment.

The pursuit of genomic counseling and testing by an individual has clear and profound implications for other family members. Consideration should be given to helping the client understand the potential reactions and effects that their decision to pursue genomic testing could have on close family members. The health professional can play a role in assisting the client in considering ways to share the information with selected significant others. Similarly, consideration should be given to the effect of such information on the spouse or significant other.

Individuals who have psychiatric susceptibility are arguably more likely to enter genetic counseling with higher baseline levels of mood disturbance and may be more likely to respond negatively to predictive testing information. The important role of stress in the onset and recurrence of psychiatric symptoms must also be considered; by providing an at-risk individual with stressful, anxiety-provoking risk information, might providers inadvertently hasten the onset of psychiatric symptomatology? More research in this area is vital to ensuring that clinicians do not take too paternalistic a stance, refusing wanted information to individuals who might benefit psychologically and medically (as well, refusing to provide wanted information may be a stressful, anxiety-provoking experience for a client), while on the other hand considering the inherent vulnerability in a population at risk for psychiatric

Telegram: @medical_k

www.konkur.in

illness. It is likely that the manner in which these delicate conversations unfold is important to client outcomes and that a focus on counseling around these issues is key.

Given the complexity and uncertainty that comes with genomic testing, the pretest counseling, ordering, interpretation, and communication should be made by experienced researchers and clinicians. When considering genomic testing, we recommend consultation with a genetics professional.

ADDITIONAL ETHICAL, LEGAL, AND SOCIAL CONSIDERATIONS

Key questions for the clinical applications of genetic testing in psychiatry concern uncertainty around when our knowledge is “ready” for clinical implementation, when, how, and to whom to offer to test, and critical issues regarding equity. Specifically, given the populations (predominantly of European ancestry) from which datasets for PRS are generated, these tests will be more informative for some groups than others. Although there are many benefits of genomics knowledge, scientists and the lay public have worried, from the beginning of genetic research, about the potential for harmful consequences of knowing one’s genomic makeup. How will family members, neighbors, communities, employers, health care providers, and insurance companies react to such information? Might healthcare providers request that persons at increased genomic risk take psychiatric medications prophylactically? Might employers limit job opportunities for those with increased risk for psychiatric illness, keeping them in positions with lower levels of stress? Will persons at increased risk be pressured not to have children? Might providing such risk information induce significant enough anxiety/stress to trigger the onset of illness? And finally, how will we educate families and the public about the availability of susceptibility testing for psychiatric illness? Public messages about susceptibility testing should be crafted in a way that does not increase the already heavy burden of stigma attached to individuals with psychiatric disorders and does not add to “courtesy stigma” attached to at-risk relatives. Increased public awareness of the hereditary component of psychiatric illness may heighten stigmatization. Conversely, having an identified, biologic basis may supplant current public perceptions that mental illness is somehow a personal or family failure in moral, spiritual, or attitudinal perspectives.

Telegram: @medical_k

www.konkur.in

The ability to provide susceptibility testing is likely to make psychiatric practice more complicated and will challenge the process of education, counseling, and informed consent. Psychiatrists are accustomed to communicating and receiving information that requires special consideration owing to its sensitive nature; handling genomic information from clients will be yet another sensitive topic to be considered from social and ethical perspectives. The diagnosis of a genomically influenced disorder may create risks not only for the patient but also for others within the family. Some clients may not choose to share genomic information with relatives, even though the information could be relevant to reproductive decisions, relationships, or even medical care. Coercion of affected relatives to undergo testing may become an issue, especially in the case in which at-risk relatives are pursuing genetic counseling to help guide their decisions. Parents may desire susceptibility testing of children even in the absence of preventive interventions and may risk stigmatizing the children and forcing information on them without informed consent. These situations call for careful attention to the confidential nature of the information, as well as the need to encourage family communication to discuss the potential for the associated personal, family, and social risks.

Historically, some attribution of psychiatric illness has been focused on child-rearing and the home environment. The current focus on the biologic nature of the psychiatric illness has been important for reducing guilt and feelings of blame in many families. It is unclear how a more nuanced understanding of environmental risk factors, potentially including home environment and parenting style, might affect perceptions of guilt. It is important that messages about risk reduction be crafted in such a way as to not lend credence to outdated notions of parental causation.

It can be anticipated that many individuals with clear-cut psychiatric diagnoses will not be found to have identified susceptibility variants. Test results with no identified variants are likely to cause some individuals to question the validity of their psychiatric diagnoses and may have a negative effect on treatment compliance. In addition, the absence of an identified genomic susceptibility might increase parental guilt and “force” responsibility for their child’s illness on their parenting efforts. A key aspect of pretest genetic counseling will be discussions about the meaning of a “negative” result.

Conversely, based on the very nature of susceptibility testing, many individuals identified as having susceptibility variants will never develop a

Telegram: @medical_k

www.konkur.in

psychiatric disorder. Counseling around the notion of susceptibility is complex, as is the necessary support for individuals who are at risk. Although the potential harm for such individuals is apparent, many may perceive benefits (perhaps related to perceived control and coping with vulnerability) that outweigh risks. If benign environmental modifications that reduce risk are identified, the concern around individuals with "positive" test results will decrease.

Finally, it is not yet clear how the public will react to genomic tests that indicate levels of risk that are not definitively predictive (like PRS), and indeed only modify risk estimations based on family history by a marginal amount. People with no psychiatric illness may perceive the importance of genomic results differently than those who have a psychiatric condition, while those who have a history of mild symptoms may re-evaluate past symptoms based on the results. It may be that individuals will interpret the resulting risk as higher than appropriate or that the predictive limitations will lead them to discount the results. Such appraisals are likely to vary greatly among individuals based on their history, personality types, and coping styles.

As individuals within society become more aware of the identification of genomic factors within the complex etiology of psychiatric disorders, it is anticipated that requests for psychiatric genetic counseling will increase. Although genomic testing may provide important psychological benefits for many individuals, the uncertainties inherent in the current level of knowledge pose challenges in the education and counseling of clients. Psychiatrists are appropriately positioned to provide genetic counseling (or referrals for genetic counseling) and ongoing therapy to families experiencing psychiatric disorders. The greatest opportunity for a benefit to clients will be provided through a multidisciplinary team comprised of mental health and genetics professionals who adhere to the basic principles of genetic counseling and maintain an awareness of the latest research findings relevant to psychiatric genetics. Genetic counselors within the geographical area of the psychiatrist can be identified through the National Society of Genetic Counselors (http://www.nsgc.org).

30.3 Physical Violence on Adults

Shannon F. Stromberg, M.D., Kyle Owen, D.O., and Nancy Martin, M.D.

Violence remains a significant public health concern that can include abuse, assault, domestic violence, torture, and homicide. While there are multiple types of violence, there is no common denominator for them all. Victims span all races and genders; however, fixed risk factors are identified for specific groups. For example, the leading cause of death for black males continues to be homicide. Women continue to be at the

Telegram: @medical_k

www.konkur.in

highest risk for lifetime sexual assault. Additionally, the type of work in which one engages may predict violence. For example, sex workers or law enforcement officers may face threats daily. Statistics indicate that most Americans will become victims of violent crime during their lifetime.

The costs of violence may lie well beyond mortality. The morbidity for an individual exposed to violence results in decreased productivity, medical disability, and psychiatric sequelae. Morbidity can have far-reaching societal implications, with violence or perception of violence impacting where people decide to live, raise and school their children, how late they stay out, or even where they walk or drive.

During the past 2 decades, there has been increased emphasis on education and prevention. Statistics indicate an overall decrease in the total number of cases and rates of violence during that time. Education and resources available for victims and those at risk continue to improve. Treatment modalities available to victims have significantly expanded and have led to decreased morbidity in survivors; however, there is a need to continue preventing violence in all forms.

TYPES OF ASSAULT, PREVALENCE, AND RISK FACTORS

Assault can be viewed in the context of two variables: who is being assaulted and where it occurs. With these parameters, assault can be classified into several categories. Violent crime, rape, domestic violence, workplace violence, and torture are the most commonly used identifiers to classify assault. These different types of assaults are most often reported via two different data collection systems: the Federal Bureau of Investigation's Uniform Crime Report (UCR), which collects reported crime information from local law enforcement agencies, and the Bureau of Justice Statistics' National Crime Victimization Survey (NCVS). This survey generates estimates of the likelihood of victimization from different types of assaults. For each type of assault, there have also been attempts to develop risk factor assessments. Age, gender identity, sexuality, race, history of a prior assault, past psychiatric history, substance abuse, and income have been found to impact assault risk for different categories of assault.

VIOLENT CRIME

Telegram: @medical_k

www.konkur.in

The UCR defines violent crime as murder and nonnegligent manslaughter, forcible rape, robbery, and aggravated assault. These categories exclude simple assault, which in the UCR is defined as an assault or attempted assault in which no weapon was used, or no serious injury occurred to the victim. Simple assault includes stalking, intimidating, coercing, and hazing.

Prevalence

In 2019, there were an estimated 5,813,410 violent crimes in the United States. Aggravated assaults accounted for an estimated 1,019,490 of this total, simple assaults were estimated at 3,800,190, and robberies were estimated to be 534,420. From 1993 to 2019, the rate of violent victimization (excluding simple assault) declined by 75%. The rates of all types of violent crimes in 2019 were lower than the rates observed in 2013.

Risk Factors

Males are more likely to experience violent crime than females. LGBTQ individuals are nearly four times more likely to be victims of violent crime, and they have higher rates of victimization in all types of violent crimes except robbery. Age plays a larger role, with those younger than 25 years at the highest risk. Racial and ethnic groups also appear to have different violent crime victimization rates. The groups most at risk for experiencing violent crime are persons of two or more races, American Indians and Alaska Natives. Black and Hispanic groups have higher rates than whites, while Asians have the lowest rate of any group. Lower-income households are more likely to be burglarized, and homelessness has also been shown to be a factor in increased physical assaults. Finally, multiple studies have shown substance abuse to increase the risk of victimization.

Perpetrators

Both the UCR and NCVS have limitations regarding the report of offender characteristics. It excludes any data from assaults and robbery not resulting in arrest. Another problem is that data are primarily generated based on the victim's incident report. Although these incident data can be used to define the victim's characteristics, they cannot be used accurately to define the offender. For example, the NCVS reports on victimization as

Telegram: @medical_k

www.konkur.in

reported by the victims. However, a tool as developed as the NCVS does not exist for offending as reported by the offender. Furthermore, incident data for victims cannot control for a situation in which one offender has assaulted multiple victims.

RAPE

The legal definition of rape varies from state to state. Some states strictly define rape, whereas others describe any sex crime as varying degrees of sexual misconduct or sexual assault. The UCR defines rape as follows: “penetration, no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person, without the consent of the victim.” In this section, rape refers to forced oral, vaginal, or anal penetration, and sexual assault refers to any forced sexual contact. The stereotype of the perpetrator being a stranger has been proven inaccurate by research, with nearly two-thirds of all sexual assaults being committed by someone known to the victim.

Prevalence

Unfortunately, obtaining accurate statistics is difficult because of underreporting and unacknowledged assault. The Rape, Abuse, and Incest National Network (RAINN) and NCVS estimate that nearly 70% of sexual assaults go unreported. Over 5 years, there were 463,634 victims ages 12 or older of rape and sexual assault each year in the United States. An estimated 139,815 rapes (UCR definition) were reported to law enforcement in 2019. This estimate was 2.7% lower than the 2018 estimate and 10.8% higher than the 2015 estimate. Native Americans remain at the most significant risk of sexual violence, experiencing 5,900 sexual assaults per year. RAINN estimates that 1 in 6 U.S. women and 1 in 33 U.S. men are victims of sexual assault. An estimated 21% of TGQN (transgender, genderqueer, or nonconforming) college students have been sexually assaulted, compared to 18% of non-TGQN females and 4% of non-TGQN males. In addition to being underreported, there are many rapes that the victim does not acknowledge. They often refer to the assault in more benign terms, such as a misunderstanding, even though it meets the legal definition of rape. Research has reported that this percentage is substantial; more than 50% of sexual assaults may go unacknowledged and, thus, unreported. Victims who fail to acknowledge

Telegram: @medical_k

www.konkur.in

having been raped usually believe that rape involves two strangers and greater force, as opposed to the views of those who acknowledge having been sexually assaulted.

Risk Factors

Although females are usually victims of rape and sexual assault, greater than 10% of victims are estimated to be male. Furthermore, most experts believe that males underreport more than females. Nevertheless, females 16 to 19 years of age have four times the risk of any other group of becoming a victim of sexual assault. Eighty percent of all rape victims are younger than 30 years, and the Bureau of Justice Statistics indicates that women 16 to 24 years of age are at the most significant risk for rape in the United States. Having been a victim of childhood abuse or previous assault increases the likelihood of further assault of all types. Many studies have also shown substance use and abuse to be a risk factor for sexual assault.

Perpetrators

Rape is considered a crime of power and aggression. However, controversy remains about whether the sexual predator's motivation is anger, power, sexual gratification, or control. Multiple research studies indicate that victims know the majority of perpetrators. Nonstrangers commit approximately 73% of all sexual assaults and 66% of rapes.

The Centers for Disease Control and Prevention (CDC) noted several factors for perpetration, including individual and relationship components. Individual risk factors included prior sexual victimization or perpetration, substance use, difficulty with empathy, aggressiveness and acceptance of violence, different sexual issues (early initiation, coercive fantasies, and impersonal sex), and hostility toward females. Relationship risk factors for perpetration included family environments characterized by physical violence, emotionally unsupportive families, associating with sexually aggressive peers, and poor parent–child relations.

DOMESTIC VIOLENCE AND INTIMATE PARTNER VIOLENCE

Domestic violence is defined as a pattern of abusive behavior in any relationship with the intent to gain power or control. It may be physical,

Telegram: @medical_k

www.konkur.in

sexual, emotional, economic, or psychological. This abuse can be directed toward children, elders, or partners. Intimate partner violence (IPV) is domestic violence by a current or former partner or spouse. Domestic violence is often broken down into two categories: “high-severity abuse,” which includes being threatened or hurt with a weapon, burned, choked, hit or kicked, and resulting in broken bones and head or internal injuries; and “low-severity abuse,” which includes being slapped, hit, or kicked without injury, but could also include bruising, minor cuts, and sprains. The CDC has defined four subtypes of IPV: physical violence, sexual violence, stalking, and psychological aggression.

Elder abuse is a variant of assault either when the abuser is an unrelated caretaker or due to domestic violence. Elder abuse can include physical, sexual, emotional, or financial abuse.

Prevalence

Prevalence estimates of domestic violence in the United States vary widely, and many studies include psychological or emotional abuse. However, one consistent statistic is that nearly 30% of women and 10% of men in the United States have experienced some form of physical or sexual abuse from an intimate partner. The National Intimate Partner and Sexual Violence Survey (NISVS) from 2011 found that 27.3% of women and 11.5% of men experienced sexual violence, physical violence, or stalking by an intimate partner during their lifetimes. The NCVS reported more than 521,870 domestic violence incidents in 2019 and 310,320 cases of IPV. The prevalence rates for both are unchanged over the previous 15 years.

Risk Factors

Studies have found that certain individual, relationship, community, and societal risk factors are associated with domestic violence and IPV. Individual risk factors may include younger age, pregnancy, low income, substance use, exposure to violence and abuse as a child, low level of education, and having traits of borderline or antisocial personality disorder. Relationship risk factors include marital discord and instability, economic stressors, the male having multiple partners, and male dominance in the family. Multiple studies have shown that community and societal risk factors such as poverty, overcrowding, acceptance of IPV or

Telegram: @medical_k

www.konkur.in

lack of sanctions against it, and traditional gender roles, or norms play roles in increased domestic violence and IPV rates.

Perpetrators

The perpetrators of domestic violence are represented across all races, cultures, ethnicities, genders, religions, educational backgrounds, and socioeconomic levels. Many studies have shown that having been a victim of abuse or witnessing abuse in the home increases the risk of someone becoming an abuser. Substance abuse is often a risk factor for episodes of perpetration. Various typologies have been used to describe perpetrators of domestic violence, grouped into two types of offenders. The first is described as being “emotionally dependent,” with a high level of jealousy, interpersonal dependency, anger, and low self-esteem. These abusers are prone to interpret their partner’s behavior as betrayal, and their anger can explode into violence. The second type is the “antisocial/narcissistic” person, who tends to have low empathy and hostile attitudes toward women. These abusers become less physiologically aroused as violence escalates and have the highest rates of alcohol dependence. Several traits can be associated with domestic violence and IPV perpetrators, including exhibiting verbal abuse, projecting blame, objectifying the victims, and isolating them from social support. Finally, abusers are noted to be charming and have manipulative personalities in public while being cruel and hostile to their intimates.

WORKPLACE VIOLENCE

Acts of violence at work include simple assault, aggravated assault, robbery, rape/sexual assault, and homicide.

Prevalence

Between 2007 and 2015, an estimated 10.3 million acts of workplace violence occurred in the United States. During that period, nonfatal workplace violence accounted for about 22% of nonfatal violent crimes. From 2014 through 2019, the number of firearm workplace homicides increased steadily after a 2-decade decline prior to that. Roughly 80% of these workplace homicides involved firearms. With some variation, total violent crime in the workplace did decline 35% between the years 2002

Telegram: @medical_k

www.konkur.in

and 2019. This reduction correlates with a similar 37% decrease in all violent crimes (workplace and nonworkplace) during the same period.

Risk Factors

Unlike other violent crimes, workplace crime rates are higher among whites than other races. An important component of workplace violence is the relationship between the risk of violence and the type of occupation. The NCVS found that people working in law enforcement are at high risk for victimization (48 per 1,000) and constituted 19% of all workplace assaults. This included law enforcement officers, security guards, and corrections officers. Other high-risk occupations include bartenders (79.9 per 1,000), the mental health fields (20.5 per 1,000), transportation fields (12.2 per 1,000), and high school teachers (13.5 per 1,000). Preschool and college/university teachers are at the lowest risk for victimization (0.9 and 1.9 per 1,000, respectively).

Perpetrators

There are several distinct characteristics among perpetrators–of which gender is the most pronounced. As reported by the victims, four-fifths of all violent workplace crimes are committed by men, regardless of the victim's gender. The offender's race is most often white (55%), followed by black (30%). Substance use in the offender is reported more often by victims in the law enforcement, medical, and retail sales occupations as opposed to the teaching fields. Unlike domestic violence, workplace violence is more often perpetrated by strangers (53%) than by acquaintances (12%) or known intimates (1%). Mental health and education are the only fields in which attacks occur more often at the hands of a known perpetrator.

SEQUELAE OF VIOLENCE AND ASSAULT

Survivors of violence have varied reactions, but they are similar to those exposed to other types of trauma. Furthermore, the severity of the sequelae varies with the individual. However, multiple studies have shown that many people who experience violence have diminished physical and mental health, resulting in higher utilization of health care services.

The most common reported sequelae after sexual assault in women are post-traumatic stress disorder (PTSD), affective disorders, substance

Telegram: @medical_k

www.konkur.in

misuse, disordered eating, and sexual disorders. Perceived life threats and physical injury are also linked to a diagnosis of PTSD. One of the most protective factors in ameliorating the development of trauma-related symptoms is social support. Furthermore, the lack of social support or the perception of being treated differently can be quite detrimental to the survivor, causing increased trauma-related symptoms.

Domestic violence has been associated with depression, anxiety, low self-esteem, substance abuse, sexual dysfunction, functional gastrointestinal disorders, headaches, chronic pain, and multiple somatic symptoms. Research has also shown a dose-effect of escalating violence and increasing physical complaints.

Physical signs and symptoms associated with current abuse:

Loss of appetite
Frequent or serious bruises
Nightmares
Vaginal discharge
Eating binges or self-induced vomiting
Diarrhea
Fractures
Sprains or serious cuts
Pain in the pelvic or genital area
Fainting
Abdominal pain
Breast pain
Frequent or severe headaches
Difficulty in passing urine
Chest pain
Problems with sleeping
Shortness of breath
Constipation

Many studies have shown that survivors of domestic violence attempt suicide more frequently than those who have not experienced violence. Substance abuse appears to be a significant factor for both the survivor and the perpetrator. It is both a risk factor for abuse and a consequence of it.

Telegram: @medical_k

www.konkur.in

The relationship between childhood abuse and adult abuse is complex. Childhood abuse is a risk factor for abuse as an adult, and it increases both physical and mental health sequelae of adult abuse. Survivors of sexual assault or domestic violence who are older and without a history of childhood abuse have fewer symptoms.

TREATMENT ISSUES

In evaluating assault victims, multiple treatment issues need to be addressed. Assessing safety, treating acute psychiatric and medical issues, and evaluating the need for hospitalization are primary foci of the initial assault workup. Another critical issue is the mandatory reporting requirements for abuse victims. After these treatment issues have been addressed, the clinician should assess whether the patient may benefit from psychotherapeutic or pharmacologic intervention. Evaluating assault victims requires creating a safe environment and establishing rapport reflecting the delicate nature of the circumstances. Efforts should be made to assess and respect the patient's wishes and requests for a safe therapeutic alliance at the patient's pace.

Initial Evaluation

Many victims of assault initially present to a medical provider to treat their injuries. In emergency departments, patients may often be treated for their injuries without the assault being recognized or addressed. Consequently, it is vital to consider any injuries as being potential stigmata of an assault. The patient may be avoidant when asked about the cause of injuries that appear related to an assault. This may be further complicated by the need to complete specific tasks (rape kit, photo documentation, reporting of legal concerns) that require the patient to describe and relive the recent assault.

Consequently, it is paramount to establish rapport while completing a thorough evaluation. The process of evaluation should be explained to the patient before initiating. Allow the patient to direct the pace and content of the interview and direct the process. The crime may represent a time when they lacked control, and similar feelings in the initial interview can trigger traumatic or anxious responses. Finally, the physician should remain attuned to nonverbal patient responses that signify discomfort and conduct the interview accordingly. This early therapeutic contact with

Telegram: @medical_k

www.konkur.in

assault victims may help influence their future prognosis. Furthermore, when a patient discloses domestic violence, this should be documented in the chart for future follow-up and possible future legal documentation.

Safety

After an assault, a safety assessment should be addressed with the patient, including the potential for suicidal and homicidal ideation pertaining to the recent assault. The patient's safety from further assault also needs to be addressed, especially in a setting where the perpetrator was an intimate partner or known acquaintance. Screening for severe psychological symptoms that would cause difficulty in self-care should be identified, including acute mood deterioration or affective instability, self-destructive behaviors, dissociative symptoms, or psychosis. If the evaluation indicates these areas are inadequate to ensure patient safety, then a plan needs to be developed and should provide for the patient's physical safety with attention to a safe space to sleep, eat, and recuperate.

Hospitalization

If the patient's safety cannot be guaranteed, hospitalization may be necessary. Common indications for hospitalization include (1) severe medical injuries, (2) suicidality or homicidality, (3) dissociative or psychotic symptoms, (4) mood instability or affective dysregulation, (5) self-destructive behaviors, and (6) continued serious threat to the patient's life or well-being. An individualized multidisciplinary treatment plan should be developed if the victim is admitted to the hospital. Safety, milieu therapy, mood stabilization, and medication evaluation are the primary treatment modalities provided in the hospital and reflect the short-stay nature of most psychiatric facilities. A coordinated inpatient-to-outpatient transition will provide ongoing treatment in the community, including psychiatric, medical, and social work issues being addressed prior to discharge.

Legal Issues

According to state law, a physician evaluating an assault victim must adhere to mandatory reporting requirements. Mandated reporting of child, elder, and developmentally disabled abuse exists in all 50 states. In cases of assault secondary to domestic violence, states do not usually require

Telegram: @medical_k

www.konkur.in

mandatory reporting; however, many require physicians to report serious injuries due to acts of criminal violence. Thus, in the setting of injury secondary to domestic violence, this can sometimes be considered a de facto mandatory reporting situation.

Continuing the Assessment

Victims of assault may report various psychiatric symptoms and psychosocial issues, including feelings of depression, anxiety, aggression, guilt, shame, and low self-esteem. Interpersonal relationships may suffer, and substance abuse may occur. These symptoms and issues should be addressed early because of the risk to the patient of future psychological sequelae. Victims of assault are at increased risk for PTSD, major depression, agoraphobia, OCD, social phobia, and simple phobia. The likelihood of these illnesses developing varies according to the type of assault and risk factors related to being assaulted. Therefore, a treatment plan must be developed that (1) assists the patient in dealing with psychiatric symptoms that they are currently experiencing because of the assault and (2) assists the patient with psychiatric symptoms that may arise later.

Postassault Psychotherapy Treatment

After the patient's safety has been ensured and the initial evaluation is complete, a variety of psychological interventions can be initiated. Cognitive-behavioral approaches are the most researched techniques demonstrating efficacy. Exposure therapy is a variant of CBT that has been shown to help victims emotionally process the assault by decreasing their fear of memories or cues of the event. Recent literature has shown that brief trauma-focused CBT may accelerate recovery in victims manifesting acute PTSD and is superior to supportive therapy. Eye movement desensitization and reprocessing (EMDR) has been shown to help patients process upsetting memories, thoughts, and feelings. These individual psychotherapies may be augmented with group psychotherapy, art therapy, dance and movement therapy, music therapy, and body-oriented approaches if these might prove beneficial to the patient.

Postassault Psychopharmacologic Treatment

Telegram: @medical_k

www.konkur.in

Although medications are not recommended in the acute treatment of all assault victims, they may be beneficial in certain circumstances and target specific symptomatology. The clinician may decide to medicate patients with incapacitating anxiety, extreme aggression toward themselves or others, or dissociation or psychoses immediately after an assault. The patient's safety and the safety of those around the patient will help decide the need for pharmacologic intervention. Most medication treatment will be initiated much later after the assault as the patient develops symptoms of PTSD, depression, anxiety, OCD, or psychosis. Although medications may be helpful in symptom management, they should not be viewed as a replacement for psychotherapy aimed at trauma symptom resolution.

30.4 Complementary, Alternative, and Integrative Approaches in Mental Health Care

JAMES H. LAKE, M.D.

DEFINITIONS AND HISTORICAL BACKGROUND

The National Center for Complementary and Integrative Health (NCCIH) of the National Institutes of Health defines complementary and alternative medical (CAM) practices as "those healthcare and medical practices that

Telegram: @medical_k

www.konkur.in

are not currently an integral part of conventional medicine." In the United States and other Western countries, where biomedicine is the dominant healing tradition, *alternative* treatments are approaches for which a mechanism of action is not supported by *current* biomedical theory. Acupuncture is regarded as an alternative form of treatment in Western countries because Chinese medicine postulates the existence of an energetic principle called "*qi*" that is not congruent with the assumptions of current science. In contrast, complementary therapies are based on mechanisms that are empirically verifiable by current science and consistent with biomedical theory but remain controversial or are not endorsed by biomedicine for ideologic or other reasons. St. John wort (SJW) is presently regarded as a complementary treatment in the United States. Although the postulated mechanism of action of the herbal is consistent with biomedical theory and well-designed studies have demonstrated beneficial effects in depressed mood, there is an ongoing debate in biomedical psychiatry over the appropriate uses of SJW in the treatment of depressed mood. Integrative medicine is a rapidly evolving subspecialty that encompasses both biomedicine and CAM and is personalized to the unique history, needs, and values of each patient.

In North America, Europe, and other industrialized world regions, an increasing percentage of the population is using complementary, alternative, and integrative approaches to treat or *self-treat* medical and mental health problems. Large patient surveys have reported that females, college graduates, and persons who believe they receive poor health care from conventionally trained providers are more likely to use CAM and that roughly one-half of individuals who use CAM notify their health care providers. The majority of CAM users are well educated, committed to personal growth, satisfied with conventional care, and use both medications and CAM for the same problem. An increasing number of medical schools, nursing schools, and psychology graduate programs offer courses on CAM. Symposia on CAM modalities are included in the annual meetings of the American Medical Association (AMA), the American Psychiatric Association (APA), and other professional medical associations. Approximately half of U.S. physicians—and the majority of European physicians—believe that acupuncture, chiropractic, and homeopathy are valid therapeutic modalities and refer patients to practitioners of these therapies. Increasing numbers of primary care

Telegram: @medical_k

www.konkur.in

physicians are becoming certified to practice massage, acupuncture, herbal medicine, homeopathy, and other nonallopathic modalities.

Persons diagnosed with a major psychiatric disorder are significantly more likely to use CAM treatments than the general population, and the majority of people who use CAM to self-treat a mental health problem take one or more psychotropic drugs concurrently. Almost one-half of persons diagnosed with major depressive disorder or panic disorder use at least one CAM treatment, compared to less than one-third of the general adult population. Roughly two-thirds of severely depressed or anxious persons who use CAM consult with a mental health professional, and 90% of the time, this is a psychiatrist. The majority of persons who use CAM therapies for a mental health problem do not disclose this to their mental health care provider. More than one-half of persons who self-treat severe depression or anxiety using CAM take one or more psychotropic medications concurrently, resulting in potentially serious safety problems.

LEGAL AND ETHICAL ISSUES

CAM use in mental health care raises important legal and ethical issues for psychiatrists and allied mental health professionals. The increasing use of CAM in mental health care is resulting in competing demands of patient expectations, clinical judgment, and liability considerations. Clinicians who recommend or prescribe CAM often do so in the absence of institutional oversight or professional guidance. This is complicated by the absence of treatment guidelines, policies, and procedures to help clinicians deal with liability issues.

Scope of practice refers to legally authorized boundaries of care for a particular conventional medical specialty or CAM practice. There is no clearly established legal–ethical framework that defines the scope of practice for physicians or CAM practitioners who treat patients using CAM modalities. Furthermore, substantial differences may exist between state jurisdictions for the kinds of medical practices that are legally sanctioned for a particular CAM specialty. For example, chiropractors are authorized to give nutritional advice in some states, but not others and massage therapists are prohibited from engaging in mental health counseling in most states but not all. All health care providers are ethically obligated to provide competent professional care. This duty includes the demonstration of professional competence when treating patients and the

Telegram: @medical_k

www.konkur.in

exercise of sound judgment when referring a patient to other conventionally trained medical specialists or CAM practitioners. Medical practitioners who use interventions that are not recognized as falling within the scope of their professional competence may invite disciplinary action by the state medical board or other regulatory agencies if patients or professional peers make formal complaints to those bodies. Disciplinary action may result in probation, suspension, or revocation of a professional license to practice.

It is prudent for health care providers who recommend or prescribe CAM approaches to first learn about all applicable restrictions imposed by their state medical boards on the scope of medical practices in their respective states. When a patient's medical or mental health problem is outside of the scope of the provider's expertise and experience, the provider is ethically obligated to refer the patient to an appropriate and competent provider. A conventionally trained provider who refers a patient to a CAM practitioner assumes liability for negative outcomes resulting from the referral, including harmful effects that may result from treatment. Referrals should be made only after confirming that a particular CAM practitioner is qualified to practice in their specialty. Malpractice refers to negligence, which is defined as failure to use due care in treating a patient, resulting in injury to the patient. Courts make rulings on malpractice using different standards of care for physicians and CAM practitioners. The issue of malpractice insurance coverage pertaining to the practice of CAM is poorly defined. States vary significantly in their requirements for malpractice coverage, and in a given state, different insurers often vary in their coverage of the same CAM therapy. Statutes pertaining to fraud in health care are intended to prevent intentional deception of patients by physicians and other providers. Submitting a reimbursement claim for a treatment that is medically unnecessary may lead to charges of fraud.

SAFETY

Evaluating the safety of CAM and integrative approaches poses complex challenges. Many herbal treatments are widely regarded as safe because of their long-standing historical use in traditional healing practices. There are limited safety data on the majority of natural supplements used to treat medical or mental health conditions. The safety of imported herbal

Telegram: @medical_k

www.konkur.in

medicines and other natural supplements used for medicinal purposes from Asia is generally more difficult to assess than Western botanicals because of the absence of strong import controls.

Herbals and other natural supplements may cause adverse effects and potentially interact with other supplements or drugs with harmful consequences. In contrast, few safety risks are associated with somatic therapies, mind–body practices, and the so-called "energy" healing. Most safety information on CAM comes from case reports of limited reliability, and published reviews of adverse effects often cite conflicting findings. SJW has the greatest number of reported cases of adverse effects because it is one of the most widely used CAM treatments of depressed mood. In contrast, relatively little is known about adverse effects and toxicities associated with the majority of natural supplements. Safety information on natural supplements is especially incomplete with regard to young children, pregnant and nursing women, and patients with serious medical illnesses. As already noted, many individuals who take medications self-treat using natural supplements without disclosing this information to their prescribing physician, resulting in unknown risks of toxic interactions and underreporting of potentially serious interactions between medications and natural supplements.

Patients should be advised about adverse effects or toxic interactions before taking *any* natural supplement alone or in combination with *any* medication. Table 30.4–1 shows adverse effects, potential interactions, and contraindications of select natural supplements widely used in North America, Western Europe, and Australia to treat or self-treat psychiatric disorders.

Rare cases of injury or adverse effects have been reported with CAM therapies that are not based on discrete biologic mechanisms of action, for example, therapeutic massage, acupuncture, yoga, *qigong,* and Reiki. Where applicable, these safety concerns are reviewed in the text.

OVERVIEW OF CAM ASSESSMENT APPROACHES IN MENTAL HEALTH CARE

Recent advances in neuroscience suggest that the causes of mental illness are more *subtle* and more *complex* than the prevailing biopsychosocial model is capable of elucidating. Models of consciousness based on complex systems theory, quantum mechanics, and other

Telegram: @medical_k

www.konkur.in

emerging theories may be consistent with the assumptions of “energetic” assessment used in Chinese medicine and other nonallopathic systems of medicine. CAM assessment approaches may eventually permit a more *complete* “picture” of underlying psychological, biologic, and *energetic* causes of symptoms. CAM approaches used to assess the causes of mental illness include assays of biologic structure or function, measurements of scientifically validated forms of energy or information, and measurements of postulated *subtle* forms of energy or information that cannot be explained by current science. Quantitative electroencephalography (QEEG) and heart rate variability (HRV) analysis are examples of scientifically validated assessment methods that provide useful clinical information about functional dysregulations of electromagnetic activity in the brain and heart related to symptoms of mental illness. Assessment approaches that purport to detect *subtle* energetic phenomena associated with both physical and mental illness include pulse diagnosis in Chinese, Tibetan, and Ayurvedic medicine and analysis of electrodermal potentials following acupuncture or medical *qigong.*

Table 30.4–1.
Safety Issues Associated With Botanicals and Other Natural Products

Telegram: @medical_k

www.konkur.in

Natural Product	Adverse Effects	Potentially Toxic Interactions and Contraindications
Ginkgo biloba	May increase bleeding risk if used before surgery or labor/delivery Gastrointestinal discomfort, skin allergy, dizziness, headache	**Contraindicated** in combination with warfarin due to interference with platelet activation factor (PAF)
Kava (*Piper methysticum*)	Gastrointestinal discomfort (generally mild), allergic skin rashes, mild headache Case reports of severe hepatoxicity (always recommend routine liver function tests for all patients taking kava products)	Warn against combined use with benzodiazepines Case reports of lethargy and disorientation when used with alprazolam, other benzodiazepines
St. John wort (*Hypericum perforatum*)	Uncommon adverse effects include mild stomach discomfort, allergic skin rashes, tiredness, restlessness Rare case reports of mania Rare case reports of mild serotonin syndrome	**Contraindicated** in combination with cyclosporine, other immunosuppressive agents, oral contraceptives, warfarin, protease inhibitors, and other antiretroviral drugs (may induce cytochrome P450 hepatic enzymes, causing increased metabolism and decreased serum levels of these drugs)

Telegram: @medical_k

www.konkur.in

Valerian (*Valeriana officinalis*)	Uncommon reports of morning grogginess; headache Caution against driving for up to a few hours after using	Warn against combined use with benzodiazepines or barbiturates (may potentiate central nervous system sedating effects)
L-Tryptophan	Uncommon adverse effects include drowsiness, dry mouth, and blurred vision Fatal cases of eosinophilia-myalgia syndrome (EMS) attributed to a single contaminated batch of L-tryptophan in the late 1980s L-Tryptophan remains in widespread use and no subsequent cases of EMS have been reported	Rare case reports of possible serotonin syndrome when combined with SSRIs and other antidepressants
5-Hydroxy-tryptophan (5-HTP)	Case reports of mild nausea, dry mouth, stomach irritation, and drowsiness at commonly used doses (50–100 mg thrice daily)	No case reports of serotonin syndrome when used in combination with SSRIs, other antidepressants
S-Adenosyl-methionine (SAMe)	Well tolerated Dose-related gastrointestinal distress is most common side effect (can range from mild	Case reports of serotonin syndrome when used in combination with SSRIs, other antidepressants

Telegram: @medical_k

www.konkur.in

	nausea to vomiting and diarrhea) Case reports of mild nervousness and insomnia	Warning: Risk of mania induction in bipolar patients; should be avoided in this population
Omega-3 fatty acids	Well tolerated at low doses, but there are reports of nausea and loose stools at higher doses; gastrointestinal side effects are reduced by taking with meals	Mild blood-thinning activity but no bleeding problems caused when used alone or with aspirin Warning: Increased risk of hypervitaminosis A and D with chronic high doses of cod liver oil because of high concentrations of vitamins A and D Caution: Pharmaceutical-grade products are recommended to minimize the risk of contamination with heavy metals, polychlorinated biphenyls, organochlorines

SSRI, selective serotonin reuptake inhibitor.

Functional medicine is an interdisciplinary field that uses established quantitative analysis methods to assess relationships between nutritional status, neurotransmitters, endocrine and immune function, and psychological symptoms. Functional tests used to evaluate mental health problems include urinary assays of neurotransmitters and their metabolites and serum assays of cholesterol, triglycerides, vitamins, minerals, amino acids, and their metabolites, hormones, fatty acids, proinflammatory cytokines (e.g., interleukin-6 [IL-6], IL-8, and IL-1b), and immunologic factors. Discrete biomarkers of specific psychiatric disorders

Telegram: @medical_k

www.konkur.in

have not been identified, and functional assessment findings generally do not provide insights about specific treatments that improve outcomes. For example, although low serum folate has been causatively linked to depressed mood, research findings are inconsistent, and this *apparent* relationship may be due to chance, bias, confounding, or reverse causality. Preliminary findings suggest that total cholesterol and triglyceride levels may be inversely correlated with the severity of depressed mood. Depressed patients who attempt suicide frequently have abnormally low serum total cholesterol and triglyceride levels, which may provide useful clinical markers for suicide risk. Nonsuicidal depressives tend to have cholesterol levels in the vicinity of 180 mg/dL, while severely depressed suicidal patients tend to have significantly lower serum total cholesterol levels in the vicinity of 150 mg/dL. On the basis of these findings, it is prudent to check cholesterol levels of severely depressed patients, make appropriate dietary recommendations, and address issues related to the use of cholesterol-lowering medications. In contrast to abnormal low cholesterol in severely depressed patients, *elevated* serum cholesterol may be a sensitive marker for anxiety disorders, including generalized anxiety disorder (GAD), panic disorder, and possibly OCD. Amelioration of anxiety in response to anxiolytics is often associated with a reduction in serum total cholesterol to normal levels. Assessment of vitamin deficiency states is important when working with patients who do not take supplements or who are at risk of one or more vitamin deficiency syndromes because of chronic malnutrition or a medical problem that interferes with normal absorption or metabolism.

Low serum zinc levels result in impaired zinc transport to the brain and have been cited as a possible factor in the formation of amyloid fibrils. Consistently reduced red blood cell (RBC) membrane levels of two fatty acids—arachidonic acid (AA) and DHA—have been reported in nonmedicated schizophrenics compared to medicated schizophrenics and healthy controls. Low brain levels of fatty acids and cholesterol may indirectly affect the number and activity of neurotransmitter receptors by modifying their three-dimensional structure in the lipid bilayer of nerve cell membranes. Assessing flushing response following niacin challenge may provide useful information when evaluating individuals with symptoms of psychosis. Research findings suggest that normal flushing response to niacin is attenuated in schizophrenia and other psychotic disorders. Approximately 80% of patients with schizophrenia do not flush when

Telegram: @medical_k

www.konkur.in

challenged with niacin compared to healthy controls. In one series, 43% of patients with schizophrenia experienced abnormally low vasodilation in response to a 200-mg challenge dose of niacin, compared to only 6% of individuals diagnosed with bipolar disorder. The mechanism of action probably involves dysregulation of phospholipid-dependent signal transduction and increased phospholipase A2 activity.

There is preliminary evidence for the clinical utility of HRV monitoring and QEEG in psychiatric assessment; however, both approaches are still mainly used for research. Abnormal EEG findings occur in up to 40% of depressed patients, and *small sharp spikes* are often seen in severely depressed suicidal patients. QEEG analysis of unipolar depressed patients typically reveals increased alpha or theta power and decreased interhemispheric coherence. In contrast, bipolar depressed patients often have reduced alpha activity and increased beta power. Reduced alpha activity and increased beta power are more likely in bipolar disorder than in depression. EEG changes frequently associated with anxiety include decreased alpha activity in generalized anxiety, increased theta activity in OCD, and paroxysmal activity in patients who experience panic attacks. QEEG findings may predict differential medication response rates in patients with OCD. In one series, approximately 80% of OCD patients who exhibited increased alpha power *responded* to SSRIs, compared to 80% of OCD patients with increased theta activity who *failed* to respond to SSRIs. QEEG findings associated with other anxiety disorders are highly inconsistent. Neurometric brain mapping is a specialized QEEG approach that compares EEG characteristics of the individual being evaluated with normative databases for the same age group. Neurometric mapping helps clarify functional brain correlates of cognitive impairment and yields useful information when planning EEG biofeedback protocols addressing different symptoms (see discussion of EEG biofeedback). Neurometric brain mapping is being increasingly used to differentiate cognitive impairments due to head injuries, medical disorders, progressive dementia, alcohol or substance abuse, depressed mood, and learning disorders.

Cordance is a measure of localized electrical brain activity relative to averaged brain EEG patterns. More than one-half of patients with severely depressed mood who subsequently had the highest response rates to SSRIs showed significant decreases in prefrontal cordance during the first 48 hours of therapy, suggesting that improvement was due to

Telegram: @medical_k

www.konkur.in

normalization of abnormal low CNS serotonin levels. In contrast, nonresponders to SSRIs or placebo did not show negative prefrontal cordance following treatment, suggesting that low serotonin was not the primary cause of depressed mood in these cases. It has been suggested that differences in prefrontal cordance may also predict response differences of depressed patients to homeopathic remedies.

Assessment approaches used by energy healers are based on the belief that *imbalances* in postulated subtle energies manifest as psychological symptoms. Analysis of the pulse is used to assess energetic imbalances associated with both physical and mental symptoms in Chinese medicine, Ayurveda, and Tibetan medicine. A treatment plan consisting of psychological, physical, and energy "balancing" therapies are constructed with the goal of normalizing energetic imbalances and improving health. Anecdotal reports suggest that subtle characteristics of the pulse described in Chinese, Ayurvedic, or Tibetan medical theory correspond to specific energetic *imbalances* that manifest as physical or psychiatric symptoms. For example, mild to moderate symptoms of anxiety and depressed mood are often associated with a "tight" or rapid rate when the pulse is palpated at the pericardium position or as a subtle sensation of "smooth vibration" over the entire pulse at all depths. More severe symptoms of mental illness are often associated with a "rough vibration" over the entire pulse or a sensation of "slipperiness" in some aspects of the pulse. Severe psychiatric symptoms such as psychosis and acute mania are reportedly associated with the most abnormal energetic pattern of the pulse.

Electrodermal skin testing (EDST), the measurement of electrodermal potentials at specific acupoints, may provide useful information when assessing clinical responses to acupuncture or *qigong.* EDST may also help determine whether conventional or subtle energy treatments of anxiety are likely to be effective for a particular patient. Healing Touch (HT) practitioners conducted six trials comparing anxiolytic effects of applied relaxation with HT and concluded that EDST reliably measured changes in "bioenergy" in meridians following both conventional and subtle energy treatments of anxiety.

COMPLEMENTARY, ALTERNATIVE, AND INTEGRATIVE APPROACHES USED TO TREAT

Telegram: @medical_k

www.konkur.in

MENTAL ILLNESS

Advances in the understanding of the pathogenesis of mental illness have important implications for therapeutic uses of natural supplements for treating depressed mood, anxiety disorders, bipolar disorder, schizophrenia, and other disorders. Select natural supplements and other CAM modalities such as regular exercise, bright light therapy, and biofeedback are based on well-understood mechanisms of action and are substantiated by positive findings from large placebo- or sham-controlled studies. However, many CAM modalities reviewed in this chapter presently lack compelling evidence. Studies on "energy" therapies, including Reiki, *qigong,* HT, and energy psychology, pose complex challenges to contemporary Western-style research methods. A comprehensive understanding of clinical benefits associated with light, electricity, and sound, as well as *"energy"* therapies, may require conceptual advances in the foundations of science and greater openness to emerging models of physics, including complex systems theory, quantum mechanics, and other nonclassical theories.

Approaches used as treatments in both biomedicine and nonallopathic systems of medicine can be assigned to five general categories corresponding to differences in known or postulated mechanisms of action (Table 30.4–2):

- *Biologic treatments* operate through one or more discrete biologic mechanisms of action at the molecular or cellular level (examples include conventional medications, vitamins, minerals, medicinal herbs, amino acids, and omega-3 fatty acids).
- *Somatic therapies* improve general well-being and affect the body as a whole but do not operate through a discrete (i.e., molecular or cellular) biologic mechanism of action (examples include exercise, massage, and dance therapy).
- *Mind–body and mindfulness practices* use a particular mental technique or combine a mental technique with physical training with the goal of optimizing mental or mind–body functioning and alleviating symptoms (examples include yoga and mindfulness-based stress reduction [MBSR]).
- *Scientifically validated forms of energy or information* have been investigated and verified by research studies. Examples include electromagnetic fields, bright light, dim light, microcurrent electrical

Telegram: @medical_k

www.konkur.in

stimulation, high-density negative ions, music, binaural sound, and biofeedback. Specific therapeutic applications use different durations, frequencies, and power characteristics of these established forms of energy to achieve beneficial effects.

- *Postulated forms of energy or information* have not been validated by (current) science but are theorized to be the mechanisms underlying “energy” healing approaches, including Reiki, *qigong,* prayer, HT, Therapeutic Touch (TT), and energy psychology.

Identifying Appropriate CAM Modalities

Deciding on which CAM or integrative approach to recommend to a patient poses many complex issues. When formulating clinical treatment recommendations, five basic issues should be kept in mind:

- The symptom or disorder that is the focus of clinical attention.
- The patient's history of response to previous treatments for the same mental health problem.
- The relative strength of evidence for various biologic, somatic, mind–body, and energy therapies.
- Practical and personal considerations, including safety, cost, availability of treatment, and cultural and personal preferences that will lead to realistic and acceptable treatment recommendations.
- Appropriate methods for assessing treatment response.

REVIEWS OF COMPLEMENTARY, ALTERNATIVE, AND INTEGRATIVE APPROACHES

The balance of this section is devoted to a review of the evidence for specific CAM and integrative modalities in current use to treat or *self-treat* common mental health problems. Because of space constraints, only modalities that have been validated by research findings are discussed in detail, whereas CAM and integrative approaches supported by limited evidence are briefly reviewed.

Pharmacologic and Related Treatments

Dietary Modification. Dietary patterns that result in a suboptimal intake of specific macro- and micronutrients such as omega-3 fatty acids, magnesium, methylcobalamin (B12) and zinc, negatively impact the microbiome and gut–brain axis and are associated with increased risk of depressed mood. Reducing or eliminating refined sugar and caffeine can significantly improve mood in some depressed patients. Caffeine consumption increases serum epinephrine, norepinephrine, and cortisol levels, resulting in general feelings of "nervousness" and increased risk of panic attacks in predisposed individuals. Foods rich in folate, pyridoxine

Telegram: @medical_k

www.konkur.in

(B_6), and methyl-cobalamin (B_{12}) such as legumes, leafy greens, and beets may have mood-enhancing benefits as these vitamins function as essential cofactors for the synthesis of serotonin, dopamine, and norepinephrine. Important dietary sources of omega-3 fatty acids include salmon, halibut, other deep-sea fish, and flaxseed oil. Relatively greater intake of omega-3 fatty acids (i.e., compared to omega-6 fatty acids) is correlated with lower C-reactive protein levels and reduced risk of inflammatory-mediated disorders, including possibly depression and Alzheimer disease. Prevalence rates of severe depression and suicide attempts are lower in countries where fish is an important part of the average diet. In Japan, where fish consumption is very high, the annual incidence of depressed mood is only 0.12%, compared to 6% in New Zealand, where fish consumption is relatively low. A large epidemiologic study concluded that fish consumption two to three times weekly significantly reduced the risk of cognitive decline in the older adults. High fish consumption was inversely correlated with cognitive impairment. In contrast, individuals who preferred foods rich in linoleic acid (an omega-6 fatty acid) exhibited significantly higher rates of cognitive decline. Lifestyle factors—including exercise and alcohol consumption—and educational level are associated with dietary preferences, and thus a relatively lower risk of developing Alzheimer disease cannot be ascribed to fish consumption alone.

Excess caloric intake and high-fat intake promote the formation of free radicals that cause diffuse neuropathologic changes in the brain. High-fat, high-calorie diets correlate with a significantly greater risk of developing Alzheimer disease compared to diets with lower fat and fewer calories. A meta-analysis of findings from 18 community-wide studies concluded that the risk of Alzheimer disease increased linearly at a rate of 0.3% with every 100-calorie increase in daily intake. In the same meta-analysis, the average daily fat consumption was strongly correlated with an increased risk of developing dementia. Epidemiologic studies suggest that moderate but not heavy consumption of wine (two to four glasses per day) is associated with a reduced risk of Alzheimer disease. In a large 5-year cohort study, 19,000 women aged 70 to 80 years who drank 14 g of alcohol daily (the equivalent of one and a half glasses of wine or one 12-oz beer) were 20% less likely to experience significant cognitive impairment compared to nondrinkers. Ketogenic diets intended to shift the metabolism from primarily glycolysis to ketosis are sometimes used in

Telegram: @medical_k

www.konkur.in

individuals with treatment-refractory seizure disorders. Limited findings, mainly from animal studies, suggest that the ketogenic diet may have both antidepressant and anxiolytic effects.

Chronic alcohol abuse is often associated with malnutrition due to malabsorption of essential nutrients through the mucosa of the stomach and small intestines resulting in significantly reduced blood levels of thiamin, folate, B_6, and important trace minerals. Hypoglycemia can result from toxic effects of alcohol on the liver, manifesting as confusion, anxiety, and impaired cognitive functioning. Alcoholics who improve their overall nutrition may have a better chance of maintaining sobriety than those who do not. In one study, 80% of alcoholics who stayed on a caffeine-free, low-refined sugar diet high in wheat germ and fruit remained abstinent at 6 months.

Probiotics. The putative health and mental health benefits of probiotics have been the focus of intensive research in recent years. Emerging findings suggest that the pathogenesis of many neuropsychiatric disorders, including autism spectrum disorders, depressed mood, anxiety disorders, and schizophrenia involves dysregulation of the microbiota–gut–brain (MGB) axis. It has been suggested that reported antidepressant effects of probiotics are mediated by immune modulation, anti-inflammatory effects, and modulation of neurotransmitter pathways, including serotonin, glutamate, dopamine, GABA, norepinephrine, and acetylcholine. Inter-individual variation in gut microbiota compositions may call for a highly individualized approach to selecting a probiotic formula that is most likely to yield therapeutic benefits for depressed mood or other mental health conditions.

Preliminary findings suggest that taking probiotics may have therapeutic effects on mild to moderate depressive symptoms but not more severe forms of depressed mood. In a small 8-week RCT (N = 71), adults with mild to moderate depressed mood randomized to a patented probiotic supplement experienced a significantly greater reduction in symptom severity compared to placebo. The probiotic formula did not significantly alter gut microbiota; however, a significant correlation was found between a specific microorganism (*Ruminococcus gnavus*) and depressed mood. The significance of findings was limited by the small study size and a high attrition rate. A meta-analysis of placebo-controlled studies on probiotic supplementation in depressed adults (total N = 1,349) found non-

Telegram: @medical_k

www.konkur.in

significant overall differences in mood in subjects taking probiotics versus placebo. A comprehensive review of probiotic supplementation in prophylaxis and treatment of depressive and anxiety disorders found inconsistent evidence for reductions in both depressed mood and anxiety. A 1-year placebo-controlled RCT (*N* = 423) found that supplementation with a probiotic formula containing *Lactobacillus rhamnosus* HN001 in pregnant and postpartum women significantly reduces the severity of depressed mood and anxiety and lowers the risk of postpartum depression. Findings of studies on probiotics in neuropsychiatric disorders are limited by small study size, methodologic problems, and the absence of clinical populations in most studies. Different outcomes in response to probiotics are poorly understood and may reflect differences in probiotic formulas, study populations, and study design. Further research is needed to establish optimal formulations and dosages of probiotics for the treatment of depressed mood. Probiotics are generally well tolerated in healthy individuals. Probiotics are contraindicated in individuals who are immune-compromised or have serious illnesses as they may result in severe medical complications, including pneumonia, endocarditis, and sepsis.

Vitamins

B-FAMILY VITAMINS. Folate is required for the synthesis of *S*-adenosylmethionine (SAMe) from homocysteine. Folate deficiency results in increased serum homocysteine levels and an increased risk of depressed mood. Folate in the form of L-methylfolinic acid does not require methylenetetrahydrofolate reductase (MTHFR) to become activated, more readily crosses the blood–brain barrier, and is a more effective adjuvant than dietary folate. In one study, clinical improvement in depressed patients treated with an SSRI and L-methylfolate (0.5 to 1 mg) was 30% greater than that in matched patients treated with an SSRI only. A systematic review of controlled studies (total *N* = 247) concluded that folate augmentation (1 to 15 mg per day) enhanced the efficacy of antidepressants. The findings of a double-blind study (*N* = 75) suggest that folic acid at 200 to 400 µg per day might enhance the therapeutic benefits of lithium carbonate in acutely manic patients.

Widespread folate deficiency in patients with schizophrenia is probably caused by chronic malnutrition and the effects of antipsychotic

Telegram: @medical_k

www.konkur.in

medications on absorption. Abnormal low brain folate levels in patients with schizophrenia may result from a heritable deficiency in glutamate carboxypeptidase II (GCPII), the enzyme required for folate absorption through the gut. Patients with schizophrenia who take daily folic acid in the form of methylfolate 15 mg adjunctive to their antipsychotic medication may have fewer positive and negative psychotic symptoms and may respond more rapidly than patients taking antipsychotics alone. Low serum levels of folic acid, niacin, and thiamin are associated with cognitive impairment in general. Individuals with dementia frequently have normal RBC folate levels and fail to improve with supplementation; however, the evidence for vitamin B supplementation as a treatment of cognitive impairment, including dementia, is inconclusive. In a prospective study (*N* = 370), a deficiency of folate or B_{12} doubled the risk of developing Alzheimer disease. However, a systematic review of four studies found weak evidence supporting the use of folic acid with or without B_{12} as a treatment of dementia or other forms of severe cognitive impairment. Because folate supplementation can mask the macrocytic anemia caused by B_{12} deficiency, patients should be checked for B_{12} deficiency before starting folate. However, supplementation with L-methylfolinic acid does not mask B_{12} deficiency and can be started without first checking B_{12} levels.

Vitamin B_{12} is often recommended for older adult nondemented individuals who complain of impaired cognition; however, research findings are inconsistent. In a pilot study (*N* = 22), 18 older adult patients with abnormally low serum B_{12} levels and cognitive impairment were treated with B_{12} (1 mg/day intramuscularly) for 1 week, followed by weekly 1-mg injections for 1 month, then monthly 1-mg injections for 6 months. Patients who had been cognitively impaired for less than 1-year experienced significant improvements in cognitive function, whereas patients who had been impaired for longer than 1 year became worse, suggesting that supplementation may ameliorate symptoms related to B_{12} deficiency only in the early stages of cognitive impairment. Chronic alcoholics are often deficient in thiamin, folate, B_6, and B_{12} because of the toxic effects of alcohol on the mucosal lining of the stomach and small intestine and may benefit from supplementation with a broad-spectrum vitamin B supplement. Thiamin is essential for the metabolism of acetylcholine and its release from presynaptic neurons. Depressed

Telegram: @medical_k

www.konkur.in

patients report improved mood and energy with daily thiamin supplementation of 50 mg. Thiamin (vitamin B_1) 500 mg TID adjunctive to an antipsychotic may lessen symptom severity in patients diagnosed with schizophrenia. Thiamin-dependent enzymes may be abnormal in Alzheimer disease; however, research findings on high-dose thiamin (3 to 8 g per day) supplementation in Alzheimer disease are inconsistent. Animal studies suggest that low serum thiamin levels are associated with increased alcohol craving. Niacin in the form of 1.25 g per day of nicotinamide taken with a meal before drinking may protect the liver against the acute toxic effects of alcohol in individuals who have relapsed. Early double-blind RCTs reported that large doses of niacin (up to 3 to 8 g per day) ameliorated symptoms of schizophrenia. A combined regimen of high-dose niacin and a conventional antipsychotic medication reportedly resulted in differentially greater improvement in positive psychotic symptoms compared to schizophrenic patients treated with an antipsychotic alone. A subsequent review of 53 trials on niacin and other vitamins in the treatment of schizophrenia and other chronic psychiatric disorders identified methodologic flaws in early studies and concluded that findings reached only marginal statistical significance. Nevertheless, high-dose niacin has become standard therapy for schizophrenia in orthomolecular psychiatry, and case reports of dramatic outcomes continue to be published. A retrospective analysis of negative findings of controlled trials reported that nonmedicated patients with schizophrenia in the early acute phase of illness may experience significant and sustained benefits from high doses of niacin, in contrast to medicated patients with schizophrenia or individuals in the chronic phase of the illness.

Inositol is regarded as a member of the B family of vitamins and is the precursor of phosphatidyl inositol, a second messenger required for normal neuronal function. A systematic review and meta-analysis of seven RCTs (N = 242) on inositol in mood and anxiety disorders found nonsignificant benefits for inositol over placebo for depressed mood, OCD, PTSD, and generalized anxiety, and a trend toward superior response over placebo for premenstrual dysphoric disorder. In a 4-week, double-blind, crossover study (N = 21), inositol at 12 g per day and imipramine were equally effective in reducing the frequency and severity of panic attacks in individuals diagnosed with panic disorder with and without agoraphobia.

Telegram: @medical_k

www.konkur.in

VITAMIN D-3 (CHOLECALCIFEROL). Vitamin D_3 has anti-inflammatory, immunomodulatory, and neuroprotective effects and increases levels of the rate-limiting enzyme needed for the synthesis of serotonin, dopamine, and norepinephrine. Vitamin D deficiency is common in Western populations—especially among the older adults—and may be associated with an increased risk of depression in susceptible populations. Preliminary findings suggest that daily supplementation with vitamin D_3 at doses of 400 to 800 IU may reduce the severity of depression in patients diagnosed with seasonal affective disorder when serum D_3 levels are raised to 35 ng/mL or greater. Findings of RCTs suggest that vitamin D supplementation is more effective against major depressive disorder than milder forms of depressed mood. A meta-analysis of RCTs on vitamin D supplementation in MDD identified 4 trials (total N = 948) and concluded that vitamin D at doses of 1,500 to 7,000 IU/day resulted in moderate improvement in depressed mood. Parenteral vitamin D was no more effective than oral vitamin D. Daily supplementation with high doses of vitamin D up to 100,000 IU per day may be more effective than bright light therapy in the treatment of seasonal depressed mood.

Minerals. Magnesium is essential for maintaining neuronal cell membrane fluidity and neuroplasticity and plays a central role in the brain's antioxidant protective mechanisms. Magnesium deficiency is an established risk factor for overall poor mental health, depressed mood, and cognitive impairment. Zinc has general neuroprotective effects, is involved in hippocampal neurogenesis, and modulates the activity of the hypothalamic-pituitary axis. Increased risk of depressed mood associated with abnormal low zinc serum levels may be mediated by dysregulation of the immune system. Dietary sources of zinc include seafood and red meats; hence strict vegetarian diets may result in zinc deficiencies.

Research findings on the mood-enhancing effects of magnesium and zinc are inconsistent. A systematic review and meta-analysis that included 11 RCTs on zinc depressed mood found that zinc supplementation 25 mg/day resulted in modest improvements in symptom severity. A different systematic review found no evidence for antidepressant effects of magnesium supplementation at doses between 225 and 4,000 mg/day. A narrative review of preclinical and human studies investigating putative antidepressant effects of supplementation with magnesium, zinc, or selenium found modest evidence for zinc and inconsistent findings for

Telegram: @medical_k

www.konkur.in

magnesium and selenium. Preliminary evidence from randomized controlled studies supports the antidepressant efficacy of zinc supplementation used as an adjuvant to prescription antidepressants. Animal studies and preliminary human findings suggest that abnormally high copper levels may be a causative factor in the pathogenesis of Alzheimer disease by damaging the molecule required to eliminate amyloid-beta plaques soon after they are formed.

The trace element selenium is believed to reduce the risk of cancer, cardiovascular disease, and infectious diseases, including HIV. It is estimated that a significant percentage of the world's population is selenium deficient because of geographic differences in selenium in the soil. Selenoproteins play important roles in healthy brain function. The findings of animal studies suggest that severe selenium deficiency may cause degeneration of the GABA neurotransmitter system, increasing the risk of Alzheimer disease, Parkinson disease, and other neuropsychiatric disorders. Limited findings suggest that selenium supplementation may reduce symptoms of anxiety and depressed mood in some populations. In a 5-week double-blind RCT (N = 50), healthy adults randomized to selenium 100 mcg versus placebo reported improvements in mood and decreased anxiety. In a 12-month RCT (N = 63), HIV^+ adults were randomized to selenium 200 mcg/day reported generally increased vigor, reduced levels of anxiety but no improvements in measures of depressed mood.

Amino Acids

5-HYDROXYTRYPTOPHAN, L-TRYPTOPHAN. 5-hydroxytryptophan and L-tryptophan have been extensively investigated for their putative antidepressant and anxiolytic effects. Therapeutic dosages for depressed mood range between 1,500 and 5,000 mg/day. L-Tryptophan is moderately sedating and is typically used at night. Early studies reported antidepressant effects at doses of 2 g/day; however, a systematic review of placebo-controlled RCTs found equivocal evidence of efficacy. 5-HTP is generally preferred over L-tryptophan because it crosses the blood–brain barrier more readily, is converted into serotonin more efficiently than L-tryptophan, and has more marked antidepressant effects. Findings of placebo-controlled studies support that 5-HTP starts to have antidepressant effects at doses between 100 and 300 mg/day. In a small

Telegram: @medical_k

www.konkur.in

8-week double-blind study (*N* = 70), depressed patients randomized to 5-HTP versus fluoxetine reported equivalent improvement in mood. Patients were started on 5-HTP in three divided doses starting at 150 mg for the first 2 weeks, increased to 300 mg in three divided doses starting week 3, and further increased to 400 mg after the fourth week. Both groups showed significant and equivalent reductions in depressed mood scores starting at week 2 and continuing to study end. 5-HTP is moderately sedating, and doses greater than 100 mg should be taken at bedtime. RCTs have reported consistent anxiolytic effects of 5-HTP for generalized anxiety and panic disorder. 5-HTP dosed at 50 to 100 mg thrice daily is well tolerated alone or in combination with antianxiety agents. In a double-blind study, 58% of generally anxious patients (*N* = 79) randomized to 3 g per day of L-tryptophan reported significantly greater reductions in baseline anxiety compared to placebo. L-Tryptophan, 1 g, at bedtime reduces time to sleep onset in mild situational insomnia, and doses up to 15 g may be necessary for severe insomnia. Case reports suggest that nighttime use of 5-HTP at 300 to 600 mg may improve mild to moderate insomnia and lessen sleep disturbances related to obstructive sleep apnea and narcolepsy.

Recent findings suggest that treatments employing the amino acid precursors of serotonin (i.e., 5-HTP) and dopamine (i.e., L-tyrosine) must be properly balanced in order to be efficacious over the long term. These findings come mainly from studies on monoamine transporter optimization (MTO). According to MTO theory, competitive inhibition resulting from taking exogenous 5-HTP or L-tyrosine alone leads to the unbalanced synthesis of the “opposite” neurotransmitter resulting in its relative deficiency compared to the dominant monoamine neurotransmitter. It has been suggested that imbalances in the monoamine neurotransmitters resulting from chronic antidepressant use leads to gradual loss of efficacy, increased incidence of adverse effects, and (over time) complete loss of efficacy when the nondominant neurotransmitter has diminished below a critical threshold level in the CNS. Limited research evidence suggests that the optimal balance between serotonin and dopamine is achieved in response to a daily regimen that includes 5-HTP, L-tyrosine, and L-dopa.

Uncommon, usually mild side effects of both L-tryptophan and 5-HTP include dry mouth, gastrointestinal distress, and fatigue. Both amino acids are contraindicated in combination with MAOIs as the combination may result in a serious serotonin syndrome. Both amino acids are also

Telegram: @medical_k

www.konkur.in

contraindicated in combination with lithium because they can elevate serum lithium levels to toxic levels.

ACETYL-L-CARNITINE. Acetyl-L-carnitine (ALC) has been investigated as a novel antidepressant because of its beneficial effects on neuroplasticity, neuronal cell membranes, and neurotransmitter modulation. Emerging findings suggest that ALC may slow the rate of cognitive decline in normal aging, dementia, and traumatic brain injury. Most studies on ALC in older adult depressed patients report sustained antidepressant effects after 1 month of treatment at doses of 2 to 3 g/day divided into three to four doses. ALC may accelerate response when taken as a monotherapy or an adjunct to antidepressants. A narrative review found consistent positive evidence for the superiority of ALC over placebo. **A 2018** systematic review and meta-analysis of placebo-controlled RCTs on ALC as a monotherapy or adjunctive to antidepressants found comparable efficacy of ALC and antidepressants. Relatively greater antidepressant effects were observed in older subjects, and side effects were significantly lower in subjects taking ALC. Findings of RCTs suggest that ALC 1.5 to 3 g/day improves age-related symptoms of cognitive impairment in healthy older adult nondemented individuals and depressed older adult patients. In a 2-month RCT, depressed patients with dementia randomized to ALC 3 g/day experienced significantly greater improvements in mood and global cognitive functioning compared to the placebo group. RCTs show that ALC 1,500 to 3,000 mg/day improves reaction time, memory, and cognitive performance in patients with dementia and may slow the rate of progression of cognitive impairment. A systematic review of 11 RCTs of ALC in dementia confirmed significant positive effects at weeks 12 and 24. However, improvements were not sustained at 1 year with continued treatment. Younger individuals experiencing presenile dementia may benefit more than older individuals, and for unclear reasons, 62 years may be the “optimal age” beyond which ALC loses much of its cognitive-enhancing effects. ALC is generally well tolerated and may be safely used in combination with antidepressants and cholinesterase inhibitors.

L-THEANINE. L-Theanine (*N*-ethyl-L-glutamine) is found in green tea and is widely used in Asian countries to treat anxiety and depressed mood. Animal studies confirm that L-theanine increases brain serotonin, dopamine, and γ-aminobutyric acid (GABA) levels and may have general

Telegram: @medical_k

www.konkur.in

neuroprotective effects. Anxiety-reducing effects of L-theanine are believed to be mediated by enhanced EEG alpha activity in the occipital and parietal regions that are dose-dependent and reportedly similar to EEG changes observed during meditation. Calming effects may last 8 to 10 hours and are usually experienced within 30 minutes following ingestion of L-theanine at doses between 50 and 200 mg. Moderately severe anxiety often responds to L-theanine 200 mg twice daily, and more severe anxiety may require doses up to 600 to 800 mg per day divided into 200-mg increments every 3 to 4 hours. In one RCT (*N* = 16), healthy adult volunteers randomized to alprazolam (1 mg) versus L-theanine (200 mg) or placebo experienced equivalent and nonsignificant anxiolytic effects during an experimentally induced anxiety state. In another RCT (*N* = 12), individuals taking L-theanine experienced a relatively greater reduction in acute stress response as measured by changes in HRV and salivary immunoglobulins (s-IgA) compared to the placebo group. These findings suggest that stress-reducing effects of L-theanine may be mediated by inhibition of cortical neuron excitation. In a crossover study, healthy adults were randomized to L-theanine (250 mg) alone or in combination with caffeine (150 mg). Compared to the L-theanine–only group, the combination group experienced improved visual information processing, reduced mental fatigue, faster reaction time and faster working memory, generally increased alertness, and fewer headaches. A 2020 systematic review of RCTs on L-theanine for reducing stress-response and anxiety symptoms in healthy individuals found consistent positive evidence for efficacy at doses of 200 to 400 mg/day. The significance of findings on L-theanine in anxiety is limited by small study sizes and the use of nonclinical populations in most studies. L-Theanine is generally well tolerated, and there are no published reports of serious adverse side effects or interactions with other natural products or conventional medications.

***N*-ACETYL-CYSTEINE.** The findings of animal and human studies suggest that NAC decreases neuronal glutamate release. Limited findings suggest that NAC 2 to 3 g/day may be a safe and effective adjunctive treatment of moderately severe OCD and trichotillomania (TTM) in adults but not severe OCD or TTM in children and adolescents. In a 16-week double-blind placebo-controlled study (*N* = 40) adults with treatment-refractory

Telegram: @medical_k

www.konkur.in

OCD randomized to NAC 3,000 mg/day versus placebo while continuing on their medications experienced equivalent non-significant reductions in OCD symptom severity by study end.

In a 12-week double-blind placebo-controlled trial (*N* = 50) adults with TTM were randomized to NAC (1,200 to 2,400 mg/day) versus placebo while continuing their current medications. Individuals in the NAC group experienced significantly greater reductions in hair-pulling behavior compared to the placebo group, and no adverse effects were reported. In contrast to adult TTM, adjunctive NAC is probably not an effective adjunctive treatment of pediatric TTM. In a placebo-controlled trial (*N* = 39), children and adolescents randomized to NAC while continuing treatment as usual reported nonsignificant differences in hairpulling compared to the placebo group. Findings on NAC in bipolar disorder are inconsistent. In a 2-month open-label phase of a randomized placebo-controlled study, 149 moderately depressed bipolar patients treated with NAC 1 g BID experienced significantly decreased indices of functioning and improved life quality compared to the placebo group. In a subsequent double-blind placebo-controlled study, 149 stable bipolar patients randomized to NAC 2 g/day versus placebo while continuing on treatment as usual did not experience significant differences in recurrence rates or quality of life.

GLYCINE. Glycine functions as an inhibitory neurotransmitter. Glycine and glutamate are required co-agonists for the activation of NMDA receptors. Case reports and RCTs suggest that glycine and other naturally occurring NMDA agonists help correct NMDA receptor dysfunction underlying negative symptoms and cognitive impairments in schizophrenia. However, only a few small clinical trials have been done, and findings are inconsistent. A small open trial found that negative psychotic symptoms improve with glycine at doses up to 60 g per day. In a 6-week crossover RCT (*N* = 22), patients with treatment-resistant schizophrenia randomized to glycine at 0.8 g/kg in addition to their antipsychotic versus placebo plus antipsychotic experienced a 20% to 30% greater improvement in negative symptoms compared to drug plus placebo. In a multicenter 16-week RCT (*N* = 157), inpatients diagnosed with schizophrenia or schizoaffective disorder were randomized to glycine versus D-cycloserine or placebo. No significant differences in outcomes were observed in negative psychotic symptoms or cognitive impairment. In a 10-week open-label prospective

Telegram: @medical_k

www.konkur.in

study, stable patients diagnosed with schizophrenia (*N* = 29) randomized to glycine (up to 60 g per day) while continuing on antipsychotic medications experienced significant improvements in depressed mood and reductions in extrapyramidal symptoms. Glycine is well tolerated.

LYSINE AND ARGININE. Limited findings suggest that lysine and arginine may enhance stress-response and reduce general anxiety when used alone or in combination. In a 10-day placebo-controlled RCT (*N* = 29), healthy male volunteers with high trait anxiety were randomized to receive a formula containing L-lysine and L-arginine (10 g/day) or a placebo before being exposed to a psychosocial stressor (Jezova et al., 2005). The group receiving the amino acid formula experienced enhanced ability to cope with a psychosocial stress (i.e., being asked to give a public speech) that was mediated by increased cortisol. In a 1-week placebo-controlled RCT (*N* = 108), healthy adults were randomized to receive a formula containing L-lysine (2.64 g/day) and L-arginine (2.64 g/day) versus placebo. The group receiving the amino acid formula was observed to have significant reductions in both short-term stress response and state anxiety. L-Lysine and L-arginine are generally well tolerated, and serious adverse effects have not been reported.

***S*-ADENOSYL METHIONINE.** SAMe is a methylation product of the amino acid methionine and adenosine triphosphate. The molecule is essential for many important biosynthetic pathways, including transmethylation reactions required for the synthesis of serotonin, dopamine, and norepinephrine. After donating a methyl group, SAMe is converted to *S*-adenosyl-homocysteine, which has been implicated in the pathogenesis of Alzheimer disease, atherosclerosis, and other inflammatory diseases. SAMe is a widely used treatment of depression, arthritis, and fibromyalgia. The compound is available by prescription in Europe in oral, injectable, or intravenous forms, but in the United States, it can be obtained only as a nonstandardized, over-the-counter oral supplement. Folic acid and B_{12} are required cofactors for re-methylation of homocysteine back to SAMe and are routinely recommended to patients taking SAMe.

Although SAMe has been widely used for many years to treat depressed mood, large placebo-controlled studies have been conducted only in the last few decades. Recent well-powered studies and systematic reviews have reported non-significant or inconsistent findings. A

Telegram: @medical_k

www.konkur.in

systematic review published in 2016 included eight trials (total *N* = 934 adults) comparing both oral and parenteral SAMe with placebo, imipramine, desipramine, or escitalopram found non-significant response differences between SAMe and placebo, and non-significant outcome differences when SAMe and placebo were used adjunctively to an SSRI. A 2020 systematic review that included 8 placebo-controlled randomized trials (total *N* = 1,011) evaluating SAMe at doses between 200 and 3,200 mg/day as a monotherapy or adjunctive therapy reported inconsistent and nonsignificant findings.

Although the evidence supporting SAMe is uneven, some patients report significant sustained improvements in depressed mood. Advantages of SAMe over antidepressants include relatively rapid onset of action, usually within 1 week of starting treatment, the absence of clinically significant interactions with drugs, and relatively few side effects compared with antidepressants. The standard maintenance regimen for depressed mood is between 800 and 1,600 mg in two to four divided doses. Absorption is improved when SAMe is taken before meals.

The butane–disulfonate form of SAMe has significantly greater bioavailability than the tosylate form and is available as an enteric-coated tablet for longer shelf life. SAMe is generally well tolerated. However, transient mild anxiety, insomnia, gastrointestinal side effects, tachycardia, dry mouth, and dizziness have been reported. Rare cases of mania or hypomania have been reported in patients with bipolar disorder.

Omega-3 Fatty Acids and Phosphatidyl Serine

OMEGA-3 FATTY ACIDS. Omega-3 fatty acids (n3 PUFA) are polyunsaturated fatty acids found in oily fish, algae, nuts, and seeds. Two omega-3 fatty acids, EPA and DHA, have been extensively investigated as treatments of depressed mood, ADHD, schizophrenia, and other psychiatric disorders. Several mechanisms of action may help explain observed beneficial effects of omega-3 fatty acids, including increased CNS serotonin activity, anti-inflammatory effects, and suppression of phosphatidyl–inositol second messenger activity. There is strong evidence that omega-3 fatty acids (N-3 PUFA)—especially formulas containing high doses of purified EPA—are effective adjunctive treatments of depressed mood but are not effective when used as a monotherapy. Effective adjunctive doses are 1 to 2 g/day. Formulations containing more EPA than

Telegram: @medical_k

www.konkur.in

DHA may have greater antidepressant efficacy. Consistent findings of high-quality RCTs support that formulas containing higher EPA dosages are associated with better outcomes than formulas with higher amounts of DHA. Omega-3 may have the greatest antidepressant efficacy in obese individuals and others with abnormally high levels of inflammation. The finding that omega-3 fatty acids may reduce the incidence of coronary artery disease by influencing the production of pro-inflammatory cytokines in the heart may help to explain the observed correlation between heart disease and major depressive disorder. Preliminary evidence suggests that omega-3 supplementation may reduce anxiety associated with substance abuse or withdrawal, test-taking anxiety, and in premenstrual, pregnant, or menopausal women. Omega-3 fatty acids are generally well tolerated. Mild adverse effects include gastrointestinal upset, nausea, bloating, and diarrhea. There is a small risk of increased bleeding time, and concomitant use with anticoagulants should be avoided.

A meta-analysis of RCTs on omega-3 fatty acids in bipolar disorder identified only one study in which omega-3 fatty acids used adjunctively with a mood stabilizer showed a differential beneficial effect on depressive but not manic symptoms. EPA augmentation may be an effective preventive strategy in individuals at high risk for developing schizophrenia or in the early prodromal phase of psychotic illness but not as a treatment of established cases of schizophrenia. The neuroprotective role of omega-3 fatty acids during the early prodromal phase of schizophrenia may be related to general effects on the brain's antioxidative intracellular defense mechanisms or direct interactions between EPA and the glutamate receptor system. EPA augmentation may be especially appropriate for younger or antipsychotic naïve individuals in the early phase of illness or cases in which metabolic or sexual adverse effects may result in medication nonadherence and relapse. Preliminary findings suggest that a combination of EPA and DHA may reduce the rate of transitioning to full-blown schizophrenia in high-risk populations, including individuals who chronically abuse substances or already have impairments in neuropsychological functioning. A meta-analysis of placebo-controlled studies on EPA augmentation in patients with chronic schizophrenia or other psychotic disorders found no evidence for a greater benefit of EPA augmentation over antipsychotic medications alone. All studies included in the meta-analysis lasted 12 weeks and used EPA doses between 2 and 3 g per day. Possible explanations of reported negative findings include

Telegram: @medical_k

www.konkur.in

small study size, absence of clinical efficacy of EPA supplementation in chronic schizophrenia, and a “ceiling effect” on response to EPA augmentation associated with concurrent treatment with antipsychotics.

A systematic review and meta-analysis of studies on the effects of omega-3 supplementation on cognitive development, function, and decline throughout the life span concluded that omega-3 supplementation —especially DHA—may significantly improve cognitive development in infants but not in children, adolescents, adults, or the older adults. omega-3 fatty acids supplementation was not associated with a reduced rate of cognitive decline in healthy older adults or with a slowing in the rate of progression of Alzheimer disease. A systematic review and meta-analysis of placebo-controlled trials on omega-3 fatty acids in the treatment of ADHD in children and adolescents reported inconclusive findings due to methodologic problems including small sample sizes, variability of selection criteria, and type and dosage of supplements and short-term follow-ups. Studies done in Japan following the 2011 tsunami investigated the effectiveness of pretreatment with omega-3 fatty acids in preventing the development of PTSD following exposure to trauma in first medical responders. In a small, 8-week controlled trial (N = 30), women diagnosed with moderately severe borderline personality disorder randomized to ethyl-EPA (1 g/day) versus placebo reported less severe symptoms of aggression and depressed mood compared to the placebo group.

Omega-3 fatty acids are generally well tolerated and pose few safety issues. Transient mild gastrointestinal distress is sometimes reported by patients who take omega-3 fatty acids. There is one case report of apparent hypomania induced by omega-3 fatty acids. Rare cases of increased bleeding times have been reported in patients who take aspirin or anticoagulants concurrently.

PHOSPHATIDYL SERINE AND PHOSPHATIDYL CHOLINE. Phosphatidyl serine is one of the most important phospholipids in the brain and is an essential component of nerve cell membranes. Findings of RCTs suggest that phosphatidyl serine (300 mg per day) may improve global functioning and memory in the early stages of Alzheimer disease. However, the findings are inconsistent. Controlled trials on older adults suggest that phosphatidyl serine (300 mg per day) may result in small but consistent improvements in age-related cognitive decline. Open trials and one small controlled trial reported that supplementation with phosphatidylcholine

Telegram: @medical_k

www.konkur.in

(PC) 15 to 30 g/day reduced the severity of both mania and depressed mood in bipolar patients and that symptoms worsened when PC was discontinued. Cytidine 5-diphosphocholine (CDP-choline) is a precursor of PC and other important structural phospholipids in neuronal cell membranes. CDP-choline increases mitochondrial energy production, increases CNS noradrenaline and dopamine levels and has general neuroprotective effects following hypoxic or ischemic brain injury. Preliminary findings suggest that CDP-choline (1,000 mg per day) may improve cognitive performance in the early stages of Alzheimer disease. Two systematic reviews concluded that CDP-choline has consistent positive effects on recovery rate following stroke and mitigates the severity of cognitive impairment related to cerebrovascular disease in older adult individuals.

Multinutrient Formulas. A systematic review of RCTs on micronutrient formulas for the treatment of diverse psychiatric disorders found evidence of efficacy for a high-dose vitamin B complex formula and three different micronutrient formulas for acute stress, general anxiety, and PTSD. In general, high-dose formulas had differentially greater effects compared to low-dose formulas. The significance of findings was limited by small study size, nonblinding of many studies, heterogeneity in designs, and the absence of clinically diagnosed subjects in most studies. A systematic review of RCTs on single supplements and supplement formulas including essential fatty acids (EFA), B vitamins, vitamin C, Mg, and/or Zinc for female stress and anxiety identified 14 studies that met inclusion criteria. Significant findings included stress-reducing effects of EFAs during pregnancy and in premenopausal and menopausal women; reduced premenstrual anxiety in response to combined Mg and B6 (but no anxiolytic effects when either supplement was used alone); reduced anxiety in older women in response to B6; high-dose vitamin C reduced anxiety and blood pressure in response to stress. Micronutrient formulas are generally well tolerated at doses commonly recommended for treating psychiatric disorders. Some micronutrient formulas contain very high amounts of vitamin A, other vitamins, trace minerals, and amino acids, potentially resulting in toxicity. There have been case reports of hypervitaminosis A when taking micronutrient formulas that contain very high amounts of vitamin A.

Telegram: @medical_k

www.konkur.in

Findings from several case series suggest that a proprietary nutrient formula (EMP+) containing 36 separate constituents, including chelated minerals, vitamins, essential fatty acids, amino acids, phytonutrients, and trace elements, may significantly reduce symptoms of mania, depressed mood, and psychosis in patients with bipolar disorder when taken alone or together with mood stabilizers. The putative mechanism of action involves the correction of inborn metabolic errors that manifest as cyclic mood changes when the diet is deficient in certain micronutrients. In a 10-week double-blind placebo-controlled RCT (*N* = 93), children with ADHD randomized to EMP+ experienced significant improvements in inattentive symptoms, emotional regulation, and aggressive behavior, but no improvements in hyperactive or impulsive symptoms. Preliminary findings suggest that taking EMP+ before exposure to trauma may increase emotional resilience and reduce the severity of PTSD symptoms following exposure. The significance of findings on EMP+ is limited by the small study size and the absence of a placebo group, blinding, and randomized protocols. Potentially toxic micronutrient–medication interactions have been reported in patients taking EMP+ with mood stabilizers, and individuals taking the formula should be closely monitored by a knowledgeable physician.

Botanicals

ASHWAGANDHA (*WITHANIA SOMNIFERA*). Ashwagandha is used in Ayurvedic medicine to enhance general wellbeing, improve stamina, and treat a range of medical and mental health conditions. The bioactive constituents (withanolides) have anti-inflammatory and antioxidant properties, influence the GABA neurotransmitter system, and affect the HPA axis resulting in a reduction in cortisol levels. Findings of RCTs support that Ashwagandha is an effective monotherapy of anxiety symptoms related to chronic stress and may be an effective adjunctive treatment of GAD. A systematic review of RCTs on Ashwagandha for anxiety and stress found evidence for consistent positive effects at doses between 125 and 1,200 mg/day. Limited findings suggest that Ashwagandha may be an effective adjunctive treatment of GAD. In a 6-week placebo-controlled RCT (*N* = 40), adults diagnosed with GAD were randomized to a standardized Ashwagandha formula (1 g/day) versus placebo while continuing on an SSRI. The group receiving adjunctive Ashwagandha experienced

Telegram: @medical_k

www.konkur.in

significantly greater reductions in anxiety symptoms starting at the second week of treatment. Adjunctive treatment in combination with SSRIs was well tolerated. The significance of findings on Ashwagandha in GAD is limited by publication bias, small study size, heterogeneity of study designs, and variability in dosing strategies. Ashwagandha is generally well tolerated. Uncommon mild adverse effects include gastrointestinal distress and diarrhea. Ashwagandha may cause miscarriages and should be avoided during pregnancy.

CANNABIDIOL (*CANNABIS SATIVA*). Cannabidiol (CBD), a constituent of *Cannabis sativa,* has been extensively investigated as a potential treatment of diverse neuropsychiatric disorders. Findings of animal studies and early clinical trials suggest that CBD may be an effective treatment of GAD, panic disorder, social anxiety disorder (SAD), OCD, and PTSD. Anxiolytic effects are believed to involve modulation of CB1, CB2, and 5-HT1A receptors in limbic structures such as the amygdala, hippocampus, hypothalamus, cingulate cortex, as well as the prefrontal cortex. A retrospective chart review of a large case series (N = 103) found evidence for consistent anxiety-reducing effects of CBD. A review of animal and human studies investigating CBD as a potential treatment of panic disorder found promising early evidence; however, all clinical trials done to date have been in healthy volunteers. A systematic review of RCTs on the safety and efficacy of CBD as a treatment of diverse psychiatric disorders identified 27 studies, including 2 RCTs on CBD in SAD. In both studies, never-treated individuals with SAD randomized to receive CBD at doses of 400 or 600 mg experienced significantly greater reductions in social anxiety compared to the placebo group. CBD is well tolerated at doses up to 1,500 mg/day. Uncommon generally mild adverse effects include dry mouth, low blood pressure, lightheadedness, and drowsiness. There are no described contraindications to CBD use.

GOLDEN BOUQUET (*GALPHIMIA GLAUCA*). Galphimia is used as a sedative and anxiolytic in traditional Mexican medicine. The findings of animal studies suggest that the mechanism of action is mediated by the modulatory effects of Galphimine-B on dopamine, NMDA, and serotonin. Findings of RCTs support that a standardized extract of the herbal dosed at 310 mg BID has anxiolytic effects comparable to or greater than benzodiazepines in individuals diagnosed with GAD. In a 15-week study

Telegram: @medical_k

www.konkur.in

(*N* = 191), subjects with GAD randomized to Galphimia experienced significantly greater reductions in anxiety than subjects treated with lorazepam (1 to 2 mg/day). No adverse effects were reported by subjects taking Galphimia, and one-fifth of subjects taking lorazepam reported excessive sedation. In a 10-week placebo-controlled RCT (*N* = 167), individuals with moderate or severe anxiety were randomized to a standardized Galphimia formula versus alprazolam experienced significant, equivalent reductions in anxiety. No adverse effects were reported in the Galphimia group, and over 20% of subjects taking alprazolam reported daytime sleepiness. Galphimia is generally well tolerated. Mild adverse effects include headaches, gastrointestinal distress, and sedation.

GINKGO BILOBA. Ginkgo (*Ginkgo biloba*) extract is used in Europe and North America to treat dementia and other neurodegenerative diseases. Most commercially available preparations are standardized to two bioactive constituents: 24% flavone glycosides and 6% terpenoids. The flavonoid constituent functions as a strong antioxidant and is believed to have a general neuroprotective effect. The terpenoid fraction antagonizes platelet-activating factor (PAF), facilitating poststroke recovery through vascular reperfusion by decreasing thrombosis and nerve cell death associated with cerebral ischemia. Constituents of ginkgo may inhibit neurotoxicity and nerve cell death caused by nitric oxide. Two RCTs found that a compound herbal product containing both *G. biloba* (160 or 320 mg) and *Panax ginseng* (400 mg) resulted in transient improvement in recall performance in healthy adults. Enhanced cognitive functioning appears to reach its peak approximately 6 hours after the herbal preparation is taken. Preliminary findings suggest that combining ginkgo with another traditional Chinese herbal, *dangshen* (*Codonopsis pilosula*), may improve cognitive performance in healthy adults more than either herbal alone. In a 24-week, double-blind RCT, patients with mild to moderate dementia were randomized to a standardized ginkgo extract (160 mg per day) versus the cholinesterase inhibitor donepezil (5 mg per day) or placebo. At 24 weeks, patients taking ginkgo and donepezil experienced equivalent improvements in cognitive performance and global functioning. A meta-analysis of 11 clinical trials on standardized ginkgo extracts in older adults cognitively impaired individuals who did not meet full criteria for dementia suggested consistent cognitive-enhancing effects. Early systematic

Telegram: @medical_k

www.konkur.in

reviews of RCTs on ginkgo in dementia concluded that ginkgo preparations in doses between 120 and 600 mg per day taken over several weeks to 1 year result in modest improvements in memory, general cognitive functioning, and activities of daily living in mild to moderate Alzheimer dementia and multi-infarct dementia. However, a systematic review of all RCTs published up to 2006 on ginkgo in the treatment of dementia, and other types of acquired cognitive impairment found inconsistent evidence, noting that early trials were generally small or methodologically flawed, including the absence of standardized preparations and the use of different dementia rating scales across studies. Findings of a recent systematic review and meta-analysis support that ginkgo has beneficial effects on behavioral and psychological symptoms associated with dementia, including aggressive behavior, apathy, and anxiety. Ginkgo is generally well tolerated. Mild transient adverse effects include upset stomach, dizziness, and headaches. Cases of spontaneous bleeding have been reported. Ginkgo should be avoided in patients taking aspirin, warfarin, or heparin. *G. biloba* preparations should be discontinued at least 2 weeks prior to surgery. *Ginkgo. biloba* may cause elevation of hepatic enzymes, and there are case reports of possible serotonin syndrome when taken with SSRIs.

GINSENG (*PANAX GINSENG*). Individuals diagnosed with schizophrenia frequently show marked deficits in working memory, which can limit functional improvements with conventional drug treatment. In a 4-week placebo-controlled trial, 64 stable individuals diagnosed with schizophrenia were randomized to a proprietary North American ginseng extract versus placebo while remaining on treatment as usual. Visual working memory was significantly improved in patients receiving the ginseng preparation but not in the placebo group. Of note, individuals taking the ginseng preparation reported significantly fewer neurologic adverse effects after 4 weeks than the placebo group. Further studies are needed to confirm these findings and determine the optimal dosing of ginseng as an adjuvant to antipsychotics.

KAVA (*PIPER METHYSTICUM*). In traditional Polynesian cultures, Kava (Fig. 30.4–1) is used for ceremonial purposes and as an inebriant. Preclinical studies suggest that kavalactones in the roots interfere with serotonin neurotransmission in the amygdala, act as norepinephrine

Telegram: @medical_k

www.konkur.in

reuptake inhibitors that have a binding affinity with both GABA and NMDA receptors. Kava may also reduce anxiety by directly modulating vagal heart tone.

Most studies on Kava use preparations standardized to 70% kava lactones at doses between 70 and 240 mg per day for the treatment of “stress” and moderate anxiety in healthy adults. Early RCTs and systematic reviews reported consistent positive anxiolytic effects of Kava; however, most studies were small, of short duration, or did not enroll subjects with diagnosed anxiety disorders. More recent studies have reported inconsistent findings. In a 4-week double-blind RCT (N = 69), older adult individuals with diagnosed DSM-5 anxiety disorders were randomized to a high-dose Kava formula (containing 200 mg/day of kavalactones) versus a low-dose Kava formula (20 mg/day of kavalactones). At the study end, the high-dose Kava group reported statistically significantly greater reductions in anxiety compared to the low-dose group. In contrast, a large 16-week multicenter study found equivocal evidence for Kava 120 mg/day in individuals diagnosed with GAD. Findings of the most recent systematic review of placebo-controlled RCTs on Kava in individuals with diagnosed GAD identified only three studies that met inclusion criteria (total N = 130) and found modest anxiolytic effects of Kava that were not superior to placebo.

Kava is generally well tolerated at therapeutic doses. However, some individuals report nausea, rash, headaches, or dizziness. Kava use should be avoided during pregnancy. Kava may potentiate the sedating effects of alcohol and benzodiazepines. Rare case reports of hepatitis and fulminant liver failure have led to restrictions in the sale of kava products in many European countries and a warning by the FDA. A thorough review concluded that most reported cases of liver failure were associated with a processing mistake resulting in potentially toxic levels of alkaloids in a single batch of kava.

Telegram: @medical_k

www.konkur.in

FIGURE 30.4–1. Kava (*Piper methysticum*).

LAVENDER (*LAVANDULA OFFICINALIS*). The essential oil of lavender has been widely used in traditional Persian medicine for millennia to treat medical disorders and mental health problems, including anxiety, insomnia, and depressed mood. The findings of animal and human studies suggest that the essential oil of lavender has significant anxiolytic properties mediated by the effects of linalool and linalyl on serotonin and NMDA receptors. A systematic review of studies on different lavender preparations found evidence for modest anxiolytic effects of lavender essential oil but nonsignificant evidence for aromatherapy. A systematic review and meta-analysis of RCTs on lavender aromatherapy in populations with or without clinical anxiety that included 22 trials found evidence for modest anxiety-reducing effects. Placebo-controlled RCTs and systematic reviews of studies on Silexan, a standardized oral preparation of lavender oil support comparable efficacy to SSRIs and benzodiazepines in individuals with GAD or anxiety-related restlessness and disturbed sleep. When dosed between 80 and 160 mg/day, Silexan has comparable or superior efficacy to paroxetine and lorazepam. One placebo-controlled study found superior efficacy of Silexan 160 mg/day compared to lorazepam 0.5 mg for symptoms of generalized anxiety.

Telegram: @medical_k

www.konkur.in

ROSEROOT (*RHODIOLA ROSEA*). *R. rosea* is used in traditional Russian medicine to enhance stamina, reduce fatigue, improve sleep, and enhance mood. Findings of in vitro and animal studies suggest that bioactive constituents of *R. rosea* affect the HPA axis reducing serum cortisol levels reducing fatigue, and decreasing stress-related anxiety. Recent placebo-controlled RCTs support that standardized extracts of *R. rosea* at doses of 340 to 680 mg/day are superior to placebo for mild to moderate depressed mood and may be an effective adjuvant of antidepressants. In a 12-week double-blind placebo-controlled RCT by Gao and colleagues (*N* = 100), patients with mild to moderate depressed mood were randomized to sertraline plus *R. rosea* 0.6 g/day, sertraline plus *R. rosea* 0.3 g/day, or sertraline plus placebo. At the study end, both *R. rosea* groups reported significantly greater reductions in depressive mood symptoms compared to the placebo group. Subjects receiving the higher dose of *R. rosea* responded better than subjects receiving the lower dose. Limited findings of small RCTs suggest that standardized preparations of *R. rosea* dosed at 200 mg BID have significant stress-reducing effects. To date, only one small open-label study has investigated *R. rosea* in individuals with GAD with positive findings. Findings of recent open studies suggest that 500 mg of a standardized *R. rosea* extract has antidepressant effects, improves overall mental performance and stamina, and may accelerate the recovery of normal cognitive functioning following traumatic brain injury.

R. rosea is generally well tolerated at doses used to treat stress-related fatigue. Uncommon adverse events include dizziness, dry mouth, and excessive salivation. *R. rosea* can be safely combined with antidepressants and may augment antidepressant efficacy. There are no cases of serious adverse effects or drug–drug interactions; however, there have been reports of possible mania induction. Patients diagnosed with bipolar disorder should be advised against using this herb.

SAFFRON (*CROCUS SATIVUS*). Saffron, obtained from the stigmas of the flower of *Crocus sativa*, is widely used as a spice and medicinal agent in traditional Persian medicine. Antidepressant effects may involve anti-inflammatory and immunomodulatory effects and reuptake inhibition of serotonin, norepinephrine, and dopamine. Findings of meta-analyses and systematic reviews suggest that saffron 20 to 30 mg/day has comparable efficacy to antidepressants for mild to moderately severe depressed

Telegram: @medical_k

www.konkur.in

mood; however, recent double-blind RCTs have reported inconsistent findings. So far, only one study has investigated saffron as a potential adjunctive treatment of MDD. In an 8-week double-blind RCT (*N* = 160), depressed individuals were randomized to a standardized saffron extract (14 mg BID) versus placebo while continuing on their antidepressant medication. Clinicians rated the saffron group as showing greater improvements in the depressed mood; however, subjects in the saffron group did not report subjective improvements in mood. Preliminary findings suggest that saffron may have comparable efficacy to cholinesterase inhibitors in Alzheimer's patients. Saffron is generally well tolerated as a monotherapy and in combination with antidepressants. In a 6-week RCT, saffron supplementation improved sexual adverse effects associated with fluoxetine. Uncommon mild adverse effects include nervousness, nausea, headache, and increased appetite.

ST. JOHN WORT (*HYPERICUM PERFORATUM*). SJW (Fig. 30.4–2) is widely used to treat depressed mood. Different constituents function as serotonin reuptake inhibitors, decrease binding to benzodiazepine receptors, weakly inhibit monoamine oxidase (MAO), and possibly also bind to *N*-methyl-D-aspartate (NMDA) receptors. Hyperforin probably contributes more to the antidepressant efficacy of SJW than hypericin. However, many commercial preparations are standardized to 0.3% hypericin. Therapeutic doses of standardized SJW preparations for moderate depression typically range from 300 mg twice daily to 900 mg twice daily. More than 40 controlled trials on SJW in patients with depressed mood have been conducted with mixed methodologic quality and inconsistent results. A systematic review of 27 trials (total *N* = 2,200), 17 of which were placebo-controlled, found that SJW is significantly more effective than placebo for the treatment of mild to moderate depressed mood. However, a more recent meta-analysis using stringent inclusion criteria controlling for publication bias and small study effects found significantly lower antidepressant efficacy than reported in previous meta-analyses.

SJW is generally well tolerated. Uncommon adverse include nausea, restlessness, and mild sedation. There are no published reports of serotonin syndrome or other serious side effects when SJW is used as monotherapy at recommended doses, but there are several case reports of possible serotonin syndrome when SJW and a conventional antidepressant were used together. Pregnant women should not take

Telegram: @medical_k

www.konkur.in

SJW. There are no case reports of serious interactions when SJW is taken with MAOI antidepressants. However, their combined use should be avoided to minimize risk. SJW should not be taken with protease inhibitors, immunosuppressive agents, Coumadin, digoxin, and oral contraceptives.

FIGURE 30.4–2. St. John wort (*Hypericum perforatum*).

TOOTHED CLUBMOSS (*HUPERZIA SERRATA*). Huperzine A, an alkaloid derivative of the herb *Huperzia serrata* is a central ingredient of many compound herbal formulas used in Chinese medicine to treat cognitive impairment related to normal aging. Huperzine A reversibly inhibits acetylcholinesterase, the enzyme that breaks down the neurotransmitter acetylcholine, which plays a critical role in memory. Huperzine A may also slow the production of nitric oxide in the brain, reducing age-related neurotoxicity. Findings from animal studies suggest that huperzine A may be a more potent and more specific inhibitor of acetylcholinesterase than some cholinesterase inhibitors. Early controlled trials reported consistent beneficial effects in both age-related memory loss (i.e., benign senescent forgetfulness) and Alzheimer disease at doses between 0.2 and 0.8 mg/day; however, more recent studies report inconsistent findings. Two

Telegram: @medical_k

www.konkur.in

systematic reviews of placebo-controlled randomized trials on Huperzine A in patients diagnosed with AD found inconclusive evidence for improvements in memory loss and other cognitive problems. Because most studies on Huperzine A are of short duration, 8 to 12 weeks, it has been suggested that observed beneficial effects might reflect temporary symptomatic improvement. Huperzine A is generally well tolerated. Infrequent adverse effects include transient dizziness, nausea, and diarrhea.

TURMERIC (*CURCUMA LONGA*). Curcumin is the principal bioactive constituent of Turmeric. Animal studies have established that curcumin has strong antioxidant and anti-inflammatory activity, suggesting that it may have beneficial effects on a range of medical and neuropsychiatric disorders associated with chronic inflammation. The findings of animal studies suggest that antidepressant effects of curcumin may be related to the modulatory activity of the monoamine neurotransmitters serotonin, norepinephrine, and dopamine.

Recent findings support that curcumin at doses between 500 mg and 1,000 mg/day has antidepressant efficacy as a monotherapy and is a safe and effective adjuvant to antidepressants. A systematic review of RCTs on curcumin for neuropsychiatric disorders found strong evidence for antidepressant and antianxiety effects and provisional findings for beneficial effects of curcumin on PTSD, bipolar disorder, OCD, psychotic disorders, and autism. A meta-analysis of 6 placebo-controlled RCTs (total $N = 377$) on curcumin in MDD found evidence of superior antidepressant and antianxiety efficacy over placebo. Curcumin is generally well tolerated, and severe adverse effects have not been reported.

VALERIAN (*VALERIANA OFFICINALIS*). Valerian (*Valeriana officinalis*) has been widely used in many traditional systems of medicine for more than a millennium. The mechanism of action may involve both inhibition of GABA reuptake and binding to serotonin receptors by valepotriates. Findings on Valerian extract in insomnia are inconsistent. An early systematic review of RCTs on valerian for insomnia found that a standardized extract of 600 to 900 mg taken at bedtime improves the subjective quality of sleep with few side effects. However, a more recent systematic review of 29 RCTs that met rigorous criteria for study design and methodologic quality concluded that the most rigorously designed studies failed to demonstrate

Telegram: @medical_k

www.konkur.in

significant outcomes differences between valerian and placebo. Another systematic review found a statistically significant benefit of valerian extract in insomnia but noted significant methodologic flaws in most studies examined and evidence of publication bias. In a large, multicenter, 6-week study, chronic insomniacs randomized to a standardized valerian extract at 600 mg versus oxazepam at 10 mg reported comparable improvements in sleep quality and duration. There is no risk of addiction with valerian preparations, and there are no reports of daytime psychomotor slowing. Because of its potentiating effect on GABA, valerian use should be avoided with benzodiazepines or alcohol. There are rare reports of elevated liver enzymes. Valepotriates may be mutagenic, and this herb should be avoided in pregnant or nursing women.

OTHER BOTANICALS. Select herbals and other natural products can be safely used adjunctively to depressed mood and other psychiatric disorders or to mitigate adverse effects caused by psychopharmaceuticals. For example, *G. biloba* can be safely combined with antidepressants to mitigate adverse sexual effects. Limited findings suggest that Passion flower (*Passiflora incarnata*) extract may have equivalent efficacy to benzodiazepines for the management of moderate anxiety symptoms. Preparations of two botanicals used in Ayurvedic medicine, *Bacopa monnieri* and *Centella asiatica,* traditionally used in Persian medicine to treat generalized anxiety, are well tolerated and diminish symptoms of moderate anxiety. Limited findings from human clinical trials suggest that an aqueous extract of Catmint (*N. menthoides*) 400 mg BID may have anxiolytic effects. Preclinical animal studies have reported promising early evidence for many other herbals in which anxiolytic effects are believed to be mediated by GABA or cannabinoid receptors. A comprehensive narrative review of studies on plant-derived anxiolytics found evidence of the efficacy of several herbals in the treatment of generalized anxiety, including *Matricaria recutita, Crataegus* spp., *G. biloba, Scutellaria lateriflora, Silybum marianum, P. incarnata, Withania somniferum, Galphimia glauca, C. asiatica, R. rosea, Echinacea* spp., *Melissa officinalis,* and *Echium amoenum.* Acute-onset anxiolytic activity was found for *C. asiatica, Salvia* spp., *M. officinalis, P. incarnata,* and *Citrus aurantium.*

Telegram: @medical_k

www.konkur.in

Compound Herbal Formulas. Meta-analyses and systematic reviews of Chinese herbal formulas used to treat depressed mood have identified several promising formulas, including Chaihu-Shugan-San, Xiao Yao San, Ganmai Dazao, Wuling, Shuganjieyu, Wendan Decoction, and Jiu Wei Zhen Xin. Many systematic reviews have reported comparable or superior efficacy to antidepressants; however, the significance of findings is limited by methodologic flaws and possible publication bias. Significantly, most studies report very low rates of adverse effects when Chinese herbal formulas are used as monotherapies or adjunctively to antidepressants. Some studies reported that Chinese herbal formulas lessened antidepressant adverse effects.

Jiu Wei Zhen Xin Granula (JWZXG) is a Chinese herbal medicine formula that can be used alone or in combination with Western anxiolytic medications for GAD and other anxiety disorders. The formula is standardized to extracts of nine herbals with established tranquilizing or anxiolytic properties: *Panax Ginseng* (ginseng), Spina Date Seed (seed of wild jujube), *Schisandra chinensis* (the fruit of Chinese magnolia-vine), *Poria cocos* (hoelen), Radix Polygalae (the root of Polygala tenuifolia Willd), Rhizoma Corydalis (corydalis tuber), *Radix Asparagi* (Cochinchinese Asparagus Root), *Rehmannia glutinosa* (prepared Rehmannia root), and Cinnamon (cassia bark). A meta-analysis of 14 trials (total N = 1,358) on JWZXG in individuals with diagnosed GAD found superior efficacy of SSRIs but comparable efficacy of JWZXG and the azapirones. JWZXG was better tolerated than SSRIs. Although the formula is often used in combination with buspirone and other azapirones, potentially unsafe herb–drug interactions have not been evaluated. The significance of findings was limited by small study sizes, short study duration (most studies were 4 to 8 weeks long), the absence of placebo groups in many studies, inadequate blinding or nonblinding, and the small number of studies and possible publication bias. Adverse effects of JWZXG include dry mouth, constipation, dizziness, and nausea.

Kami-untan-to (KUT) is a compound herbal formula consisting of 13 different herbs used in Japanese traditional Kampo medicine to treat symptoms of cognitive impairment and dementia. Animal studies show that KUT increases CNS levels of nerve growth factor (NGF) and choline acetyltransferase (ChAT), the enzyme required to synthesize acetylcholine. KUT protects against memory impairment induced by thiamin deficiency in mice, suggesting a possible beneficial role in the

Telegram: @medical_k

www.konkur.in

management of delirium tremens and other syndromes of cognitive impairment related to thiamin deficiency. In a small 12-month open trial (*N* = 20), moderately demented patients with Alzheimer disease were treated with KUT alone versus a combined regimen of vitamin E, estrogen, and a nonsteroidal anti-inflammatory drug or placebo. Both treatment groups deteriorated at a significantly slower rate compared to the placebo group. Large, controlled trials are needed to confirm the potential therapeutic effects of this promising herbal formula in dementia.

Brahmyadiyoga is a compound herbal formula in Ayurvedic medicine used to treat syndromes resembling schizophrenia. The formula contains six herbs, including *Rauwolfia serpentina,* from which reserpine was isolated in the early 20th century and shown to have significant antipsychotic efficacy. Reserpine is seldom used to treat schizophrenia in Western countries today because of concerns over reports of severe depressed mood. In an early 2-month RCT, 108 chronically psychotic patients were randomized to 8 to 12 g per day of brahmyadiyoga, 8 to 12 g per day of valerian, 200 to 300 mg per day of chlorpromazine, and placebo. Patients treated with brahmyadiyoga and chlorpromazine reported significant comparable improvements in symptom severity. A subsequent RCT confirmed the antipsychotic efficacy of brahmyadiyoga. Findings of a systematic review of three small RCTs (total *N* = 250) comparing brahmyadiyoga with an antipsychotic or placebo were inconclusive because of small study sizes, high attrition rates, methodologic differences, and the use of nonstandardized assessment approaches. Cases of nausea have been reported with brahmyadiyoga.

Essential Oils. Essential oil extracts of certain botanicals can be inhaled as aromatherapy or applied topically; however, research findings are inconsistent. Some studies report general calming of agitated behavior in demented persons when the essential oils of lemon balm and lavender are applied to the face and arms. Other studies report that exposure to the same essential oils is no more effective than placebo in agitated patients with dementia. It has been suggested that essential oils are effective in this population through systemic absorption or the combined effects of massage and olfaction but *not* through olfaction alone. Infrequent adverse effects of essential oils include skin allergies, phototoxic reactions, and potentiation of sedative-hypnotics when used with lavender or other oils known to have sedating effects. Pregnant

Telegram: @medical_k

www.konkur.in

women should avoid topical use of essential oil therapies because of possible toxic effects on the fetus or the uterus caused by systemic absorption.

Hormones

DEHYDROEPIANDROSTERONE. Dehydroepiandrosterone (DHEA) is a precursor of testosterone and other hormones. The sulfated form of DHEA —DHEA-S—is the most abundant steroid in the body. DHEA is an important neuroactive steroid and modulates neuronal excitability by acting as an antagonist at the GABA receptor complex. Preclinical studies suggest that the putative mood-enhancing effects of DHEA are mediated through androgen receptors, estrogen receptors, serotonin, GABA, NMDA, and possibly norepinephrine. DHEA's antipsychotic effects may involve increased dopamine release in the frontal cortex and increased activity of NMDA and sigma receptors. Physiologic replacement doses of DHEA 30 to 90 mg/day, corresponding to DHEA serum levels at age 40, may improve mood in middle-aged or older adult depressed patients. Higher serum levels of DHEA and its sulfated form DHEA(S) are associated with healthy aging. A recent study found that healthy older adult individuals with relatively higher DHEA(S) levels are at reduced risk of developing depressed mood.

Findings of placebo-controlled RCTs support that DHEA supplementation of 90 to 450 mg/day reduces the severity of depressed mood; however, many studies are underpowered or lack methodologic rigor. In one 6-week RCT (N = 46), moderately depressed adults were randomized to DHEA 90 mg/day for 3 weeks followed by DHEA 450 mg/day (150 mg TID) for three weeks versus placebo (Schmidt, 2005). A 50% or greater reduction in depressive symptoms was observed in the majority of patients in the DHEA group, most of whom reported improvements in baseline sexual functioning, and most responders remained asymptomatic at 12 months follow-up. The findings of a recent study showing that higher circulating DHEA(S) levels correlate to increased remission rate in depressed individuals taking SSRIs suggests that DHEA may be a safe and effective adjunctive treatment of depressed mood.

Pilot studies suggest that DHEA (25 to 50 mg per day) improves memory and enhances general cognitive functioning in healthy adults.

Telegram: @medical_k

www.konkur.in

However, findings are inconsistent, and negative findings have been reported at doses less than 90 mg per day. A systematic review of RCTs on DHEA or DHEA-S in healthy older adults found no evidence of improved memory or cognitive functioning. DHEA may differentially improve memory in older adult patients who have low DHEA serum levels more than in healthy adults with normal serum levels. However, no correlations were found between serum DHEA-S levels and severity of cognitive impairment or cumulative mortality in a large cohort of individuals newly diagnosed with Alzheimer disease. Preliminary findings suggest that 200 mg per day of DHEA may improve symptoms of cognitive impairment in multi-infarct dementia; however, no placebo-controlled trials have been done. Large prospective studies of at least 1 year or longer are needed to further investigate claims of long-term cognitive benefits of DHEA.

In a 6-week RCT (*N* = 30), inpatients with schizophrenia randomized to DHEA at 100 mg per day in addition to their regular antipsychotic medications experienced significant improvements in *negative* psychotic symptoms, including reduced apathy and social withdrawal. However, there were no significant changes in *positive* psychotic symptoms, including auditory hallucinations and delusions. Findings of another small RCT (*N* = 30) suggested that augmentation of antipsychotics with DHEA 100 mg/day for 6 weeks significantly reduces negative symptoms and may be especially effective in women. However, a systematic review that included three small RCTs (*N* = 126) on DHEA as an adjunctive to antipsychotics found equivocal evidence for an augmentation effect on measures of positive and negative symptoms, global functioning, and quality of life.

Increased severity of PTSD is correlated with reduced DHEA blood levels, and limited findings suggest that DHEA may lessen symptoms of PTSD. In an open-label pilot study (*N* = 5), women with treatment-refractory PTSD related to early childhood abuse who had not responded to pharmacologic therapy reported decreases in numbing, re-experiencing, hyperarousal, and other PTSD core symptoms, as well as improved sleep and improved libido with DHEA at doses between 25 and 100 mg/day.

DHEA is generally well tolerated at therapeutic doses, but cases of acne, hirsutism, and rare cases of mania have been reported with chronic high doses. DHEA supplementation may promote cancer in women who

Telegram: @medical_k

www.konkur.in

have a history of estrogen receptor-positive breast cancer and may increase the risk of prostate cancer in men with early or undetected prostate cancer. DHEA should be avoided in men at risk of prostate cancer and women who have a history of estrogen receptor-positive breast cancer. Women should be cautioned about an increased risk of heart disease and breast cancer.

MELATONIN. Melatonin is a hormone manufactured in the pineal gland and plays an important role in regulating the sleep–wake cycle. Synthetic over-the-counter forms of melatonin are widely used to treat insomnia. A meta-analysis of 17 RCTs (total $N = 284$) found that exogenous melatonin at doses between 0.3 and 3 mg decreases the time needed to fall asleep and increases total sleep duration. Doses that replace normal physiologic levels (0.3 mg) in insomnia patients with low serum melatonin levels improve restful sleep in the middle part of the sleep cycle. Higher pharmacologic doses (3.0 mg) also improve sleep quality but may cause hypothermia, elevated daytime melatonin levels, and residual grogginess. A systematic review of 10 RCTs found that melatonin in jet lag was effective at doses of 0.5 to 5.0 mg when taken close to bedtime in the country of destination. Overall efficacy was relatively less for westward flights and relatively greater when more time zones were crossed. Melatonin has been used with moderate success to treat insomnia in patients with schizophrenia and agitated patients with mania. Uncommon mild adverse effects include headaches and itching.

Psychedelics. Psychedelics including D-lysergic acid diethylamide (LSD), ketamine, psilocybin, and ayahuasca are extensively investigated as potential treatments of depressed mood, anxiety disorders, PTSD, and other psychiatric disorders. Antidepressant effects of LSD and psilocybin are believed to be related to modulatory activity on serotonergic, dopaminergic, and glutamatergic neurotransmitter systems. A comprehensive review of studies on psychedelics for all psychiatric disorders published between 2007 and 2019 identified a total of 1,603 articles, including 14 articles reporting well-designed clinical trials investigating LSD, MDMA, psilocybin, and ayahuasca for mood and anxiety disorders, PTSD, substance use disorders and end-of-life care. The review found preliminary but promising evidence for MDMA in the treatment of PTSD, and for psilocybin in the treatment of depressed mood

Telegram: @medical_k

www.konkur.in

and cancer-related anxiety. A 2019 systematic review of RCTs on psychedelics in mood and anxiety disorders (7 studies, total *N* = 130 subjects) found that low doses of ayahuasca, psilocybin, and LSD consistently resulted in rapid onset significant antidepressant and anxiolytic effects that often persisted for months following treatment. A systematic review of RCTs on psychedelics in unipolar depressed mood that included 19 studies (total *N* = 423) found that almost 80% of subjects experienced improvements in depressive mood symptoms. A different systematic review found that psychedelics also have beneficial effects on group therapy in diverse populations and clinical indications. A 2018 systematic review of systematic reviews on the efficacy, safety, and tolerability of psychedelic agents found evidence of beneficial effects of psilocybin and LSD on anxiety and depressed mood, alcohol and tobacco dependence, and of ayahuasca on depressed mood, including cases of treatment-refractory depression. The significance of findings on psychedelics as treatments of unipolar depressed mood and other psychiatric disorders is limited by the small size of many studies, absence of blinding in many studies, and short study duration.

Psychedelics are generally well tolerated when taken at doses established to have antidepressant effects and do not carry a risk of dependence. Psychedelics can cause intense negative psychological effects, including paranoia and psychosis, and it is prudent to take them in medically controlled environments. Concomitant use of psychedelics and SSRIs may result in serotonin syndrome and should be avoided. Commonly reported generally mild adverse effects include transient anxiety, nausea, headaches, and mild transient increases in heart rate and blood pressure.

Somatic Therapies

Exercise. Infrequent physical activity is an established risk factor for developing depressed mood. Physical exercise increases the levels of brain-derived neurotrophic factors and may enhance neural plasticity and new synapse formation. Regular exercise is associated with increases in the relative size of the frontotemporal and parietal lobes, which are important centers for learning, memory, and executive functioning. Brain levels of endorphins, dopamine, norepinephrine, and serotonin are increased following sustained exercise. Two meta-analyses of controlled trials confirmed consistent positive effects of regular exercise on

Telegram: @medical_k

www.konkur.in

depressed mood. Aerobic conditioning and strengthening exercises are equally effective against depressed mood. The optimum duration and frequency of exercise for depression have not been determined but are probably related to age and fitness level. In a 16-week study (*N* = 156), depressed patients older than 50 years randomized to aerobic exercise three times a week versus sertraline (up to 200 mg per day) versus exercise plus sertraline experienced equivalent improvements in standardized measures of mood, self-esteem, and negative thoughts. Patients in the antidepressant-only group initially improved faster. However, patients in the exercise-only group had a lower 6-month relapse rate. The antidepressant effects of running or fast walking may be equivalent to those of CBT and conventional antidepressants for moderate depressed mood. Depressed individuals who exercise in a brightly lit (2,500 to 4,000 lx) indoor environment reported greater improvements in mood and vitality than depressed individuals who exercised indoors in ordinary room light (400 to 600 lx).

Routine physical activity is associated with a reduced risk of all categories of dementia. More than 2,000 physically nonimpaired men aged 71 to 93 years were followed with routine neurologic assessments at 2-year intervals starting in 1991. At the end of the study period, men who walked less than 1/4 mile daily had an almost twofold greater probability of being diagnosed with any category of dementia than men who walked at least 2 miles daily. Findings of the Nurses' Health Study based on biannual mailed surveys over 10 years showed that women aged 70 to 81 years who engaged in regular vigorous physical activity were significantly less likely to have been diagnosed with dementia than women with more sedentary lifestyles. A small RCT found that regular daily exercise in individuals with moderate dementia receiving in-home care reduced depressed mood but did not improve cognitive functioning, suggesting that regular exercise does not slow the rate of cognitive decline once dementia has begun.

A period of 20 to 30 minutes of regular daily exercise significantly reduces symptoms of generalized anxiety. A prospective 10-week study on exercise in individuals diagnosed with panic disorder found that regular walking or jogging (4 miles three times a week) reduced the severity and frequency of panic attacks. In a small open study, alcoholics who regularly exercised while hospitalized for acute detoxification reported significant improvements in mood and general well-being. Abstinent alcoholics

Telegram: @medical_k

www.konkur.in

enrolled in outpatient recovery programs reported improved mood with regular strength training or aerobic exercise. A systematic review of studies on the relationship between exercise and sleep in the older adults concluded that exercise probably enhanced sleep quality and improved overall quality of life.

Expressive Movement Therapies. Dance therapy and other expressive movement therapies are widely used in both outpatient and inpatient settings as treatments for depression, anxiety disorders, and schizophrenia. Most studies on expressive movement therapies are qualitative in design and difficult to analyze because of methodologic differences, small study sizes, and the absence of blinding. However, evidence suggests that the regular practice of dance therapy and other expressive movement therapies is associated with significant reductions in the severity of anxiety and depressed mood.

Animal-Facilitated Psychotherapy. Animal-facilitated therapy provides a sense of social connection and renewed purpose and has beneficial effects on mood, anxiety, and global cognitive functioning in both outpatient and inpatient settings. Animal-facilitated psychotherapy has not been rigorously evaluated in controlled trials; however, observational studies suggest that regular contact with therapy dogs and other animals may reduce anxiety, improve mood, and increase attention span. Preliminary findings suggest that the use of animal companions in the context of psychotherapy probably improves general emotional well-being in depressed and anxious persons.

Massage. The anxiety-reducing effects of massage are believed to be mediated by decreased cortisol and increased parasympathetic tone. However, the mental health benefits of massage are difficult to quantify. Findings of open trials suggest that regular massage therapy reduces the severity of chronic moderate state anxiety related to test-taking, problem-solving, or work stress. A review of massage techniques for depressed mood identified several open studies with positive outcomes.

Snoezelen. Snoezelen is a multimodal treatment of dementia that employs music, light patterns, tactile surfaces, and essential oils to stimulate the senses of sight, hearing, touch, taste, and smell. Snoezelen sessions are usually administered two to three times weekly to patients

Telegram: @medical_k

www.konkur.in

with dementia in skilled nursing homes. A systematic review of RCTs of snoezelen in dementia concluded that apathy, speech skills, and psychomotor agitation improved in demented patients after four to eight sessions.

Mindfulness Training and Mind–Body Practices. Mindfulness training includes many styles of meditation and guided imagery. Mind–body practices include *taijijuan, qigong,* yoga, and others. Improved capacity for focused attention and reflection has been proposed as an important nonspecific psychological benefit of mind–body practices. MBSR and mindfulness-based cognitive therapy (MBCT) are secular approaches widely used to treat mental health problems. Research findings support that MBCT is a beneficial adjunctive therapy for unipolar depression and both MBSR and MBCT are beneficial adjunctive interventions for anxiety disorders. The regular practice of a mind–body skill may be as effective as CBT or antidepressants in patients with moderately depressed mood. Mindfulness training combined with cognitive therapy may enhance outcomes compared to cognitive therapy alone. Findings of a small open pilot study suggest that regular use of MBCT may significantly improve executive functioning, memory, and ability to complete tasks in stable patients diagnosed with bipolar disorder. Improvements in executive functioning persisted up to 3 months after treatment ended. Twelve individuals diagnosed with bipolar disorder who participated in 12 weekly group sessions of MBCT exhibited increased mindfulness, lower residual depressive mood symptoms, increased capacity for emotional regulation abilities, and generally improved psychological well-being and psychosocial functioning. Large prospective trials are needed to confirm these findings and determine the optimal type and frequency of MBCT for cognitive symptoms of bipolar disorder.

Relaxation Techniques. Relaxation techniques include sustained deep breathing, progressive muscle relaxation, guided imagery, and systematic desensitization. The mechanism of action may involve reducing muscle tension using behaviors or cognitions that diminish tension and autonomic arousal. The regular practice of progressive muscle relaxation or sustained deep breathing at bedtime reduces the time needed to fall asleep in chronic insomniacs. Individuals who have difficulty falling asleep because of somatic complaints respond better to progressive muscle relaxation, whereas those who stay awake because of chronic worrying

Telegram: @medical_k

www.konkur.in

are more likely to sleep better using guided imagery. A meta-analysis of 66 studies (total *N* = 2,000) on somatic and mind–body treatments of insomnia concluded that all interventions resulted in “reliable and durable benefits” that were superior to placebo, including improved quality of sleep and reduced sleep latency. A separate meta-analysis concluded that nonpharmacologic treatments of chronic insomnia are initially more expensive and require more time than conventional drug therapy but are reliable, yield sustained benefits, and are thus more cost-effective in the long run.

In a 5-month prospective study, individuals diagnosed with GAD randomized to relaxation only versus antidepressants plus relaxation experienced equivalent and significant improvements in state anxiety levels by the end of the trial. In a small RCT (*N* = 36), anxious adult outpatients randomized to 12 weekly sessions of applied relaxation versus conventional cognitive therapy experienced significant and comparable reductions in anxiety. Depressed patients who had previously been diagnosed with somatoform disorders experienced greater improvements in mood when guided imagery was combined with antidepressants than with antidepressants alone. In an open trial, 60 women reporting anxiety and postpartum depressed mood experienced significant reductions in both anxiety and depressed mood using a combined relaxation-guided imagery protocol during the first four weeks after childbirth. Guided imagery has beneficial effects on the immune system, physiologic stress responses, and general mental-emotional functioning.

Yoga. More studies have been done on yoga than any other mind–body discipline. The calming effects of yogic breathing are probably related to the modulation of parasympathetic–sympathetic tone. The regular practice of yoga postures (asanas) probably results in beneficial changes in autonomic activity, resulting in improved cardiorespiratory performance and increased feelings of general well-being. A review of recent studies on yoga in depressed persons reported significant positive findings, but most studies were limited by methodologic flaws. Combining a mindfulness practice with yoga may have greater mood-enhancing benefits than forms of yoga that do not include mindfulness. Moderately depressed patients improved significantly by the end of a 5-week class in Sudarshan kriya (SK) yoga. Improvements associated with SK breathing practices in severely depressed hospitalized patients were comparable to

Telegram: @medical_k

www.konkur.in

responses achieved with antidepressants and only slightly less robust than patients receiving electroconvulsive therapy. Preliminary findings support that the regular practice of forms of yoga that do not include specialized breathing exercises also improve depressed mood, including hatha yoga, Omkar meditation, and Iyengar yoga. Regular SK yoga practice may reduce the need for anxiolytics in individuals diagnosed with GAD. Findings of a small RCT suggested that the regular practice of a specific kundalini yoga left-nostril breathing technique may significantly reduce symptom severity in patients with OCD. A review of studies on yoga and other mind–body practices used to treat PTSD found that many approaches in current use reduce some PTSD symptoms, including intrusive memories, avoidance, and emotional arousal.

Meditation. Meditation has been extensively investigated as a treatment of anxiety. Beneficial physiologic effects of meditation include decreased oxygen consumption, respiratory rate, and blood pressure, and decreased autonomic arousal. Findings of RCTs show that the consistent practice of mindfulness meditation significantly reduces generalized anxiety. MBSR is an eclectic approach that incorporates elements of different Eastern meditation practices and Western psychology. In one series, the majority of anxious individuals (N = 322) who successfully completed a 10-week MBSR program reported significantly decreased physical and emotional distress, improved quality of life, enhanced general well-being, greater optimism, and increased feelings of control. Patients diagnosed with irritable bowel syndrome (IBS), a frequent concomitant of generalized anxiety, experienced significantly fewer symptoms of IBS and anxiety when practicing two brief (15 minutes) daily sessions of mindfulness meditation.

Studies have evaluated mindfulness training, mantra reciting, and compassionate meditation (i.e., “Vipassana”) for their potential beneficial effects in PTSD. A review of meditation practices aimed at preventing PTSD found more evidence supporting mindfulness meditation than mantra reciting or compassionate meditation. Preliminary findings suggest that symptoms of reexperiencing and psychic numbing may be less responsive to meditation than other PTSD symptoms. In a 12-week pilot study (N = 5), veterans from the middle east conflict diagnosed with PTSD who trained in transcendental meditation experienced significant

Telegram: @medical_k

www.konkur.in

improvements in overall quality of life and reductions in core PTSD symptoms.

Therapies Based on Scientifically Validated Forms of Energy and Information

CAM approaches based on scientifically validated forms of energy or information include biofeedback, sound, full-spectrum bright light exposure, dim blue light, high-density negative ions, virtual reality graded exposure therapy (VRGET), brain–computer interface (BCI) technologies, and microcurrent electrical stimulation. Research findings point to both direct and indirect effects of well-understood forms of energy and information on the psychological and neurophysiologic causes of mental illness.

Music and Sound. In a small RCT (N = 40), anxious adult patients were randomly assigned to conventional cognitive therapy versus music-assisted reframing. Patients in the music group experienced greater reductions in overall anxiety. When headphones are used to route sounds of slightly different frequencies to the right and left hemispheres, the brain stem “constructs” binaural beats based on the frequency difference between sounds processed in each hemisphere. Preliminary findings support that certain binaural beats (16 to 24 Hz) may improve depressed mood, enhance attention, and improve short-term and immediate recall in healthy adults, whereas binaural beats at lower frequencies may consistently induce a calm, relaxed state. Although antidepressant effects of music have not been established, frequent listening to music probably has beneficial effects on endorphins and other neurotransmitters that enhance mood.

Findings of RCTs suggest that music alone or in combination with guided imagery improves mood in depressed patients with cancer. Patients with cancer who participated in weekly sessions of combined music and guided imagery reported greater improvements in depressed mood and overall quality of life than patients in a wait-list group. Depressed outpatients reported significant improvements in mood and beneficial changes in heart rate and blood pressure soon after listening to tranquil music. A meta-analysis of studies on music therapy in individuals with dementia concluded that regular singing, engaging in dance therapy, listening to music, and participating in musical games improve cognitive

Telegram: @medical_k

www.konkur.in

and behavioral functioning in individuals with severe dementia, resulting in reduced agitation, reduced wandering, enhanced social interaction, improved mood, reduced irritability or fear, and increased cooperative behavior. Calming background music significantly reduces irritable behavior, anxiety, and depressed mood in nursing home patients with dementia. Regular music therapy reduces irritability and improves expressive language in demented individuals.

Light. Light of different intensities and colors is used in both biomedicine and many nonallopathic systems of medicine to treat diverse medical and psychiatric disorders. Entrainment of sleep–wake cycles by external bright light cues and the associated suppression of melatonin production by the pineal gland is the established mechanism of action underlying the therapeutic benefits of light exposure on sleep and daytime fatigue. Exposure to natural sunlight, especially in the early morning, has significant antidepressant effects and may reduce the length of hospital stays in severely depressed inpatients. A systematic review of controlled studies confirmed antidepressant effects of bright light (10,000 lx) exposure therapy in seasonal depressed mood but provided only limited evidence supporting bright light as a treatment of nonseasonal unipolar depressed mood. A more recent meta-analysis of controlled studies concluded that bright light exposure or dawn simulation for *seasonal* depressed mood and bright light exposure (but not dawn simulation) for *non*seasonal depression had comparable efficacy to antidepressants. Findings of a small RCT suggested that bright light therapy may be an effective alternative to antidepressants in pregnant depressed women. Recent studies suggest that regular exposure to dim red or blue light might be as efficacious as bright light, especially in seasonal depressed mood. In a 4-week single-blind study (N = 57), patients diagnosed with seasonal affective disorder were randomized to daily bright light versus dim red light exposure. Both groups experienced an equivalent and significant (40%) reduction in symptoms. Preliminary findings suggest that antidepressant effects of early-morning exposure to narrow-spectrum blue or green light may be equivalent to benefits obtained from full-spectrum bright light exposure.

Exposing depressed patients to low-intensity artificial light approximately 2 hours before they would naturally be exposed to early-morning daylight increased the speed of response to antidepressants.

Telegram: @medical_k

www.konkur.in

Thirty depressed inpatients treated with citalopram 40 mg/day were randomized to early-morning dim green light, 400 lx, versus a sham, non–light-emitting device during the first 2 weeks of drug treatment. Patients in the combined citalopram–light exposure group reported significantly greater and more rapid improvements in mood compared to the citalopram-only and placebo groups.

An expert consensus report on light treatment for sleep disorders concluded that there is compelling evidence for the efficacy of bright light exposure in the management of circadian rhythm sleep problems but not for other types of insomnia. Most protocols recommend 30 to 40 minutes of bright light exposure daily for beneficial effects in shifting circadian rhythms and changing sleep–wake cycles. Beneficial effects of bright light exposure therapy are usually noticeable within a few days, and an appropriate treatment plan often resynchronizes the patient's sleep–wake cycle with their time zone in 2 to 3 weeks. Correct timing of light exposure is essential for successful treatment of circadian sleep problems, and bright light exposure between the hours of the late morning and late afternoon probably has no effect on circadian rhythm phase. Preliminary findings suggest that melatonin used in conjunction with bright light exposure may achieve more rapid normalization of the sleep–wake cycle.

Some patients exposed to bright morning light at 10,000 lx on a regular basis reported transient side effects, including mild jitteriness or headaches (10%) and mild nausea (16%). Sporadic cases of hypomania have been reported, especially in winter depressives or bipolar patients exposed to early-morning bright light. Almost two-thirds of patients who use bright light exposure therapy in the evening report insomnia. Patients interested in bright light exposure therapy should be cautioned to avoid using sun lamps (which emit harmful ultraviolet rays) and instructed to keep the eyes open while viewing the light fixture at an oblique (approximately 45 degrees) angle to avoid excessive eye strain. No adverse effects have been reported with regular exposure to dim light.

High-Density Negative Ions. Regular daily exposure to high-density negative ions may be an effective treatment of seasonal depressed mood and may have comparable efficacy to bright light exposure for this condition. Twenty-five depressed patients with seasonal depressed mood were randomized to high-density negative ions (2.7×10^6 ions/cm^3) versus low-density negative ions (1×10^4 ions/cm^3) using in-home ion

Telegram: @medical_k

www.konkur.in

generators 30 minutes daily for 3 weeks. Fifty-eight percent of patients exposed to high-density negative ions experienced significant improvements in mood on standardized rating scales, compared to 15% of patients exposed to low-density negative ions. In a 2-week RCT (*N* = 158), patients with seasonal depressed mood were randomly assigned to bright light exposure (10,000 lx) versus high-density or low-density negative ions. Patients exposed to high-density negative ions or bright light experienced significant and equivalent improvements in mood. In an RCT (*N* = 128), bright light exposure, a pleasing auditory stimulus, and high-density negative ions resulted in equivalent and rapid improvements in mood and alertness in mildly depressed and nondepressed adults. A review of studies on the effects of air ionization on mental health found evidence for a consistent antidepressant effect of high-density negative ions (but not low-density ions) on unipolar depressed mood and seasonal depressed mood and no consistent effects on anxiety, mood, relaxation, sleep, and measures of well-being. Adverse effects have not been reported with regular daily exposure to negative ions following the protocols used in published studies.

Biofeedback Using EEG and HRV. Electroencephalographic (EEG) biofeedback and HRV biofeedback employ information extracted from the body's intrinsic electromagnetic rhythms as sources of feedback. EEG biofeedback (also called *neurofeedback*) translates electrical brain activity into a visual or auditory signal with the goal of modulating the *general arousal level* of the brain or correcting *dysrhythmias* in specific brain regions or frequency domains to achieve therapeutic changes in psychological and psychosomatic symptoms associated with depressed mood, bipolar disorder, generalized anxiety, PTSD, social anxiety disorder, attention-deficit disorder, and other psychiatric disorders. HRV biofeedback is based on the theory that positive emotional states result in increased *coherence* of several physiologic aspects of heart rhythm and that feed-forward and feedback loops between the heart, brain stem, and neocortex result in complex relationships among specific emotional or mental states and specific patterns of HRV.

Double-blind studies have evaluated the efficacy of EEG biofeedback (also called *neurofeedback*) as a treatment of anxiety, depressed mood, attention-deficit disorder, and PTSD. Sustained "shifts" in the dynamic equilibrium of electrical brain activity have been proposed as a general

Telegram: @medical_k

www.konkur.in

mechanism underlying the therapeutic effects of EEG biofeedback. Case reports and controlled studies show reductions in the severity of depressed mood using photic stimulation or alpha-asymmetry EEG biofeedback protocols. Beta-frequency training in EEG biofeedback may result in improved performance on standardized intelligence tests in nonimpaired individuals. EEG biofeedback has been successfully used to treat depressed mood in chronic alcoholics and to reduce relapse rates. Regular EEG biofeedback training and conventional antianxiety medications may have comparable efficacy for the management of generalized anxiety.

Recent research findings support that EEG biofeedback involving very low frequencies, between 0.02 and 0.2 Hz, results in rapid, significant reductions in the severity of PTSD symptoms and improvements in global cognitive functioning. It has been suggested that *infra-low* frequencies (ILF) may induce therapeutic shifts in the functional connectivity of the brain's resting-state networks resulting in reduced overall arousal, enhanced cognitive functioning, and increased emotional resilience. At a large military base, more than 500 active-duty combatants diagnosed with PTSD were trained in ILF EEG biofeedback. Training was done one to three times per week and was administered by licensed psychotherapists certified in EEG biofeedback therapy. Symptom severity was evaluated weekly using the PCL-5—the military version of the PTSD Checklist. A cohort analysis of 300 Marines in the original cohort found that 75% of persons with moderate to severe PTSD symptoms experienced significant clinical improvement, including reductions in psychological, cognitive, psychophysiological, and physiologic symptoms. Twenty-five percent of subjects in the cohort reported that all PTSD symptoms had completely resolved with fewer than 20 EEG biofeedback sessions; another 50% experienced significant reductions in symptom severity after 40 sessions. The remaining subjects took much longer to respond to treatment, continued to report clinically significant symptoms, discontinued training prematurely, or were nonresponsive to the neurofeedback training protocol.

In a review of nonpharmacologic treatments of insomnia, EEG biofeedback was found to be more effective than progressive muscle relaxation. The American Academy of Sleep Medicine recommends EEG biofeedback as a treatment of chronic insomnia. Several EEG biofeedback protocols are beneficial in insomnia, but a protocol that

Telegram: @medical_k

www.konkur.in

modulates alpha and theta activity along the primary sensory and motor regions in the frontal and prefrontal areas of the cortex may yield the most consistently beneficial outcomes in improving the overall quality of sleep and reducing the frequency of middle awakenings.

Biofeedback using information obtained from measures of HRV may have therapeutic benefits in anxiety, depressed mood, and PTSD. Abnormal low HRV is associated with deficits in attention and short-term memory in combat veterans diagnosed with PTSD. Case reports support that HRV biofeedback may improve depressed mood and anxiety resulting from chronic stress and significantly reduces arousal, and improves general emotional well-being in individuals who are subjected to acute job-related stress. Beneficial changes in baseline anxiety achieved with HRV biofeedback are associated with decreased serum cortisol levels and increased serum DHEA levels. In a 4-month RCT, the majority of 29 police officers trained in HRV biofeedback reported significant improvements in baseline anxiety compared to 36 officers assigned to a wait-list group who did not improve. Individuals diagnosed with GAD reported significant improvements in general emotional well-being and reduced baseline anxiety with regular HRV biofeedback training. Preliminary findings support that increased cardiac coherence may lessen the severity of PTSD; however, results are inconsistent. In a small 3-week open exploratory study, a group of active-duty service members diagnosed with PTSD or depressed mood who received HRV biofeedback plus treatment as usual did not report greater reductions in symptom severity compared to a group receiving treatment as usual only. Correlations between electrocardiogram (EKG) and EEG activity provide evidence for complex feed-forward and feedback loops between the heart and brain that regulate emotion. This integrative biofeedback approach is called “energy cardiology” and is only beginning to be examined in controlled trials.

Virtual Reality Graded Exposure Therapy. VRGET is a rapidly evolving therapy with important implications for the management of PTSD and severe phobias that are difficult to treat using more conventional therapies. VRGET combines advanced computer graphics, three-dimensional visual displays, and body-tracking technologies to create realistic virtual environments with the goal of simulating feared situations or objects. Virtual environments have been designed to provide visual,

Telegram: @medical_k

www.konkur.in

auditory, tactile, vibratory, vestibular, and olfactory stimuli to patients in highly controlled settings. During a virtual exposure session, the therapist closely tracks the patient's state of arousal by monitoring physiologic indicators of stress, including heart rate and respiration. Patients are ready to practice in vivo exposure to the feared object or situation after they have been desensitized to a virtual environment.

VRGET is more effective than conventional imaginal exposure therapy and has comparable efficacy to in vivo exposure therapy for the treatment of specific phobias, agoraphobia, panic disorder, and PTSD. Like in vivo and imaginal exposure therapy, VRGET desensitizes the patient to a situation or object that would normally cause anxiety or panic. In one RCT, VRGET and conventional CBT were equally effective in panic disorder with agoraphobia. Patients who underwent VRGET required 33% fewer sessions to achieve similar results. RCTs confirm that VRGET is an effective treatment of fear of flying, fear of heights, fear of small animals, fear of driving, and other specific phobias. VRGET is as effective as and more cost-effective than in vivo exposure therapy for fear of flying because patients and therapists avoid significant time commitments and the need to use airplanes.

A virtual environment simulating the devastation of the September 11, 2001, attacks on the World Trade Towers has been successfully used to treat individuals diagnosed with severe PTSD following the attacks. Findings of a study on combined multisensory exposure and VRGET reported significant reductions in the severity of PTSD symptoms in active-duty combatants who had failed to respond to other forms of exposure therapy. Several subjects reported significant improvement following only five VRGET sessions; however, there was considerable variability in the number of VRGET sessions needed to reduce symptom severity to the same level. Combining VRGET with D-cycloserine, a partial NMDA agonist may yield differentially greater improvement in symptoms of acrophobia compared to VRGET alone.

Considerable research is ongoing to develop virtual reality tools for assessing and preventing combat-related PTSD. STRIVE (stress resilience in virtual environments) is a highly integrative "stress resilience training" program aimed at enhancing emotional coping strategies prior to active deployment. STRIVE employs an immersive VR environment to simulate combat situations that includes a "virtual mentor" who guides the combatant through a virtual experience while coaching them in relaxation

Telegram: @medical_k

www.konkur.in

and emotional self-regulation skills. The intensity of the virtual stimulus used is determined by the individual's habituation based on HRV and other measures of autonomic arousal. Physiologic biomarkers of the stress response are measured before and after VRGET sessions. The STRIVE system permits users to be immersed in stressful combat scenarios and interact with virtual characters for training in a variety of coping strategies that may enhance resilience in the face of extreme stress. The STRIVE protocol may provide a useful tool for predicting the risk of developing PTSD or other psychiatric disorders in new recruits prior to actual combat exposure. It has been suggested that recruits who display high resilience and are presumably at relatively lower risk of developing PTSD might be more suitable for direct combat roles, while individuals who display low resilience might preferentially be assigned to noncombat roles.

Future integrative approaches to phobias, panic attacks, and other severe anxiety disorders will combine VRGET with biofeedback in outpatient settings or in the patient's home via broadband Internet connections, with CBT, relaxation, mind–body practices, and appropriate medications. Combining VR environments with real-time feedback based on neurophysiologic responses to stress may permit each unique patient to optimize the level and type of VR exposure to enhance resiliency training and speed the rate of recovery from PTSD. Human–computer interface (HCI) systems based on CBT and biofeedback are being developed for resilience training in individuals at risk of developing PTSD following exposure to trauma. Larger studies on patient populations diagnosed with PTSD using head-mounted displays and other technologies that create more immersive virtual environments are needed to determine whether combining VRET and EEG biofeedback is practical in clinical settings and yields superior outcomes compared to either approach alone.

Infrequent cases of disorientation, nausea, dizziness, headache, and blurred vision have been reported following VRGET. Intense sensory stimulation during VRGET can trigger migraine headaches, seizures, or gait abnormalities in individuals who have these disorders. Patients with schizophrenia should not use VRGET because immersion in a virtual environment can exacerbate delusions.

Telegram: @medical_k

www.konkur.in

Cranioelectrotherapy Stimulation. Cranioelectrotherapy stimulation (CES), also called microcurrent electrical stimulation, is based on the application of extremely weak electrical current to the head and neck to treat anxiety, insomnia, and substance use disorders. The mechanism of action may involve stimulation of endorphin release and induction of EEG frequency changes that reduce the severity of anxiety. A meta-analysis of controlled trials comparing CES with a sham treatment found that generalized anxiety improved in seven of eight studies, and the magnitude of improvement reached statistical significance in four studies. A review of 34 sham-controlled trials concluded that regular CES treatments resulted in short-term symptomatic relief of generalized anxiety through direct effects on autonomic brain centers. Patients diagnosed with one or more phobias reported significant reductions in state anxiety when exposure to the phobic stimulus was followed by 30 minutes of CES treatment. Daily application of weak electrical current to the neck or the head may stimulate global brain activity, resulting in beneficial modulatory changes in neurotransmitters implicated in dementia. A meta-analysis of three studies on CES in patients with dementia found evidence of significant but transient improvements in word recall, face recognition, and motivation immediately following treatment that was not sustained at 6-week follow-up.

CES is also used to lessen symptoms of alcohol and drug withdrawal. The postulated mechanism of action involves stimulation of release of endorphins, enkephalins, and other endogenous opioid peptides and may prove to be similar to the mechanism underlying electroacupuncture. In a 4-week RCT (N = 20), depressed alcoholics were randomized to receive 20 CES treatments at 70 to 80 Hz, 4 to 7 mA, versus sham treatments. Patients who received CES treatments experienced significantly reduced anxiety by the end of the study. Findings of a sham-controlled study (N = 60) on inpatient alcohol or polysubstance abusers suggest that daily 30-minute CES treatments significantly improves cognitive functioning and reduces stress and anxiety during the acute phases of withdrawal. In a 7-year prospective study of CES in the treatment of alcohol, drug, and nicotine addiction, acute and chronic withdrawal symptoms were diminished, normal sleep patterns were restored more rapidly, and more patients remained addiction-free following regular CES treatments compared to those receiving psychopharmacological management. The discrepancy between largely positive outcomes from studies on CES and

Telegram: @medical_k

www.konkur.in

frequent negative findings on electroacupuncture (see the section on acupuncture) in detoxification may be partly attributable to suboptimal current or frequency settings in electroacupuncture protocols investigated for this clinical application.

CES is widely used to treat insomnia; however, the findings of sham-controlled studies are inconsistent. Whereas some studies found no beneficial effects of CES in insomnia, others have reported sustained improvements in the timing of sleep onset and total sleep duration. Disparate findings on the therapeutic benefits of CES in insomnia may be related to differences in equipment, protocols, and duration, and timing of treatment. Serious adverse effects of microcurrent electrical brain stimulation have not been reported.

Therapies Based on Postulated Forms of Energy or Information Not Validated by Current Science

In contrast to scientifically *validated* modalities, treatments based on postulated *subtle* forms of energy or information are not verified by *current* science. CAM approaches based on hypothesized *subtle* forms of energy include acupuncture, homeopathic remedies, HT, *qigong,* Reiki, and energy psychology. Beneficial effects of these modalities rest on the postulated role of poorly characterized energetic *fields* or directed human intention that are difficult to examine using contemporary research methods and may, in fact, not be *explainable* by current science. Chinese medicine, Ayurveda, and Tibetan medicine posit the existence of a subtle "energy" body and a gross physical body. All Asian healing traditions use physical, psychological, and spiritual approaches to treat postulated *energetic* imbalances and restore optimal health. In Chinese medicine, "*qi*" is regarded as a fundamental kind of energy that cannot be explained by contemporary science but may have properties consistent with quantum mechanics. Ayurveda posits an analogous energetic principle called "*prana.*" In both systems of medicine, a central goal of treatment is to restore "balance" in the energetic and physical body, thus enhancing the body's capacity for self-healing.

Like Asian healing traditions, homeopathy posits that physical and emotional symptoms result from imbalances in a fundamental *vital force.* Current science cannot explain the postulated curative mechanism of homeopathic remedies, which are typically *diluted beyond the limit of possible biologic action*. Reiki holds that a fundamental energetic

Telegram: @medical_k

www.konkur.in

principle, "*ki,*" promotes healing when guided by a skilled practitioner. Physical contact between the practitioner and the patient is not believed to be necessary for beneficial effects to take place. HT practitioners claim that "energetic" contact between the practitioner and the patient results in the alleviation of symptoms. In HT, the practitioner positions the hands over specific areas of the body but does not physically *touch* the patient's body. TT is similar to HT but uses gentle physical contact to promote healing. In contrast to HT and TT, the Reiki practitioner does not consciously direct healing intention to specific regions of the body but serves as a "conduit" for *ki* to *flow into* the patient to restore healthy energetic functioning. Somatoemotional release is an energy therapy in which the practitioner "releases" pathologic energetic states that accumulate in the body following physical injury. The technique involves gentle touch while guiding the patient to assume positions that stimulate body memories of past trauma.

Energy psychology is an eclectic combination of Western psychological theory and Chinese medical theory that posits that energetic imbalances in the meridians (i.e., pathways through which *qi* flows) are associated with different physical, emotional, and mental symptoms. "Thought field therapy" (TFT) and "emotional freedom technique" (EFT) are specific energy psychology approaches used to treat anxiety and depression. In TFT, the patient is asked to invoke a "thought field" associated with depressed mood, a traumatic memory, or other principal symptom pattern. The TFT practitioner then *reattunes* energetic imbalances associated with the target symptom by tapping on specific acupuncture points in a specified manner in an effort to alleviate symptoms. EFT is a simplified version of TFT that involves only one routine for stimulating acupuncture points. Twelve of 18 RCTs included in a review of noncontact *biofield* therapies including Reiki, HT, Johrei, and TT reported statistically significant positive outcomes; however, findings were limited by the small sample size of most studies and methodologic problems.

Acupuncture. Evaluating the clinical efficacy of acupuncture in depressed mood and other mental health problems poses complex methodologic challenges because of differences in the severity and comorbidity of mental, emotional, and physical symptoms in study populations; concurrent use of other conventional or CAM treatments; conceptual differences between Chinese medicine and biomedical

Telegram: @medical_k

www.konkur.in

diagnoses; and the use of individualized acupuncture treatment protocols reflecting each patient's unique "energetic" balance. Sham-controlled studies suggest that conventional needle acupuncture, electroacupuncture, and computer-controlled electroacupuncture (CCEA) have consistent beneficial effects on depressed mood. The findings of a double-blind, sham-controlled study support that traditional manual acupuncture (i.e., needles in the absence of electrical current) is an effective treatment of severe depressed mood. By the end of the 8-week study, 68% of 33 female outpatients being treated with a specialized acupuncture protocol directed at depressed mood had achieved full remission. However, matched depressed women in a wait-list group showed equivalent improvement. In a large 6-week, multicenter study (N = 241), depressed inpatients randomized to receive electroacupuncture plus placebo versus electroacupuncture plus amitriptyline experienced equivalent improvements in mood. Significantly, electroacupuncture was found to be superior to amitriptyline in patients who did not report comorbid anxiety. Patients treated with electroacupuncture had significantly elevated plasma norepinephrine concentrations following a 6-week course of treatment, suggesting that the mechanism of action of electroacupuncture involves stimulation of norepinephrine release. CCEA uses computer-guided modulation of the frequency and waveform of electrical current delivered through acupuncture needles. Preliminary findings suggest that high frequencies (up to 1,000 Hz) may yield responses in depressed patients superior to both conventional acupuncture and electroacupuncture. A narrative review of controlled studies, outcomes studies, and published case reports on acupuncture as a treatment of anxiety and depressed mood supported that sham-controlled studies are associated with consistent improvements in anxiety using both conventional acupuncture and electroacupuncture.

A review of prospective trials on acupuncture as a treatment of PTSD identified four quality sham-controlled studies and two quality uncontrolled trials that met inclusion criteria. One high-quality trial included in the review showed statistically significant differences between the acupuncture and wait-list group but nonsignificant differences between the acupuncture and CBT groups. Patients receiving acupuncture or CBT continued to report clinical improvements in PTSD symptoms 3 months after the study endpoint.

Telegram: @medical_k

www.konkur.in

Findings on acupuncture for relapse prevention in alcohol abuse are inconsistent, reflecting differences in the selection of acupuncture points, the treatment protocol used (i.e., conventional vs. electroacupuncture), frequency of treatments, the duration of total treatment, and the relative skill or specialized training of practitioners. While some sham-controlled trials have reported significant reductions in alcohol craving and relapse rate in recovering alcoholics, other studies have found nonsignificant differences in craving or relapse rates between subjects receiving an acupuncture protocol traditionally used to treat addiction, sham transdermal stimulation on random points, and a wait-listed group.

Findings of most controlled trials on acupuncture for smoking cessation have been negative or equivocal. Three meta-analyses of sham-controlled studies on the efficacy of acupuncture for smoking cessation (total *N* >2,000) concluded that therapeutic acupuncture protocols and sham acupuncture have equivalent efficacy, suggesting a significant placebo effect. Two systematic reviews of sham-controlled trials found that both conventional acupuncture and electroacupuncture are equally *ineffective* in reducing symptoms of nicotine withdrawal and controlling cocaine addiction. A large study examining three auricular acupuncture protocols for relapse prevention in narcotics abusers concluded that all three protocols were associated with reductions in drug use over time. An 8-week RCT (*N* = 32) compared acupuncture with two drugs versus placebo in cocaine addicts on methadone maintenance therapy. Half of the subjects dropped out; however, almost 90% of those who completed the study achieved abstinence by study end. Subjects who achieved abstinence reported diminished craving and significantly improved mood.

A systematic review of all studies on acupuncture for insomnia published in the English language through 2002 identified few studies for analysis because most studies had not employed randomized, double-blind procedures. Acupuncture may be beneficial for insomnia associated with generalized anxiety and schizophrenia. In a large-case series (*N* = 500), schizophrenics reported significant improvements in sleep following acupuncture treatments. In a small RCT (*N* = 40), patients complaining of insomnia were diagnosed using Chinese medical assessment methods and randomized to an acupuncture protocol addressing the specific energetic “imbalance” underlying their sleep disturbance versus a sham protocol. Significant and sustained improvements in the subjective quality of sleep and changes on EEG polysomnography reflecting normalization

Telegram: @medical_k

www.konkur.in

of sleep were found in the treatment group but not in the sham group. The absence of standardized acupuncture treatment protocols for insomnia has interfered with efforts to design rigorously controlled double-blind studies. The significance of findings of studies on acupuncture in psychiatric disorders is limited by small study size, the absence of standardized symptom rating scales in most studies, limited follow-up, and poorly defined differences between protocols used in different studies.

Uncommon transient adverse effects associated with acupuncture include bruising, fatigue, and nausea. Infrequent cases of infection with human immunodeficiency virus, hepatitis B, and hepatitis C have been reported when nonsterilized needles are used. Rare cases of pneumothorax and cardiac tamponade have been reported as a result of accidental puncturing of the lungs or the pericardium.

Homeopathy. Preliminary findings from open studies suggest that certain homeopathic remedies may improve depressed mood. Short-term and long-term constitutional remedies are used, depending on symptom severity, personality factors, and the “energetic pattern” associated with depressed mood. Homeopathic preparations are widely used to self-treat generalized anxiety and other anxiety symptoms; however, research findings are inconsistent and based largely on case reports. Case reports of symptomatic improvement following the administration of specific homeopathic remedies have been published for PTSD, social phobia, panic disorder, and OCD. However, the findings of two placebo-controlled studies were negative or equivocal. Students with test-taking anxiety (N = 62) randomized to a specific homeopathic preparation (*Argentum nitricum* 12X) versus placebo twice daily for 4 days reported equivalent modest reductions in anxiety. In a 10-week prospective study (N = 44), patients diagnosed with GAD were randomized to an energetically appropriate homeopathic treatment versus placebo. All subjects were medication-free at least 1 month prior to the start of the study. All subjects were individually diagnosed by a classically trained homeopathic physician and treated with a homeopathic remedy addressing identified “energetic imbalances.” Significant and *equivalent* improvements in baseline anxiety were found in the placebo and treatment groups at week 5 and at the end of the study. Homeopathic remedies are generally too dilute to potentially cause adverse effects. However, rare cases of toxicity have been reported when low dilutions of arsenic, cadmium, or other heavy metals are used.

Telegram: @medical_k

www.konkur.in

Concerns about the possible carcinogenic effects of remedies containing *Aristolochia* have been raised, and there are rare reports of allergic reactions.

Healing Touch and Therapeutic Touch. HT practitioners claim to be able to intuitively assess energetic *imbalances* manifesting as physical or psychological symptoms and "*direct*" healing energy to specific bodily regions to correct purported imbalances, resulting in improved functioning or enhanced well-being. In a 3-week open study (*N* = 30), moderately to severely depressed patients were randomized to receive HT versus a waitlist. Individuals in the treatment group received two HT sessions weekly. Control patients received no treatment, including no exposure to a sham HT protocol. By the end of the study, patients in the treatment group experienced significantly improved mood that was sustained at 1-month follow-up. Open studies, case reports, and one double-blind trial suggest that HT and TT may reduce the severity of agitation in dementia. In one small open study, measures of agitation improved significantly in 14 individuals with dementia in a residential setting who received three HT treatments weekly over 4 weeks. Three individuals in the study needed fewer sedating medications during the active treatment phase, and two residents required dose increases in the first 2 weeks after HT treatments were stopped. In a small 5-week, sham-controlled study, two weekly 10- to 20-minute HT treatments were administered to patients with Alzheimer disease. Patients who received regular HT treatments displayed consistent reductions in disruptive behaviors, globally improved emotional and cognitive functioning, enhanced socialization, a more regular sleep schedule, improved compliance with nursing home routines, greater emotional stability, and improved communication with staff. Individuals who received regular HT treatments complained of physical distress or discomfort significantly less often than the control group. Measures of agitation improved significantly in the HT group but did not change in the control group. In a double-blind study (*N* = 57) that included mock-TT in the control arm, agitated patients with dementia who received two brief TT treatments daily for 3 days exhibited significantly fewer behavioral symptoms of dementia, including reduced restlessness and fewer disruptive vocalizations, compared to patients who received mock-TT. In a 3-week RCT (*N* = 123), active-duty military diagnosed with PTSD randomized to semi-weekly sessions of HT plus guided imagery

Telegram: @medical_k

www.konkur.in

experienced greater improvement in PTSD symptom severity and quality of life compared to those receiving treatment as usual. The significance of research findings on TT and HT is limited by study design flaws, including lack of blinding, the confounding influence of frequent human contact, small numbers of enrolled subjects, the lack of standardized methods, and the absence of control groups receiving sham HT or TT treatments in most studies.

Qigong. *Qigong* is an ancient energy healing method used in Chinese medicine that has its origins before written language. Most published studies have examined the effectiveness of regular *qigong* practice on general indicators of physical or emotional health. Individuals can engage in a regular *qigong* practice or receive "emission *qigong*" treatments for a particular medical or psychological problem from a skilled *qigong* master. Findings of open trials on *qigong* as a treatment of "neuroticism" suggest that anxiety, depressed mood, and quality of sleep were significantly better in subjects who had practiced *qigong* consistently for at least 5 years than in those who had never practiced *qigong.* An open study reported that depressed individuals who practiced *qigong* consistently for at least 2 years experienced improved mood and general improvement in their baseline emotional state. In a 2-month open pilot study (N = 39), patients with a diagnosis of major depressive disorder, dysthymic disorder, or bipolar disorder based on criteria of the text revision of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) received *qi* "emission" treatments administered by *qigong* masters. Half of the subjects engaged in the regular daily practice of *qigong.* By the end of the study, standardized ratings of depressed mood had improved for all subjects, and there were no significant differences in response between individuals who practiced *qigong* while receiving *qi* "emission" therapy and subjects who received *qi* "emission" therapy only. A systematic review and meta-analysis of studies on qigong "exercise" for stress and anxiety in adults identified seven RCTs that met the inclusion criteria. Four RCTs reported positive findings of qigong for generalized anxiety, and three studies reported beneficial effects on stress; however, the significance of findings was limited by methodologic flaws and small study size. A systematic review and meta-analysis of 15 studies on qigong for anxiety, depressed mood, and psychological well-being found no conclusive evidence for qigong as a treatment of a specific mental health

Telegram: @medical_k

www.konkur.in

condition; however, the findings suggested that regular qigong practice may have positive effects on general psychological well-being in patients with chronic illnesses.

The *unskillful* or excessive practice of *qigong* can result in serious psychological or psychosomatic symptoms. Psychotic symptoms that have been reported following *erroneous qigong* are described as a culture-bound syndrome, "*qigong* psychotic reaction," in the DSM. Schizophrenics and individuals diagnosed with severe personality disorders should be cautioned to practice *qigong* moderately and only under the guidance of a skilled *qigong* instructor.

Reiki. Findings of a 6-week, single-blind, sham-controlled trial of Reiki on depressed mood (N = 73) suggested that regular Reiki treatments may increase feelings of general well-being and reduce stress. The study population consisted of volunteers who complained of depressed mood or "stress" but did not meet diagnostic criteria for a major psychiatric disorder. Subjects were randomized to weekly 1½-hour, hands-on Reiki versus distant Reiki or distant sham Reiki treatments. Patients who received hands-on or distant Reiki treatments experienced significant and equivalent improvements in depressed mood and stress, which were sustained 1 year after treatment was terminated. No one in the sham Reiki group improved during or following the study. In a small sham-controlled study (N = 12), chronic pain patients were randomized to receive Reiki versus sham Reiki, progressive muscle relaxation, or no treatment. Improvements in pain and state anxiety were significantly greater among patients receiving Reiki than sham-Reiki and relaxation training. Preliminary findings are suggestive of the therapeutic effects of Reiki. However, large sham-controlled studies in clinical populations are needed to evaluate the putative mood-enhancing and stress-reducing effects of hands-on and distant Reiki.

Energy Psychology. EFT, TFT, and body psychotherapy are "energy psychology" techniques used to treat mood disorders, phobias, and other anxiety disorders. Few controlled studies have been done, most studies are methodologically flawed, and findings are highly inconsistent. EFT treatments can be self-administered using a manual following an initial training session, and no technical expertise is required. In a double-blind, prospective trial (N = 35), patients who met DSM-IV-TR criteria for a specific phobia were randomized to receive one EFT treatment versus

Telegram: @medical_k

www.konkur.in

one session of diaphragmatic breathing (DB) while exposed to a feared small animal. EFT-treated patients experienced greater improvement than DB-treated patients in four of five measures of anxiety, and improvements were sustained at 3 months in the absence of further EFT or DB treatments. The above findings were replicated in a follow-up study. A study comparing EFT and sham-EFT in anxious individuals who had not been formally diagnosed found no differences in anxiety reduction between a defined EFT protocol and a sham protocol. These findings suggest that the therapeutic benefits of EFT may be attributable to desensitization and distraction. A sham-controlled study on EFT in depression found equivalent nonsignificant changes in mood following EFT and sham treatment.

Somatoemotional Release and Craniosacral Therapy. Practitioners of craniosacral therapy gently guide the spinal and cranial bones with the goal of bringing the CNS into greater "harmony." The movement of the cerebrospinal fluid (CSF) is believed to be restricted by bodily trauma or chronic stress. Gentle manipulation of the spine, the skull, and fascia is believed to ease restrictions on the openings through which nerves pass while optimizing the flow of CSF through the spinal cord. Vietnam veterans (N = 22) diagnosed with PTSD completed a 2-week intensive program in which they were treated with both somatoemotional release and craniosacral therapy. The majority of veterans reported significant reductions in pain and physical distress and improvements in depressed mood, anxiety, suspiciousness, guardedness, and behavioral isolation. The significance of findings on somatoemotional release and craniosacral therapy is limited by the small study size, the absence of a sham treatment arm, lack of follow-up, and the use of nonstandardized symptom rating scales.

Shamanic Healing. A shaman is a person who is regarded by their tribe or sociocultural group as having the power to heal the sick, predict the future, and communicate with the supernatural world, including primitive natural forces and spirits of the dead. The term *shaman* has ancient roots in Siberia. However, similar traditions of spiritual healing can be found in all world regions. Shamanic healing ceremonies often focus on retrieving the patient's *lost soul*, which is believed to be a root cause of many physical and psychological illnesses. The therapeutic goals of ritual acts, stories and chants used in shamanic healing vary widely depending

Telegram: @medical_k

www.konkur.in

on the parent culture. Research on shamanic healing is generally descriptive, and there are few published studies using clinical research methodology. One study reported on shamanistic contributions to the treatment of schizophrenia and other mental illnesses in Japan. Another study examined the outcomes and satisfaction of 188 patients treated by shamans in Taiwan with a matched sample of patients treated by physicians. Five distinctive sickness types were identified, including mental health problems. Patient and experimenter reports suggested that three-fourths of patients improved. However, shamanic treatment was more likely to be described as difficult or uncomfortable than conventional medical treatment. Findings of a more recent study suggested that shamanic healing approaches contribute to the psychiatric stability and general emotional well-being of individuals diagnosed with bipolar disorder.

Outcomes research on shamanic healing is at a very preliminary stage. Applying standard biomedical research designs to indigenous healing practices poses many complex challenges, resulting in studies that are primarily naturalistic and observational in design. However, increasing interest in indigenous healing practices in the context of promising early findings on shamanic healing and the importance of fostering cultural belief systems in community mental health care will probably lead to the growing acceptance of shamanic healing in North America, Western Europe, and other developed world regions.

30.5 Micronutrient Monitoring and Supplementation in Psychiatric Illness

JESSICA L. PRINCIPE, M.D., M.S., AND NORMAN K. POLLOCK, PH.D.

There is growing interest in using micronutrient supplements as an adjunct to standard psychopharmacology or monotherapy for common psychiatric illnesses. Indeed, inverse relationships between micronutrient intake, nutrition biomarkers, and psychiatric illness are widely reported; however, these associations cannot be used to guide treatment decisions as the studies on which they are based do not support causal relationships. Placebo-controlled randomized controlled trials (RCTs) of nutrition interventions are often unavailable, vary in quality, and conflicting results can limit practice decisions. Meta-analyses of RCT, considered the gold standard for practice guidance, are often sparse; however, given the added cost for patients and potential for adverse effects, recommendations for nutrition supplementation should be based on the highest level of available evidence. Therefore, this chapter will focus on available evidence from published meta-analyses to supplement four nutrients of historical interest due to purported neuropsychiatric benefits: vitamin D, vitamin B12, folate (vitamin B9), and omega-3 fatty acids. In intervention trials, an effect size is calculated to quantify the magnitude of difference between two groups (and therefore the magnitude of benefit, if any) of treatment compared with placebo.

Effect sizes are expressed as Cohen *d* or standardized mean difference (*SMD*), whereas

***SMD* = 0.2** is a small effect size
***SMD* = 0.5** is a moderate effect size
***SMD* > 0.8** is a large effect size
***SMD* ≥ 1.3** is a very large effect size.

For reference, in depression, effect sizes for antidepressant medications are often small to moderate (*SMD* = 0.19 to 0.62), with

Telegram: @medical_k

www.konkur.in

potentially larger effect sizes seen with transcranial magnetic stimulation (TMS) (*SMD* = 1.33) and the largest with electroconvulsive therapy (ECT) (*SMD* = 2.83). Hopefully, keeping these in mind will allow the reader to put into context the magnitude of benefit (or lack thereof) reported for individual micronutrients discussed in this chapter.

For each nutrient, potential mechanisms, epidemiologic associations, and considerations regarding biomarker measurement will be addressed, while emphasis will be on evidence for the efficacy of supplementation, guided by biomarker monitoring where applicable, in common psychiatric, neurodevelopmental, and neurocognitive disorders. Please note that this chapter's scope does not include a review of the evidence for micronutrient supplementation in peripartum, trauma, obsessive-compulsive, or substance use disorders (SUDs). Furthermore, concentration is solely on benefit for individuals with psychiatric illness or clinically significant symptoms and *not on prevention* of illness or symptoms, as this is an entirely different topic.

VITAMIN D

Vitamin D is a fat-soluble steroid hormone, created endogenously with sufficient exposure to UV light and present in a few foods. Vitamin D is a unique nutrient because its requirement can be met endogenously from sunlight and dietary sources, complicating determining nutritional requirements. Serum 25-hydroxyvitamin D [25(OH)D] is considered the optimal biomarker of vitamin D status due to its relatively long half-life of 15 days and its reflection of endogenous production as well as vitamin D obtained from food and supplements. The most commonly used cut-points for serum 25(OH)D levels are: >75 nmol/L (>30 ng/mL) for vitamin D sufficiency, 50 to 70 nmol/L (20 to 29 ng/mL) for insufficiency, and <50 nmol/L (<20 ng/mL) for deficiency. Due to modern lifestyles and the importance of limiting sunlight exposure to reduce skin cancer risk, vitamin D deficiency and insufficiency are not uncommon. According to data from the National Health and Nutrition Examination Survey (NHANES) 2001–2010, one in three U.S. adults was considered vitamin D deficient, and an additional 40% met the criteria for insufficiency. Risk factors include dark pigmented skin, older age, obesity, physical inactivity, smoking, limited milk intake, limited sunlight exposure, fat malabsorption, primary hyperparathyroidism, chronic granulomatous disease, and

Telegram: @medical_k

www.konkur.in

medications (anticonvulsants, glucocorticoids, anti-HIV). Various mechanisms for a beneficial role of vitamin D in psychiatric illness have been suggested, including support for neurodevelopment, neurogenesis, neurotransmitter synthesis, immune modulation, anti-inflammatory actions, and HPA axis regulation. Inverse relationships between biochemical vitamin D status and depression, psychosis, attention-deficit/hyperactivity disorder (ADHD), autism spectrum disorder (ASD), and neurocognitive disorders have been reported; however, evidence for vitamin D supplementation as an adjunctive or stand-alone treatment option in most psychiatric disorders is limited.

Vitamin D and Depression

A meta-analysis of four RCTs (N = 948) in adults with unipolar depression showed that vitamin D supplementation improves depressive symptom scores (measured by Hamilton Depression Rating Scale or Beck Depression Inventory-II) with a moderate effect size (SMD = 0.58, P < .05). Two trials were selected for patients with depression and vitamin D deficiency at baseline, and in the two studies that did not select for vitamin D deficiency at baseline, average baseline vitamin D levels were in the insufficient range. However, subgroup analysis was not performed to determine whether vitamin D deficiency or insufficiency at baseline predicts response. Supplementation strategies varied from oral 1,500 IU cholecalciferol (vitamin D_3) daily, oral vitamin D 50,000 IU weekly, or one-time single-dose intramuscular injection of vitamin D 150,000 IU or 300,000 IU. It is relevant to consider that supplementation strategies of 50,000 IU cholecalciferol weekly, and 1,500 to 2,000 IU daily are supported by current Endocrine Society Guidelines for managing vitamin D deficiency in normal-weight adults (Table 30.5–1). Adjunctive antidepressant therapy was either excluded or not reported, except in one study, where 1,500 IU cholecalciferol daily was tested as adjunctive to fluoxetine therapy with positive results. Study durations ranged from 8 to 52 weeks, and no significant adverse events were reported. Overall, these results suggest that oral or parenteral vitamin D supplementation may be a clinically effective adjunctive or stand-alone intervention for improving depressive symptoms in adults with depression. However, it is important to note that vitamin D is a fat-soluble vitamin, excess supplementation poses the risk of toxicity, and many participants had vitamin D deficiency or insufficiency at baseline. Therefore, checking serum 25(OH)D levels in

Telegram: @medical_k

www.konkur.in

individuals with depression prior to initiating vitamin D supplementation and following evidence-based guidelines (Table 30.5–1) for repletion and maintenance dosing is the most responsible practice.

Vitamin D and Attention-Deficit/Hyperactivity Disorder

A recent meta-analysis of four RCTs (*N* = 256) in children and adolescents aged 2 to 18 years with ADHD demonstrated that vitamin D supplementation as adjunctive therapy to methylphenidate significantly improved ADHD symptoms. Small effect sizes were seen in ADHD total scores (*SMD* = 0.39), while medium effect sizes were seen in inattention (*SMD* = 0.67), hyperactivity (*SMD* = 0.60), and behavior (*SMD* = 0.54) (all $P < .01$). Supplement doses ranged from oral vitamin D 1,000 to 3,000 IU daily or 50,000 IU weekly and study durations ranged from 6 to 12 weeks. Three of the four RCTs in this analysis reported deficient average vitamin D levels at baseline; however, only one RCT performed subgroup analysis to determine whether vitamin D deficiency at baseline predicted improvement. In this study, subgroup analysis revealed that children with deficient or insufficient vitamin D levels at baseline improved with vitamin D supplementation while those with adequate baseline levels did not. Only one study reported adverse events, and no differences were found between vitamin D and placebo groups. Given the limited available evidence, vitamin D supplementation as adjunctive therapy to methylphenidate appears to improve inattention, hyperactivity, and behavior in children and adolescents with ADHD without serious adverse events associated with improved vitamin D status. As mentioned previously, due to the risk of toxicity with over-supplementation, it is most prudent to check vitamin D levels before supplementing per published guidelines in children or adolescents (Table 30.5–1) with ADHD and evidence of vitamin D deficiency or insufficiency.

VITAMIN B12

Vitamin B12 is a water-soluble vitamin naturally found in animal foods and necessary for normal neuronal function. Vitamin B12 status is measured in serum or plasma with 200 to 250 pg/mL as lower limits for most laboratories; however, some suggest that levels up to 400 pg/mL should be screened further for deficiency. In these borderline cases, methylmalonic acid (MMA) is recommended as a more sensitive measure

Telegram: @medical_k

www.konkur.in

of vitamin B12 status, with elevated MMA level (>0.271 μmol/L) as a reliable cutoff indicating deficiency. Estimates of Vitamin B12 deficiency in older adults range from 1.5% to 15%, and low vitamin B12 status has been linked to depression and cognitive dysfunction. Deficiency symptoms include depression, irritability, insomnia, cognitive slowing, and psychosis. Risk factors for deficiency include older age, vegan or vegetarian diet, pernicious anemia, malabsorption syndromes (gastric bypass surgery, inflammatory bowel disease, celiac disease, small intestinal bacterial overgrowth, ileal resection), and chronic use of metformin, proton-pump inhibitors, and histamine-2 receptor antagonists. Vitamin B12 deficiency may be increasing in younger adults. Data from the Framingham Offspring Study found similar deficiency rates in age groups 26 to 49 years, 50 to 64 years, and 65 years and older.

Unfortunately, few RCTs to date have tested isolated vitamin B12 supplementation as an intervention in patients with psychiatric illness. Vitamin B12 intervention trials in psychiatry almost exclusively employ cosupplementation with folate or vitamin B6. For this reason, it is not possible to make specific, evidence-based recommendations regarding vitamin B12 supplementation in psychiatric illnesses at this time. However, due to this compound's water-soluble nature, excess quantities are not stored to a significant degree, and supplementation poses *little risk of toxicity*. Additionally, given that many, albeit nonspecific, neuropsychiatric symptoms can be associated with low B12, it is not unreasonable to check vitamin B12 levels in patients presenting with symptoms consistent with deficiency, as above, and consider supplementing per published guidelines if deficient or borderline levels are found. If a practitioner desires a more formal diagnosis of deficiency prior to supplementation, checking serum MMA is a reasonable confirmatory step to guide decision-making regarding the initiation of vitamin B12 supplementation. A 2018 *Cochrane* review by Wang and colleagues established that low-quality evidence exists to indicate that daily oral supplementation with 1,000 to 2,000 mcg of vitamin B12 is as efficacious, safe, and potentially more cost-effective than IM supplementation in vitamin B12 deficiency.

www.konkur.in

Table 30.5–1.
Endocrine Society Guidelines for Treatment of Vitamin D Deficiency

Patient Characteristics	Supplementation[a]	Duration[b]	Maintenance[c]
Children/adolescents ages 1–18 years	2,000 IU/day or 50,000 IU/week	≥6 weeks	600–1,000 IU/day
Adults ages >18 years	50,000 IU/week or 6,000 IU/day	8 weeks	1,500–2,000 IU/day or 50,000 IU q2 weeks
Obese adults (Also: malabsorption syndromes, medications affecting vitamin D metabolism[d])	6,000–10,000 IU/day	Monitor level and adjust dose to achieve 30 ng/mL	3,000–6,000 IU/day

[a]Supplementation with cholecalciferol (vitamin D3) or ergocalciferol (vitamin D2) is acceptable.

[b]Durations estimated to achieve sufficient level of ≥30 ng/mL (>75 nmol/L).

[c]Maintenance doses estimated to keep steady levels ≥30 ng/mL (>75 nmol/L) without inducing toxicity.

[d]Anticonvulsant medications, glucocorticoids, other medications that enhance the activation of the steroid xenobiotic receptor, which results in destruction of 25(OH)vitamin D.

Note: Vitamin D deficiency is defined here as ≤20 ng/mL (<50 nmol/L) per 2011 Endocrine Society Guidelines. While no formal guidelines exist for the treatment of vitamin D levels in the insufficient range (21–29 ng/ml; 50–70 nmol/L), it is reasonable to follow dosing guidelines for deficiency with shorter duration before initiating maintenance dosing, or alternatively, initiate maintenance dosing and re-check level in 3–6 months to ensure sufficiency ≥30 ng/mL (>75 nmol/L).

FOLATE (VITAMIN B9)

Telegram: @medical_k

www.konkur.in

Folate is a water-soluble vitamin known for its role as an enzymatic cofactor involved in many essential neuropsychiatric processes, namely: neurotransmitter synthesis, central nervous system (CNS) phospholipid synthesis, and homocysteine metabolism. Folate deficiency (defined as serum folate <3 ng/mL) is rare in the United States, owing to the 1996 Food and Drug Administration mandate requiring folate supplementation of enriched grain products, completed in 1998. Indeed, a 2014 report of outpatient serum folate testing in 84,187 individuals in Boston, MA, found folate deficiency in only 0.06% and low to normal levels in only 0.2% of individuals tested. However, recent data from NHANES 1999 to 2016 reported that folate insufficiency rates are ~20% in the general population. This rate is significant considering folate insufficiency (serum folate approximately <7 ng/mL) in women of childbearing age is a risk factor for neural tube defects in offspring. Risk factors for folate deficiency include inadequate diet, excessive alcohol intake, women of childbearing age, non-Hispanic black women, pregnancy, dialysis, celiac disease, inflammatory bowel disease, and methylenetetrahydrofolate reductase (MTHFR) gene mutation. Symptoms of folate deficiency include cognitive impairment and depression, and low folate levels have been associated with major depressive disorder (MDD), dementia, and schizophrenia.

Folate and Depression

A meta-analysis of nine RCTs (N = 1,061) found folate supplementation as adjunctive to antidepressant therapy improved depressive symptoms in adults with MDD with a small effect size (SMD = −0.38, P = .01). Folate supplementation was also associated with a higher remission rate (NNT = 8, RR = 1.46, P = .008), with remission induced in 48% of patients in the folate group compared to 27% in patients receiving placebo. Supplement strategies included folic acid 0.5 to 10 mg/day and L-methylfolate 15 mg/day, with a mean study duration of 15.2 weeks. The mean age of the participants was 42.1 years, and 35.9% were male. Subgroup analysis revealed significant effects in trials lasting less than 15 weeks and in participants younger than 42.1 years, with a weakening of the effect size in predominantly female studies. Gender differences in effects of folate supplementation for depression are controversial with mixed results to date, with some studies suggesting a need for increased folate dose in men and limited effect of supplemental folate in older than middle-aged women, but these findings are not confirmed. Age effects on folate

Telegram: @medical_k

www.konkur.in

benefits in depression are also unclear, but it has been suggested that an age-dependent decrease in folate absorption plays a role. In this study, subgroup analysis was not performed to evaluate the effects of baseline folate level, folate dose, or formulation (i.e., folic acid vs. L-methylfolate, the most active form, which does not require MTHFR activity for metabolism, and which crosses the blood–brain barrier.) Rates of discontinuation due to any reason were not significantly different between groups. In summary, folate supplementation as an adjunct to antidepressant therapy appears effective for reducing depressive symptoms and inducing remission in adults with MDD. However, the role of monitoring folate levels to guide treatment decisions and optimal folate dose and formulation remains unclear. It is important to note that, in contrast to vitamin B12, the Food and Nutrition Board at the National Academies of Sciences, Engineering, and Medicine has set an upper limit for supplemental folate of 1 g/day for adults >19 years. This limit is due to concerns of exacerbating anemia and cognitive concerns associated with vitamin B12 deficiency, acceleration of preneoplastic lesions, and lower cognitive scores in children of mothers who consumed greater than 0.4 to 0.999 mg/day folic acid (400 to 999 mcg/day) during pregnancy. Additionally, with the use of L-methylfolate 15 mg/day, a few cases of triggered irritability and agitation have been reported (albeit one of these cases was in a patient with bipolar disorder type 1). For these reasons, and considering that no additional benefit of folate supplementation >15 weeks was found in the meta-analysis above, in select patients with inadequate response to standard treatment, it may be reasonable to trial folic acid doses up to 1 g/day or L-methylfolate 15 mg/day for no longer than 15 weeks, with close monitoring for irritability and agitation with L-methylfolate. Future studies may suggest additional biomarkers that will predict response to L-methylfolate supplementation.

Folate and Schizophrenia

A small meta-analysis of four RCTs (*N* = 210) in adults with schizophrenia (mean age of 38 years) demonstrated that folate supplementation as an adjunct to standard treatment was not superior to placebo in terms of total psychopathology, positive, negative, or general symptom scores. The mean study duration was 13 weeks, and 62% of participants were male. Doses ranged from 2 mg/day of folate to 15 mg/day of L-methylfolate. Rates of discontinuation due to any reason and adverse reactions were

Telegram: @medical_k

www.konkur.in

similar between folate and placebo groups. Subgroup analysis of the type of folate supplementation or baseline level was not performed; however, in one small RCT (n = 17), patients with schizophrenia and low or borderline folate levels who received 15 mg/day of methylfolate showed improved Clinical Rating Scale scores after 6 months ($P < .01$). A second RCT utilizing 15 mg/day of L-methylfolate (n = 55) for 12 weeks showed improvement in PANSS total, negative, and general psychopathology scores with moderate effect sizes (Cohen d = 0.63, 0.68, and 0.84, respectively) along with beneficial changes in magnetic resonance imaging measures (working memory-related activation, resting connectivity, and cortical thickness) (all $P < .05$).

Interestingly in this study, total and general PANSS scores appeared to depend on genotype, specifically a variant of *MTR,* notably the same variant that influenced response to L-methylfolate in depression, while improvement in PANSS negative scores did not. These individual RCT results suggest a differential effect of L-methylfolate and the possible importance of baseline level in this population, but further evidence is needed. In patients with schizophrenia who are compliant with standard treatment, who have low or borderline folate levels, or for whom nutrient supplementation is appealing, L-methylfolate at 15 mg/day may be a safe and effective intervention for reducing symptom burden with the caveat that evidence is limited, and standard therapy should be prioritized.

OMEGA-3 FATTY ACIDS

Omega-3 fatty acids are considered essential fatty acids, which means they are not produced in adequate amounts endogenously and must be consumed. To date, there is insufficient evidence on which to base a recommended daily allowance (RDA) or estimated average intake (EAR), so an adequate intake (AI) recommendation is utilized instead. Current AIs for total omega-3 fatty acid intake range from 0.7 to 0.9 g/day in ages 1 to 8, 1.0 to 1.6 g/day in ages 9 to 19, and 1.1 to 1.6 g/day in adulthood. Various biomarkers may be utilized in a research setting to determine biochemical status; however, none are used clinically at this time, and no cutoffs have been established to indicate deficiency. The two most prominent omega-3 fatty acids in brain tissue are docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), with DHA accounting for 40% of total brain membrane phospholipids. DHA is thought to play important

Telegram: @medical_k

www.konkur.in

roles in neurologic development, maintenance of membrane integrity and fluidity, receptor binding, neurotransmission, and signal transduction, while EPA is thought to have potent anti-inflammatory and antioxidant effects. Omega-3 fatty acids are perhaps the most widely studied nutrients in neuropsychiatry to date. Inverse associations have been found between omega-3 intake or biochemical status and depression, anxiety, ADHD, ASD, bipolar disorder, schizophrenia, mild cognitive impairment, and Alzheimer dementia.

Omega-3 Fatty Acids and Depression

A recent meta-analysis of 26 RCTs (N = 2,160) demonstrated that supplementation with omega-3 fatty acids resulted in a small but statistically significant improvement in depressive symptom scores in adults with MDD or depressive symptoms. Depression symptom rating instruments included: Hamilton Depression Rating Scale (16 studies), Montgomery-Asberg Depression Rating Scale (4 studies), Beck Depression Inventory (4 studies), and Geriatric Depression Scale (2 studies). The supplemented doses of EPA ranged from 180 to 4,000 mg/day, whereas DHA ranged from 120 to 2,000 mg/day. Trials ranged in duration from 4 weeks to 6 months. The effect size for all types of omega-3 supplementation was small (SMD = −0.28, P = .004); however, subgroup analysis revealed increased therapeutic effects based on EPA formulation. EPA-pure formulations (containing 100% EPA) and EPA-major formulations (containing ≥60% EPA), each delivering a total EPA dose of up to 1 g/day of EPA, demonstrated significantly greater benefits when compared with other omega-3 formulations. The greatest effect size was seen in EPA-major formulations (containing ≥60% EPA, delivering total EPA up to 1 g/day) with a large effect (SMD = −1.03, P = .03). The effect size for EPA-pure supplements (containing 100% EPA, delivering up to 1 g/day of EPA) was moderate (SMD = −0.50, P = .003). Studies included treatment with antidepressants (10 studies), without antidepressants (8 studies), and or a mixed sample (8 studies). Subgroup analysis was not performed to determine differences in mono- versus adjunctive therapy. Studies included patients with medical comorbidities (8 studies), without medical comorbidities (11 studies), and mixed samples (7 studies). This meta-analysis did not report adverse events or time to discontinuation in treatment versus placebo groups. Based on available data, the use of daily omega-3 fatty acid supplementation containing

Telegram: @medical_k

www.konkur.in

≥60% EPA, delivering up to 1 g/day of EPA, appears to be an effective intervention in adults with MDD or clinically significant depressive symptoms.

Omega-3 Fatty Acids and Anxiety

In a recent meta-analysis of 19 RCTs (*N* = 2,240) in adults with clinically significant anxiety symptoms, supplementation with omega-3 fatty acids resulted in a small but significant improvement in anxiety symptoms (*SMD* = 0.37, *P* = .01). Reflecting the range of anxiety disorders and symptoms studied, a large number of rating instruments were used to determine clinically significant anxiety symptoms as follows: Yale-Brown Obsessive-Compulsive Scale, Profile of Mood States, State-Trait Anxiety Inventory, Hamilton Anxiety Rating Scale, Generalized Anxiety Disorder Questionnaire, Depression, Anxiety, and Stress Scales, Clinician-Administered Post-traumatic Stress Disorder Scale, Beck Anxiety Inventory, Visual Analog Scale of Anxiety, Impact of Event Scale-Revised, Conners Score Anxiety Subscale, Neuropsychiatric Inventory, Test Anxiety Severity, Hospital Anxiety, and Depression Scale Anxiety Subscale, and Child Behavior Checklist anxiety subscale. Psychiatric and medical conditions in participants also varied widely, including no specific clinical conditions, acute myocardial infarction, borderline personality disorder, mild-to-severe depression, obsessive-compulsive disorder, severe accidental injury, traumatized by disaster, substance abuse disorder, premenstrual syndrome, Alzheimer disease, Parkinson disease, generally healthy undergraduate college students with test anxiety, children with ADHD, and individuals with Tourette syndrome. The total omega-3 fatty acid supplementation doses ranged from 225 to 4,074 mg/day, and the treatment duration ranged from 3 to 24 weeks. In subgroup analysis, patients with a clinical diagnosis of an anxiety disorder experienced a moderate benefit of omega-3 supplementation compared to those without a clinical anxiety diagnosis (*SMD* = 0.51, *P* = .01). Further subgroup analysis demonstrated that omega-3 fatty acid doses ≥2 g/day resulted in a small but significantly increased benefit compared to doses <2 g/day (*SMD* = 0.21, *P* = .02). Subgroup analysis of trials utilizing EPA supplements containing less than 60% versus 60% or more were opposite to the depression literature, with supplements containing less than 60% EPA conferring benefit versus placebo, whereas supplements containing 60% EPA or more did not. Adverse effects were not reported, and

Telegram: @medical_k

www.konkur.in

subgroup analysis was not performed to determine differences in monotherapy versus adjunctive therapy. Modest sample sizes and significant heterogeneity in the included studies should be considered; however, this study lends support to the idea that omega-3 fatty acids, particularly in doses >2 g/day and perhaps with <60% EPA, may be an effective intervention to reduce anxiety symptoms in individuals with clinical anxiety disorders. Further study in more narrowly defined illness groups would be helpful to clarify the optimal dose.

Omega-3 Fatty Acids and ADHD

In a meta-analysis of eight RCTs (N = 628) in children with ADHD aged 7 to 14 years, omega-3 fatty acid supplementation demonstrated small but significant improvement in parental reports of inattention (SMD = 0.42), hyperactivity (SMD = 0.48), and total ADHD symptom scores (SMD = 0.38) (all $P < .05$). Subgroup analysis revealed that inattention and total ADHD symptom scores improved with EPA doses <500 mg/day and ≥500 mg/day, with small effect sizes (SMD) ranging from 0.36 to 0.48, while EPA doses ≥500 mg/day showed a large effect on hyperactivity scores (SMD = 0.81, P = .02). Mixed (EPA and DHA) omega-3 doses used in the trials ranged from 80 to 650 mg/day of EPA and from 3 to 640 mg/day of DHA. Trials ranged in duration from 12 weeks to 6 months. Data on adverse effects and concurrent medication use were not reported. Omega-3 fatty acid supplementation in modest dosages appears to improve ADHD symptoms in children with greater benefit in hyperactivity seen with mixed supplements containing EPA ≥500 mg/day.

Omega-3 Fatty Acids and ASD

In a small meta-analysis of five RCTs (N = 183) in children with ASD aged 2 to 17 years, there were no differences between the omega-3 fatty acid and placebo groups in Aberrant Behavior Checklist (ABC) scores of irritability, stereotypy, hyperactivity, or inappropriate speech assessed by teachers/clinicians or parents. However, omega-3 supplementation demonstrated significant improvement in parents' ratings of ABC lethargy (SMD = 1.98, P = .02), but not when assessed by teachers/clinicians (P = .58). In studies using the Behavioral Assessment System for Children scoring tool, parent ratings reflected significant externalizing behavior and social skills worsening. One study used the Vineland Adaptive Behavior Scale and reported significant improvement in the daily-living component

Telegram: @medical_k

www.konkur.in

with omega-3 supplementation. Omega-3 doses used in the trials ranged from 375 to 840 mg/day of EPA and from 200 to 1,125 mg/day of DHA. Trials ranged in duration from 6 weeks to 6 months. No significant differences in adverse effects were observed between the omega-3 and placebo groups. Concurrent medication administration use was not reported in the trials, but this should be understood with the context that the mainstay of treatment for symptoms in ASD is nonpharmacologic. Given the paucity of data and mixed results, no recommendations can be made regarding the benefit of omega-3 supplementation for improving symptoms in ASD at this time.

Omega-3 Fatty Acids and Mild Cognitive Impairment

In a recent meta-analysis of 15 RCTs (N = 2,524) in adults with MCI, supplementation with mixed omega-3 fatty acids (EPA + DHA) revealed small but statistically significant improvements in memory (SMD = 0.31) and executive function (SMD = 0.19) (both $P < .01$). Trials ranged in duration ranged from 2 months to 26 weeks. Mixed omega-3 doses ranged from 60 to 2,187 mg/day of EPA and 180 to 1,550 mg/day of DHA. Subgroup analysis showed that the effect size for improvement in either domain was not related to the dose of EPA or DHA. Data on adverse effects were not reported. The results of this review suggest that mixed EPA + DHA omega-3 supplementation may confer benefit in the cognitive domains of memory and executive function in adults with MCI, albeit with small effect sizes, and further study is needed to outline more specific dose ranges.

Omega-3 Fatty Acids and Alzheimer Disease

A recent meta-analysis of six RCTs (N = 758) in patients with Alzheimer disease demonstrated that omega-3 fatty acid supplementation did not improve cognitive deterioration, cognitive dysfunction, or neuropsychiatric symptoms measured by the Mini-Mental State Examination, Alzheimer Disease Assessment Scale-Cognitive subscale, and the Neuropsychiatric Inventory, respectively. Variability in DHA or DHA/EPA doses ranged from 240 mg/day to 2.3 g/day, and treatment periods ranged from 90 days to 1.5 years. The authors suggested that variability in DHA or DHA/EPA dose, the ratio of DHA/EPA, concurrent medications, and lack of information on participant diets may have limited conclusions. Adverse effects were reported in two of the studies, and neither found significant

Telegram: @medical_k

www.konkur.in

group differences in the incidence of events. The current evidence does not suggest that omega-3 fatty acid supplementation improves cognition or neuropsychiatric symptoms in adults with Alzheimer disease.

SUMMARY AND FUTURE DIRECTIONS

Given that many patients will choose to utilize dietary supplements, the psychiatrist needs to offer evidence-based recommendations when feasible. Additionally, given the often inadequate responses to standard treatment approaches, it is worthwhile for mental health providers to be aware of nutrition-related evidence-based interventions to augment standard therapy or offer alternative approaches when appropriate. Considering that the first vitamin was isolated just under 100 years ago, it is heartening to see well-designed studies emerging to help elucidate relationships between specific micronutrients and mental illnesses, particularly since trials of this kind did not emerge to a large degree until the 1990s. More well-designed RCTs are still needed to determine the role of supplemented micronutrients outlined in this chapter (vitamin D, vitamin B12, folate, and omega-3 fatty acids) in many psychiatric disorders.

Our review suggests a benefit for

- Vitamin D supplementation (depression, childhood ADHD)
- Folate (depression)
- Omega-3 fatty acids (depression, anxiety, ADHD, and mild cognitive impairment)

Supplementing with nutrients should be undertaken with care, guided by biomarker monitoring where applicable, and dosed appropriately (in amount and duration) for specific conditions based on the available evidence. As interest in this area appears to be ongoing, providers should hopefully expect additional data to emerge to guide practice recommendations for using these and other nutrients in psychiatric illness in the future.

30.6 Disaster Psychiatry: Disasters, Terrorism, and War

David M. Benedek, M.D., Joshua C. Morganstein, M.D., James C. West, M.D., and Robert J. Ursano, M.D.

Disasters impact hundreds of communities and affect the lives of millions of people around the world every year. They may result from the destructive forces of nature and climate-related events (e.g., hurricanes, earthquakes, tsunamis, or infectious disease outbreaks, such as COVID-19), accidents (e.g., plane crash, industrial fire), negligence (e.g., forest fires sparked by carelessness), or deliberate acts (e.g., large-scale

Telegram: @medical_k

www.konkur.in

terrorist attacks or military combat operations). Regardless of origin, the frequent chaos of disaster can be pervasive and enduring over time. Psychological injury often occurs in conjunction with physical injury, exposure to the injury and death of others, loss of social connections, disruption of the physical environment, and accompanying feelings of terror and helplessness. Many disasters have both climate and environmental causes that are often exacerbated by human systems and behaviors. Hurricane Katrina began as a storm that exposed weaknesses in levees; The triple-disaster of Fukushima began as an earthquake that created a tsunami that damaged vulnerable nuclear reactors; COVID-19 appears to have been initially transferred by animals, but then rapid, mass global travel quickly transmitted the virus around the world.

Disaster psychiatry is an area of psychiatry that includes public health planning, clinical care, and research. Core to this area is anticipating the scope of behavioral, emotional, and distress-related responses of individuals and communities, planning mental health disaster response, and, ultimately, providing care for those exposed. War and terrorism are subtypes of human-caused disasters and typically cause more significant adverse psychological impacts than natural and climate-related disasters. During war, military personnel may die or be injured in combat, but noncombatant civilians are also intentionally or unintentionally injured and killed during military operations. As a result, war is a particularly unique form of disaster, exposing various groups and populations to distressing and grotesque imagery and physical harm, creating risk for adverse psychological and behavioral outcomes.

Because war, military peacekeeping, and humanitarian relief operations place military health care providers in direct and prolonged contact with disaster-affected populations, the knowledge base, skills, and professional attitudes required for psychiatric practice in military operations are closely aligned with those necessary for other types of disasters. A psychological injury must be addressed promptly in any disaster, including war and terrorism. Mental health care must be provided in hospitals or clinics and near sites of chaos and destruction, where traditional medical resources may be scarce or overwhelmed. Care providers use public health models of health surveillance, outreach, and education to overcome barriers to care, including those safety and survival interests coexisting with mental health needs, limited physical and psychiatric care resources, and stigma associated with requesting or receiving mental health assistance. Military

Telegram: @medical_k

www.konkur.in

and disaster psychiatry disciplines address these care demands in nontraditional environments and mass casualty situations in which resources are overwhelmed by emphasizing disease prevention through a range of interventions by individuals, teams, and leaders that foster resilience.

Disaster psychiatry highlights the importance of integrating mental health and public health. Care in these environments relies on not only psychiatrists but also other physicians, social scientists, epidemiologists, nurses, and emergency responders such as police and firefighters. The coordination of these diverse care providers is necessary to ensure that needs are met and that no subgroup of victims is overlooked. This approach to population health care delivery and management, including primary (prevention), secondary (early treatment), and tertiary (treating established disease and rehabilitation) care, is a critical aspect of disaster psychiatry.

In the United States, the terrorist attacks on the Pentagon and the World Trade Center and the distribution of anthrax-tainted mail in the following weeks resulted in widespread fear and uncertainty in the American public. Subsequently, around the globe, the issues of severe acute respiratory syndrome (SARS), Sarin gas attacks in Tokyo, train bombings in Spain, and the earthquake in Fukushima drew attention to disaster care for individuals and groups across explosive, radiologic, and biologic agents. Most recently, nations worldwide have grappled with the global COVID-19 pandemic and resultant economic crises, political upheaval, and social unrest. These events also resulted in neuropsychiatric syndromes in many survivors and their relatives. Response to these events involved numerous government, public health, law enforcement agencies, civilian disaster relief organizations, military medical, mental health, and law enforcement personnel. The response to the COVID-19–related crises in the United States, as well as military participation in humanitarian relief efforts after the Southeast Asian tsunami of December 2004, Hurricanes Katrina and Rita of 2005, Haiti earthquakes of 2010, the Philippines' Typhoon Haiyan of 2013, West Africa Ebola outbreak of 2014, and COVID-19 pandemic, illustrate the complex response required for disasters of all types.

ENVIRONMENTS OF CARE IN DISASTER AND MILITARY OPERATIONS

Telegram: @medical_k

www.konkur.in

The term *disaster* has several definitions or connotations. The word is derived from the Latin words *dis* (meaning *against*) and *astrum* (meaning *stars*)—*the stars are against us.* Ancient societies may have conceived of disasters, such as floods or earthquakes, as acts of the gods. However, the distinction between *natural* disasters, such as earthquakes, and *human-caused* or technologic disasters, such as explosions or plane crashes, is increasingly challenging to make. Much of the death and destruction from an earthquake may result from damage to poorly constructed housing in urban areas—thus, there is often a human-caused aspect even to natural disasters. Certainly, human-caused disasters can result from accidents (e.g., factory explosions), but human-caused disasters also result from intentional acts in the cases of war or terrorism. The degree to which a disaster may be anticipated and the characteristics of the affected population (soldiers or civilians) may be more critical distinctions than whether the disaster was natural or human-caused.

War is an all-too-common human-caused disaster. At the time of writing, there are more than 57 ongoing armed conflicts involving 45 countries occurring around the globe. War has been defined as a political act (generally involving violence) to achieve national objectives or protect natural interests. In these actions, militaries create their own and civilian casualties in armed conflicts of all kinds. During recent years, militaries worldwide have also been prominently engaged in humanitarian disaster relief, as for hurricanes and pandemic response in the United States, earthquakes in Turkey, and the recent tsunami in Southeast Asia, to name only a few. Indeed, military forces typically represent the most significant portion of disaster-response personnel resources for most countries. In addition, militaries are involved in government stabilization and peacekeeping efforts (military operations other than war). Terrorism, like war, involves violence to achieve political objectives and may occur between members of different countries or spawn from internal, domestic threats. Here, however, the objective is to create fear or terror to undermine society's confidence in its government and leaders. As such, fear, anxiety, and a sense of chaos are the goals of terrorism rather than the (albeit predictable) aftereffects observed in wars and other human-caused or natural disasters. Therefore, mitigating the emotional and psychological effects of terrorism is crucial to sustaining and protecting a nation from the impact of terrorist attacks.

Telegram: @medical_k

www.konkur.in

The causes of emotional symptoms in response to disasters, including war, have been historically attributed to sources ranging from the gods, the concussive force of a passing cannonball, and various natural or supernatural sources of contagion. Emotional consequences are alluded to frequently in the descriptions of the terror induced by the hero's attack in Homer's *Iliad.* Ancient Greeks attributed epidemic illness to Apollo's wrath after the desecration of his temple. The French military surgeon Dominique-Jean Larrey commented clearly on the ill effects of war on the health of Napoleon's soldiers. Combat-related behavior, similar to the symptoms of posttraumatic stress disorder (PTSD), defined in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), is described in Civil War medical treatises. The science of neurology entered military medicine with Weir Mitchell's work in this era. During the remainder of the 19th and 20th centuries, concepts of neurasthenia, dissociation, hysteria, and psychological suggestion were developed to define psychoneurologic states for which no demonstrable neuroanatomical pathology could be identified. Military physicians in the Russian–Japanese War made similar observations. Recognition that nontraumatic injuries followed train derailments occurred even as World War I and II physicians initiated treatment models for conditions such as *shell shock, gas neurosis,* and *conversion paralysis.* Civilian physicians have also long recognized the concept that war results in physical and emotional human suffering. In 1859, Henri Dumont arranged for civilian medical services for the injured after observing soldiers die from lack of medical attention during the Battle of Solferino. His efforts led to the establishment of the International Red Cross and international guidelines for the humane care of the sick and wounded during wartime.

Beginning in the last quarter of the 20th century, the Red Cross, and other international medical and relief agencies, such as Doctors without Borders and Partners in Health, have increasingly provided mental health-related consultation and direct care for victims and responders in the aftermath of war and natural and human-caused disasters. Observations during these military and civilian medical efforts formed the basis for today's understanding that aspects of the environment and the unwanted environmental changes brought about by war or disaster result in emotional trauma.

Regardless of the source, potential stressors in disaster and military environments include exposure to the dead and grotesque, immediate

Telegram: @medical_k

www.konkur.in

and pending threat to life, loss of loved ones, loss of personal property, and physical injury with associated disability and pain. Such stressors may occur transiently but must be endured for months or years more often. Although the military brings supplies and logistical infrastructure, including food, shelter, and specialized equipment and clothing to protect soldiers at war, civilians exposed to combat in modern times may be subject to large-scale destruction within their communities. They may become refugees and experience shortages of food or shelter that threaten life. These noncombatant victims often do not receive treatment for psychiatric symptoms that may emerge because of exposure to bombings, battles, rape, torture, and genocide. Although an earthquake may last only seconds or minutes, the traumatic experiences resulting from the destruction of home, geographic displacement from familiar surroundings, a loss of employment, or because of injury or loss of loved ones may continue for weeks, months, or, possibly, years. Combat environments, ongoing terrorist campaigns, and cases of natural disasters, such as earthquake exposure, over time may include vaguely anticipated or entirely unexpected life-threatening experiences, followed by daily life in an austere or disrupted environment.

TRAUMATIC STRESS RESPONSE IN POPULATIONS AND INDIVIDUALS

Psychological and behavioral responses after a disaster change over time. Understanding the phases of psychological response to disaster can inform planning and caring for the mental health needs of individuals and communities. A *predisaster phase* occurs when an event is anticipated or an advanced warning is given, such as a tropical cyclone or wildfire. Feelings of vulnerability and worry about safety are common in this phase and, for some, will promote protective behaviors such as evacuation. For others, these feelings are ignored, not present, or may lead to paralysis with indecision or feeling emotionally overwhelmed.

In the immediate aftermath of an event, during the *impact phase*, survivors experience disbelief, numbness, fear, and confusion as they witness devastation and suffering. These are the “normal,” that is, expected, emotional responses to an extraordinary event. A *heroic phase*, lasting days to weeks, typically follows. Rescue and survival activities are the central focus. Disorientation may persist for some and render them

Telegram: @medical_k

www.konkur.in

unable to participate in response and recovery. Injury or separation from family can produce increased anxiety and worry and detract from immediate problem-solving. The *heroic phase* includes the initial appearance of outside assistance and marks the beginning of adaptation to the postdisaster environment.

The *honeymoon phase* follows as outside assistance becomes fully available and communities band together in response to shared adversity, giving and receiving assistance. Survivors are hopeful that the help they receive will make them whole again. During this phase, disaster behavioral health workers are often perceived as helpful and readily accepted by community members, developing a foundation to assist in the future.

As the challenges of prolonged recovery set in, optimism gives way to *disillusionment*. Assistance agencies and volunteer groups begin to pull out of the community, and resources for recovery are stretched thin, leading to feelings of disappointment and resentment as hopes for a restoration of the predisaster environment are not met. The sense of community, so strong in the *honeymoon phase*, diminishes as individuals focus on personal needs or express frustration over unmet needs. Ill will and resentment may surface as survivors receive unequal monetary compensation for what they perceive to be equal or similar damage. Survivors may be physically and emotionally exhausted in the face of enormous multiple demands: financial pressures, relocation or living in a damaged home, family discord, bureaucratic challenges, and a reduced time for recreation or self-care. New health problems and exacerbation of preexisting conditions emerge because of ongoing stress and fatigue. *Anniversary reactions* should be anticipated and represent an opportunity for leaders to support the psychological well-being of disaster victims through memorializing, helping make meaning of the events, and focusing on “building back better.” Failure to effectively address a disaster anniversary experience can demoralize survivors and exacerbate underlying psychological distress and feelings of disillusionment.

As needs are met, and communities stabilize, the *reconstruction phase* emerges and may last for years. Survivors face deciding whether to return to old jobs or find new work, rebuild homes or relocate, reestablish social ties and emotional support systems, or develop new ones. Individuals may find meaning and experience posttraumatic growth, emerging from the disaster with an increased sense of personal strength.

Telegram: @medical_k

www.konkur.in

Individuals and communities progress through the phases of disaster at variable rates. Planning and delivering care to disaster victims must recognize this. Depending on the intensity and duration of trauma exposure, resources available, and individual coping skills, individuals may develop persistent symptoms requiring prolonged treatment. Failure to account for these factors in medical and psychological response plans can lead to anger at caregivers and community leaders.

Symptoms versus Functioning

Disaster psychiatry addresses the clinical concerns of identified patients and supports interventions to prevent potentially incapacitating morbidity in entire populations. Distress-related symptoms are universally experienced during an evolving disaster, as they are during combat. Symptoms occurring in persons who are not functionally impaired are, by necessity, a secondary concern when resources are overwhelmed.

The label given to clusters of symptoms has political, economic, and research-related significance. However, in the context of ongoing battle or relief efforts, the perception that one is ill can lead to impaired functioning, which may compromise these efforts and increase long-term disability. Indeed, transient and nearly universal symptoms that represent normal responses can become medicalized if health care personnel reinforce a view that these symptoms constitute a disease. Therefore, initial mental health interventions must focus on mobilizing effective functioning to allow rescue and relief efforts or battle in the context of war-related disasters to continue.

Psychological and Behavioral Syndromes in the Aftermath of Disasters, Terrorism, and War

A considerable body of literature exists on the effects of traumatic events on individuals and communities in response to disasters and war. Each of these informs the other. Many individuals emerge with limited or no adverse effects, effectively resuming their social and occupational roles (resilience). Some may even experience an increased sense of competence, self-efficacy, and belief in their ability to manage future stressors (sometimes termed “posttraumatic growth”). However, a sizable minority experiences a range of adverse psychological and behavioral effects, including distress reactions, health-risk behaviors, and psychiatric disorders (Fig. 30.6–1).

Telegram: @medical_k

www.konkur.in

In the immediate aftermath of a disaster, distress reactions predominate. Individuals feel a sense of vulnerability and often blame, scapegoat, and express anger at organizations and leaders perceived as responsible. Demoralization and a loss of faith may also occur. Many individuals experience insomnia, irritability, and feelings of distractibility. Some present to health care settings with physical symptoms as a manifestation of psychological distress. Symptoms such as headache, dizziness, nausea, fatigue, and weakness are common in the wake of a disaster, even when an identifiable physical disorder cannot be found. In addition, alterations in health-related behavior are not uncommon after traumatic events. Increased use of alcohol, tobacco, and illicit or prescription drugs may occur as individuals seek to manage feelings of distress.

Disasters are time-consuming and lead to work-life imbalance leading to erratic sleep, deterioration in eating habits, and reduced exercise. Family conflict and violence may also occur. These are common reactions to extraordinary events. Planning for these distress reactions and risky health behaviors requires adequate resources to respond to individuals with distress symptoms in a timely and supportive manner and triage at emergency and other health care settings to enable the management of other physical and mental disorders.

Much of disaster psychiatry focuses on the neurobehavioral responses to stressful, emotional events. Well-defined psychiatric illnesses certainly result from such exposures. The DSM-5 definition of PTSD necessitates direct or indirect exposure to death, threats to the physical integrity of self or others, or aversive details about an event. PTSD includes (1) intrusion symptoms, such as involuntary memories, traumatic nightmares, or dissociative reactions; (2) avoidance manifested by persistent efforts to avoid trauma-related thoughts, feelings, or external reminders such as people, places, or activities; (3) negative alternations in cognition and mood, including the inability to recall key features of the traumatic event, persistent negative beliefs about oneself and the world, distorted beliefs, diminished interest in activities and constricted affect; and (4) alterations in arousal and reactivity demonstrated by irritability or aggression, self-destructive behavior, hypervigilance, concentration problems, and sleep disturbance. When such symptoms result in functional impairment and persist for more than 1 month, PTSD is diagnosed. Transient symptoms occurring during the first month and resulting in dysfunction are diagnosed

Telegram: @medical_k

www.konkur.in

as *Trauma and Stressor-Related Disorder Not Otherwise Specified or Adjustment Disorder.* War, disaster, and terrorist attacks often result in exposure to stressors meeting the criterion for PTSD. PTSD is conceptualized as a response to catastrophic trauma or stressor. It has been as carefully defined as many other psychiatric disorders and targets symptoms that military and disaster psychiatric preventive and evidence-based treatments seek to mitigate.

In addition to PTSD, other disabling responses to trauma may occur (Table 30.6–1). Adjustment disorders (characterized by anxiety, depression, and changes in behavior) can occur in response to the stressors associated with war, terrorism, or disaster. Conversion disorders are characterized by unexplained deficits in sensory or motor function (e.g., sudden paralysis of an extremity) without demonstrable neuroanatomical injury. Bereavement may occur in response to the death of a loved one as a result of war, disaster, or another catastrophe. Other observed distress-related responses include anxiety and depressive syndromes and antisocial behavior (including criminal behavior, military misconduct, and war-related atrocities).

FIGURE 30.6–1. Psychological and behavioral responses to disasters, terrorism, and war include distress reactions, health risk behaviors, psychiatric disorders, and resilience.

Telegram: @medical_k

www.konkur.in

The constellation of symptoms, severity, and refractoriness of symptoms to conservative measures distinguishes between subsyndromal responses and psychiatric disorders.

Combat and Operational Stress and Medically Unexplained Physical Symptoms

Besides DSM-5 conditions, in the practice of military and disaster psychiatry, *combat and operational stress* (previously termed “battle fatigue”) are also significant. These terms encompass a variety of somatic and emotional responses to disaster and military operations that do not fully match the specific constellations of symptoms seen in major depressive disorder, adjustment disorder, PTSD, or conversion disorder. Symptoms such as gastrointestinal (GI) distress, tremulousness, and perceptual disturbance, including depersonalization and derealization, occur transiently in response to the traumatic exposure, sleep deprivation, loss of social support, or any combination of these stressful situations factors associated with military operations. Minor injury, parasitic infection, starvation, heat exhaustion, or cold injury may also contribute to a decreased ability to cope and, therefore, to operational stress symptoms.

www.konkur.in

Table 30.6–1.
Psychological Responses to Disaster and War: Associated Mental Disorders and Symptoms

Mental Disorders
Acute stress disorder
Posttraumatic stress disorder
Generalized anxiety disorder
Panic disorder
Major depressive disorder
Brief psychotic episode
Adjustment disorders
Alcohol abuse
Substance abuse
Symptoms
Anger and irritability
Fear
Restlessness
Concentration and attention difficulties
Sadness
Insomnia (with or without nightmares)
Somatic complaints
Headaches, gastrointestinal distress, musculoskeletal pain
Exacerbation of existing medical illness
Increased alcohol and tobacco use
Diminished interest in activities

Finally, war historians and military and civilian physicians have observed that unexplained physical syndromes are a common sequela of combat. Syndromes such as *soldier's heart* and various physical symptoms (e.g., arthralgias, rashes, and dysesthesias) have been attributed variously to undetected neurologic or chemical attacks, Agent Orange, depleted uranium, or other toxic factors on the battlefield. Although debates among scientists, clinicians, veterans, and journalists persist, the consistent appearance of these syndromes—affecting various persons in various ways—after wars or other military operations points to the likelihood that psychosocial factors contribute to etiology.

Telegram: @medical_k

www.konkur.in

A 28-year-old Army sergeant was involved in U.S. military operations in Afghanistan. His commander escorted him to the troop medical clinic because “he just isn’t acting right.” On interview, he reported that he had been involved in frequent combat, fighting from house to house for over 5 days. His temperature was 100°F, and his pulse was 90 beats per minute; his blood pressure and respiratory rate were normal. His physical examination was unremarkable. His mental status examination was notable for poor grooming; he was unshaven and smelled of perspiration. He was oriented to month and year but unsure of the day and date. He displayed poor eye contact and psychomotor retardation. His thought processes were logical, but he asked for several questions to be repeated. There was no evidence of psychosis, but he seemed focused on his perceived need to “get back to my men.” He noted that he and others had been under machine-gun fire for “a few days, I guess,” and that members of his unit were wounded, and two were killed because of a grenade blast. He reported these events with little display of emotion. He denied any history of psychiatric illness or contact with mental health professionals and denied any such history in his family.

DISCUSSION

This service member’s history suggests an adjustment disorder or acute stress disorder. However, the presentation was also consistent with a combat stress reaction. His mental status examination indicates the possibility of depression. His vital signs suggest that dehydration may be contributing to his presentation. Infectious diseases endemic to the region may also contribute. His report of proximity to a hand-grenade explosion suggests the possibility of blast-related traumatic brain injury (TBI) as well. Appropriate initial interventions include rest, rehydration, and respite from the ongoing battle. In addition, applying psychological first aid (PFA) steps, such as establishing safety and calming, will aid recovery and help differentiate a brief stress reaction from persisting illness or impairment. Additional history from members of his unit might clarify the extent of his involvement in previous combat and his degree of resiliency to these exposures. A negative evaluation for infectious disease, head injury, or other medical conditions and a rapid return to baseline function with respite and nourishment suggests a combat stress reaction and would allow him

Telegram: @medical_k

www.konkur.in

to return to duty. The possibility of future emotional sequelae from this event points to the need for continued surveillance.

ETIOLOGY AND EPIDEMIOLOGY

The mental health effects of a disaster have been historically well recognized. Epidemiologic data derived from methodologically sound studies in the aftermath of disaster have increased in recent years but are limited understandably, given the research challenges imposed by the chaotic environment of disasters. Studies conducted in Manhattan and Washington, D.C., in the months after the September 11, 2001, terrorist attacks demonstrated a substantial burden of PTSD and depression, as well as increased use of alcohol, tobacco, and marijuana. Rates of PTSD ranged from 7% to more than 17%, and rates of depression ranged from 9% to 15%. In one survey, nearly 29% of persons reported increased alcohol, cigarettes, or marijuana use. Studies of the terrorist bombing of the Oklahoma City Federal Building demonstrated that nearly 35% of the directly exposed population developed PTSD within 6 months of the event. Of importance, nearly 40% of those with PTSD had no history of a psychiatric disorder. The National Comorbidity Replication Study Survey established a prehurricane prevalence rate for mental disorders of 15% in the region affected by Hurricane Katrina.

In contrast, a posthurricane survey of the same population effectively demonstrated a doubling of overall rates of mental disorders to 30% 6 months after the hurricane. A systematic review of suicidality following a wide range of international and U.S. natural disaster events revealed a trend toward decreased suicidality in the first few months following a disaster, during the “Honeymoon” phase. However, numerous studies observed increased rates of suicidal thinking and behavior, which commonly began during the 6- to 12-month period following a disaster event, coinciding with the “Disillusionment” phase. Consistent with these findings, when compared to predisaster data, surveys given to greater than 1,000 affected residents 9 to 18 months following Hurricane Katrina found an increase in suicidal ideation (6.4% vs. 2.8%) and suicide plans (2.5% vs. 1.0%).

Considering exposure to war, historically, the suicide rate in the U.S. military has been below that in the civilian population, but it climbed steadily after the beginning of the Iraq and Afghanistan conflicts to the

Telegram: @medical_k

www.konkur.in

point where suicide is presently the second leading cause of death behind combat deaths and has exceeded demographically matched civilian rates since 2008. The rise in U.S. Army suicides has persisted despite substantial efforts to publicize and encourage the use of mental health services. The Department of the Army responded to these trends by collaborating with the National Institute of Mental Health (NIMH) to fund the Army Study to Assess Risk and Resilience in Service members (Army STARRS; http://www.armystarrs.org), a multicomponent epidemiologic and neurobiologic study of risk and resilience factors for suicidality and its psychopathologic correlates among Army personnel. Army STARRS is the most extensive study ever to address risk and protective factors for suicide in the U.S. Military, which has leveraged big data analytics to more precisely determine where risk is concentrated and develop actionable interventions to protect health and enhance military readiness.

A 2002 study of 2,583 veterans aged 18 to 54 years who received standardized psychiatric interviews in the National Comorbidity Survey demonstrated that combat exposure resulted in high rates of psychiatric diagnoses and psychosocial difficulties: 28% had PTSD; 21% engaged in spousal or partner abuse; 12% experienced a loss of employment (9% unemployed at the time of the survey); 8% reported substance abuse problems within 1 year after combat, and 7% reported symptoms consistent with major depressive disorder. In its oft-cited 2008 study, the RAND Corporation, Center for Military Health Policy Research, examined the prevalence of PTSD among previously deployed Operation Enduring Freedom and Operation Iraqi Freedom (Afghanistan and Iraq) Service members. PTSD was assessed using the PCL, as in the Gulf War Veterans study. Among the 1,938 participants, the prevalence of current PTSD was 13.8%. The study also showed that a substantial proportion of Iraq War veterans accessed mental health services in the year after returning home and suggested that concerns over stigma and potential career implications prevented others from doing so. Traumatic brain injury, resulting from blast and other injuries in disaster and other settings, has received increased attention, including as a comorbidity with PTSD when occurring in the context of exposure to psychologically traumatic events. The presence of TBI is associated with more complex and chronic dysfunction and impairment, particularly when comorbid with trauma-related psychological disorders. As the incidence and prevalence of intermediate and long-term effects of combat have become more

Telegram: @medical_k

www.konkur.in

apparent, so too have the neurobiologic and psychosocial explanations for observed psychopathology.

Predisposing Factors

PTSD, other anxiety and depressive disorders, and physical syndromes in response to a stressor are more frequently diagnosed among women than men. Explanations for this involve neurobiologic and psychosocial factors, including the greater rate at which women seek treatment for stress-related symptoms and the fact that the duration of illness may be longer for women and, therefore, may be more likely to reach clinical attention. In the aftermath of a disaster or during war, women are at higher risk for victimization through intimate partner violence and physical and sexual assault outside the home. Women may also be at increased risk due to having greater responsibility for managing family emotions and distress. Men are at greater risk for posttraumatic problems with substance abuse and antisocial and violent behavior. Gender-specific cultural factors and as-yet-unspecified neurophysiologic factors are likewise implicated in these differences.

The level of functional impairment in the aftermath of combat or disaster is also related to pretrauma functioning. Individuals who function marginally in social or occupational roles before combat or disaster exposure are at increased risk of poor function after trauma exposure. A history of childhood abuse or significant traumatic exposure generally appears to be a risk factor for developing PTSD after exposure in adulthood. If persons have successfully negotiated disaster or combat situations in the past, they may be less adversely affected by subsequent exposures (even if the circumstances of the trauma change from combat to disaster or vice versa). On the contrary, if past traumatic experiences produced PTSD or other psychiatric syndromes, further traumatic exposures may trigger exacerbations or the emergence of new psychiatric disorders. Specific subpopulations, such as children, may be particularly vulnerable with the well-being of children intimately tied to their caregiver's level of distress and function. While a history of mental health diagnosis does not necessarily increase risk, those with serious and persistent mental illness may be more vulnerable to the emotional consequences of traumatic experience due to a dependence on systems of care (e.g., case manager, injectable medication, day treatment programs), which may be disrupted or inaccessible during a disaster event. Older adults with

Telegram: @medical_k

www.konkur.in

cognitively impaired or limited mobility are less able to respond to the requirements of a disaster environment, including movement, evacuation, and seeking medical care, and are generally at increased risk for psychological injury. However, age and experience are also protective during disasters. For instance, older adults across various nations throughout the COVID-19 pandemic frequently reported lower levels of distress and health risk behavior than younger counterparts; a reminder that disasters create unique risk, and it is essential to be aware of assumptions risk (e.g., “being older makes someone vulnerable”). The loss of social support after disasters and in war-torn societies also results in the need for assistance in others who may have been previously able to cope (Figs. 30.6–2 and 30.6–3). The loss of access to medical care (i.e., medications) and health care providers is an indirect but substantial cause of casualties after disasters and terrorism.

Precipitating Factors

Precipitating factors are the proximate circumstances—the traumatic event itself—that initiate the various sequelae of trauma. For disaster responders and military populations, disaster and combat deployments and peacekeeping missions create additional stressors at the onset, including disrupting families. The high intensity and long duration of disaster or combat exposure increase the likelihood of psychiatric casualties. Specific experiences, such as physical injury or witnessing grotesque deaths, torture, or other atrocities, place individuals at increased risk for adverse mental health consequences. Rape, harassment, or assault can precipitate significant distress or illness in those victimized. Sexual assault is a powerful precipitant of adverse neurobehavioral changes.

Mitigating or Perpetuating Factors

Ongoing factors, including the security and safety of recovery environments, the extent of secondary traumatization, and—in first responder and military populations—rotation schedules, the degree of recognition or compensation for efforts, and one’s belief in the mission all affect the trajectory of the stress or illness/recovery response and the rate and severity of psychiatric illness and distress symptoms. Personal attributes or behaviors, such as over-dedication to the task at hand, may further contribute to dysfunction development. Symptoms in victims of

Telegram: @medical_k

www.konkur.in

disaster and war may be mitigated or exacerbated by perceptions of community leadership's preparedness for disaster, response to a crisis, recognition of heroes, and the distribution of resources such as the provision of medical, financial, or emotional assistance immediately after the crisis and over time.

Nongovernmental organizations (NGOs), such as the American Red Cross and the Salvation Army, help minimize the stress after a disaster. By attending to basic human needs, such as food, clothing, and shelter, they reduce the psychological and physiologic effects of the event. In recent years, the American Red Cross and other NGOs have developed training for volunteer health care workers to recognize, minimize, and treat stress responses in disaster workers and victims of disaster based on PFA principles.

Protective Factors

In groups such as military units, police, firefighters, and paramedic rescue units, protective factors may diminish the potential sequelae of trauma. Loyalty and interpersonal cohesion among members of such organizations may provide immediate access to social supports during the acute experience of a disaster and its aftermath. When such organizations possess strong leaders, these persons create and foster an environment of strong loyalty, mutual trust, and respect. Effective leaders communicate, manage their own stress, model self-care, and address issues of grief that are universal in disasters. Such an environment may reduce the extent to which one member of the group becomes excessively critical of another's performance during an emergency, may contribute to voluntary participation in high-risk rescue-and-recovery or combat missions, and may facilitate the synchronization of individual efforts that is necessary for success in these types of operations.

A critical factor in developing such trust and synchronization is the number of demanding, specific, and repetitive overtraining exercises in which elite police, rescue-and-recovery, and combat units participate. Disaster responders (firefighters, police, physicians, and civic leaders) assemble to train for responding to terrorist attacks, as well as natural disasters. Government emergency preparedness agencies, such as the U.S. Federal Emergency Management Agency, are increasingly coordinating such training. If the level of training is high, individuals in such units rely on ingrained principles aimed at mutual support in a quest

Telegram: @medical_k

www.konkur.in

for mission success. In addition, the National Center for Disaster Medicine and Public Health and Center for the Study of Traumatic Stress published disaster behavioral health curriculum recommendations that provide a comprehensive overarching framework for the development of training in disaster behavioral health preparation and response.

FIGURE 30.6–2. Children are particularly vulnerable to the emotional consequences of disaster.

Telegram: @medical_k

www.konkur.in

FIGURE 30.6–3. Separation from social support networks contributes to stress reactions in the context of military operations.

The nature and extent of the fit between persons, equipment—such as chemical protective suits and masks, remote-controlled bomb detonators, or mine detectors—and the environmental extremes that may be experienced during a disaster (e.g., heat, cold, and sleep deprivation) modify stress responses in individuals and communities. The fit between the pilot, aircraft, and other aircrew members may also be improved by specific training. The extent to which subtler factors within the environment may modify stress response has been noted in those forced to exist in close quarters with limited contact with the outside world, such as those aboard submarines or ships. Although these factors cannot be eliminated from the practice of military operations or disaster response

Telegram: @medical_k

www.konkur.in

efforts, the extent to which these additional stressors exacerbate responses to other primary stressors may be reduced through training.

MANAGEMENT AND CARE DELIVERY

General Principles

Disasters, including terrorist attacks and military conflicts, shatter the expectation of a just and safe world within populations in which such notions of basic safety and justice are cultural norms. Because a lack of emotional preparedness makes chaos and disorder more likely after such events, primary prevention must begin with a recognition of the need for rapid dissemination of information regarding the threat (e.g., early warnings for tornados and hurricanes or reporting of anticipated terrorist attacks gleaned from reliable intelligence sources). The development of a planned response should follow this effort, including the practice of that response and the provision of funding and facilities supporting the plan. These steps can mitigate a community's sense of helplessness before such an event occurs and increase a community's capacity to provide social support to victims.

Secondary prevention (i.e., early intervention) begins with the initial triage and treatment of victims. First responders, medical care personnel, and mental health care providers must be prepared to provide psychoeducation and symptomatic relief for individuals with acute (and frequently transient) emotional or behavioral disorganization or other symptoms. It is vital to create a *holding environment*—locations in which such symptoms can be observed and monitored. This area should be sufficiently removed not to disrupt the ongoing triage and stabilization of life-threatening physical injuries but should be close enough to allow re-evaluation and further medical intervention should symptoms worsen. A holding environment may also prove to be a location in which affected individuals attend to such basic needs as food, shelter, and personal hygiene, which are critical to restoring a sense of normalcy after a disaster or traumatic event (Table 30.6–2). For military personnel and other responders, maintaining individuals near other units or team members maintains a sense of social connection and identity, which can aid in symptom resolution and return to normal function.

Initially, establishing a safe environment and managing life-threatening physical injury and the myriad disease possibilities that result from lack of

Telegram: @medical_k

www.konkur.in

food, potable water, or infection are the most critical psychiatric interventions. Subsequently, identifying high-risk populations, such as disaster workers, persons at impact zones, children, and the chronically ill, can focus further interventions. Outreach and public education strategies are critical because disaster and trauma victims rarely specifically seek mental health care. It is important to educate medical and community groups about the normal and predictable responses to traumatic events of disaster and war and when to refer for additional mental health treatment. Informing community and governmental leaders about the behavioral and emotional sequelae associated with disasters ensures the allocation of funds and resources for these phenomena in the disaster recovery plan.

Table 30.6–2.
Disaster Mental Health Response: Management Principles

Primary Interventions
Early warning systems
Development, rehearsal, and resource allocation for event response, including identification and roles of responders, methodology for information dissemination, potential locations for triage, initial treatment, and holding environments
Secondary Interventions
Initial triage and identification of at-risk individuals or subpopulations
Creation of holding environment, ensuring that needs for food, shelter, and hygiene are met, and allowing for close observation and medication management of acutely agitated individuals
Brief support and psychoeducation, application/implementation of the principles of psychological first aid
Tertiary Interventions
Medication management
Cognitive-behavioral therapy
Population surveillance for further development of symptoms or disorders

The responsibility for preventive measures and the initial recognition and treatment of the psychological consequences of disaster cannot be limited to available psychiatrists. General physicians, psychologists, and other social scientists must use their diverse skills to care for the victims

Telegram: @medical_k

www.konkur.in

of disasters and wars. It may be necessary for well-trained allied professionals to make preliminary diagnoses and provide initial psychoeducation and consultation to medical and surgical colleagues and other first responders. PFA has been developed as a concept to organize evidence-based and informed interventions in the acute phase of trauma and disaster exposure. A manual for PFA was developed by the National Center for PTSD and the National Child Traumatic Stress Network for mental health professionals.

Mobile apps and online resources for mental health are increasingly used during disaster events. PFA Mobile is an app-based adaptation of the PFA manual for use in the field, and online training is also available. Other organizations, such as the Substance Abuse and Mental Health Services Administration, have developed apps and other resources that use principles of PFA to support a variety of responders and emergency workers, including school crisis teams, clergy, emergency medical personnel, and military rapid deployment teams. Online training in PFA for leaders and supervisors is also available from the National Association of County and City Healthcare Organizations. During the global COVID-19 pandemic, the Covid Coach app has provided helping resources and support for lay persons. The Heroes Health app offers regular self-health assessments and local resources to understand better the health and well-being of personnel to tailor interventions.

Table 30.6–3.
Core Actions of Psychological First Aid

Telegram: @medical_k

www.konkur.in

Action	Goal	Examples
Contact and engagement	Initiate or respond to contacts by survivors	"Hi. My name is _____. I'm just checking in to see how you are doing."
Safety and comfort	Create a physically and emotionally safe environment	Get survivor to a protected location Offer a blanket or water
Stabilization	Promote calming	Engage survivor in relaxation or focusing exercises Enlist the help of caregivers
Information gathering	Identify immediate needs	Ask about injuries and concerns. Ask about family or friends the survivor may be concerned about Ask about losses or other concerns
Practical assistance	Address immediate needs Develop an action plan (promote efficacy)	"It sounds like your most important concern right now is finding out where your sister may be. Let's think through some ways you might find out."
Connection with social supports	Facilitate connectedness with family, friends, community	Assist with phone contact with family Help identify other persons nearby that might offer support
Information on coping	Provide information about stress reactions and encourage adaptive coping	Explain intrusive reactions, avoidance, and hyperarousal as expectable reactions to trauma

Telegram: @medical_k

www.konkur.in

		Discuss health risk behaviors and healthy coping
Link with collaborative services	Connect survivors to needed services	Assist with referral to assistance organizations as appropriate

PFA is an evidence-informed intervention framework that operationalizes social support, psychoeducation, stress management, and cognitive restructuring across the domain of short-term and intermediate mental health response supported by empirical evidence. The goals of PFA are to establish and enhance individuals' actual and experienced safety; increase feelings of and ability to calm; foster and provide skills in self-efficacy; enhance social connectedness, and instill hope. These "essential elements" are associated with improved psychosocial function after disasters. Actions to facilitate these essential elements are listed in Table 30.6–3.

Therapeutic Interventions

Other interventions are needed for those with significant disease/illness or developing symptoms. Symptoms ranging from lethargy and depression to disorientation, dissociation, hallucinations, paranoia, and cognitive dysfunction may be observed in the immediate aftermath of a disaster. The diversity of response is complicated by the fact that symptoms may result purely as an emotional response because of a neurologic injury from a blast or other blunt trauma or, in the case of terrorist attack, from the neurotoxic effects associated with specific chemical or biologic agents (Tables 30.6–4 and 30.6–5). Rapidly identifying the underlying infectious, chemical, or physical insult to the brain directs the treatment strategy. It may be difficult to differentiate transient distress reactions from lasting illness in the acute setting. Acutely agitated patients may endanger themselves or other disaster workers and place exceptional demands on treatment staff that would otherwise be unavailable to deliver group-related interventions and education.

Pharmacologic interventions in the immediate aftermath of a disaster tend to be problem-focused and straightforward. The importance of keeping treatment as simple as possible under these confusing circumstances cannot be overemphasized. When a safe environment

Telegram: @medical_k

www.konkur.in

exists, brief supportive interventions or observation may alleviate the need for psychotropic medication. Sleep disruption will be a common complaint, and short-acting hypnotics may be used to restore standard sleep patterns. Antipsychotic and anxiolytic medications may be helpful to manage acute agitation from a range of causes. However, their metabolism by way of the hepatic cytochrome P450 system may alter levels of antimicrobial agents and acetylcholinesterase inhibitors used to treat biologic or chemical terrorist attack victims. The potential for drug–drug interactions bears on selecting antibiotics, chemical antidotes, and antipsychotic agents in specific cases. Persisting symptoms of depression, anxiety, and PTSD will respond to treatment with antidepressant medication, and treating persisting symptoms may enable survivors to engage in recovery activities more effectively.

Table 30.6–4.
Neuropsychiatric Syndromes or Symptoms in Selected Biologic Agents

Biological Agent	Syndrome or Symptom(s)	Comment
Anthrax	Meningitis	May be rapidly progressive
Brucellosis	Depression, irritability, headaches	Fatalities associated with central nervous system involvement
Q fever	Malaise, fatigue	In one-third of patients
	Encephalitis, hallucinations	In advanced cases
Botulinum toxin	Depression	Due to lengthy recovery
Viral encephalitides	Depression, cognitive impairment	Other mood changes are also possible
All biologic agents	Delirium	Acutely impaired attention and memory and perceptual disturbances

Telegram: @medical_k

www.konkur.in

Beyond pharmacologic intervention, several psychosocial interventions have been described as helping prevent PTSD or other neurobehavioral responses to disaster, often, however, without evidence-based support. Community meetings or informal debriefings in which survivors can share experiences and offer mutual support can be helpful and should be encouraged. This practice should not be confused with originally proposed Critical Incident Stress Debriefing, which was for all people regardless of symptoms or exposure and can aggravate or create symptoms in those with none or few symptoms.

Cognitive-behavioral psychotherapeutic approaches (CBT) can target anxiety, social withdrawal, depressive symptomatology, and hyperarousal. CBT may reduce the immediate symptoms of depression, anxiety, and PTSD and may diminish the development of long-term morbidity. Trauma-focused psychotherapies have some evidence in the acute aftermath of trauma, mainly the benefit of brief exposure and cognitive restructuring. Trauma-focused psychotherapies are indicated and effective for those with persisting symptoms of PTSD. Because medical resources may be quickly overwhelmed in a large-scale disaster or combat situation, appropriate training of nonphysicians in delivering these therapies may allow for more effective delivery of care.

Telegram: @medical_k

www.konkur.in

Table 30.6–5.
Neuropsychiatric Effects of Chemical Agents

Organophosphates (nerve agents such as sarin, soman, VX, and tabun)	Depression, sleep disturbance, and impaired cognition; poor judgment, attention, and short-term memory; poor concentration, confusion, drowsiness, delirium, irritability, insomnia with nightmares, excessive dreaming, and psychosis
Atropine (treatment for organophosphates)	Blurred vision, tachycardia, dry mouth, sweat suppression, urinary retention, cognitive impairment, psychosis, and delirium (disorientation, hallucinations, and delusions)
Cyanide	Anxiety, confusion, giddiness, and hyperventilation
Blistering agents, mustard gas, and phosgene	No direct acute effects; inactivation of charcoal may result in sensations of suffocation or anxiety; psychic distress over disfigurement
Mycotoxins (fungal toxins)	Psychosis and somatic complaints, involuntary movements, anxiety, and agitation

Telegram: @medical_k

www.konkur.in

Three weeks after a train derailment, a 42-year-old budget analyst presented to the mental health clinic. He noted that he was embarrassed to seek care, as he was previously a firefighter, but he felt that he needed “some reassurance that what I’m experiencing is normal.” He reported that, since the wreck, he had been feeling nervous and on edge. He experienced some difficulty focusing his attention at work, and he had occasional intrusive recollections of “the way the ground just shook; the tremendous ‘bang’ and then the screaming when the train rolled over.” He noted that he had spoken with five business colleagues on the train, and three acknowledged similar symptoms. However, they said that they were improving. He was more concerned about the frequency of tearful episodes, sometimes brought on by hearing the name of a severely injured friend, but, at other times, occurring “for no particular reason.” In addition, he noted that, when he evacuated the train, rescue workers gave him explicit directions about where to report, and, although he complied, he now felt extremely guilty about not returning to the train to assist in the rescue of others. He reported a modest decrease in appetite and denied weight loss but noted that he had stopped jogging during his lunch break. He had difficulty initiating sleep, so he had begun consuming a “glass or two” of wine before bed to help with this. He did not feel rested on awakening. He denied suicidal ideation or any psychotic symptoms. His sister took an antidepressant several years ago, but he did not desire medication. He feared that side effects could further diminish his ability to function at the workplace and could cause him to gain weight. Although this individual reported initially experiencing intrusions and altered arousal symptoms, these symptoms did not necessarily follow an expected improving trajectory in the weeks after the trauma, suggesting acute stress disorder. His family history of depression suggests that major depressive disorder may also be possible. Given the patient’s reticence to take medication, brief supportive and cognitive-behavioral therapeutic approaches are appropriate. In addition to allowing time for trust and rapport to develop, early response to simple interventions may suggest a more transient course and negate the need for medication.

SPECIAL TOPICS IN DISASTER PSYCHIATRY: RESPONDING TO NATURAL, HUMAN-MADE, AND WAR EVENTS

Military Mental Health Care in Peacetime

Military health care is part of disaster response around the globe for nonwar events and war. When not directly involved in combat operations, peacekeeping, or humanitarian relief, military psychiatric practice is, in many ways, like civilian practice, except for the fact that military psychiatrists go to work in military uniforms. The U.S. Department of Defense has tertiary care hospitals throughout the United States, Europe, and Asia. These institutions all have outpatient psychiatry or interdisciplinary behavioral health clinics or inpatient wards for severely mentally ill military personnel and family members. Some military psychiatrists receive their undergraduate medical and residency training at civilian institutions. However, the U.S. Congress in 1975 authorized the Uniformed Services University of the Health Sciences (USUHS) to provide medical education and produce physicians for military service. USUHS provides a 4-year medical degree program and several graduate degree programs in the basic and clinical sciences. The USUHS Center for the Study of Traumatic Stress conducts research and consults communities and federal and international agencies on matters surrounding individual and community responses to trauma, disaster, and war. Japan, Great Britain, and Russia are among nations with institutions that teach military-specific curricula to military medical care providers. As in other nations, these countries also call to national duty physicians not explicitly trained in military institutions during war or crisis.

The U.S. Department of Defense has residency programs in psychiatry at tertiary care Army, Air Force, and Navy Medical Centers within the United States. Congress mandates these institutions to provide military-unique curricula to ensure that the physician in training will provide care in combat or disaster environments. This type of training is not necessarily provided in civilian programs. Military training programs also introduce physicians to aspects of the military lifestyle (e.g., frequent moves and separations from family, living and working overseas, special occupational duties, and requirements for maintaining security over classified information) that affect military members and families, even when service

Telegram: @medical_k

www.konkur.in

members are not deployed. In addition, the USUHS offers the nation's only Disaster Psychiatry Fellowship in collaboration with the Center for the Study of Traumatic Stress.

The U.S. military has attempted to decrease the incidence and severity of combat and operationally induced psychiatric disorders through several mechanisms. Mental health teams are now routinely assigned to U.S. forces in combat and are deployed in operations other than war. Each branch of the U.S. military services has specialized rapid intervention teams to provide consultative assistance and acute treatment as necessary to units that have experienced traumatic events. These teams provide prompt needs assessments, educate leaders on likely behavioral responses to stressful events, and recommend leadership interventions to reduce negative stress responses. Embedded behavioral health teams have served within military units throughout the wars in Iraq and Afghanistan in the U.S. armed forces and many allied nations.

Military units frequently are involved in disaster and other humanitarian response missions. Military units can quickly provide services and supplies to affected areas with the ability to rapidly deploy resources and an existing command and control structure. The U.S. military has been called upon to respond to disasters ranging from the Great Japan Earthquake to establishing field hospitals in the United States during COVID-19. Combat and operational stress control (COSC) has been a central part of these missions. In preparation for deployment, COSC entails educating personnel on hazardous exposures they can expect to encounter, expectable psychological reactions to these exposures, and techniques of self-care and peer support to manage stress reactions. During a response, COSC involves monitoring exposures of personnel through a needs assessment or simply through personnel presence walking around and offering immediate emotional support. Following humanitarian or disaster response, COSC is focused on educating responders on typical recovery trajectories, facilitating healthy self-care and peer support, screening for more severe symptoms, and treating as appropriate. This model was highly successful in the military response to COVID-19 in New York City and led to the dissemination of COSC principles throughout health care systems in the area.

In addition, embedded mental health teams have been established to improve access to care for those who might not otherwise request assistance and destigmatization of those who seek mental health care.

Telegram: @medical_k

www.konkur.in

Military leadership has strongly supported the increased use of these units to establish immediate access to care that reduces distress and improves functioning. There are ongoing efforts to study the efficacy of such interventions in reducing the incidence of PTSD and somatic symptom syndromes that may be tied to psychological responses to combat. These teams have also provided consultation and intervention in military humanitarian relief efforts after hurricanes, floods, infectious disease outbreaks, and other natural disasters within the United States and abroad. In addition to direct patient care, military psychiatrists provide consultation to community leaders and civilian physicians not accustomed to responding to large-scale physical and emotional traumas. During the COVID-19 pandemic, at the request of city officials in hotspot outbreak locations, such as New York City, the military deployed embedded mental health teams in civilian health care facilities to train personnel and leaders in the principles of COSC.

Historically, different mission types, patterns of deployment, and medical support systems among the various branches of the U.S. military posed challenges to developing a unified tri-service approach to the management of operational stress. For instance, Armies typically deploy large units for extended periods and allocate large amounts of medical assets to support these units. This medical support includes specialty services. The Navy and Marine Corps deploy smaller units at sea and ashore. General medical officers and nonphysician providers furnish medical support, and specialty care is not routinely available in the operational theater. The Air Force has short- and long-range missions and, increasingly, deployment in place through remote drone warfare. However, the past decade has seen an increased emphasis on the use of fundamental principles of COSC that are predicated on the essential elements of PFA. The Department of Psychiatry at the Uniformed Services University provides a tri-service curriculum that educates uniformed medical students on these principles and provides support, including efforts to enhance standardization, to military psychiatry residency programs. While each uniformed service will likely continue to have different mission tasks resulting in exposure to some unique stressors, trauma responses to these events are similar and standardized interventions based on evidence-based principles will enhance operational sustainment and military readiness.

Telegram: @medical_k

www.konkur.in

In the United States, definitive treatment of psychiatric illness is often provided in the military's system of hospitals. Medical care is provided to active duty personnel and their families. Other mental health specialists, nurses, social workers, and psychologists augment this care. Military members who develop psychiatric disorders while on active duty are eligible for medical retirement disability pay and continued treatment through a system of Veterans Administration hospitals. Under present regulations, some individuals may be separated from service because of personality disorders that existed before service entry without disability payment or ongoing medical care from the military.

Other nations with recent wartime or military operational experience, such as Israel, Croatia, and Canada, have developed programs to evaluate and treat soldiers and civilians exposed to combat or other operational stressors. Their experiences are somewhat different from experiences in the United States because they rely much more heavily on reserve forces. These nations and many of our North Atlantic Treaty Organization (NATO) allies have a more inclusive social, medical infrastructure; therefore, treatment programs are less reliant on the military medical system. Nonetheless, coordinating civil and military medical treatment efforts (e.g., in response to the COVID-19 pandemic) across member nations and partners has become a priority of military medical planners. Other nations are increasingly confronted with operational stress management in peacekeeping and humanitarian missions. Asian nations that have recently experienced natural disasters and terrorist events are also studying approaches to evaluating and treating individuals exposed to trauma and are incorporating lessons learned into their pandemic response.

FUTURE CHALLENGES AND EVOLVING ISSUES

As political, social, scientific, and technologic factors evolve, societies will change their responses to the consequences of disasters and wars. The psychiatric practice associated with wars and disasters has changed with the evolution of the scientific understanding of illness. In the future, the resources to deal with the consequences of disaster or war and the relative importance assigned to dealing with the resultant injuries and disabilities are likely to be influenced by political and sociocultural values and advances in knowledge of disease processes, treatment paradigms,

Telegram: @medical_k

www.konkur.in

and technology. Disaster and military psychiatry must anticipate these changes to ensure that current trainees can deliver care in a changing environment.

Emerging Threats

The COVID-19 pandemic has raised international awareness of the disruption and calamity resulting from global infectious disease outbreaks, and increased focus on availability and access to protective equipment, medications for prevention and acute treatment, the likelihood of widespread morbidity, death, chaos, and distress, as well as the convergence of multiple disasters, including concomitant economic crisis, political upheaval, and widespread social unrest. Implementing necessary physical distancing measures (e.g., quarantine, isolation, the closing of schools and workplaces) required to control infection spread created significant obstacles to the establishment of a holding environment and the fostering of social connectedness critical to public health response in a disaster. Ongoing uncertainty and shifting public health requirements taxed societies worldwide and required health risk and crisis communication. The unprecedented surge in health care demand altered the delivery of health and the frequency with which people accessed it. The COVID-19 pandemic refocused awareness of society on the role of preparedness and the critical importance of all-hazards planning, which considers the full breadth of threats and mitigating strategies.

Advanced technology has implications for those responding to human-caused disasters, such as terrorist attacks involving chemical, biologic, radiologic, and nuclear agents (CBRN). In the United States, the terrorist attacks on the Pentagon and the World Trade Center and the fatal distribution of anthrax-tainted mail in the fall of 2001 precipitated an ongoing “war” on terrorism. These events intensified efforts to increase coordination among civilian, nonmilitary, governmental, and military agencies for response to future terrorist events within the United States and abroad, as the scope of terrorist activity has become more globalized and technologically advanced. Though post-9/11 concerns about escalating CBRN terrorist attacks went largely unrealized, the use of coordinated multisite attacks has become an increased terror threat. Recent such events worldwide have resulted in unprecedented levels of community fear and disruption. Clarifying the roles of military and civilian responders and integrating mental health and public health activities in

Telegram: @medical_k

www.konkur.in

terms of triage, treatment, consultation, and education in any joint responses to crisis are challenges for military and disaster psychiatrists.

New technologies in combat continue to require modification to the means of sorting and treating persons with medical and psychiatric injuries for those exposed to war. Militaries in technologically advanced nations are increasingly smaller, move more rapidly across the battlefield, use advanced sensors, and direct intense fire across a considerable distance. These capabilities, coupled with the use of weapons of mass destruction, will likely make the battlefield more chaotic and inhospitable to human life. The increasing use of uncrewed aerial vehicles in combat operations and disaster reconnaissance has reduced exposure to physical injury but, paradoxically, created a new avenue for psychological and emotional distress as those who remotely operate this technology have a close-up and personal experience of human suffering and death, possibly at their own hands. Individuals who gather intelligence information from unmanned aircraft engaged in combat operations are effectively "deployed in place," creating several potential challenges that result from being persistently exposed to the stimulus of war without the geographic or psychological distance afforded to traditional combat units. For instance, the disruption to unit cohesion and mission focus, coupled with a need to balance and manage personal life stressors by night while participating in warfare during the day, has created unique personnel sustainment challenges. For special operators working within small, remote units, emergency care and evacuation of those with disease and injury may become increasingly difficult. The inability to maintain contact with rapidly moving units may preclude returning individuals to their original units. Future military casualties may increasingly rely on unit buddies, medics, and front-line leaders rather than specialized medical units or specialists at hospitals in the rear. Underdeveloped nations may have limited access to advanced technologies, so more traditional ways of organizing medical and psychiatric practice may remain relevant in certain circumstances.

Additional changes in how war is waged have altered risk and care delivery. The evolution of highly mobile units on widely dispersed battlefields will decrease the opportunity for exchanging rested troops from the rear area for those exhausted by front-line combat. Provision of brief respite for exhausted troops—a hallmark of battle fatigue management—may become impossible because each individual performs

Telegram: @medical_k

www.konkur.in

a critical specialized task. Small medical units operating within the combat area are likely to be eliminated from this technology-intensive battlefield. Although treatment may, by necessity, move to the battlefront, medical specialists at the rear may render triage decisions and diagnoses using telemedicine communication technology, the use, and familiarity of which has rapidly accelerated due to the shift to telepsychiatry during the COVID-19 pandemic. Experience has shown that front-line mental health providers take a pragmatic view of acute psychiatric symptoms and tend not to make hasty formal diagnoses on overstressed troops. Rear-echelon providers, by contrast, tend to assign formal psychiatric labels that may be inaccurate and that may stigmatize troops without contributing to treatment. Rear-echelon mental health specialists in future battles must address the challenge of providing practical therapeutic advice from afar while avoiding unnecessary diagnostic stigmatization.

Cyber terrorism represents a rapidly increasing global threat. Cyber-attacks have become increasingly complex and malicious in recent years, with governments and large corporations becoming frequent targets of hacking with the intent to extort financial payments. For instance, the corporation that manages petroleum supply for the eastern half of the United States was attacked in 2021, disrupting gas access for individuals and corporations that precipitated fear-based excess buying and widespread shortages. This event added to the ongoing uncertainty and distress of the COVID-19 pandemic, enhancing a sense of fear and concern within the communities most affected. Infiltration of electrical grids, water supplies, and fuel reserves and the systems that deliver these to citizens represent potential mechanisms of inflicting catastrophic harm and inducing a sense of terror within a society, with developed nations potentially most vulnerable. Beyond financial gain, the use of cyber-attacks by those intended to disrupt and harm represents real and present threats requiring coordination and collaboration by intelligence, military, homeland security, and private sectors to protect national resources upon which societies rely.

Cultural Issues

Social scientists note that trauma responses may be considered normal or pathologic, depending on the cultural context. Many have expressed fears that mental health practitioners, motivated by profit, will try to convince individuals experiencing normal uncomfortable responses that they need

Telegram: @medical_k

www.konkur.in

treatment. Because of the persistent stigma associated with mental health care, a future challenge to military efforts at aiding other nations in crisis may be overcoming the belief that accepting assistance signals weakness.

Most individuals exposed to traumatic events deserve to be reassured that they will recover with a return to work, community, and family. However, some individuals (and, perhaps, some cultures) will experience more significant psychopathologic responses and more prolonged symptoms after trauma. The nature of the behaviors and symptoms associated with trauma response across cultures is uncertain. Psychiatrists providing care during combat and humanitarian environments in a cross-cultural environment must do so with an awareness of the unique aspects of how culture influences the experience of mental illness. The extent to which social supports, biologic–genetic predisposition, concurrent illnesses, and other political and economic parameters contribute to variability across cultures is unknown. Although it appears clear that the severity of the trauma is important, reliable severity measures remain to be determined. Trauma may, under some conditions, create the opportunity for personal growth as well, and further understanding of this potential must also be exploited to reduce morbidity.

Ethical Challenges

Providing care in the mass casualty situation raises ethical questions about the equitable distribution of resources and the application of moral values. The hyper-suggestibility of individuals recently exposed to trauma has, at times, led to the exercise of political influence and the manipulation of loyalties. Governments in trouble have withheld treatment to minority racial or political groups—clearly, an ethical breach. Because governmental terrorism is a common form of terrorism, care providers and leaders must be sensitive to the possibility that disasters can afford unscrupulous leaders an opportunity to manipulate citizens for their purposes. As seen in previous public health emergencies, the COVID-19 pandemic highlighted these concerns as political strife and elections worldwide focused primarily on varying messages and agendas about the appropriate pandemic and societal responses, often leveraging the frustrations of highly distressed communities for political purposes.

Military and combat operations raise challenging ethical dilemmas. To facilitate command assessment of troop health status, militaries have

Telegram: @medical_k

www.konkur.in

denied members' confidentiality in medical communication. Mental health care providers must strike a balance between a promise of privacy that encourages persons to seek care and responsible reporting to higher command regarding situations that pose a danger to larger groups. Thus, dual allegiance to individuals and the larger community presents an ethical challenge that the military care provider must negotiate. Persons in extreme circumstances may behave in ways that they later view as shameful. This self-view may contribute to symptom development and, at the same time, discourage care-seeking.

An innate aspect of war involves the collection of military intelligence to enhance the effectiveness of combat operations. Prisoners of war or other detainees are often a source of intelligence information. Commanders may seek the involvement of mental health care personnel in managing detainees. Providers will be asked to deliver mental health care to alleviate detainee suffering. They may also be sought out to guide behavioral interventions to facilitate intelligence information gathering. Physicians must be aware of ethical prohibitions against participating in cruel, inhumane, or coercive practices with prisoners of war or other detainees and of the challenges that emerge when their involvement is intended for purposes other than the direct provision of care. In addition to personal ethical dilemmas that arise, medical and allied professional organizations have provided guidance regarding the appropriateness of these roles.

Disaster triage is frequently carried out in large open areas that allow everyone present to hear what patients say to caregivers. Given the social stigma assigned to the manifestations of psychiatric illness, it is easy to understand patients' reluctance to communicate and doctors' reluctance to inquire. Research on disaster- and war-exposed populations also raises significant ethical issues surrounding balancing requirements to develop knowledge and to help others with the potential exploitation of those in need. Perhaps re-educating the population can reduce ethical and therapeutic problems associated with stigma. However, altering deeply ingrained cultural expectations is just as challenging as providing privacy in chaotic triage environments.

CONCLUSION

Telegram: @medical_k

www.konkur.in

Natural and human-caused disasters, including terrorism and war, disrupt societal function. Wars and acts of terrorism, with their attendant large-scale death, injury, and destruction, affect populations much like massive natural disasters. However, these events' intentional, human-caused nature increases their mental health consequences. Disasters and war leave in their wake populations experiencing psychological disturbances that have been described by social scientists, civil leaders, physicians, and other care providers throughout the ages.

The consequences of exposure to disaster and war may take the form of distress reactions, health risk behaviors, or psychological disorders, such as PTSD, or may manifest as various (and sometimes more subtle) forms of behavioral change, anxiety, or depression. Symptoms may present at different times during and after traumatic exposure. Many factors complicate the evaluation and treatment of neuropsychological syndromes in the aftermath of war or disaster. Resources are overwhelmed, life-threatening illnesses require immediate treatment, and psychological casualties are often reluctant to seek assistance.

Progress has been made in identifying the nature of trauma-related psychological responses. Predisposing, exacerbating, and mitigating factors have been identified, as have traumatic, stress-related, neuronal, and intercellular events. The value of multidisciplinary preparation and training for disaster management and the need for outreach programs have also been demonstrated. The U.S. experience in the aftermath of September 11, 2001, the ongoing war on terrorism, and increased frequency of large-scale natural disasters, including the recent global COVID-19 pandemic, have clarified the need for greater integration among military, government, and civilian organizations charged with the responsibility of mental health response to these events. However, further study must clarify how psychotropic medications and various forms of psychosocial support and psychotherapy in the treatment of war- and disaster-related morbidity can be delivered by cooperating agencies in times of national need. With technologic advances and global economic shifts, the nature of war and other human-caused disasters has changed. Disaster and military mental health care delivery must anticipate future changes to develop improved prevention, evaluation, and care methods for individuals and groups devastated by war or disaster.

30.7 Psychiatry and Spirituality

SHWETA KAPOOR, M.D., PH.D.

Historians have traced the slow but progressive decline of religion since the 16th century, particularly in the West, when the Protestant Reformation led to the fragmentation of Christianity. Among the key events contributing to secularization are the scientific revolution started by Copernicus, the rise of mathematics and empirical investigation, the Age of Enlightenment in which intellectuals opposed religion as an institution, the French Revolution that expunged religious influence from public life, and the 19th-century theories of thought that dispensed with God by stressing the importance of economics (Karl Marx), biologic evolution (Charles Darwin), and sexual urges (Sigmund Freud). Secularization in the West is epitomized by increasingly empty European churches: 72% of the population of Britain and Germany identify as Christians, but less than 2% attend church regularly. Most indicators of traditional religiosity are either stable or declining; for example, there is lessening confidence in religious leaders and a decline in those choosing religious vocations. In the current times, the transforming sociocultural environment and reformative norms have facilitated engagement in life without necessitating the integration of religion, such as attending school, marrying, making social connections, and entertainment.

Spirituality has emerged as an important construct parallel to the waning prominence of religion. Spirituality embraces a diverse set of definitions, theories, and explanations. Earlier on, it was described as “a fuzzy concept that embraces obscurity with passion.” More recently, with the accelerating empirical interest in this construct, more distinct

Telegram: @medical_k

www.konkur.in

descriptions have emerged. Social scientists have variously described it as a “sacred connection with God” and “a subjective experience of the sacred.” The word itself has biblical origins and derives from the Latin translation of the Hebrew word variously meaning breeze, wind, breath, and by extension, the breath of life. Traditionally, it has been linked with religion, but in polls, many people, particularly those born between 1980 and 2000 (Millennials or Generation Y), self-identified as “spiritual but not religious.” They seem to be put off by religious dogmatism and intolerance. While they still may profess a belief in God, they are more likely to encounter God while walking in the woods at sunset rather than at a place of worship. Consistent with this trend, those born after 2000, commonly referred to as Generation Z, are the least likely to profess a religious identity. In fact, they are two times more likely to identify as atheists than the general United States adult population. To many of them, the problems and suffering they see in the world appear to be a significant source of ambivalence in believing in a just and loving God and finding value in more traditional forms of religion.

George Vaillant describes spirituality as an amalgam of positive emotions—compassion, forgiveness, love, hope, joy, faith/trust, awe, and gratitude. The spirituality that arises from these emotions “binds humans to one another to experience ‘God’ as we may understand Him/Her/Them.” The positive emotions have an evolutionary basis and architecture. In this regard, our limbic system plays an important role and underlies spirituality. The human neocortex has evolved over 200 million years to generate science, culture, ideas, behaviors, and religion and has brought the limbic positive emotions into consciousness. Cultural evolution, working over a shorter time frame, was facilitated by the development of language that allowed for mastery of past and future tenses. A transformative cultural evolution occurred during the Axial Age, variously described as ranging from about 800 BCE to 100 CE, when in many areas of the world major religions were formed along with the development of moral conscience. As rationalism in political and ethical behavior became increasingly important, the concepts of self-consciousness and a transcendent element in life gained prominence. The third evolution in the development of spirituality is that which occurs when the positive emotions are learned and grow during the maturation process from infancy to old age. Love, for example, is Vaillant’s shortest definition of spirituality and “lives in the anterior cingulate gyrus.” It is

Telegram: @medical_k

www.konkur.in

catalyzed by genes and by neurochemistry; for example, oxytocin in limbic dopaminergic centers is linked with lasting human attachment. It is learned both through cultural examples—poetry, songs, stories—and through identification with persons who exemplify it by their behaviors.

Religiosity and spirituality are often used interchangeably. However, now more than ever, scholars in this area are delineating the two constructs, and increasingly these two are very different from each other. Religion arises solely through cultural evolution with its sacred texts and dogmas, where it has played an uneven role. It has produced intolerance and rigid beliefs and behaviors while being an opening through which the positive emotions are brought to conscious attention and reflection. Religion often involves a rigid set of beliefs, it binds believers to their own community, and it is imposed from without. On the other hand, all the positive emotions that relate to spirituality are grounded in a threefold evolutionary heritage. They allow for transcendent moments that appear to represent "religion without the side effects." Spirituality primarily involves emotions and trust, accepts the experiences of others as valuable, is democratic, and is imposed from within. The ultimate promise of many of the world's religions is a happy eternal afterlife in some sort of heaven, but the promise of spirituality is living an ethical, moral, and compassionate life guided by the positive emotions and sometimes punctuated by transcendent moments.

A biologic basis for religious experiences has long been evident in cases of persons with temporal lobe epilepsy and religious delusions and obsessions in the context of Schizophrenia and Obsessive-Compulsive Disorder. Over the past few decades, there has been mounting evidence that spirituality positively influences a person's health and well-being. Neurologic studies have generally revealed a frontal parietal circuit in which increased frontal-lobe activity is associated with advanced meditative/prayer states and with an enhanced propensity for the representation of religious concepts. A more robust finding is that decreased activity in the right parietal lobe (RPL) is associated with a decreased focus on the self and is the primary neuropsychological foundation for spiritual transcendence. More recently, studies have suggested a possible common brain circuit for both spirituality and religiosity in the periaqueductal gray. The latter is located in the brainstem and is related to pain and altruism.

Telegram: @medical_k

www.konkur.in

Brick Johnstone has been a pioneer in developing a functional geographic model based in part on the studies of persons with traumatic brain injury, where it is possible to relate specific cerebral structures and neurophysiologic abilities to specific spiritual traits and abilities. After administering comprehensive neuropsychologic evaluations and various measures of spirituality and religion, he determined that decreased activation of the RPL, due to brain injury, surgery, transcranial magnetic stimulation, or meditation/prayer practices, provides the foundation for transcendent experiences. The decreased activation results in the experience of selflessness and a diminished personal reference to space, time, or relationships. This selflessness "allows individuals to focus on and emotionally connect with things beyond the self, i.e., the very definition of self-transcendence." The reason that this selflessness is experienced as spiritual transcendence rather than typical symptoms of RPL dysfunction such as anosognosia or left-sided neglect "appears to be partially related to the context in which the selflessness is experienced, e.g., in an artistic/musical context, personal relationships, religious/spiritual setting, etc."

Johnstone notes that neurologically based spiritual transcendence can be perceived as a numinous connection with God or a high power or as a mystical connection with the universe based on the environmental context and a person's religious and cultural upbringing, for example, numinous if reared in a monotheistic/polytheistic culture or mystical if reared in Buddhist culture. Differences in neurologic processing may reflect different cultural values, such as the Western independent self in contrast with the East Asian collective self. With its connection to the limbic system, the left temporal lobe may serve as a brain center for the universal experience of common religious archetypes (God, demonic figures, prophets, etc.) that can be a basis for differing theologic, ethical, and moral constructs. Increased frontal lobe activity is associated with increased frequency of prayer attendance, but its association with transcendence is unclear. It may have a role in focusing attention on spiritual thoughts, beliefs, and practices.

In addition to rational understandings of spirituality, there is also an esoteric tradition exemplified by the Greek Eleusinian and Northern European Odinic Mysteries. New Age spirituality emerged in the 1950s. It emphasizes irrational personal experiences and notions such as spirituality-laden force fields, extraterrestrial and earthly vibrations, and

Telegram: @medical_k

www.konkur.in

topsy–turvy interpretations of quantum mechanics. It is amazing that so many people worldwide hold such irrational, albeit usually harmless, beliefs.

FORMS AND METHODS OF ACHIEVING SPIRITUALITY

Because of the exceedingly broad definitions that people apply to the notion of spirituality, there are myriad ways people employ to achieve a spiritual moment and lead a spiritual life. Being a vegetarian, for example, may be considered by some people to be spiritual because it aims at sparing animals from being slaughtered, thus preserving the sanctity of living creatures. This section describes some of the many ways that people induce or enhance spirituality. It is extremely broad in scope, though, and to capture it all is a challenge. For instance, some individuals utilize altered states of consciousness while others do not. Some individuals rely on reducing sensory stimuli, whereas others rely on increasing stimuli. Some persons find spirituality deep within themselves, whereas others find it in the world around them.

Consciousness

Consciousness is difficult to define or explain except to state that it is the context in which one experiences the physical world and their mental world, including a sense of self. How it emerges is unknown. In addition to awareness, it has an unconscious component—dream states and the memories and feelings of past experiences that are not readily available to conscious attention. It is scientifically possible to parse the various contents of consciousness but attempts to explain any findings and to understand why they are experienced lead people in circles because any explanations and understandings arise from the totality of consciousness itself.

Consciousness can be altered and the sense of self changed, but the concept of self is multilayered. I can cut myself, for example, but I cannot cut my Self. Be that as it may, one perspective on spirituality is that it is a meaningfully interpreted alteration of consciousness, especially the sense of self.

People spend much of their lives in an altered state of conscious sleep, during which they have dreams. For almost a millennium, dreams have

Telegram: @medical_k

www.konkur.in

been associated with spirituality. In ancient Greece, asclepeions were healing temples sacred to the god Asclepius. Sick pilgrims slept overnight in the temple and reported their dreams to a priest, who then prescribed a cure. If barren women dreamed of snakes, they believed this to portend pregnancy. Throughout the Bible, God interacts with people through dreams. Many religious visions may have actually been remembered dreams.

When people are awake, altered states of consciousness are brief (from a moment to an hour, except in cases of pathologic dissociation, drug intoxications, or sicknesses such as coma or delirium), typically pleasurable, unusual experiences that cause a break with their normal sense of reality. This detachment is a form of dissociation and a gateway to the world of spirituality. Depending on the social context, the altered state of consciousness may be interpreted as having either a religious or a naturalistic meaning. The psychologist Abraham Maslow, for example, depicted a hierarchical pyramid ranging from basic physiologic needs upward to safety, love, esteem, and self-actualization needs. At the top of the triangle is the “peak experience,” which consists of a sudden moment of well-being, wonder, awe, and at times an awareness of a higher truth and the unity of everything in the world. Triggers for these peak experiences can come from exposure to beautiful scenes of nature or to great art and music, intense feelings of love, and a confrontation with severe illness or death. Maslow believed these moments were therapeutic because they increased empathy, creativity, self-determination, and personal growth. He claimed that everyone can experience peak moments and that they should be cultivated.

FIGURE 30.7–1. Martin Luther (1483–1547) led the Protestant Reformation and spurred the movement to translate the Bible into local languages. He believed that salvation could not be achieved by good deeds but rather by

Telegram: @medical_k

www.konkur.in

faith alone. (Frederick Kemmelmeyer. Corcoran Collection [Museum Purchase], National Gallery of Art.)

It is not uncommon for people to experience inexplicable fleeting insights that are less than peak moments. The latter may fall short of an actual altered state of consciousness but still serve as a spiritual dimension and may incorporate into a person's spirituality. Martin Luther (Fig. 30.7–1), for example, wrote that when he heard a fellow monk recite the words from the Apostle's Creed, "I believe in the forgiveness of sins," he saw Holy Scripture in an entirely new light, felt that he was born anew, and had found the door of paradise thrown wide open. A single word or phrase, a line in a poem or a song, particular sounds from a symphony or an opera, even the play of sunlight on rocks or water can strike a chord of a seemingly important moment.

Meditation

Meditation is an activity usually practiced in a tranquil setting that attempts to self-regulate the mind by freeing it of wandering thoughts and emotions, especially negative ones, by promoting psychophysiologic relaxation. Routine practice is shown to help with emotion regulation and promote peace within oneself. There are many types of meditation practices that are best understood by relating them to the specific sociocultural traditions from which they arose. Generally, Western meditation practices focus on increasing a deeper love for God and a sustained focus on religious symbols and the revelations found in sacred texts. Spirituality is achieved when the mind is filled with thoughts of God and devotional images. Transcendent states may be welcomed but play a minor role. Eastern meditation practices, especially Buddhist ones, focus on the primacy of the mind without reference to religion or faith. Spiritualism is achieved when the foundations of the self are transcended by comprehending that the self is an illusion and by eliminating all thoughts. In both traditions, when meditation practices are mastered—no easy task—they can cause decreased activation of the RPL that may result in transcendent moments.

As the world is in the throes of a deadly pandemic, COVID-19, meditation may provide a way to alleviate a part of the intense levels of stress being experienced by the population in general but particularly frontline health care workers. Meditation has the potential to provide some form of relief. Meditation is known to provide multifold benefits such as

Telegram: @medical_k

www.konkur.in

decreased stress, anxiety, and mood disturbances. Neurologic investigations have indicated that regular meditation practice brings about brain changes and provides a window to the mechanism of neuroplasticity. It can be tailored by the patients to maximize positive impacts, and in the midst of the pandemic with all its uncertainties, meditation is ideal to introduce to patients. It also provides access to a more indigent population as it is an inexpensive method of addressing the myriad of stressors.

Mysticism

The quintessential example of pure spirituality is the intense altered state of consciousness known as a mystic experience, which has traditionally been described within a religious context. There are several characteristics of these experiences. Individuals who have these experiences claim that they are so uniquely personal that their quality and worth cannot be fully communicated to others. They are a totally absorbing combination of feelings and revelatory insights felt to be of such enormous significance that they transcend logic and intellectual comprehension. During the experience, mystics lose their sense of will and feel totally absorbed by the awe of the unity of the universe and their immersion in the infinite ocean of God or of nature or of nothingness. They feel an elation and joyfulness unlike any other experience. The ultimate phase of the intense mystic experiences, at least in the Christian tradition but probably in others as well, is often preceded by what St. John of the Cross called “the dark night of the soul.” It is a period of helplessness that may be brief or last for decades before the Self disintegrates, surrenders itself to the divine will, and eventually merges in rapture with the only true reality God. As normal consciousness returns, mystics who have had this experience return to normal life but have been transformed into intercessors between God and humankind. Although today such claims are met with skepticism, it was not uncommon in the past for mystics to claim ecstatic raptures in which they dueled with devils and interacted with Jesus and the angels. One of the best-known mystics is St. Teresa of Avila (1515–1582). In one of her most famous raptures, she described an angel who pierced her heart into her entrails with a long dart with a fiery gold tip. As he withdrew it, she burned with a great love of God: “So great was the pain that it made me give those moans; and so utter the sweetness that this sharpest of pains gave me, that there was no

Telegram: @medical_k

www.konkur.in

wanting to stop, nor is there any contenting of the soul with less than God." This orgasmic rapture is immortalized in a statue in the Roman Church of Santa Maria della Vittoria by Gian Lorenzo Bernini.

Dhyana. *Dhyana* is a form of concentrated meditation taught by Buddha and Hinduism. It is a practice of controlling your mind to achieve an altered state of consciousness during which all thinking is abolished and truth is realized. Some practitioners of *dhyana* own only one appropriate garment, eat simple foods in small quantities, live in a quiet, humble abode, and are disentangled from worldly affairs. They must censor the desires that arise from the five senses, depriving themselves of gratifications and their ensuing cravings. They must clear their minds of thoughts that may result in greed, anger, laziness, sleepiness, recklessness, remorse, and doubt. They must sit quietly in a certain position, cross-legged with the spine erect, and breathe silently for 1 to 6 hours. Their minds must be tranquil and in harmony with their bodies and their breathing, and they should be totally aware of the emptiness and deceptive nature of the world with all its fraud and suffering. They may have visions of swollen, dead bodies with pus oozing out and maggots fattening on them so as to lose all pride and confidence in the ego-self and in the selfhood of others and thus develop a dissolution of all attachments, as well as compassion for all sentient beings. They then realize that neither the phenomena of the world nor the ego-self are real. As they focus on the merits and purity of all the Buddhas, they experience a pervasive sense of bliss and safety. They are desireless and develop insight into both the emptiness of all phenomena and the potentiality within their emptiness, an insight that allows them to follow a "middle way" to attain supreme, perfect wisdom and Nirvana, which ends the cycle of reincarnation.

Samadhi. In Hinduism, *Samadhi* is a process of meditation that also leads to awareness of one's existence without the distractions of normal consciousness. It often involves an initial trance state that evokes a joyous sense of well-being and then, with the help of spiritual masters known as gurus or yogis, grows into detachment from one's body and eventually from one's ego. The meditator may attain the deepest moment of self-actualization during which the heart supposedly stops beating, breathing ceases, and there is dissolution into the "divine ocean of love" and a realization of the unity of the universe.

Telegram: @medical_k

www.konkur.in

Zen. The core practice of Zen Buddhism is *zazen,* the Japanese word for seated meditation in which a spiritual master instructs his students, some of whom will go on to become masters themselves, thus establishing a lineage of authority. Zen meditation uses *koans,* paradoxical or seemingly meaningless dialogues or questions, to test students' progress. "What is the sound of one hand clapping?" is an example of a *koan* and is akin to the Christian theologic question, "How many angels can dance on the head of a pin?" The goal of *zazen* is an epiphany (*satori* in Japanese) or lasting enlightenment about the true nature of creation.

Meditation in the Christian tradition is primarily an intellectual, sustained focus on spiritual themes such as Christ's suffering on the Holy Cross and his resurrection. Meditation on verses from the Bible is a common practice and derives from the book of Joshua 1:8, which states, "Do not let this Book of the Law depart from your mouth; meditate on it day and night, so that you may be careful to do everything written in it, then you will be prosperous and successful." Adoration of the Eucharist, which demands focused concentration, sometimes for hours at a time, is a particularly Catholic practice.

Transcendental Meditation. Transcendental meditation, derived from Hindu meditative practices again, is the most popular form of New Age meditation. It was trademarked by its founder, Maharishi Mahesh Yogi, in 1958. Although it is "officially" nonreligious, its goals are to attain "God Consciousness" and "Unity Consciousness," which are described as pure states of "being" in which a person sees the Self as integrated into all creation. This form of meditation uses physical exercises with softly spoken suggestions that result in a mild trance facilitated by a group setting with teachers. Repetitive suggestions of what is and what will happen lead students to believe what they are told. Maharishi refers to Transcendental Meditation as a pathway to God. Some clergy see spiritual value in it, whereas some critics see it as bogus, as in the false claim that people actually levitate during Transcendental Meditation, whereas all that happens is that meditators sit cross-legged on rubber mats and hop-forward on their derrieres while being told and believing that they are levitating.

Mindfulness Meditation. The concept of mindfulness meditation and its practices derives from a Buddhist tradition that focuses on the true

Telegram: @medical_k

www.konkur.in

nature of reality. In 1979, Jon Kabat–Zinn developed a secular Mindfulness-Based Stress Reduction (MBSR) program for the treatment of chronically ill patients. It is now also used to promote better mental and physical health for persons in the community and in schools, businesses, government agencies, prisons, and veterans' centers. The book *Waking Up: A Guide to Spirituality Without Religion* by Sam Harris is a thoughtful presentation of mindfulness.

A simplistic view is that it is the nonjudgmental, undistracted acceptance of all person's thoughts, emotions, and sensations in the present moment. For Harris, a person's experience "is always now" and what is subjectively real in every moment. In advanced mindfulness meditation, the uncluttered mind aims not at being lost in thought or thinking more clearly about experiences but rather at experiencing consciousness itself more clearly. Thinking is indispensable to life, but a person's identification with thoughts and failure to recognize thoughts as experiences in consciousness is a primary source of human suffering and of the illusion that a separate sense of self lives inside one's head. The self is an illusion, even though people feel that it exists as their body and brain. Mindfulness breaks the spell of thought and of an illusory self. It allows a person to know what pure consciousness is between one thought and the arising of the next one and reveals that consciousness is intrinsically selfless. "The conventional self is a transitory appearance, and it vanishes when it is looked for." Enlightenment, the direct experience of pure consciousness, reveals a void filled with everything and is the basis of a spiritual life. Selflessness gives rise to spiritual/mystical experiences and gives one's life a moral dimension. Despite Harris's belief that it is conducive both to physical and mental well-being, specific health claims have probably been exaggerated.

Prayer

For most of humankind, prayer is a primary source of entry into the world of spirituality. Prayer is a method of communicating with what is believed to be a supreme spiritual being, other spiritual beings (angels, saints, the Virgin Mary, totemic animals, etc.), or ancestors. The communication may be verbal or silent, private or public; sung, danced, or acted out behaviorally; spontaneous or planned as part of a religious service, spinning prayer wheels, reciting the rosary, praying at certain times of the day, assuming a particular physical position, or facing a specific direction.

Telegram: @medical_k

www.konkur.in

Prayer may be used to worship or to placate spiritual beings; to confess sins; to petition for help in a variety of cases such as illness or poverty; to seek guidance, justice, or mercy; to enhance spiritual growth; to curse enemies; and to exorcise demons (Fig. 30.7–2).

FIGURE 30.7–2. The monastery of Grigoriou on Mount Athos, Greece, the major center of institutions devoted to Christian Greek orthodox prayer. (Courtesy of Scott Cairns.)

People who pray assume that their prayers are received by an appreciative spiritual being who may or may not acknowledge or act on them. Prayer, as defined traditionally, posits a spiritual universe that can become operational in the phenomenal world—that is, prayer activates a spiritual energy that becomes manifest in everyday reality. Belief in a deity who has a personal interest in the life of all persons heightens the intensity of the prayer experience, but the experience may also be salient for those who believe in an impersonal deity that is not a being but rather is *being* itself, the god above god, the force of ultimate reality from which grace flows and on whom everything is dependent (Fig. 30.7–3).

Spirit Possession

Belief that a supernatural entity may enter into and even control a person's body and mind is an ancient and still-current spiritual belief found

Telegram: @medical_k

www.konkur.in

in most cultures. It is a belief that underlies such comments as “What’s gotten into you?” or “What possessed you to do that?” and serves as the original prototype for Axis I mental disorders that people may have but from which they may be dispossessed with treatment. The possessing spirits may be malevolent or benevolent, and the possessed person may be perceived to be disturbed and sick or to be a healer or a prophet. A worldview that allows for spirit possession can be understood fully only on its own terms and not scientifically. Within a given culture, spirit possession may be quite logical, and the pantheon of consensually validated spirits is unlike a projected paranoid pseudocommunity.

In Egypt, Sudan, Ethiopia, and the Arabian peninsula, *zar* spirits, somewhat akin to *jinn,* are thought to possess women and cause headaches, anxiety, nightmares, and similar symptoms. The diagnosis of *zar* possession is made during a ceremony. A possessed woman will twitch and dance when a song that becomes special to her is played by musicians. She then goes into a trance, and her possessing *zar* will demand gifts such as jewelry or clothing as an appeasement price for it to depart. The woman’s husband and family give her the gifts, which she can keep for a while before returning them as her symptoms disappear. Thus, the *zar* interaction results in the woman’s gaining the attention of her husband and asserting her position as a wife whose wishes should be respected. Many communities have weekly *zar* ceremonies during which women dance when their special song is played.

FIGURE 30.7–3. A Lao Hmong shaman who is a specialist in curing opium addiction prays as he ties a group of addicts to a sacrificial pig that will travel as a messenger to the opium divinities with "spirit money." The therapeutic ritual is meant to free the addicts' souls from dependence on opium. (Courtesy of Wolfgang Jilek.)

The utility of spirit possession is demonstrated in many shamanic rituals. A shaman is a generic term for a person who follows a divine call to healing, has received instructions directly from spiritual contacts, and may be a medium who communicates those spiritual instructions. Different types of shamans can be found in almost all cultural groups, such as Haitian *hungans,* West Indians *obeah* men, Puerto Rican spiritists, and Christian faith healers. Psychosocial profiles of shamans show that some are imposters, some are mentally disturbed, and some are mentally healthy, mature persons with a special cognitive style. The last may be considered true shamans who possess an ability to deal with and organize unconscious needs and primary process thinking. Often, through the mechanism of trance and spirit possession, the shaman acts as an agent of a powerful spirit and is thus able to perform psychological cures that may be temporary or permanent; for example, the spirit may declare that a patient's lost soul has been retrieved, as in cases of *susto* (spirit loss) in Hispanic cultures (Fig. 30.7–4).

Telegram: @medical_k

www.konkur.in

Shamanic rituals are usually public affairs, and the persons in attendance include not only identified patients or troubled persons but also family, friends, community members, and cult devotees. This openness helps dissipate the stigma of illness, clearly expresses societal approval for attempts at remediation, and demonstrates recognition of the connection between the private health of individuals and the public health of society. The healing experience often involves altered states of consciousness in both the shaman and the patient. Persons who enter a trance state as part of a healing ritual are relieved from personal responsibility for what they say or do because it is the possessing spirit who is "really" talking or acting. Such a mechanism allows for the expression of thoughts or emotions that otherwise might remain suppressed or repressed. It can bring out into the open any interpersonal and social conflicts that are troubling individuals, families, or the entire social group. Such conflicts have a better chance of resolution when they are brought out in the context of a healing ritual rather than in other forms or private confrontations.

FIGURE 30.7–4. Horse possession dance (*Kuda lumping*) in Java, a ceremony performed for spiritual and health benefits. Participants are possessed by the spirits of horses of historical heroes. In trance states, they act like horses and dance-jump to exhaustion. (Courtesy of Wolfgang Jilek.)

www.konkur.in

In Puerto Rican *espiritismo,* there are several procedures for removing pathologic spiritual influences. In *despojo* (exorcism), the mediums may fumigate patients with cigar smoke and stroke their necks. In addition to attracting benign spirits to the patients, the mediums may also attempt to draw off the evil spirits into themselves. *Trabajando la causa* (working the cause) is a technique used when special pathogenic spirits have been identified; it is the treatment of choice for sorcery. Possessed mediums interrogate the patients' spirits and try to convince them to depart. *Dando la luz el spirito* (giving light to the spirit) is a technique in which a patient follows a set of rituals to remove a spirit's harmful influences, such as purchasing flowers or candles, performing specific therapeutic tasks, and attending meetings at the medium's *centro. Desarollo* (spiritual development), which is indicated for persons with dissociative symptoms, is a process by which patients are taught to display their symptoms at culturally and ritually appropriate times and places.

Many religions allow for possession by both benign and evil spirits. In Christianity, for example, possession by the Holy Spirit is a highly esteemed experience, especially among Pentecostals, in whom it may become manifest in the gifts of speaking in tongues and prophecy. The exorcism of harmful possessing demons is prominent in the New Testament. Nearly 20% of the Gospels are devoted to Jesus' healings, with the commonest ailment being illness caused by demon possession. According to Christian teaching, he passed on this ability to all baptized Christian believers: "And these signs will follow all who believe; in my name they will cast out demons; they will speak in tongues; they will take up serpents; and if they drink anything deadly, it will not hurt them; they will lay hands on the sick, and they will recover" (Mark 16:16–18).

Almost all religions have rituals for exorcising demons. Exorcisms were common in the early centuries of Christianity and then fell to a low level until a renewed interest in healing emerged at the turn of the 20th century, especially in the U.S. Midwest. The Catholic Church retains its formal, infrequently used rite of exorcism, although one or more simple exorcisms are routinely pronounced in the sacrament of baptism. Fundamentalist ministers perform exorcisms when they perceive evidence of often-dramatic demon possession. Televangelists have become more sophisticated in their approach; they are more apt nowadays to speak of demonic *oppression,* especially in persons with impulse control problems

Telegram: @medical_k

www.konkur.in

such as alcohol and substance abuse, self-injury, gambling, bulimia, and promiscuity.

Psychedelics

Psychedelics have been used throughout the world for over a millennium as a portal into the world of spirituality. Drugs such as LSD (lysergic acid diethylamide), DMT (*N,N*-dimethyltryptamine), peyote, ayahuasca, and psilocybin are called hallucinogens, although they rarely cause hallucinations. In the lay press, they are more properly called psychedelics ("mind-manifesting"). The new name for these drugs, especially among those who use them, is entheogens (derived from the Greek word for "God within").

The psychedelic experience can range from mild to very intense, depending on the dose of the drug and, perhaps more importantly, on the psychological expectations of the user and the social setting of the drug use. The experience, or "trip," involves visual, auditory, and time distortions as well as synesthesia. At its peak, the drug users have a loss of ego with feelings of merging with space and objects or the universe. They may feel a sense of reaching to the beginning or end of space and time. The psychiatrist Daniel X. Freedman, a pioneer in psychedelic research, described the portentousness of the LSD experience: "The capacity of the mind to see more than it can tell, to experience more than it can explicate, to believe in and to be impressed with more than it can rationally justify, to experience boundlessness and boundary-less events, from the banal to the profound." The use of psychedelics may alter peoples' concept of reality, change their views on life or death, and challenge or promote their most passionately held beliefs. Like spiritual transcendence or ecstatic religious rapture, the peak LSD experience cannot be fully described verbally. However, when "trips" go sour, the experience can be devastating, nihilistic, fearful, and filled with demonic visions.

Psychedelics have come a long way from outright rejection to skepticism to being embraced by a diverse set of multidisciplinary researchers. In the 1970s, the FDA classified psychedelics as controlled schedule I drugs, accessibility was severely limited, and research stalled for almost 20 years. As more results came out suggesting extremely positive and clinically meaningful outcomes in those treated with psychedelics for a variety of psychiatric disorders (anxiety, depression,

Telegram: @medical_k

www.konkur.in

OCD, etc.), funding became more accessible. As a result, the research on psychedelics has exploded in recent years. They are being studied as novel psychotherapeutics. Notably, neuroscientific studies have indicated that psychedelics operate through pathways in the brain that influence immunity and neurotransmitter systems. In a blinded study, 36 volunteers with spiritual or religious learning who had never taken a psychedelic drug were administered alternate doses of psilocybin and methylphenidate for an 8-hour session in a comfortable room. Based on responses to a Mystical Experience Questionnaire, 60% had a mystical experience, and 70% rated the experience among the top five in their lives, on a par with the birth of a child or the death of a parent. The effects persisted for 16 months and were confirmed by persons who knew the subjects intimately. Unpleasant sessions manifested by short-term anxiety and troublesome personal struggles were reported in 22% of subjects, some of whom nonetheless found the experience meaningful. More recently, a considerable interest in psychedelics for the treatment of Posttraumatic Stress Disorder (PTSD) has gathered momentum, and psilocybin is being envisioned as one of the most efficacious modes to alleviate stress-related symptoms. These have shown a positive and significant treatment effect in treatment-resistant disorders.

Psychedelic-assisted psychotherapy is another modality linked with this class of substances and is gaining prominence. It entails providing psychotherapy sessions in conjunction while patients are receiving psychedelics. It is postulated that, during this time, the patient is more open to getting in touch with their innermost self and open to authentically experience and be much more engaged in therapy. Different psychotherapeutic modalities may be employed, and a supportive form of therapy is popular. Individuals often describe their experience as a life-changing, effective, and transcendental connection with Self.

Drugs

Cannabis enjoys an important place in several religions for a variety of reasons and is considered an entheogen, a substance used to attain spiritual bliss. It has been used to achieve spirituality since ancient times and is still used in more ritualized fashion during religious ceremonies. It is consumed as a drink called *bhang* by many Hindus during the festival of Holi, and it is smoked by devotees of Lord Shiva. Although the Qur'an forbids wine, most Muslims interpret this to include all drugs that affect

Telegram: @medical_k

www.konkur.in

consciousness. Sufis are known to have used cannabis for spiritual reasons. The Rastafari religion, which emerged in Jamaica in the 1930s, equates cannabis with the biblical Tree of Life and encourages its use sacramentally as a means of discovering the truth and getting close to JAH (God). Rastafari claim that the drug must be used regularly in order to achieve cosmic consciousness and to rid their hearts of corruption. Its use is often associated with Bible study and with truth-seeking group discussions. The Ethiopian Zion Coptic Church, a small religious movement incorporated in Florida in 1975, equates cannabis with the Christian Eucharist (consecrated communion wafer). In the 1960s, marijuana became almost synonymous with the "Hippie movement," and it was described as a way to achieve spiritual peace and attain a transcendental state of bliss. With the legalization of cannabis in several states in the United States, it is more freely available. It will be some time before we know if the patterns and epidemiology of cannabis use have changed.

Alcohol has long had spiritual connotations. Many Greeks worshipped the god Dionysus, who supposedly invented wine. At sacred rites, better known by their Roman name, the bacchanalia, his religion was characterized by the drinking of wine, which then released almost bestial emotions. Women were especially attracted to the chaste orgies, where they were free to forget their domesticity, dance ecstatically in the darkness of the mountains, and transcend human cares and fears. With alcohol-driven superhuman agility and strength, they ripped apart wild animals and devoured them sacramentally, believing that each bloody morsel contained a bit of Dionysus himself. The wine cult spread rapidly to areas as far apart as India and Britain. It also took hold in Palestine and Asia Minor, where, according to some scholars, the Dionysian orgy evolved into the Canaanite Feast of Tabernacles.

The Bible refers to wine as "the blood of the grape," and in its most revered transformation, it signified the blood of Christ. At the Last Supper, Christ instituted the Eucharistic sacrifice, in which he offered his disciples bread and wine that he declared to be his body and blood. For many Christians, this is of prime importance and serves as a reminder of His death and resurrection. By remembering Jesus Christ's sacrifice, people urge Him to lead them and provide direction and safety in their lives.

The psychologist William James wrote of alcohol's intoxicating power to stimulate human nature's mystical qualities and provide a core religious

Telegram: @medical_k

www.konkur.in

feeling of transcendence and a sense of meaning in life for alcoholics. Alcohol's physiologic power to transform consciousness can, depending on the context, be interpreted as a transcendence of everyday life, an entry into the cosmic world of spirituality. Alcohol fosters an experience of trust, relatedness, and unity through an illusory closeness to others. In some ways, alcoholism is religion gone awry, a metabolic error of the religious impulse. Over time, as alcohol dominates the lives of alcoholics, it replaces a higher spiritual power with itself, and alcoholics turn to it for redemption and the alleviation of guilt and insecurity.

Body Modification and Mortification

Nonmedical alteration and mortification of body tissue, such as tattooing, flagellation, and piercing for spiritual reasons, have a lengthy history. Pope Benedict XIV (1675–1758) wrote: "With the exception of the martyrs, the Church venerates and gives the sanction of her authority to the sanctity of those only whom she finds to have been zealous in the modification of the flesh and senses." One such person was a mystic Heinrich Suso (1300–1366) who, naked, beat himself with a spiked scourge until blood poured off his arms, legs, and torso, and bits of his flesh were ripped from his body. Gazing at his beaten body, he was reminded of the beatings endured by Christ. Another was St. Catharine of Siena (1347–1380), who ate very sparingly, whipped herself with chains for 90 minutes three times a day, and deliberately scalded her body. After drinking the pus that oozed from the breasts of a cancerous woman, she said that she was visited by Christ, who invited her to drink the blood from his wounds.

Flagellation was a common Christian practice. In the 14th century, for example, itinerant bands of self-flagellators were received as heroes by a public who prayed that the bloody penitents would protect them from the plague. Mild flagellation is today practiced during prayer by some strict monastic orders and, along with brief crucifixions, by lay penitents in the Philippines and Latin America. In Islam, the death of the martyr Husain ibn Ali, Muhammed's grandson, is memorialized yearly by Shiites. On this day, some mourners beat themselves, often severely, with chains and spiked clubs while recalling his words, "Trial, afflictions, and pains, the thicker they fall on men, the better do they prepare him for his journey to heaven."

Telegram: @medical_k

www.konkur.in

Within the Eastern Orthodox tradition, the sect known as the Skoptsi (eunuchs) included castration as a central religious practice. Its founder believed a medieval legend that Adam and Eve were born sexless. After they ate the forbidden fruit in the Garden of Eden, God supposedly grafted the halves of the fruit onto Adam as testicles and onto Eve as breasts. Only through castration and removal of the nipple or breasts in women could believers return to the pristine state of purity that existed before original sin. Despite severe repressive measures by the Russian government, the sect persisted for several hundred years until the turn of the 20th century.

Among Hindus, the yearly festival of Thaipusam commemorates both the birthday of the deity Lord Murugan and the day he was given a *vel* (lance) to conquer an evil demon. The highlight of the festival is a brief pilgrimage to a holy site before which devotees, after much preparation, enter a trance state and then pierce their skin, tongue, and cheeks with a *vel.* Because Lord Murugan's conveyance is a peacock, some persons carry a *kavadi* (somewhat of a portable altar) that may weigh 100 lb on their shoulders. The *kavadi* is festooned with peacock feathers and is attached to the carriers by hooks in their backs and chests. The festival, a joyous event held in several sites, is growing in popularity. Those who pierce themselves not only give thanks to the deity but also accrue spiritual merits. In Islam, some Sufis practice potentially dangerous forms of body piercing to achieve a spiritual state.

Fakir Musafar, the adopted name of a Caucasian South Dakotan, is a primary founder of the Modern Primitive movement. He has devoted his life to understanding the spirituality of body modification in rituals throughout the world and putting this knowledge into practice. He is a shaman of sorts who has established a licensed school for body piercing and modification in California in which he indoctrinates students into the spiritual underpinnings of his craft.

Confession, Penance, and Reconciliation

Sins are offenses against the deities, ancestral spirits, and certain taboos in many religions. Sins, especially grave ones such as blasphemy and murder, separate people from God and destroy the charity and love of God in their hearts. Only by confession and reconciliation with God can sinners avoid divine punishment, sometimes in this life or certain eternal damnation in the afterlife, restore a right relationship with God, and regain

Telegram: @medical_k

www.konkur.in

spiritual purity. In many religions, atonement is achieved by participation in holy rituals. For example, Christians believe that atonement comes from the sacrificial crucifixion of Jesus Christ, which washed away the sins of the world and allowed humankind to be reconciled with God.

Visiting Spiritual Sites

Every religion and culture has designated sites considered sacred and whose spiritual forces may affect the lives of visitors. The sites may be churches, temples, or natural landmarks such as mountains, rivers, or rock formations. The Temple Mount in Jerusalem is one of the holiest places on earth. The Church of the Holy Sepulcher has been a pilgrimage destination for Christians since the fourth century, who believe that it contains the sites of both Jesus' crucifixion and burial. Also on the Mount is the Islamic shrine, the Dome of the Rock, which Muslims believe is the place from which Muhammad made his Night Journey to visit Allah in heaven. This site was built over a Roman temple devoted to Jupiter and, before that, the Jewish Temple. The rock or Foundation Stone in the center of the Dome is thought by Jews to be the place where the patriarch Abraham was tested by God to see whether he was willing to sacrifice his son, Isaac.

Charity and Altruism

In all the major religions, charity is considered the greatest or among the greatest of all spiritual values. Its fullest explication in Christianity is found in Paul's First Letter to the Corinthians. Paul used the Greek word *agape,* which denotes the purest and most absolute level of unconditional love. The word also refers to the theologic virtue by which people love God above all things for his own sake and love themselves and their neighbors for the love of God.

The love of one's neighbors, a highly spiritual virtue, can be manifested physically by engaging in acts of kindness and providing both comfort and material things to the less fortunate. The Salvation Army, for example, aims to save people's souls but provides shelter, food, and clothing to the poor. Giving alms is one of the Pillars of Islam. Hindus give food to sadhus and Buddhists to monks. Such giving enhances the spirituality of the giver. Buddhist monks may demonstrate against unjust political rulers by walking with their begging bowls face down, thus denying their oppressors the opportunity to give them food.

Telegram: @medical_k

www.konkur.in

For some individuals, irrespective of their religious affiliation, altruism serves as a means to finding a deeper meaning and purpose in life. Altruism is a secular term referring to a selfless obligation of benevolence, respect, and caring for humankind, all living creatures, and the environment. Philanthropists and those who selflessly give food and clothes to those in need, preserve and improve the environment, shelter the homeless, care for the sick, protect the defenseless, assist the weak, and enlighten the uneducated achieve a sense of peace and the belief that they have accrued spiritual merits for their good deeds.

New Age Spirituality

The term New Age refers to a cultural movement that began in the late 20th century with multiple roots, beliefs, and concerns that vary widely and include aspects of the following: mainstream religious traditions, Sufism, mesmerism, shamanism, Kabbalah, occultism, neopaganism, theosophy, magic, karma, unidentified flying objects (UFOs), meditation, psi energy, astrology, synchronicity, numerology, fortune-telling, parapsychology, ecologic responsibility, guardian angels, cosmic forces, yoga, fasting, contact with aliens, near-death experiences, levitation, dream interpretation, and Wicca. This list is hardly inclusive but does give a sense that New Age spirituality has no sacred texts, central organization, membership, clergy, central headquarters, dogma, or creed.

New Age believers are generally optimistic and eager to enhance human potential by tapping into so-called spiritual vibrations and powers that emanate from the cosmos, crystals, pyramidal objects, and geographic locations such as Sedona, Arizona, where the Center for the New Age employs psychic readers and energy healers specializing in spiritual quests and inner transformation.

A major result of the New Age movement is the development of a thriving spiritual tourism industry. Using a computer in the comfort of one's home, it is possible to book spiritual pilgrim tours anywhere in the world. Thus, one can seek spirituality among the Kung Bushmen of the Kalahari Desert, Australian aborigines, Amazonian shamans, or at exclusive spas in Bali or ashrams in India. Such tours often may dramatically affect the lives of participants.

Spirituality and Yoga

Telegram: @medical_k

www.konkur.in

Yoga is a form of exercise consisting of performing a variety of bodily postures while being aware of your breath, your thoughts, and being in the moment. It is often described as a practice promoting a deeper mind–body connection leading to a profound sense of peace and well-being. Yoga is seen as a way to bring harmony and closeness between an individual's emotional and physical self. There are a variety of forms and routines rooted in the healing process and promoting mindfulness about one's own self in relation to the world outside. Yoga is increasingly being studied for its significant beneficial outcomes in chronic physical and psychiatric illnesses such as depression, PTSD, chronic pain, and pervasive anxiety. Yoga has universal appeal, regardless of religion, attributed to its association with spiritualism and meaningfulness.

SPIRITUALITY AND RELIGION IN CLINICAL PRACTICE

Spirituality can be a positive force in peoples' lives. In 1984, the California Psychological Association's Task Force on Spirituality and Psychotherapy provided a new definition of spirituality as "The courage to look within and to trust what is seen and what is trusted appears to be a deep sense of belonging, of wholeness, of connectedness, and openness to the infinite." The psychologist David Elkins outlined the values of spiritual persons. These include beliefs in "a greater self" or a personal God; a sense of purpose in life and a quest for meaning; acceptance of the sacredness of nature and all human experience; knowledge that ultimate fulfillment is found in spirituality and not in material things; altruism; idealism; awareness of suffering and death; and leading a life that has a positive effect on people, nature, and their relationship with whatever they consider to be the ultimate and transcendent reality. This is an impressive list, but it is a challenging task, for example, to reconcile spirituality in the sacredness of nature and the occurrence of devastating tsunamis, tornados, volcanic eruptions, earthquakes, congenital malformations, and stillbirths unless they are considered as part of God's great plan for humankind, which includes all the wonderful and horrible events of the past and present or as tough-love warnings by Mother Nature to tread lightly on the Earth.

The list of spiritual values would also seem to apply to religious values, perhaps the closest being those of Buddhism. However, in the case of

Telegram: @medical_k

www.konkur.in

Christianity, for example, the list would need to contain specific beliefs about Jesus Christ as the savior of humankind, personal salvation as the ultimate goal in life, participation in church rituals, and acceptance of the Bible as the only true sacred text of the only true religion. Consideration would then have to be given to sectarian beliefs such as obedience in spiritual matters to a church hierarchy, reservation of the priesthood for men, a wife's duty to be obedient to her husband, and denial of homosexuality as an acceptable form of human personhood.

Religion, Religiosity, and Spirituality

Religion, religiosity, and spirituality may have some overlapping dimensions, but the concepts are not interchangeable. Spiritual persons may neither participate in religion nor possess religiosity, or they may participate in religion but lack religiosity, or they may participate and have religiosity. Other permutations are possible; for example, people who attend church may be spiritual but lack religiosity, or people may possess religiosity but not attend church, and so on. Great confusion results when these distinctions are not made. Thus, in many studies, "religion" is measured by participation in religious services at a church, mosque, synagogue, or temple. However, some people attend only a few special services each year, whereas others may call themselves a Christian, Jew, and so on, and consider themselves to be a member of a religion even though they have not attended services for years.

Religiosity refers to peoples' devotion to their religion; Allport and Ross's Religious Orientation Scale, for example, contains the statement, "My whole approach to life is based on my religion." An affirmative answer ideally implies a sincere commitment to one's religious beliefs, which are internalized and serve as the guiding motivation of behavior. In reality, religiosity is not an all-or-none phenomenon. More than 20 variables have been identified as components of religiosity, and people may score high or low on different variables. Religiosity usually does conform to many spiritual values, but it may be spiritually destructive, for example, in the case of cults that prey on children and vulnerable persons who are disillusioned with life, frustrated by failed relationships, lonely, or experiencing a sense of disorientation that may be apparent, for example, in newly arrived college students, foreigners, and runaways. Destructive cults use deceitful recruiting practices and masterful indoctrination programs that, often in the course of several days, can cause persons to

Telegram: @medical_k

www.konkur.in

abandon their autonomy and conform to the groups' behavioral norms in exchange for a false sense of well-being and exclusivity. Once indoctrinated, cult members lose their cognitive flexibility and adaptability; demonstrate a narrowing, blunting, or artificiality of affect; and develop a childish dependence on cult leaders to make decisions for them. In the worst scenarios, cults may use perverse religiosity to justify their sexual abuse of children, as was the case with the Branch Davidian cult in Waco, Texas, whose compound was destroyed and many of its members (including 21 children) killed during a raid by federal agents in 1993.

In an effort, perhaps to counterbalance the overwhelming focus of medicine on biology and biotechnology, it is not surprising that a host of the major health care, medical, graduate medical education, nursing, and social work organizations have jumped onto the spirituality bandwagon. Most medical schools have courses on spirituality and health, and residents in psychiatry, family medicine, and internal medicine are required to learn about spirituality. The movement has gained traction through numerous correlational and cross-sectional studies that make unwarranted conclusions about the effects of religion and prayers on medical and psychiatric illnesses.

The lay press has publicized widely exaggerated claims about the "God spot," an area in the brain that supposedly demonstrates the biologic basis of spirituality. Neurologists have long known that patients with temporal lobe epilepsy may develop a newfound religiosity (often obsessive in nature), have transcendent experiences, and experience religious auditory and visual hallucinations. Some have speculated that St. Paul's "thorn in the flesh" was temporal lobe epilepsy, which facilitated his conversion to Christianity on the road to Damascus. In fact, before Hippocrates, epilepsy was known as "the sacred disease." The controversial psychologist and countercultural icon of the 1960s Timothy Leary championed the use of LSD for its therapeutic and spiritual benefits; he wrote a book titled *Your Brain Is God.* Recent functional magnetic imaging studies have shown that a large number of neural circuits involving the frontal, prefrontal, temporal, and cingulate cortices; the caudate nucleus; and the parietal lobes "flickered into life" when 15 Carmelite nuns reported feeling the presence of God. The psychiatrist Herbert Benson stated, "To put it simply, we're wired to God." Albert Ellis, the psychologist who developed rational emotive therapy, retorted, "The whole field is off its rocker." Benson reasoned that because faith in a

Telegram: @medical_k

www.konkur.in

medical treatment can be therapeutic in up to 90% of the most common medical problems, then “faith in an invincible and infallible source carries even more healing power.” In other words, belief in the healing power of God is the greatest placebo of all. Benson is probably correct in that this belief engenders hope, which is no small thing for people who feel hopeless.

At a conference sponsored by the Association of American Medical Colleges in 1999, a consensus of clinicians, medical educators, and chaplains agreed that spirituality involves a person’s search for ultimate meaning in life through participation in religion, as well as through relationships with God or family, and is expressed in nature, rationalism, humanism, and the arts. This declaration is somewhat idealistic in that very few persons lead an examined life, much less search for ultimate meaning. Sages from the West, wise men from the East, prophets, philosophers, poets, priests, psychiatrists, and Ph.D. candidates have all struggled to find the ultimate meaning of life. Multiple answers have been proposed—to have offspring and occupy and subdue the Earth; to act justly, love mercy, and walk humbly with God; to glorify and worship God; to love one’s neighbor; to defeat one’s enemies; to experience oneness with the universe; to be content with cultivating one’s garden; to experience pleasures; to seek truth and be wise; and so on—but no single answer suffices for everybody.

From a global perspective, most people lead simple, unquestioning lives that go from paycheck to paycheck. Sports, sex, movies, children, and television shows are more apt to be topics of concern and conversation than transcendence or the meaning of life. The consensus definition of spirituality is somewhat high-minded, although it states that spirituality “may be expressed” by listening to music or painting, for example. Does listening to rap music qualify, or must it be mostly Mozart? Does painting-by-the-numbers count? What about relationships with pets?

Because the word “spirituality” is used in many different contexts, a distinction should be made between *Spirituality* with a capital S and *spirituality.* The former refers to a unique and very special experience as defined in the following discussion, whereas lower-case spirituality is a more general term that refers to meritorious, estimable, and honorable behaviors and feelings that benefit both individuals and the common good.

Based on this distinction, Spirituality refers to the following:

Telegram: @medical_k

www.konkur.in

Spirituality is a feeling of a special connection with a person, a group, any living thing, nature, a cause, sacred or culturally significant objects or activities, the universe, or a supernatural being such as a deity. This feeling is special because it penetrates to the perceived inner core of a person's being and may evoke deep passion, intense love, joyful bewilderment, visionary experiences, or a sense of profound understanding that cannot be expressed adequately in words. The settings where this feeling occurs are highly variable, as are their degrees of intensity. Traditionally, the most exalted and intense feelings are those of mystical transcendence and understanding the true nature of reality and the ultimate meaning of life. However, equally valid and more commonly experienced are the mundane feelings of connections such as wonderment in the beauty of nature and reverence for sacred landmarks; sexual merging with a loved one; caring for children, grandchildren, or a faithful pet; working for charitable causes; cheering for a favorite sports team; and maintaining good relationships with friends, family, and neighbors in good times and bad. A person may seek after and prepare for this feeling, but it almost always comes spontaneously and lasts for a moment or, in exceptional cases of mystical transcendence, for up to 30 minutes. Although this feeling is transitory, it may have enduring effects. It can be a positive force in coping with the travails of daily life and a sustaining force, particularly in times of physical and emotional crisis and in old age, especially when the specter of death is on the horizon.

The adjective "spiritual" in everyday usage usually refers to spirituality rather than the specific feeling of Spirituality. Many persons may consider themselves to be spiritual or to lead spiritual lives because they follow the Ten Commandments and practice the behaviors specified by Jesus in his Sermon on the Mount; attend religious services regularly; pray often; fulfill the requirement of the Five Pillars of Islam; follow the Noble Path; live in a cloistered environment; evangelize for their faith; make pilgrimages; participate in charitable, patriotic, and ecologic causes; remain faithful to their marriage vows; provide for the well-being of their children, parents, and pets; accept people for the content of their character; forgive those who have harmed them; appreciate the beauty of nature; serve as positive role models; and, in certain contexts, attempt to influence otherworldly beings on behalf of humankind. This list is not exhaustive but provides a sense of the attributes of spiritual persons and spiritual lives. Spiritual persons who lead spiritual lives may never experience Spirituality as

Telegram: @medical_k

www.konkur.in

defined here but may approximate and even share some portion of it. If the Virgin Mary's love for her child Jesus was spiritual, then there is some measure of Spirituality in every mother's love for her children. If the Native American spiritual belief that all things are connected is true, then there is a potential spirituality in all the thoughts, emotions, and deeds of people's lives. Evangelical, Fundamentalist, and Pentecostal Christians claim to have a personal conversion encounter with God in which they are born again. The Biblical book of 2 Corinthians states, "Therefore, if anyone is in Christ, he is a new creation; old things have passed away; behold, all things have become new." When this conversion moment is intense and occurs suddenly, the experience may be one of true Spirituality or, at the least, a close approximation.

Unfortunately, some people who consider themselves spiritual can be misguided and create mischief and even havoc when they try to force their beliefs and values on others in the name of a cause or a religion. Much suffering can be caused by those who believe in their own righteousness. The austere Puritans, for example, escaped religious persecution by fleeing to America from England in the mid-16th century. Historians have characterized them as persons who were distressed by the thought that some people, somewhere, were enjoying themselves.

Psychiatrists' Perceptions about Religion and Spirituality

Surveys of physicians in general and psychiatrists, in particular, have always reported that they have both a lower level of belief in God and participation in religious activities than the general population. Although involving only 100 psychiatrists, a recent survey also showed a lower level of positive attitudes toward Spirituality, which was defined in terms of religion and feelings of connectedness with an entity greater than oneself that gives meaning to life. This is certainly not anything new: a medieval aphorism was, "Three doctors, two atheists." These attitudes have probably resulted from physicians' experiences in watching so many good people and innocent children die. It takes great effort to reconcile these experiences with the will of a just and merciful deity or to find in them any transcendence. Sigmund Freud contended that religion was an infantilizing, neurosis-producing, tyrannical illusion, and most psychoanalysts followed his critique, with the prominent exception of Carl Jung, who, for example, believed that every person's mind contained unconscious prehistoric memories of the real Father–God who is

Telegram: @medical_k

www.konkur.in

perceived as one's biologic father, contrary to Freud's belief that it was the other way around. When psychoanalysts had something positive to say about religion, they often managed to find a rankling counterbalance. Ernest Jones, for example, wrote about "the enormous civilizing influence of Christianity" and "sublimated homosexuality" in the same sentence. Even Henry Maudsley, the most influential British psychiatrist of his time and certainly not a Freudian, wrote in 1918 that "the corporeal or the material is the fundamental fact—the mental or spiritual only its effect." In 1975, the outspoken psychologist Albert Ellis declared that religion itself is a self-deprecating, dehumanizing mental illness. These attitudes have probably attracted some people to gravitate toward psychiatry as a career.

The change among psychiatrists to a more positive view of religion began in the 1960s and 1970s. The psychiatrists William Meissner and Ana-Marie Rizzuto each proposed a nontheologic and easier-to-accept understanding of the human experience of God through the life cycle. A child's initial image of God is based primarily on the image of their parents. The child's God may be loving and protective, as well as fearsome, cruel, and not always available to gratify the child's wishes. A positive mother–child experience at this stage results in a basic sense of trust that, in later years, may lead to a trusting faith in God, whereas a negative, insecure experience may distort the experience of God. As the child begins the process of separation and becoming an individual with some independence, it hears about something called God but lacks the capacity to understand what a spirit or transcendent force is supposed to be. The child hears that God has made the world and, thus, likens God to the most powerful person that they know, namely, both parents, but especially the father, who tends to be the more forceful or aggressive parent. Over the next few years, as the child comes to recognize that their parents neither know everything nor are all-powerful, a romantic view of a perfect, heavenly father may emerge, as well as a distorted view of the family. God and parents may be idealized as totally protecting, or there may be a split into a good God and mean parents or into good parents and a mean God. Between 6 and 11 years of age, the child begins to appreciate symbols. The concept of God shifts from that of a flesh-and-blood person to a still imperfectly understood spirit whose power must be revered and feared because God exacts punishment for every misdeed. In this stage, an immature obsessional religiosity may emerge in conjunction with ritualistic behaviors.

Telegram: @medical_k

www.konkur.in

During adolescence, God becomes more personalized as “my Savior” or “my Father” and more connected to emotions and subjective attitudes, such as love, obedience, trust, and fear. God is experienced as the ideal leader and advisor who patiently and kindly listens to one’s innermost problems and desires. When not tempered by some maturity of judgment, this realization of God may lead to fanatical tendencies. As adolescents become moralists, the burden of sinfulness emerges, and they may engage in the extremes of loose or puritanical behavior. Rebellion against parental authority may carry over to the parent’s religion, as well as to the God whom the parents symbolically represent.

As adolescents step into adulthood, they must decide whether they will follow their parents’ religion, seek a different religion, or avoid religion altogether. A study undertaken by Michaelson et al. (2016) examined the evolution of spiritual health in adolescents in six countries, including Canada and the United Kingdom. Results indicated that as adolescents advanced toward young adulthood, they continued to highly rate the importance of connection with self while their perceived importance of connection with others decreased. The authors attributed this to the development of a more independent style of thinking, challenging the traditional beliefs they grew up with, and an increased capability for abstract thought. For some, the inner representation of God remains solid; for others, it may change; and for still others, it may be rejected or replaced. Thoughts about the memory of God usually return in old age, especially when death nears. A person may decide to embrace God gracefully or grudgingly, for reasons that include mature acceptance of the cycle of life, the hope of entering a heavenly afterlife, avoidance of eternal damnation, and neurotic fear, or to spurn God’s ultimate encroachment; a person’s last breath may be an inspiration or an expiration.

Freud held that belief in God was an illusion that softens fears about the dangers of life; that the moral world order that God promises instills hope that justice will be served; and that belief in an afterlife creates an ultimate setting for the fulfillment of wishes. For Freud, this illusion was noxious because it distorted reality and promoted a state of psychic infantilism. However, in some modern psychiatric thought, God is a benevolent illusion necessary for the growth and nourishment of mental and spiritual health. God is like the baby blanket or teddy bear that is special to the infant who endows it with a unique quality, cuddles it lovingly, and sometimes hates it. As the child matures, these transitional objects are

Telegram: @medical_k

www.konkur.in

neither mourned nor forgotten but rather simply lose meaning. They are the stuff of illusion and exist mentally somewhere between subjective and objective reality. In this formulation, God is a special transitional object that does not lose meaning totally and is always available through religion. Rizzuto concluded that a person's humanity depends on illusion; the type of illusion selected, be it science, religion, or something else, "reveals our personal history and the transitional space each of us has created between his objects and himself to find a resting place to live in."

Another factor that began to emerge in the 1960s and 1970s was that psychoanalysis was giving way to the community mental health movement, which decreased the traditional role of psychiatrists as therapists. Nowadays, the majority of psychiatrist–patient interactions involve 15-minute medication checks. In such an environment, psychiatrists usually have little trouble calling on the clergy and religious institutions to help with patient care, for example, by providing relief from social isolation through attending religious activities, advising about life issues as well as spiritual ones, and giving emotional and material support. Some clergy and religious institutions are quite amenable to including persons with mental illness and mild mental retardation in their congregations, whereas others may be less inclined to do so. Psychiatrists need to be aware that the clergy, a group with diminishing members, has little to no training in providing mental health services. Their major priorities are saving souls and turning sinners toward holiness. Certainly, there are pastoral counselors, but their numbers are few, and they are most likely to be called on in hospital settings in times of impending death or major medical crises.

Undoubtedly, some psychiatrists harbor conscious and unconscious negativity toward religion and religious patients. This disdain may stem from multiple sources, such as contact with or reports of pederastic and philandering clergy; exploitative cults; greedy televangelists; anger toward God over the premature death of a loved one; personal guilt (the Semitic religions are quite effective in stirring this emotion); the belief that religion is an irrational and coercive force in peoples' lives; negative experiences while attending a religious grade school; and so on. There are also undoubtedly psychiatrists who overvalue the role of religion and religiosity in the treatment of the mentally ill. Such under- or overvaluation distorts the clinical encounter and compromises the care of religious patients, who may detect this bias and skew the information they provide, which may be

Telegram: @medical_k

www.konkur.in

interpreted as denial, resistance, paranoia, or characterologic psychopathology. It is imperative that psychiatrists be aware of their feelings and beliefs about religion and religiosity to provide appropriate clinical care. The same caveat holds true for encounters with patients whose spirituality is manifested in secular rather than religious beliefs and practices, although it would be rare for psychiatrists to harbor disdain in dealing with patients who love their family and their pets, engage in charitable and altruistic activities, and find peace in natural beauty. Psychiatrists may consider some of the practices of New Age spirituality to be odd, but, with the exception of protracted use of psychedelic drugs, these practices do not carry the same baggage as religious ones.

Spiritual Assessment

For a thorough clinical assessment of a patient, the biopsychosocial paradigm is insufficient, and the adjective "cultural" should be added to include consideration of such factors as ethnicity and spirituality. Several spirituality assessment tools have been published and share many commonalities, such as the (British) Royal Free Interview for Religious and Spiritual Beliefs and the University of Minnesota Module on Taking a Spiritual History.

The initial core question is, "Do you consider yourself to be a spiritual person?" If the answer is "No" or "What do you mean by spiritual?" some appropriate responses include "Are there any things that you feel passionate about or that give a special meaning to your life?" and "What are the things in your life that give you the strength to go on living?" Sometimes, a more dramatic question may be posed, such as "What is it that keeps you from ending your life?" The most common answers, in no particular order, are linked to pets, grandchildren, and God and/or religion.

It should be no surprise that pets are ranked so high; animals are significant in religious history and imagery. Among the ancient Israelites, the Leah tribes were linked to antelopes, the Rachel tribes to lambs, the Manasseh tribe to asses, and so on. Australian aborigines have long revered the totemic kangaroo. The Sacred Jaguar was central to the Aztec and Olmec religions and remains important to Amazonian tribes. Native Americans have animal spirit guides. Ancient Egyptian religion was polytheistic and often zoomorphic; for example, the jackal god Anubis watched over the dead; the falcon-headed Horus was the god of the sky; Menhit was the lion goddess of war, and Wadjet, the cobra goddess, was

Telegram: @medical_k

www.konkur.in

the protector of Egypt, and her image always appeared on the crown of the pharaohs. Cows are sacred to many Hindus. In Christianity, Jesus is often depicted as the Lamb of God and the Holy Spirit as a dove.

In Western cultures, dogs and cats are the most common pets, and not infrequently, patients state that they could not commit suicide because of the disastrous effect it would have on their pets. Popular fictional animals such as Snoopy the dog, Garfield the cat, and Bambi the deer demonstrate peoples' willingness to accept, be amused by, and cherish animals. Dogs, perhaps because of their fidelity, transparent emotionality, and the seemingly unlimited amount of unconditional "love" that they offer, often stir the passions of their owners: "I would kill anyone who tried to hurt my dog"; "No one understands me like my dog." Pets certainly have a calming influence, and taking care of them does provide some meaning to many peoples' lives. Asking about the status of a pet, even in a brief clinical encounter, often helps with treatment compliance because patients feel that the psychiatrist is interested in more than their symptoms. Encouraging depressed patients to take walks with their dogs exposes them to the beneficial effects of exercise and sunlight.

The birth of a grandchild often changes the relationships between grandparents and their children, especially when these relationships are strained. Grandparents may experience both delight and a renewed meaning in their lives in caring for grandchildren, passing on their wisdom, and providing some respite for weary parents. Intergenerational bonding and continuity of the family partake of the spirituality that exists in daily life.

When patients say, for example, that God helps them persevere and gives meaning to their lives, it is important for psychiatrists to gather more information by responding, for example, as follows: "Tell me about your relationship to God." "Do you believe that God somehow plays a role in your illness?" "Has God ever made his presence felt in your life?" "Has God ever disappointed you?" "Have you ever disappointed God?" "Do you believe that God will be a factor in recovering from your illness?" "How do you stand with God now?" "How do you think that God will judge you?"

It is quite rare for patients to describe themselves to psychiatrists as sinners, a trend that has grown over the last century. Karl Menninger's popular 1973 book *Whatever Became of Sin?* noted that sin no longer is the topic of daily discourse but rather has been transmuted into mental illness and criminality. In addition, in recent decades, the concepts of free

Telegram: @medical_k

www.konkur.in

will and personal responsibility, necessary components of sin, have been greatly diminished by explanations of behavior that stress genetics, childrearing practices, childhood experiences, chemical unbalances in the brain, defects in neural circuits, exposure to traumatic events, peer pressure, and the influence of advertising. Only in extraordinary circumstances is it appropriate for psychiatrists to ask patients about sin. Patients who regard sin as one factor in their mental illness should be referred to a pastoral counselor to deal with this issue but still may need to receive treatment by a psychiatrist.

When patients state that religion provides meaning to their lives, this needs to be explored. Some appropriate questions are as follows:

What religion do you belong to?
Has religion been important to you throughout your life?
Do you attend church (synagogue, mosque, temple) services? How often? When was the last time that you attended?
Are you satisfied with your church?
Do you feel that the congregation welcomes you?
Tell me about the congregation.
Were you exposed to religion as a child?
Is your current religion the same one you grew up with?
Do other family members attend religious services with you?
Do you discuss religion at home?
What is it about your religion that you find most gratifying?
Does your religion or your religious practices help you cope with stress and difficult times in your life?
Have you ever had any negative religious experiences?
Are there any aspects of your religion that you disagree with?
Do you read Holy Scripture or religious materials? Does this reading influence how you feel or how you lead your life?
If you were to die right now, would you go to heaven or hell?

Most patients tend to elaborate their responses, but if they do not, then more detailed questioning is necessary. It should not be surprising that not all congregations or church leaders are alike, even though they are members of the same religion. Each church, synagogue, mosque, and temple has its unique dynamics, personalities, and ordering of priorities. In

Telegram: @medical_k

www.konkur.in

some Sikh temples, for example, major confrontations may occur over the practice of eating at a table or on the floor. In highly hierarchical religions, such as the Catholic Church, individual members or a majority of a congregation may choose to disregard pronouncements by the pope or local cardinals or bishops over such issues as birth control and not allowing divorced persons or those who are tolerant of abortion to receive communion. Mosques attended by both Shia and Sunni Muslims may be troubled by internal politics. Congregations may be politically liberal or conservative. Some may be somber, and others joyful in their religious practices. Some may be more tolerant of the mentally ill than others. A thorough spiritual assessment should consider the characteristics of the specific church, synagogue, mosque, or temple that a patient attends.

Spiritual and Religious Problems in Clinical Practice

Asking all of the questions involved with a spiritual assessment in a respectful, nonbiased manner may set a positive tone for the doctor–patient relationship, especially with patients for whom spirituality and religion are important. However, even patients who profess no interest in religion may be intrigued by the idea that spirituality does not automatically imply religion and that even atheists can lead spiritual lives.

If a thorough biopsychosociocultural assessment demonstrates that a patient is not mentally ill but rather has a spiritual or religious problem such as issues about a loss of faith or conversion to a different religion, *Diagnostic and Statistical Manual of Mental Disorders* code V62.89 may be the appropriate diagnosis. Such problems may arise during treatment or may be the chief complaint of new patients who may think that they are mentally ill or who are seeking reassurance that they are not mentally ill. Once a diagnosis is made, a referral to a pastoral counselor should be made, even if the patient remains in treatment for an Axis I or II disorder.

Psychosis, Depression, and Anxiety. As defined in this section, some of the feelings associated with Spirituality are similar to those experienced during a psychotic episode—for example, visions, fleeting profound insights, closeness to God. There is an eeriness to a psychotic episode, however, that may be manifested by turmoil in the patient's life, by disorders of thought (loose associations, thought blocking, etc.), and often by emotion (mania, depression, etc.) and general appearance (odd clothing, mannerisms, and comportment). When one is unsure whether a

Telegram: @medical_k

www.konkur.in

patient is psychotic because of religious claims, the patient's peers—such as church members—should be consulted. They commonly will be able to identify the patient's claims as either abnormal or within the group's concept of normalcy. Psychotic persons demonstrating high religiosity and concrete thinking may interpret scriptural passages literally and are in peril of harming themselves (eye enucleation and self-castration are mentioned in the Gospels) and others (killing children during a postpartum depression to "save" them). Claims made by a person who has gone through a rapid conversion from a traditional religion to a cultic or somewhat "exotic" religion, such as Hare Krishna or Druidism, are highly suspect because such conversions are usually associated with emotional tumult and sometimes with psychotic episodes.

However, it is possible for persons with severe, chronic mental illness who are not currently psychotic to experience Spirituality or to lead spiritual lives. In a Swiss study of 100 outpatients with severe, chronic mental illnesses, some subjects reported that religion instilled hope, purpose, and meaning in their lives (71%), although it induced spiritual despair in others (14%). Subjects also reported that religion lessened (54%) or increased (10%) psychotic symptoms, increased social integration (28%) or social isolation (3%), reduced (33%) or increased (10%) the risk of suicide attempts, reduced (14%) or increased (3%) substance abuse, and fostered adherence (16%) or opposition (15%) to psychiatric treatment. Religious delusions worsen the prognosis of patients and are associated with higher severity of hallucinations, bizarre beliefs, lower levels of functioning, longer durations of illness, and the need for higher amounts of antipsychotic medication.

The relationships between depression, religion, and spiritual life are complex. In almost all cultures, severe major depression replete with suicidality, deep regression, marked agitation or immobilization, and total hopelessness has been recognized as an illness. However, the concepts of moderate depression and dysthymia have been considered pathologic conditions only in relatively recent times and have spread from Western cultures to the rest of the world. The number of adjectives that have referents to depression but are used to describe aspects of the human experience is truly vast: For example, dejected, sad, downtrodden, disheartened, downcast, despondent, disconsolate, gloomy, pessimistic, melancholic, despairing, grave, lugubrious, funeral, lamentable, sullen, grim, and so on.

Telegram: @medical_k

www.konkur.in

All persons experience both sadness and happiness in their lives, but the former tends to be more persistent and is usually interpreted as more meaningful; thus, Oscar Wilde's epigram, "Where there is sorrow, there is holy ground." The most iconic image of Western civilization is the image of Jesus on the cross, bloody and beaten. The New Testament promises Christians suffering and persecution and urges them to follow Christ's example by sharing in his afflictions. Unlike gladiators, who glistened with oil and fought for their lives, martyrs aggressively sought a passive death —the bloodier, the better. In an impassioned tract written during the worst days of Roman persecution, the theologian Tertullian boasted,

> Some Christians have been tested by the fire, some by the sword, some by the beasts; some, lashed and torn with hooks have just tasted martyrdom, and lie hungering for it in prison…. Nothing whatever is achieved by each more exquisite cruelty you invent; on the contrary, it wins men for our cause. We are made more often as you mow us down. The blood of Christians is seed (semen est sanguis Christianorum). (From Glover TR. *The Conflict of Religions in the Early Roman Empire.* Vol. 94. 1909:324.)

Over the centuries, many Christians willingly accepted suffering for Christ's sake. Perhaps the greatest devotional manual of Christianity, *The Imitation of Christ,* written in the 15th century by Thomas à Kempis, is based on the principle of self-renunciation. Many of the great mystics have recounted long periods of despair, dryness of spirit, terrible darkness, and questioning of their faith in their quest for holiness.

The ancient notion that suffering is a just punishment for sins is found in the Hebrew scriptures, but some of its writers were aware that this is not invariably the case. Thus, Jeremiah (12:1) pleaded with God to answer, "Why is it that the wicked live so prosperously? Why do scoundrels enjoy peace?" The answer that emerged was described by the theologian John Bowker as "perhaps the supreme contribution of Israel to a human response to suffering, that suffering can be made redemptive, that it can become the foundation of better things, collectively, if not individually."

In Hinduism, the deities often represent opposite and complementary qualities. Siva personifies the forces of both creation and destruction in the universe and must be propitiated on the basis of the relationships of the devourer, devoured, and devouring. Kali, the Dark Goddess, is a bloodthirsty aspect of Siva. Her teeth are fangs, and she wears a necklace of skulls and a belt of amputated limbs. Her stomach is a void that can never get enough blood from beheaded offerings in her temples. Human sacrifices to Kali were abundant until forbidden by law in 1835.

Telegram: @medical_k

www.konkur.in

However, because Siva also represents the force of creation, suffering must be put into perspective as the connection between the two conflicting universal principles, the urge to life and the urge to death. Suffering is inherent to the tensions of the cosmos and is a significant part of the human experience. It is the process of being devoured, the better to be free from worldly attachments in one's search for transcendent spirituality. Sadhus are so revered in the towns and villages of India because they allow themselves to be devoured by living a life of asceticism and of twisting their wasted bodies into odd positions, sometimes for years at a time. It is this suffering that creates true liberation from the bondage of the flesh.

Buddhism is the belief system that focuses most directly on suffering. Indeed, the First Sermon of the Buddha at Benares contained the essence of his wisdom. In this sermon, Buddha disavowed both devotion to bodily pleasures and self-mortification. Instead, he preached a middle path that gives knowledge and leads to calmness, insight, enlightenment, and Nirvana. To reach this path, a person must comprehend the Noble Truth of suffering: Aging is suffering; sickness is suffering; death is suffering; sorrow, lamentation, pain, grief, and despair are suffering; association with the unpleasant is suffering; disassociation from the pleasant is suffering; not to get what one wants is suffering; all types of attachment are suffering. The origins of suffering are cravings for bodily pleasure, for existence and nonexistence, for becoming, and for annihilation. Only renunciation and detachment from these cravings will allow a person to travel the Noble Path leading to the cessation of suffering: Right view; right thought; right speech; right action; right livelihood; right effort; right mindfulness; and right concentration. In areas where these Buddhist beliefs are prevalent, the thoughts, acts, and emotions associated with the Western concepts of moderate depression and dysthymia have been perceived traditionally as within the normal range of human experiences. It has taken a large public health campaign and much advertising by pharmaceutical companies, for example, to convince people in Japan that they are truly depressed.

Patients' declarations that they are sinners, evil persons, and, to a lesser extent, guilt-ridden are encountered less frequently by psychiatrists than in the past. Some religious patients may try to extract meaning from their depression or psychosis or feel that God is testing them. A simple and truthful approach should be used. All of the patient's symptoms

Telegram: @medical_k

www.konkur.in

should be enumerated, and the diagnosis explained. They should be told that in addition to psychosocial factors contributing to their illness, modern science has shown that disturbances in brain chemistry and neural circuitry play a significant role. In addition, it is often ill-advised to seek meaning during the course of an illness because cognitive and emotional distortions compromise their ability to reason clearly. A quest for meaning may be best after the illness has either passed or come under good control. This approach does not discount the use of spiritual or religious resources during the course of treatment.

Anxiety is an experience of everyday life, and everyone, from the born-again Christian to nasty sociopath, has anxious moments—for example, when the telephone rings in the middle of the night, when one is crossing a busy street with six lanes of traffic, when a laboratory report indicates a possibly fatal illness. Persistent anxiety can be terribly corrosive both by itself and in panic, social phobia, posttraumatic stress, and OCDs.

The literature on anxiety, religion, and spirituality is sparse and consists mostly of cross-sectional studies. The only clear findings are that the presence of religious obsession and compulsions offer a poor prognosis and that the collapse or weakening of faith in PTSD patients often results in unresponsiveness to therapy. An Internet survey of 1,402 adults examined the association between mental disorders (using a subscale of the Symptom Assessment-45 Questionnaire) and religious characteristics. The study found that frequency of prayer was significantly related to higher phobic scores, whereas belief in an afterlife was related significantly to lower phobic scores. No association was found between phobia and religious fundamentalism or religious attendance. A 2002 study of 37,000 representative Canadians is the largest on the interactions among religiousness (defined as how often a person worships in an organized religious setting), spirituality (defined by how important a search for a meaning for life was for a person), and mental illness. The study found that religiousness and spirituality were linked positively with older age, higher income, and greater social support. Separated, divorced, and widowed persons were the most spiritual. With regard to depression, manic episodes, panic disorder, and social phobia, spirituality was significantly associated with higher lifetime odds, whereas religiousness had the opposite relation. The study was unable to determine whether spirituality helped set the stage for the genesis of the

Telegram: @medical_k

www.konkur.in

disorders, was a response to the disorders, or was simply a correlative finding.

Existential anxiety was a topic of psychiatric concern, especially in the mid-20th century, when it was heralded as the root cause of all mental illness. This anxiety supposedly stemmed from the experiences of being thrown from the womb into a meaningless world and then spending one's life confronting the fearful freedom that comes with meaninglessness and eventual death, the trauma of nonbeing. People were said to cope with this anxiety by rationalizations and leaps of faith that attempted to impose some order in the world; for example, religions redefine death as the end of physical existence while allowing for the continued existence of the soul, which endures eternally. Although existentialism has a rich and provoking literary heritage, it is rarely even mentioned in modern psychiatric textbooks.

Anomalous Experiences. Psychiatrists may encounter nonpsychotic patients who report anomalous experiences that defy rational explanations, such as so-called near-death experiences, alien abductions, being touched by an angel, telepathy, and clairvoyance. Although these phenomena are odd, persons who have experienced them and have been studied do not appear to be mentally ill but rather go on to develop increased empathy with others and involvement with family members, enhanced interest in spirituality, appreciation of the purpose of life and mundane occurrences, and a stronger belief in an afterlife.

Of interest, the literature on this topic includes mystical experiences—defined in this section as true Spirituality—as anomalous events. In various surveys, up to 40% of subjects reported a mystical experience at least once in their lives. Undoubtedly, some of these represent Spirituality, but it is probable that many are out-of-the-ordinary emotional New Age experiences and may even include dissociative or brief psychotic episodes.

NEAR-DEATH EXPERIENCES. Near-death experiences or something like them have a lengthy and widespread tradition. In *The Republic,* the Greek philosopher Plato described the hero Er, who was slain in battle and carried home for burial. Twelve days later, his body, surprisingly unaffected by decay, was placed on a funeral pyre. Er then came to life and reported that his soul had left his body and gone on a journey with a

Telegram: @medical_k

www.konkur.in

great company to a mysterious place where the souls of the dead resided. He saw a rainbow-colored column of light extending through heaven and earth and scenes of judgment that were both terrifying and joyful. Descriptions have been found in Buddhist and Islamic texts and in Chinese, Siberian, Finnish, and North and South American accounts of out-of-body experiences in which a person's spiritual body experiences a bright light accompanied by joyful peace and meets with ancestors and departed friends after crossing the border between the living and the dead.

The psychologist Raymond Moody's book *Life After Death* contained 150 interviews with persons who reported near-death experiences and brought attention to this phenomenon in 1975. These experiences occur when persons are in a state of what appears to be death (they may even be pronounced dead by a clinician) but then are revived. During the period of not-quite-life and not-quite-death, many report that they were out of their bodies, looking down at themselves, and felt themselves moving through a dark tunnel peacefully and quietly. Their lives were reviewed as in a panorama. They saw a glowing light with a human shape, cities of light, or a border from which there was no return. They meet deceased relatives and friends. They heard doctors or spectators who pronounced them dead, but they were rescued from death by a spirit.

Remarkable similarities exist between the reports of near-death survivors and users of hallucinogenic and other drugs. Patients recovering from anesthesia, for example, may recall words spoken by the operating team during surgery. Bright lights and tunnel imagery can occur when drugs that mimic the effects of light on the retina stimulate the central nervous system or when the threshold for light perception is lowered, so that bright lights are seen surrounded by darkness. Published statements from hallucinogenic drug users describe:

> …bright colors not like here on earth but just indescribable…. I could see a city, a city of light…. There are tall structures all around me in all colors…. It seems like I'm getting closer and closer to the sun, and there's a geometric network or lattice in the distance.

Even the panoramic, rapid review of a person's life has been described by users of drugs that excite the central nervous system. Such excitation may also be induced by fever, exhaustion, and psychological processes associated with dying; decreased sensory input from failing body organs; a turning inward of attention and blocking out of the environment;

Telegram: @medical_k

www.konkur.in

reminiscence; and a fear of death that may trigger both comforting fantasies and dissociative mental states. A fanciful theory is that the near-death experience is so traumatic that it kindles the memory of birth trauma when the infant travels through the vaginal tunnel toward the light. Yet another theory is that all memories are stored, but most are suppressed by new experiences that create more memories. In situations such as the near-death experience, new input is markedly decreased, thus allowing the old memories to be released and to be psychodynamically experienced as hallucinations, dreams, or fantasies. When faced with imminent death, a person's thoughts often turn to God, heaven, and culturally accepted religious images.

Many scientists believe that the imagery and sensations of the near-death experience are caused by biologic processes and mediated by cultural expectations. Another example of a biologic process that results in a strange experience occurs when a person whose painful limb had been amputated feels pain as if the leg was still present. This phantom limb pain starts at the limb stump and persists in the sensory centers of the brain. A different type of experience, the autoscopic phenomenon, is associated with epilepsy and migraine headaches. It consists of the sudden, brief perception of a person's face or body as a colorless, transparent phantom that imitates the person's actions. The German writer Johann Wolfgang von Goethe described a likely autoscopic experience when, while horseback riding, he saw an approaching horseman who was his double and who then rapidly disappeared. The biologic process of sleep paralysis is associated throughout much of the world with culturally elaborated beliefs and visions of a ghost, the spirit of a dead person, or an "old hag" who presses on the sleeping person's chest. The Hmong of Cambodia claim that they see a tiny figure, or demon, which crushes their chests. In fact, so many young Hmong men die in their sleep that a sudden unexpected nocturnal death syndrome is now medically recognized. It is a genetic disorder that causes fatal ventricular arrhythmia. Survivors describe intense fear, paralysis, and pressure on their chests caused by an alien being.

Most persons endow their near-death experience with a favorable spiritual explanation, such as having been "touched by the light," which supposedly has some association with heaven and with God. Many religious traditions associate darkness with hell and the forces of evil, whereas light epitomizes heaven, goodness, and God. In *The Divine*

Telegram: @medical_k

www.konkur.in

Comedy, one of the greatest literary evocations of God in Western literature, the poet Dante saw in Paradise both a cross that brilliantly "flames forth Christ" and God, "the eternal light." Unfortunately, some near-death experiences are not so splendid. In various studies, up to 22% have been described as hellish and terrifying, with the person having a sense of being condemned to a barren void for eternity or falling into a demon-filled pit.

ALIEN ABDUCTIONS: A PSYCHOSPIRITUAL PHENOMENA? A few individuals believe that they were abducted by extraterrestrial aliens. In many reports, these abductions occur at night in a rural setting while the victim is driving a car and spots a UFO. The victim may stop to investigate, or the car will stop because of mechanical failure presumably induced by the UFO. The driver and passengers, if any, get out of the car, become amnesic for several hours, and then regain awareness. Usually, they are mystified by the lost time, but in subsequent dreams, hypnotic sessions, or regression therapy to recover memories, they remember being paralyzed, transported in a beam of light, and abducted by gray-skinned humanoids with large heads and very large, dark eyes. During this terrifying experience, the victims report being surgically probed, having devices implanted in their bodies, and being sexually abused or impregnated by the aliens. A few victims may have some sort of mystical experience, but this is soon followed by medical and psychological problems.

This scenario seems to be a North American phenomenon that first received public attention in the 1960s. Well-respected psychiatrists and psychologists who have interviewed persons claiming to be abductees have found them to be rather ordinary, with a level of mental health reflecting that of the general population. Many have created support groups and a subculture devoted to explaining the abductions, including the belief that they represent alien attempts to better understand human beings or to repopulate the Earth with human-alien hybrids, secret government mind control experiments, and so on. Similar reports of abductions from around the world tend to be more benign, with the abductors being demons or spiritual entities.

The physical reality of the abduction phenomenon is scientifically absurd, but there is no doubt that it might be a culturally elaborated psychospiritual reality. As reports of abduction rely so often on the recovery of lost memories, one theory is that the basic repressed memory

Telegram: @medical_k

www.konkur.in

is of childbirth: The fetus is forcibly plucked from the safety of the womb and placed in an alien, cold environment; bright lights are shined on it, and it sees the eyes of masked strangers who probe its body. Because newborns cannot distinguish colors, the strangers appear to be gray, which accounts for the perception of abductors as "grays."

The historical, religious, and anthropologic literature of the world contains accounts of many visionary encounters with deities, demons, and ancestors. The Hebrew Bible, for example, reports encounters with God and his surrogates. In 1149, an Irish monk wrote *The Vision of Tundal,* a highly successful book that was translated into most of the languages of Europe. Tundal saw Satan in hell viciously torturing sinners. At that time, no one doubted the veracity of Tundal's accounts or those of many other writers. The slow demise of visionary encounters began with the publication of Dante's *The Divine Comedy* in the 14th century. Dante provided a compelling and profound first-person account of his voyage to hell, purgatory, and heaven but admitted it was a poem derived from his imagination. In Western culture, skepticism about visions continued through the 17th and 18th centuries up to modern times, in which visions have usually been associated with psychosis, although in folklore and shamanic and some tribal cultures, visions are accepted as reality.

In today's world, only a few persons believe in the physical reality of the abduction phenomenon, a surprisingly larger number would endorse its possibility, and the vast majority reject the idea. John Mack, the most serious psychiatric investigator of the phenomenon, concluded that it is a modern type of visionary experience but overoptimistically felt that it might portend a dramatic change in human consciousness and a blow to the world's collective egoism in the tradition of Copernicus, Darwin, and Freud. Although it may be futile to try to convince abductees that their experiences were delusional and not physically real, Mack determined that many eventually come to regard the phenomenon more positively in that it resulted in a broadening of their consciousness.

TOUCHED BY ANGELS. Belief in guardian angels is a staple of both New Age spirituality and most persons who consider themselves religious.

Computer search engines typically show more than 2 million "guardian angel" sites ranging from offering guardian angel pins, wallpaper, and poems to tattoos, newsletters, and dog rescue teams specific to certain breeds. Large bookstores have sections devoted to angels, and in the

Telegram: @medical_k

www.konkur.in

film, *It's a Wonderful Life,* one of the most-watched movies of all time, a guardian angel saves the day. There have been literally millions of testimonials throughout history, especially in the last half-century, attesting to the power of a person's guardian angel miraculously to heal relationships and illness, provide expert guidance in life decisions, expand consciousness and spiritual evolution, and render material support in hard times. In his 1975 best-seller *Angels: God's Secret Agents,* the evangelist Billy Graham's language was probably influenced by the recent U.S. experience in Vietnam. He wrote:

> "All of the major religious traditions profess a belief in angels or similar spiritual beings, who usually are considered to be God's messengers and bringers of good news."

Treatment Issues. There is much confusion in both the literature and in most people's minds, including psychiatrists and patients, because of the conflation of the terms Spirituality, spirituality, spiritual, religion, and religiosity (or religiousness). The word Spirituality should be used to refer to the extraordinary moment or brief period of time during which a person feels a special connectedness to living beings, other forms of life, nature, causes, sacred or culturally significant artifacts, the universe, supernatural entities, or even ancestors. This feeling is special because it strikes deep into the perceived inner core of a person as a revelation or epiphany that cannot be fully described in words. Spirituality appears suddenly, and it is possible for some persons to cultivate its reappearance. Some religious mystics, St. Teresa of Avila, for example, described multiple episodes of a transcendent connectedness with God. In a secular context, the polymath S. Giora Shoham described "experiences of blissful temporary dissolution of the self's cognitive partitions" while watching the sun set behind some ruins of the Mediterranean shore while the waves, the darkening sky, and his self fused into an opaque unison. He developed a capacity to recapture the experience; for example, "By concentrating on the yellow petals of a wild chrysanthemum while the petals extended and widened, my whole self was engulfed into a vision of a single omnipresence." Some patients report having had such a moment of Spirituality (not to be confused with moments of therapeutic clarity or insight) that influenced them to lead spiritual lives. The experience of Spirituality is a highly prized phenomenon but cannot be induced by psychiatric expertise, which can only enhance the probability that it might occur.

www.konkur.in

The Spiritual Life. Patients seek psychiatric treatment because they feel ill and beset by stress and suffering. Increasingly, medication has become the most common treatment modality, but supportive psychotherapy should be an integral component of every clinical encounter, even brief ones. As opposed to more traditional psychotherapy that occurs over an extended period of time and symptom-focused, shorter-term cognitive and behavioral forms of therapy, supportive therapy is the most difficult. It presupposes that the psychiatrist understands the basic nature and course of an illness, the individual psychological and social dynamics of the case, and the patient's cultural beliefs and practices. The psychiatrist then uses this information to ensure treatment compliance through advice, exhortations, admonitions, and even threats, such as commitment to a hospital. The psychiatrist's duty should be not only to reduce or eliminate symptoms but also to enhance a patient's quality of life.

Biologic interventions rarely cure mental disorders, but they do make it possible for patients to deal with the issues that cause them stress and suffering. Through advice, exhortations, and so on, the psychiatrist's role is to point patients in the right direction on life's path. Some advice is immediately practical—for example, get a payee to help with finances or move to a different apartment to avoid the drug dealers next door. Much of the advice, however, is geared toward having patients lead spiritual lives, even if the adjective *spiritual* is not articulated by the psychiatrist or the patient.

Some of the things that constitute a good spiritual life are based on mundane experiences such as doing charitable deeds; heeding one's marriage vows; appreciating the beauty of nature; accepting the responsibilities of parenthood; caring for pets; protecting the environment; visiting the ill; forgiving those who have harmed one; maintaining good relationships with parents, relatives, and neighbors; caring for the integrity of one's body; cheering for a favorite sports team; supporting the troops, in whatever fashion one envisages; engaging in civic affairs; developing hobbies; maximizing one's talents and special abilities; refraining from illegal activities; not drinking to excess; and so on. However, no one is perfect, and a person does not have to be a saint to lead a mostly spiritual life. Very few people can follow all these precepts all of the time. There will be occasions when laziness, envy, affairs, divorces, drunkenness, and other problems will appear on the scene. When this occurs, it is the

Telegram: @medical_k

www.konkur.in

psychiatrist's role to minimize their deleterious effects and provide advice to help a patient get back on track.

THE RELIGIOUS LIFE. For some patients, a spiritual life includes religion, a facet of life that provides for both much that is wonderful and much that is horrible in human experience. In his 1902 masterpiece *The Varieties of Religious Experience,* the psychologist William James went so far as to declare that religion is an essential organ of a person's life and that it performs a function that no other portion of human nature can fulfill. He wrote that during a special state of mind known only to religious persons:

> What we most dreaded has become the habitation of our safety, and the hour of our mortal death has turned into our spiritual birthday. The time for tension in our soul is over, and that of happy relaxation, of calm, deep breathing, of an eternal present, with no discordant future, has arrived. Fear…is positively expunged and wasted away.

A contrary view is articulated in Sam Harris's 2005 book *The End of Faith: Religion, Terror, and the Age of Reason,* in which he provides voluminous accounts of the historical and current episodes of bloodshed and terror spawned by religion, such as the killing of heretics and the suicide bombing of innocent civilians.

When psychiatrists are sure that religion is not a factor in patients' psychopathology and that their participation in religious activities fosters a spiritual life, patients should be encouraged to follow their religious proclivities. Many patients find much solace simply in reading holy scriptures, even though most sacred books can be difficult to understand, contain conflicting messages, and may even lead to invidious and harmful acts if interpreted concretely or wrongly.

There is much to be said for the value of participating in organized religious activities and holding religious beliefs. Certainly, each religion imposes its particular order on life and provides rules for living that, if followed, usually result in the belief that an externally felicitous afterlife will be achieved. It gives hope to all impoverished, unfortunate, disfigured, badly treated, sick, lonely, and dying people that they might be happy and blessed in the next world, be it heaven, Nirvana, or the happy hunting grounds. Questions about the meaning and purpose of life arise, particularly in old age and during palliative treatment. In such situations, believers want to hear religious explanations rather than medical clichés. Questions about faith are also common in traumatized patients who feel abandoned by God and experience survivor guilt. Wounded soldiers may

Telegram: @medical_k

www.konkur.in

feel that they deserve to be tormented as a punishment for their wartime activities. A traumatic event may become so central to victims' lives that, especially in times of crisis or severe stress, they re-enact it in their minds or, more tragically, in their behaviors as a pathologic form of worship. A religious approach to their therapy is often needed to provide a more benign object of worship.

By belonging to a caring religious community, persons can count on emotional and material support in times of crisis, but the largest study on religion and coping with crises found that "On the face of it, people appear to be able to cope just as effectively without religion as with it." Furthermore, religious rituals in times of crisis were helpful in 40% of cases and harmful in 23%. It would seem that even for true believers, the faith, hope, and compassion offered by religion might be necessary but not sufficient for coping with crises or dealing with illness.

There is a growing literature demonstrating some health advantages for persons who attend religious services. One explanation is that better physical health leads to an increased ability to attend services. It may reflect a placebo effect or simply a correlation. There is little information comparing the relative health advantages among religions or branches of religions: Do Muslims have greater health advantages than Christians, Jews, or Hindus? How do Baptists compare to Catholics or Pentecostals? At any rate, depending on the results of a spiritual assessment, psychiatrists should encourage church-going patients to continue their religious practices. Lonely, shy, or morally lost persons who have stopped attending religious services for any number of reasons (panic attacks, getting caught up in other activities, etc.) but for whom religion was once important should be gently encouraged to at least consider searching for a church and a congregation where they feel comfortable.

Prayer is the most common form of religious worship, and there is no reason for psychiatrists to dissuade patients from praying because it does no harm but rather offers hope and consolation. Hands-on prayer often provides comfort and temporary relief from some illnesses and can be explained by psychological mechanisms. Studies of prayer-at-a-distance in which prayed-for sick persons are unaware they are being prayed for implicitly test a supposed supernatural mechanism. Such studies have not demonstrated any advantages to such subjects. A major study of 748 patients with coronary artery disease who were undergoing certain cardiac procedures showed that neither prayer-at-a-distance nor bedside

Telegram: @medical_k

www.konkur.in

MIT (music, imagery, and touch) therapy significantly affected the primary clinical outcome measure. A confounding variable in these studies is that nonprayed-for control group subjects may be offering their own prayers or know that relatives, friends, or even hospital staff are praying for them.

FIGURE 30.7–5. St. John writing his Gospel, as portrayed in a painting in St. Isaac's Cathedral in Saint Petersburg, Russia. The eagle was his representative animal and indicates the spreading of John's Gospel throughout the world. (Domenichino. National Gallery, London.)

For Christians, the New Testament contains seemingly difficult-to-understand comments on prayer. In three instances, the Gospels promise that believers who pray to God will have their prayers answered. When prayers are not answered, however, the explanation offered is that even Jesus was unable to convince God the Father to spare him from his crucifixion, recognizing that God's will must take precedence. In other words, God only answers prayers that conform to his will, and there is no way to convince him otherwise. Whatever happens, *is* God's will. Nonetheless, Christians continue to offer intercessory prayers for themselves and others. Pastoral and Christian counselors often pray with patients, as do some psychiatrists. As a general rule, however, when patients ask psychiatrists to pray with them, the most judicious response

Telegram: @medical_k

www.konkur.in

is for psychiatrists to say that they will witness the patients' prayers in respectful silence (Fig. 30.7–5).

Domesticity, particularly in Christian families, may be threatened when a family member is discovered to be a homosexual. Either the homosexual person, who may be depressed, or his angry family members may seek psychiatric treatment because, in their tradition, homosexuality is reviled as an unnatural, repulsive condition. For Christians, the basis for this attitude is biblical. The book of Leviticus contains laws that God presented to Moses; verse 20:13 reads, "If a man lies with a man as he lies with a woman, both of them have committed an abomination. They shall surely be put to death. Their blood shall be upon them." Death sentences are also proscribed for adulterers, men who sleep with their father's wife or their daughter-in-law, people who mate with animals, and fortune-tellers. The hundreds of Levitical laws condemn many behaviors, such as trimming one's beard; sitting on a seat that a menstruating woman has sat on; letting defective people such as those who are blind, dwarfs, have marred faces, very long limbs, or eczema defile the Temple sanctuary by their presence; touching a mouse; eating shellfish, rabbits, or pork; and wearing garments made of a mixture of linen and wool.

Psychiatrists should at least be aware that the concept of homosexuality, as we know it currently, did not begin to take shape until the 11th century when St. Peter Damian coined the word "sodomy." Before then, persons who were intimate with members of their own sex were simply regarded as persons with special sexual preferences. Other biblical references to "homosexuality" are ambiguous and can be interpreted in differing ways. For example, for at least two millennia, the destruction of the city of Sodom was attributed to the lack of civility and hospitality to God's angels rather than to homosexual activity. John Boswell's *Christianity, Social Tolerance and Homosexuality,* and Armando Favazza's *PsychoBible* are books that might be consulted by psychiatrists and patients for more details on this issue.

Psychiatrists should also be aware that, according to Christian theologians, Jesus overturned the Levitical laws and that Christians are neither expected nor obligated to follow them. Some theologians, however, hold that only the ceremonial laws were overturned. Even if this were the case, Christians have no problem with men being in close presence with menstruating women, men trimming their beards, and people eating pork, and they certainly do not condemn adulterers or

Telegram: @medical_k

www.konkur.in

fortune-tellers to death. The persistent Christian fixation on homosexual behavior as unnatural and homosexuality as a deliberately chosen preference is irrational from the perspective of psychiatry, which dropped homosexuality from its list of mental disorders in 1973. Fortunately, the Western culture is showing more and more acceptance of homosexuality, along with the realization that both homosexual and heterosexual persons may lead spiritual lives.

Psychiatrists are often called on to treat abused women and should be alert to the possible misuse of religion in such situations. The Semitic religions originated in patriarchal cultures, and many of their beliefs and practices reflect a belief in the superiority of men over women. The book of Ecclesiasticus, found in Catholic and Greek Orthodox Bibles, states, “From a woman (Eve) sin had its beginning, and because of her we all die.” In the book of Numbers, women are classified as chattel property. In the New Testament, Paul notes that “the head of every woman is man,” and this view is repeated in various writings: For example, “Wives, submit to your own husbands, as to the Lord” (Ephesians 5:22), and “Wives, be submissive to your own husbands” (1 Peter 2:3). In the nonbiblical Gospel of Thomas, Peter the disciple says to Jesus, “Let Mary [Magdalene] leave us, for women are not worthy of life.” Jesus replies, “I myself shall lead her in order to make her male, so that she also may become a living spirit like you males.” St. Augustine, four centuries later, settled things by declaring that man, either alone or when joined by his wife, is the image of God, whereas women alone are not. However, the Old Testament also states in Genesis 1:27, “So God created man in his own image, in the image of God he created him; male and female he created them.”

Some Christian, Jewish, or Muslim men may misuse religion by citing sacred texts to rationalize the humiliation and abuse of their wives. By using passionately pious appeals, abusers may gain the support of their in-laws and congregations. Psychiatrists who treat the victims of such persons may be portrayed as evildoers who subvert the will of God unless they endorse the status quo. However, if therapeutic efforts to ameliorate the abusive situation fail, divorce must be considered, even though the patient may find herself estranged from her family, her congregation, and maybe even her religion. Escaping from an abusive relationship is a spiritually wise decision.

Specific Spiritual Therapies. Alcoholics Anonymous (AA) exemplifies the clinical efficacy of treating a specific illness by leading a spiritual life. The movement started in 1931 when a wealthy American alcoholic was unsuccessfully treated for a year by Carl Jung. Jung advised him to place his hope in a spiritual experience, which he eventually found in the Oxford Group, an interdenominational organization devoted to re-experiencing the dynamism of Christianity's early days through inspirational talks, group discussion, and mutual support. His religious conversion and the process through which he achieved it was a founding moment of AA.

One of his alcoholic friends also experienced a conversion and, in 1934, tried to convince an alcoholic stockbroker named Bill Wilson that religion was the answer. Wilson responded by going on a drinking binge, was hospitalized by a psychiatrist, and cried out for God to show himself. He then experienced a moment of Spirituality: "Suddenly the room lit up with a great white light. I was caught up in an ecstasy where there are no words to describe." He pictured himself on a mountain in a Spiritual windstorm. "And then it burst on me that I am a free man." As the ecstasy subsided, he experienced,

> A new world of consciousness. All about me and through me there was a wonderful feeling of Presence and I thought to myself, 'So this is the God of the preacher.' A great peace came over me and I thought that no matter how wrong things seem to be, they are all right.

AA is not a religion, although it comes close, and some critics have called it a religion in denial. It is not a Christian organization either, but its roots are in Christian teachings. Each of its famous 12 steps contains a spiritual message, such as the necessity for alcoholics to turn their will and lives over to the care of God as they understand him; to make a searching and fearless personal inventory; to make direct amends to persons that they have harmed; and to carry the AA message to other alcoholics and to practice these principles in their lives.

According to AA, alcoholics' acceptance of self as human is founded on their rejection of any claim to be more than human. AA members must accept the limitation of their being: An alcoholic cannot drink alcohol safely. Formal religions take personal limitations as a problem that can be overcome by participation and belief in the mechanisms of salvation offered by a particular church. Religion aspires to perfection and contains what it considers to be absolute truths. However, organized religion

Telegram: @medical_k

www.konkur.in

promised too much for the founders of AA. When asked why AA separated from the Oxford Group, Bill Wilson replied, “The Oxford Group wanted to save the world, and I only wanted to save the drunks.”

Another example of a psychiatric therapy that utilizes guidelines for achieving a spiritual life is found in a series of DVD modules, *The Happy Life—Voyages to Well Being,* developed by the psychiatrist C. Robert Cloninger. The modules attempt to enhance character traits associated with frequent positive emotions and to enhance a sense of hope and mastery for self-directedness, kindness, forgiveness, cooperativeness, mindfulness, and finding spiritual meaning. The therapy begins with a focus on what makes patients happy or unhappy, the experience of well-being, and awakening their physical and spiritual senses. Patients then observe and strive to elevate their thoughts and human relationships, chart their maturity, and contemplate their being. The therapy ends with modules on stress reduction, quieting fears, observing the power-seekers in their life, contemplation of mysteries, and constant awareness. Although a happy life for patients is supposed to be a result of the therapy, there is a branch of psychology devoted to searching for what actually constitutes happiness. The theologian–physician Albert Schweitzer, who became depressed after concluding that Jesus had not really been resurrected, noted that “Happiness is nothing more than good health and a bad memory.” This new form of therapy is based on some solid research findings; for example, low self-directedness scores on the Temperament and Character Inventory indicate a vulnerability to major depression, whereas high scores predict a rapid and stable response to both antidepressant medication and cognitive-behavioral therapy. Whether this therapy will be widely used or proven effective is still unknown.

Evidence from psychological studies of personality points to a biologic consideration for a partial understanding of spirituality. A widely accepted model of fairly stable core personality traits rooted in biology identifies five dimensions: Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness. Each dimension has associated descriptors or facets such as degree of emotional stability, compassion, self-discipline, and so forth. Characteristics of the five dimensions arise because of environmental forces and result in the development of beliefs, attitudes, goals, and a sense of self. Adaptations come into play during a person’s lifetime experiences and are translated into behaviors and emotional reactions. In research findings, Openness to Experience,

Telegram: @medical_k

www.konkur.in

Extraversion, and Agreeableness correlate highest with spirituality. A recent study among persons from differing faith traditions suggests that spirituality may be a sixth core personality dimension. The core personality traits impacted health outcomes in this study, but spirituality and religious subscales did not. Only the forgiveness subscale predicted better mental health outcomes. Forgiveness is one of Vaillant's positive emotions that comprise spirituality, but it is possible to regard forgiveness as a coping strategy that is related to but distinct from spirituality.

The "hard-wired" for God/spirituality concept is popular, especially in the lay press, and has given rise to the pseudoscientific field of neurotheology with notions of God genes, neurons, and neurotransmitters. Monoamine neurotransmitters have been identified in a popular book as the molecules partly responsible for self-transcendence and spirituality. A variation in the vascular monoamine transporter 2 gene in some persons supposedly enhances a tendency for spirituality. However, the book ends with a strange disclaimer: Spirituality may be partly genetic, but genes are like verbal cooking recipes, and what you end up with depends upon how you interpret and execute the directions.

Most people believe that almost any type of meditation does no harm and probably does some good just by reducing stress. But only some types that are readily accessible, such as mindfulness, hold the promise of achieving spirituality. In most instances, mindfulness is practiced in group workshops, although it may be utilized in conjunction with cognitive-behavioral therapy. The attainment of mindfulness spirituality is a gradual process and may take years of hard work. In 2014, the U.S. Agency for Healthcare Research and Quality issued a review of 41 meditation trials with matched control groups. The review revealed that mantra meditation had very little if any effect on psychological stress and well-being outcomes, while mindfulness meditation had a moderately positive effect on anxiety, depression, and pain. The conclusion was that meditation programs were not more effective than exercise, progressive muscle relaxation, cognitive-behavioral therapy, or drugs in changing health outcomes. The review did not address the issue of spirituality.

30.8 Physician and Medical Student Mental Health

NEETA JAIN, M.D., AND CYNTHIA M. STONNINGTON, M.D.

The World Health Organization (WHO) defines mental health as “a state of well-being in which the individual realizes his or her own abilities can cope with the normal stresses of life, can work productively and is able to make a contribution to his or her community.”

CURRENT FORCES IN HEALTH CARE

The U.S. health care delivery systems have undergone enormous shifts over the last two decades. Consolidations and mergers greatly transformed practice structures, with many physicians now serving as employees within a larger network. Health care regulations and policies, such as the Affordable Care Act and the narrowing of commercial insurance networks and noncommercial insurances (Medicare, Medicaid), resulted in declining reimbursements. Widespread implementation of electronic medical records (EMRs) was associated with increased clerical burden due to requirements of new quality metrics, charting completion for billing purposes, and answering inbox messages, all of which lengthened workdays well into evenings and weekends (an additional 28 hours per month on nights and weekends). These “efficiencies” created a greater expectation of productivity, usually increasing workloads with the same amount of time/resources, that is, efforts to improve efficiency came at the expense of physician autonomy. Furthermore, competent and acceptable practice required physicians to stay abreast of an expanding knowledge base, implement the latest updates on regulatory requirements (meaningful use, medication reconciliation, electronic prescribing), complete burdensome maintenance of certification requirements, and face new levels of scrutiny with quality metrics and patient satisfaction surveys. These factors have taken a personal toll on health care professionals. Physicians, trainees, and learners are therefore particularly vulnerable to

Telegram: @medical_k

www.konkur.in

experiencing burnout and mental health difficulties by the nature of their workplace demands.

The impact of burnout was not only recognized as taking a toll on the individual clinician, but mounting evidence pointed to a link between burnout and quality of care, medical errors, patient satisfaction, declining productivity, and turnover, all burdening health care organizations with further financial costs. Institutions began expanding the triple aim of reducing costs, improving quality, and increasing patient satisfaction to a quadruple aim that further includes health care professionals' wellness. Medical and resident education has begun appreciating the impact of the learning environment on well-being and the need for adequate resources to support mental health in recent years. Hippocrates wrote the infamous oath in the fifth century obliging physicians to "first do no harm" to patients but disregarded to include harm to oneself. Many medical schools use the modern version of the Hippocratic Oath to include a pledge "an awareness of my own frailty."

COVID-19 Impact

Not surprisingly, health care workers can experience significant psychological distress during an epidemic or pandemic. In January of 2020, the first reported coronavirus disease (COVID-19) case appeared in the United States. In a relatively short period, the spread of the virus led to a worldwide pandemic. As was previously observed with the SARS and Ebola epidemics, the sudden onset of life-threatening illness led to exceptional levels of pressure on health care professionals. In this instance, health care workers and health care systems were faced with limited access to personal protective equipment (PPE), testing, and treatment. Early in the pandemic, 20% of the workforce caring for those with COVID-19 became infected themselves, and many physicians witnessed colleagues becoming seriously unwell or dying due to their work. Many states implemented a lockdown with many physicians abruptly required to work remotely from home, limiting direct contact with not only patients but coworkers and colleagues, increasing social isolation, and affecting family systems, with schools switching to online education and parents now straddling a new work–life schedule entirely at home. As a society, this pandemic robbed the natural inclination to seek human comfort from loved ones such as family and friends, delivering a more severe impact than other disasters.

Telegram: @medical_k

www.konkur.in

Frontline workers directly responsible in caring for COVID-19 patients not only had to face shortage of PPE, but were subjected to evolving and changing treatment guidelines, and felt inadequately supported with weighing responsibilities. Unfortunately, health care professionals entered the COVID-19 outbreak with an “empty tank,” as evidenced by multiple studies reflecting a high prevalence of stress, anxiety, and burnout among health care professionals, trainees, and students in the preceding decade. This pandemic strained the health care systems nationally and globally, reinforcing the concern for health care workers, including physician, resident, fellow, and learner burnout. The mental health impact of COVID-19 on health care workers became a major concern. The studies showed an increase in acute self-reported symptoms of depression and anxiety, as well as high rates of insomnia, substance use, and distress. A variety of studies from different countries and settings surveying health care workers during the COVID-19 pandemic revealed substantially increased prevalence rates of moderate to severe anxiety, depression, insomnia, and traumatic distress, compared to 2019. Long-term follow-up studies of health care workers who have worked in previous pandemics, for instance, the 2003 outbreak of severe respiratory syndrome, suggest that as many as 1 in 10 with early distress symptoms will have progressed to long-lasting mental health conditions for some individuals, such as post-traumatic stress disorder (PTSD). According to the Institute of Medicine, during the SARS outbreak of 2002–2003, four ethical issues arose: the roles and responsibilities of medical workers, the impact of infection on the global economy, equitable care, and the challenge of balancing public welfare and individual rights.

In the training manual for mental health and human service workers in major disasters, published in January 2000, Dr. Deborah DeWolfe outlines the psychosocial and emotional phases of disaster, including warning/threat, impact, rescue or heroic, honeymoon, inventory, disillusionment, and reconstruction or recovery. At the outset of a disaster, providing daily communication, adequate PPE, and developing safety protocols are top of mind. In the immediate aftermath, or “heroic” and “honeymoon” phases, the community comes together, appreciates the “heroes,” and may accept mental health interventions if offered. Psychological first aid is an approach used to help people in the immediate wake of a disaster decrease their acute level of distress and encourage short- and long-term adaptive functioning. During the

Telegram: @medical_k

www.konkur.in

disillusionment phase, the earlier feelings of optimism turn to discouragement and physical and emotional exhaustion and feelings of abandonment. During this time, we often see increased demand for psychiatric services. The disillusionment phase can last months and even years and is often extended by one or more trigger events, usually including the anniversary of the disaster. Similarly, the reconstruction phase may last for years, involving working through grief and loss and post-traumatic growth.

Beyond psychological first aid, a variety of services and programs can help health care professionals process the losses and stressful clinical events that they encounter. “Schwartz rounds,” for example, involve bringing staff of all levels together to have conversations about the emotional impact of their work. Peer support training teaches active listening skills, empathy, and validation so that peers can be mobilized to reach out to colleagues with offers of support. They can also normalize help-seeking when their colleague may need more professional help. Employee assistance programs and counseling services for learners are critical resources for those needing additional support. “Psychological PPE” and a variety of community and peer support offerings may gather steam during disasters but ideally would robustly always remain in place, given the prevalence of burnout, stress, and mental health conditions that physicians face even when there is not a global pandemic.

BURNOUT

The field of medicine is a highly competitive and demanding profession that attracts high-achieving and ambitious individuals. By the nature of the training, physicians have been able to endure long hours, irregular and/or inflexible schedules, increasing workloads, emotionally taxing situations, and stress that surpasses most other work environments. A growing body of literature has demonstrated a greater prevalence of occupational distress among physicians compared to the general workforce. The research has been rapidly expanding, with concerns for “burnout and moral injury” rising to a national level of public health concern.

Burnout was first recognized in many workplaces in the United States in the 1970s. This can affect workers, particularly those whose work involves an intense interaction with people (i.e., teachers, social workers, police officers, health care workers). Burnout syndrome was first described in

Telegram: @medical_k

www.konkur.in

1974 by psychologist and psychoanalyst Herbert Freudenberger, Ph.D., who often volunteered at a free clinic for substance abusers in East Village of New York City. He observed that over time, volunteer clinical staff were emotionally depleted with accompanying psychosomatic symptoms. He borrowed the term “burnout” from drug-addict slang, with the burning out of substance abusers on the street with those mental health providers who tried to help these substance abusers. Independently, Christina Maslach, Ph.D., became interested in related work issues about the same time. She developed a method for assessing burnout as a multidimensional construct by creating the Maslach Burnout Inventory (MBI) with three subsections for a total of 22 questions in 1981. Burnout has been commonly characterized by a clinical constellation of symptoms of emotional exhaustion, depersonalization (DP), and decreased feeling of personal accomplishment (PA) that result from the chronic stress of medical practice. Emotional exhaustion is when an individual feels emotionally drained and has no more to give as a caregiver. This feeling of being unable to replenish differs from depression and compassion fatigue, with the caregiver beginning to distance themselves as a protective mechanism. This can lead to DP with the arising of cynicism and detachment toward the patient. A lower personal sense of accomplishment is the result, with less efficiency at work and a lower sense of pride and job satisfaction.

Burnout is not an expected reaction to hard work, though deeply satisfying work can involve tremendous personal sacrifice. It is not the same as depression, yet severe burnout can evolve into it. For burnout to be present, interpersonal stress in the workplace is present to some degree. Self-valuation appears to be particularly low for physicians and an important contributor to burnout, for example. The interactions between individuals and organizational factors likely contribute to a high burden of responsibility, neglecting self-care and needs, low perceived control, discordance between individual and organizational values, unsupportive work environments, isolation, and loss of meaning. The components of emotional exhaustion and DP are most commonly affected. Initially, burnout might coexist with empathy, satisfaction, and caring, but unrelieved work stress for months diminishes the ability to call forth and sustain those attributes. Burnout is not an acute self-limited illness. Numerous publications have confirmed that burnout is not confined to specific practice settings (academic, government, or private practice) or

Telegram: @medical_k

www.konkur.in

career stage. For an individual to experience burnout, the presence of only one of these symptoms needs to be present. The highest rates of burnout are found among physicians in emergency medicine and the lowest rates among preventive medicine/occupational medicine. In 2019, WHO revised the definition of burnout, which aligns with but is different from the Maslach paradigm: burnout is a syndrome conceptualized as resulting from chronic workplace stress that has not been successfully managed. It is characterized by three dimensions: (1) feelings of energy depletion or exhaustion (EE); (2) increased mental distance from one's job, or feelings of negativism or cynicism related to one's job, that is, DP; and (3) reduced professional efficacy or PA. Burnout refers specifically to phenomena in the occupational context and should not be applied to describe experiences in other areas of life.

Determining the scope of physician burnout is challenging. There is substantial heterogeneity in the research method and definitions employed by investigators studying burnout, including variability in the measures used to evaluate burnout symptoms. Studies have varied in sample size, practice settings, clinician types, and participation rates. The first large, national study on burnout among U.S. physicians across all specialties was published in 2012 by Tait Shanafelt and colleagues. There were 7,288 participating physicians, with approximately 45% experiencing at least one symptom of burnout. Furthermore, this study revealed that burnout was more common in U.S. physicians than in general U.S. workers. In the past decade, several studies of U.S. physicians found prevalence rates of burnout ranging from 40% to 54%, although with variable methodologic definitions and scales.

Personal Consequences of Physician Emotional Distress

Physicians of all ages experience a milieu of emotions from guilt, despair, and isolation after a complication or judgment call with devastating consequences. Physicians suffer, generally silently, when dealing with bad outcomes, and peer reviews or mortality and morbidity rounds offer minimal comfort. Numerous studies have shown positive associations between physician emotional distress and a range of deleterious physical and psychological conditions, including increased risk for cardiovascular disease, high cholesterol levels, type 2 diabetes, musculoskeletal pain, fatigue, headaches, gastrointestinal issues, respiratory problems, and severe injuries. Resident physicians with burnout have shown higher rates

Telegram: @medical_k

www.konkur.in

of needle sticks, bodily fluid exposures, and motor vehicle accidents. Clinicians experiencing burnout may also have higher rates of alcohol misuse, which may be related to self-medicating to cope with job-related stress.

Factors Driving Burnout

In the mid-1990s, Linzer et al. identified four factors associated with burnout in primary care practices: (1) lack of control over work conditions and decision making; (2) time pressure with emphasis on productivity; (3) a chaotic and inefficient work environment that inappropriately burdens physicians to do clerical and other mundane tasks; and (4) lack of alignment among physicians and executives regarding values, mission, purpose, and compensation. Factors that can increase the risk of burnout in health care environments include job demands (work frequency, duration, and intensity), higher workloads and time pressure (working more than 52 hours/week, night calls, and taking work home), computerized physician order entry, 24/7 remote access to patient records, tests results, and administrative burdens. This is often combined with a low level of autonomy or flexibility with work schedules. Some data suggest that patient portals may increase patient phone calls and overall workload, creating additional work for health care professionals. Remotely accessing electronic health records on personal time is stolen time from families and personal activities. Clinical documentation and online patient messages are not the only professional tasks clinicians might perform on personal time. Continuing Medical Education (CME) and maintenance of certification activities are frequently performed on nights, weekends, and even vacation time, since most organizations do not provide dedicated time for their completion. Clinicians must complete a number of required training modules each year, typically mandated by regulators, covering topics such as patient safety, infection control, the Health Insurance Portability and Accountability Act (HIPAA), and human subject protections. Because the pace of medical knowledge is accelerated and rapidly expanding, the time required to stay current has also increased, which is another demand on personal time.

For academic physicians, time pressures can be particularly acute. Historically, their time has been divided between clinical work, research, and training learners in education. The performance of these physicians is typically measured using an academic yardstick, requiring them to engage

Telegram: @medical_k

www.konkur.in

in educational activities (such as lectures and presentations), publications, and grants within defined time limits as a requirement for retaining their positions. To increase revenue, many academic centers have reduced the proportion of time allocated to scholarly pursuits and increased the time devoted to clinical care without adjusting any of these academic performance expectations. Most academic centers still have similar criteria for publications, presentations, grants, and educational responsibilities, which have increasingly shifted to personal time on nights and weekends. These variables have led to the encroachment of professional tasks on interpersonal time for physicians to a much greater degree than in many other fields. Often, this work is not clearly compensated. These professional activities create problems with work–life integration as well as adequate sleep, which all fuel burnout. Of note, physicians who were able to spend >20% of their professional time on what they valued most personally were less likely to experience burnout. Finally, a culture of prioritizing patient care and being “tough” over personal needs and help-seeking has created work–life conflicts, inadequate support or space to process stressful clinical events, and increased risk of workplace attrition.

In a consensus report released in 2019, the National Academy of Medicine developed a systems-based framework that conceptualizes clinical burnout as a consequence of frontline care delivery, health care organization, and external environmental factors. The report highlighted the need for efforts to both prevent and address burnout among clinicians through the engagement of health care organizations, electronic health record developers, private payers, and other stakeholders. Accordingly, the American Medical Association (AMA)’s STEPS Forward initiative was developed as a national tool kit for disseminating strategies to ameliorate physician burnout and improve patient care and cost containment.

Consequences of Burnout

The phenomenon of burnout affects all medical disciplines. It has been associated with increased medical errors, lower patient satisfaction, longer postdischarge recovery times, and decreased professional work effort. In addition, a direct negative impact is seen on fatigue, stress, anxiety, depression, substance abuse, suicides, poor quality care, early retirements, and unexpected resignations. Furthermore, higher rates of absenteeism, chronic work disability, hospital admissions due to mental

Telegram: @medical_k

www.konkur.in

and physical disorders, higher turnover, and poorer job performance can occur. Collectively, these factors make it more difficult for health care organizations to maintain an adequate and competent professional workforce. A 2019 study estimated that the economic cost of turnover and reduced productivity due to burnout among U.S. physicians was approximately $4 billion each year.

Moral Injury/Distress

The dynamic challenges of medical practice give way to moral injury, a syndrome that has been noted in military personnel for years and is now increasingly recognized as a source of physician distress. Moral injury is the harm experienced from a violation of moral boundaries. This distress is experienced when clinicians perceive they have participated in an undesirable situation or have been unable to act in accord with their professional and ethical values under conditions of constraint or duress. Pressure to act contrary to ethical standards can arise from patients or their families, clinical teams, or external environments. Pushback on “resilience training” as an answer to burnout grew out of frustration with the current structure of the health care delivery system; targeting the intervention largely on individual physicians, who already have substantial personal resilience, fueled skepticism associated with burnout. Health care professionals described that their ability to deliver necessary care was compromised by the system at large (i.e., insurance, reimbursements, electronic health record) seen in hospitals, clinics, and medical practices. The lack of control over the work environment, lack of balance between effort and reward, lack of transparency and fairness by decision makers, fragmentation of community among providers, and incongruence between one’s personal values and work demands have eroded wellness among physicians. The most common sources of moral distress among physicians were related to a lack of resources that compromised patient care and lack of administrative action.

Personality Traits

It comes as no surprise that many medical students, trainees, and physicians endorse certain personality traits such as perfectionism, competitiveness, intellectualization, caregiver, rigidity, and strong work ethic that make this profession desirable. Focus on these qualities during admission into medical school, residency, and fellowship training

Telegram: @medical_k

www.konkur.in

programs, and physicians seeking to hire a new associate, may self-select individuals vulnerable to mental illness in the future. Ironically, some characteristics such as idealism, perfectionism, and a strong work ethic that allow physicians to excel can make them more vulnerable to burnout. Traditionally, physicians are rewarded for being the first to arrive, not attending to their physical and emotional needs, and being the last to leave. What is it about the culture of medicine? The longstanding sentiment that if you are “not strong enough” to handle the demands, then consider seeking another profession has diminished over time but not entirely disappeared. Some senior faculty and administrators express dismay about the “softening” of the culture and students. There are ingrained aspects of medical culture that may have slowed the process of change. Traditionally held beliefs are that more pressure, more hours, and more demands would lead to better educational outcomes, and with less rigorous training, standards are being lowered. Such perceived beliefs can act as barriers to seeking and receiving the help needed.

Tracy and Robin’s Model of Self-Conscious Emotions provides a well-studied theory about self-conscious emotions in medical education. Congruence between current and ideal self-representation can elicit positive emotions of pride. If there is incongruence between self-representation and ideal self, negative emotions of shame or guilt can be elicited. Medical learners are apt to hold themselves to unrealistic standards of performance. Achieving perfection is a common, if not a pervasive, goal. It is a distinguishing character trait among learners and practicing physicians. Maladaptive perfectionism has been shown to correlate with psychological distress in medical learning. This is often additive with social, personal, and family expectations maintaining a constant level of pressure. Shame and guilt are not inherently tied to this theory. How the learner perceives a negative outcome distinguishes feelings of shame (inner locus of self) compared to a specific action (guilt). If a perfectionist learner frequently falls short but attributes the shortcomings to correctable actions, they are likely to learn and grow. However, highlighting imperfection deficiencies within themselves is likely to elicit a shame reaction, which can lead to withdrawal and disengagement from learning.

While many of these attributes of being fastidious to detail and setting high performance standards for oneself may be beneficial, there is a risk for more harm than good if this mindset is characterized by excessive self-

Telegram: @medical_k

www.konkur.in

criticism leading to psychological distress called maladaptive perfectionism. Maladaptive perfectionism is related to negative feelings and psychological distress, as seen in several studies on health care professional students. It is also strongly correlated with and predictive of future burnout among medical students.

There are several studies on the psychological construct of imposter syndrome. This phenomenon is characterized by a pervasive feeling of inadequacy and irrational fear of being discovered as an intellectual fraud despite one's capabilities and accomplishments. Estimates of prevalence among medical students range from 15% to 50%, with female medical students at higher risk for experiencing significant frequency and intensity of these feelings.

Women in Medicine

Building upon years of progress, women now comprise the majority of enrolled U.S. medical students, according to the 2019 data released by the American Association of Medical Colleges (AAMC). In 2017, women represented the majority of the first-year medical class. Even so, the gender gap with women in leadership positions persists. According to the AAMC 2018 data, women accounted for 16% of medical school deans, 18% of all department chairs, and 25% of full professors. The six academic departments with 50% or more full-time women faculty, such as obstetrics, pediatrics, public health and preventive medicine, psychiatry, dermatology, and family practice, nonetheless lagged in leadership roles and academic promotions for women, with most holding midlevel or associate dean positions. Women aspire to leadership roles equally to men. There is good data that women in leadership roles improve operational performance, advance innovation, promote group performance, and increase recruiting ability. Obstacles to equity that women face remain subtle, with overt biases based on gender stereotypes and work–life conflicts.

Women across the world are affected by sexual harassment in their daily lives. The medical field is no exception. This topic rose in prominence in late 2016 with the rise of the #MeToo movement. A survey in 2016 by Jagsi and colleagues found that 30% of female clinician-researchers reported experiences of sexual harassment compared with 4% of their male counterparts. In 2018, the National Academy of Science, Engineering, and Medicine reported that in a large university system,

Telegram: @medical_k

www.konkur.in

female medical students were “220 percent more likely than non-STEM (science, technology, engineering, and mathematics) majors to experience sexual harassment by faculty and staff.”

In 1993, the Family Medical Leave Act (FMLA) was passed in the United States with the intent of helping employees balance the demands of the workplace with the needs of the family, minimizing gender discrimination, and promoting equality for men and women. FMLA allows for 12 weeks of unpaid job protection. However, the United States remains the only country that does not allocate maternity or paternity leave as a national policy. While these are well-intended policies to promote breastfeeding and provide financial support to women of childbearing age, this reinforces traditional gender roles of women as primary caregivers and stigmatize women.

Professional isolation among women can arise from a relative lack of respect, collaboration, mentorship, sponsorship, and role models and can occur at any career stage. Gender-based isolation may stem from a history of a paucity of women in academic medicine, though this doesn’t fully explain the gaps that remain today. Generational constructs persist in salary, professional opportunities for promotion, and the ability to work flexible hours with adequate work–life integration. Parenthood can pose additional hurdles for early-career mothers and fathers. Finally, compared to men, studies show that women physicians are more likely to be unmarried or be in a dual professional marriage, do more of the domestic duties, spend more time with patients, be assigned patients with more complex psychosocial concerns, have a harder time setting limits with their time, write longer notes, adhere to patient-centered communication and clinical guidelines, and provide preventive care. All the above factors may contribute to the relatively higher burnout and depression rates among women physicians.

Underrepresented Minorities

According to the Perelman School of Medicine at the University of Pennsylvania, African Americans, Hispanics, and Native American students remain underrepresented in medical schools matriculants compared to the U.S. population despite the increasing effort to create a more diverse physician workforce. As of 2019, this underrepresentation did not change significantly since the institution of Liaison Committee of Medical Education diversity accreditation guidelines of 2009. Medical

Telegram: @medical_k

www.konkur.in

schools, graduate education programs, and health systems are increasingly aware of the additional stressors faced by minority learners and physicians and the resultant disparate impact on well-being. Efforts such as new curricula to help raise awareness of implicit bias, structural racism, how to respond constructively to microaggressions, cultural competency modules, allyship groups, mentorship and sponsorship programs, and revamping educational materials and content to better represent and include minorities, promise to reduce marginalization and isolation. However, cultural change is slow, and those experiences may also be internalized, further adding to one's emotional burden and suffering.

MENTAL HEALTH CONCERNS

Illness doesn't belong to us…It belongs to them, the patients. Doctors need to be taught to be ill. We need permission to be ill and to acknowledge that we are not superhuman.

(interviewee quote from McKevitt and Morgan's 1997 qualitative study of doctors who were ill)

The debate continues about the association between burnout and depression. There is symptomatic and epidemiologic overlap; however, burnout arises predominately from workplace problems, whereas depression carries several risk factors with impairment in numerous spheres. Burnout and depression have distinct symptoms and require different interventions. In a large study designed to distinguish associations with burnout and depression, depression was independently associated with suicidal ideation, whereas burnout was directly associated with self-reported medical errors.

Physicians are not immune to a full spectrum of mental health conditions. Mental health conditions may go underrecognized and/or inadequately treated among physicians for various reasons, including reluctance to seek treatment secondary to stigma associated with mental health problems, attempting self-diagnosis and treatment, and receiving "VIP" treatment from other health care providers. There is a general reluctance to admit any emotional "weakness." Like the general population, the most common mental disorders reported among physicians are depressive and anxiety disorders.

Telegram: @medical_k

www.konkur.in

A 2010 literature review found that depression was observed in all stages of medical training. Depression tends to begin in medical school (up to 28% of medical students by the fourth year compared to 8% in the general population). Persistence of depression into residency and clinical practice is likely. Lifetime prevalence rates are 13% in male physicians and 20% in female physicians. There is some evidence that rates of mental health symptoms have gradually increased among physicians in the past three decades, with a meta-analysis suggesting that the rates of depression have increased on average by 0.5% per year. Most alarming are the rates of suicide among physicians, which are double that of the general population. Fewer studies have examined anxiety disorders among physicians. A small number of cross-sectional studies suggest rates of generalized anxiety disorder as high as 24% and rates of PTSD ranging between 4% and 16%.

Suicide rates among physicians are 1.4 times the general population for men and twice the rates for women, resulting in 300 to 400 physician deaths by suicide in the United States yearly. Physicians later in their careers have higher completed suicide rates compared to the general population, with male physicians at 40% increased risk and female physicians at 130% increased risk. Physicians who screened positive for depression were more like to have alcohol use disorder.

There is an emerging link between specialty area and the risk of suicide, with a 2019 review suggesting that anesthesiologists, psychiatrists, general practitioners, and general surgeons might have higher rates of suicide than other specialties. The apparent increased risk of suicide among anesthesiologists appears to be related to a combination of higher rates of psychological distress in addition to access to lethal means. Michael Myers and Carla Fine wrote on the aftermath of physician suicide in “Touched by Suicide: Hope and Healing after Loss.” Fine’s husband, a urologist at NYU School of Medicine, killed himself at the early peak of what promised to be a bright career. In particular, Fine wrote about the isolation and ostracization she faced from her husband’s medical colleagues after his death. Other accounts of physician suicide, both attempts and completions, anchor this life-altering event in the complexity of its biologic, personal, professional, social, and family webs. More recently, advocacy to reduce mental health stigma in the medical community grew out of the tragic suicide of Dr. Lorna Breen, a vibrant and respected emergency department director at New York Presbyterian

Telegram: @medical_k

www.konkur.in

Hospital, who died by suicide during the first wave of the COVID-19 pandemic. Dr. Breen's sister and brother-in-law started a foundation and campaign to raise awareness of the conditions within the culture of medicine. They advocated for the Dr. Lorna Breen Health Care Provider Protection Act (S. 610 and HR 1667), which unanimously passed the U.S. Senate on August 6, 2021, and aims to reduce and prevent suicide, burnout, and mental and behavioral health conditions among health care professionals. These stories drive home the magnitude of such loss and the urgency of preventative measures, education, and destigmatization of mental illness within the house of medicine. They also underscore the value of outstanding and empathic psychiatric care, not only from the perspective of the patient in treatment but also from that of the wounded healer evolving as a more sophisticated physician.

The limited published studies have estimated that the rate of physicians with mental health conditions seeking help is only between 13% and 36%, suggesting a need to address further stigma and other barriers to seeking treatment and develop a stronger culture of support. It is a shame that with many good, evidence-based treatment options available for mood and anxiety disorders, ranging from psychotherapy (individual, family, or group) and medication management to neuromodulation, medical students, trainees, and practicing physicians often fail to seek treatment. As physicians tell their stories of having a mental illness and getting treated, as barriers to treatment are reduced, and as organizations prioritize the need for mental health care, fewer physicians will have to shorten their careers or life because of mental health concerns.

Substance Misuse

Substance use is an ongoing public health concern. Just as physicians are not immune to mental health conditions, they are not exempt from the use of illicit substances. It is not uncommon to rationalize alcohol or substance use to relieve work-related distress, cope with relationship issues, or lessen physical pain. Denial is a normal defense mechanism to cope with adversity. Some may not see their misuse as problematic. Some may recognize problematic substance use but not think medical intervention is necessary, and others may acknowledge problematic use but feel unable to take further action. Most research investigating alcohol and substance misuse among physicians have been done largely through self-report surveys. Research suggests that between 5% and 20% of

Telegram: @medical_k

www.konkur.in

doctors across high-income ranges consume alcohol problematically. The data suggest that a substantial proportion of physicians have experimented with illicit substances at some point in their lifetime. The use of prescription drugs (benzodiazepines and minor opioids) occurred higher than in the general population, likely due to the ease of accessibility either through self-prescribing or through colleagues. Substance use disorder (SUD) is the most frequent cause of impairment among physicians. A national study of SUDs in a large sample of U.S. physicians was conducted in June 2011, representing specialties across all disciplines. Physicians misused alcohol at rates comparable to the general population, but opioids and benzodiazepines were misused at rates five times that of the general population. Approximately 13% of male physicians and 21% of female physicians met diagnostic criteria for alcohol use disorder, and younger and partnered physicians were more likely to be affected. There was a strong association with alcohol use disorder and a positive screen for depression, suicidal ideation, decreased quality of life, and decreased career satisfaction. Female surgeons and physicians suffered more than their male counterparts from work–life conflicts, which appeared to be associated with depression, burnout, and alcohol use disorder. On average, women progress faster to SUD after first use than men (so-called “telescoping”), and women are more likely to have a comorbid psychiatric disorder with SUD. The highest prevalence of hazardous alcohol consumption was seen among the specialty groups of dermatology, orthopedic surgery, internal medicine, and emergency medicine. Over the past 30 years, physicians consistently consumed alcohol at a similar or perhaps higher rate than their general population counterparts (15.4% vs. 12.6%). Published in 1973, one of the first major publications reporting on physician drug use and resultant impairment was “The Sick Physician.” This seminal paper called for the need to treat impaired physicians and led to the development of physician health programs (PHPs). PHPs aim to help physicians avoid the potential for serious professional and/or legal consequences of their SUD. Currently, many physicians are motivated to enter SUD treatment to avoid such consequences.

The Joint Commission (TJC) requires that medical centers have a standing committee for physician health and that physician health matters be dealt with separately from disciplinary matters. States differ in terms of the criteria of evidence required for taking action against doctors and the

Telegram: @medical_k

www.konkur.in

type of intervention. Any successful program that diverts these complaints to treatment committees also carries consequences, depending on the severity of the offending behavior. For example, a physician may need to have a chaperone present for all examinations, perform a procedure with a fellow specialist present, or be subject to random drug testing or office visits to assess record keeping. Infractions of these treatment programs can lead to a medical license suspension if the behavior continues to place patients at risk or be otherwise unamenable to treatment. The focus remains on prevention to facilitate safe, regular, and reliable participation in the program and successfully model the best ethical medical care. Each state's society provides the particular details of its program. Reassuringly, more physicians who participate in a PHP typically achieve remission and return to a fulfilling career as compared to those in the general population or without a PHP model of care. Seventy-eight percent of physicians never had a single positive test for drugs or alcohol during the first 5 years of monitoring. After successfully completing a 5-year SUD monitoring contract, 96% of participants were licensed to practice (none reported lack of licensure was related to substance use), and 91% were currently practicing medicine. Thirty-eight percent of participants voluntarily extended their monitoring at some point, and 20% reported being currently voluntarily monitored by a PHP.

Barriers to Seeking Treatment

Physicians with mental health problems might be more reluctant than nonphysicians to seek help for a variety of reasons. Major barriers include fear regarding confidentiality, the potential consequences for their career, medical board and licensure, and a belief that they can manage any symptoms on their own. Qualitative studies of physicians who have mental health problems have shown high prevalence of stigma, often driven by views that doctors should be invincible and fear of discrimination. These factors act as major barriers to seeking help and recovery and contribute to the cultural stigma in the medical profession. The most cited reasons why physicians are unwilling to seek help for depression or anxiety were lack of time (81%), fear of lack of confidentiality or privacy (41%), embarrassment (39%), and concerns of medical licensure.

To reduce fears associated with help-seeking, state medical boards and hospital credentialing processes are increasingly changing the wording of

Telegram: @medical_k

www.konkur.in

their license applications and renewals to focus on impairment rather than the mere existence of a mental health or SUD. Those physicians who lived in states where the initial or renewal application asked about mental health conditions irrespective of impairment were much less likely to seek help for a mental health condition than in states that only asked about impairment. In an effort to remove barriers to seeking help, The Federation of State Medical Boards' recommended language does not include any specific reference to a mental health condition: "Are you currently suffering from any condition for which you are not being appropriately treated that impairs your judgment or that would otherwise adversely affect your ability to practice medicine in a competent, ethical and professional manner? (Yes/No)" (https://www.fsmb.org/siteassets/advocacy/policies/policy-on-wellness-and-burnout.pdf). The hope is that physicians will seek treatment in time to prevent later impairment.

More recently, in the United States, formal avenues to address the issue of the impaired physician burgeoned beginning in 1969 (Florida) and 1971 (Texas) with the passage of "sick doctor statutes," which allowed for doctors with probable cause of distress to be referred and receive care without the actual legal allegation by a patient of harm. The number of programs providing treatment to physicians misusing substances and the accompanying statewide committees on physician health has mushroomed, and these eventually became part of every state's laws. Initially focused on SUD, physician mental health programs have grown in scope to acknowledge the impact of untreated mood and bipolar disorders, more subtle disorders of personality that may drive the sexual exploitation of patients or the abuse of colleagues, and impairment from comorbid medical conditions. Finally, the field now fully recognizes the impact of wellness and has campaigns to prevent medical illness, psychiatric disorder, or practice burnout. It recognizes the value of education of the profession at all levels of training, beginning in medical school and continuing throughout, with a constant provision of confidential access to care.

Risk Factors Unique to the Profession of Medicine

The expectation that we can be immersed in suffering and loss daily and not be touched by it is as unrealistic as expecting to be able to walk through water without getting wet.

Dr. Rachel Naomi Remen.

Telegram: @medical_k

www.konkur.in

The demands of clinical care of patients can prove exceptionally challenging and worthy of the respect bestowed on the healing professions by society. The regular grief involved with exposure to death and dying of longstanding patients; feelings of helplessness at not knowing which path to take with a patient and of limitation in the face of human nature; exhaustion from working long or emotionally taxing hours with the accompanying deprivation of sleep; and invitations to allow responsibility for clinical care to assume the weight of guilt when patients' conditions decline precipitously all contribute to the occupational hazards of the profession. Beyond the immediate clinical level, complex communications with perfection-seeking colleagues, demanding patients, or cultural and language boundaries unfamiliar to the physician add to the background stress of health care delivery. A professional culture unwelcoming of medical error, high levels of work–home interference, limited control over call schedules, and an increasing educational debt burden further magnify the impact of any given stress. Just as each of these factors creates stress, each also illuminates directions for better physician self-care and for change within the culture of medicine.

Physician Impairment, Medical Boards, and Licensure

It is not uncommon for many physicians to carry disability insurance to protect themselves and their families. Many physicians have been protected from disability-based discrimination since 1973 under the Rehabilitation Act, which has comparable provisions but less comprehensive coverage than the Americans with Disabilities Act (ADA) of 1990. The term "impaired physician" is often used to describe a disability related to psychiatric illness and alcohol use disorder or SUD. Whereas the ADA's legal definition tends to be more inclusive of physical, mental, and behavioral limitations, impairment is present when a physician is unable to perform in a manner that conforms to acceptable standards of practice, exhibits serious flaws in judgment, and/or provides incompetent care.

SUDs account for the most frequent cause of impairment among physicians. It is estimated that as many as 15% of practicing physicians suffer from SUDs at one point in their career, almost equivalent to the rates for the general population. An important distinction is that the drugs chosen by physicians are more often alcohol or prescription medications and less commonly illicit drugs.

Telegram: @medical_k

www.konkur.in

Mental illnesses such as personality or affective disorders and interpersonal issues within or outside the workplace could disrupt patient care. Numerous programs have been established across the country to help evaluate and treat disruptive physicians. Remediation programs can help identify and offer education.

Each state's medical practice act explicitly states that each physician must remain physically, mentally, and emotionally competent to practice medicine and to self-report if any of these are compromised. An affirmative "duty to report" is required of a physician health care provider if public safety is imperiled. The National Practitioner Data Bank must also be notified of disciplinary action taken against an impaired physician.

In a national survey of physicians, only 45% of respondents indicated that they had notified the state licensing board of a colleague who was incompetent or felt to be impaired. Yet almost all indicated that these individuals should be reported. An ethical requirement to report must be balanced against the obligation to maintain confidentiality.

Countertransference Issues

Physicians opens the door to a particular set of countertransference issues that can impede the provision of a high standard of care. For instance, the treating physician might fear that the physician-patient is smarter—which may well be the case—thus minimizing a contribution to the careful management of the patient, which is often more emotional in nature than an issue of "book-smarts." The treating physician (and their peers) can feel compelled to join the physician-patient in thinking about the clinical struggle as purely an intellectual one, thus depriving the patient of crucial emotional clinical data. Most significantly, the treating physician can identify with their health care professional colleagues and normalize their distress as secondary to the trials of medical training, thus stretching the realm of "normal" to miss significant avoidance of psychic pain in need of mending. The treating physician might forget to think of suicide as a central concern, given the mutually shared value of life in the profession; wish not to see a colleague as impaired; mistake the patient's high intellect as an absence of serious disturbance; or wish to avoid destructive feelings as the provider. All of these factors can lead the treating physician to buy into the medical student or physician-patient's wish to avoid treatment and the wealth of uncomfortable feelings likely experienced, even if with a sensitive, compassionate listener. Buying into

Telegram: @medical_k

www.konkur.in

a medical student or physician's wish to avoid treatment when indicated will only defer the struggle until a later time, when it may be much more difficult to handle, if only because many more people are then affected. It also postpones the very relief that is longed for physician- or medical student-patient musters the courage to pick up the phone and seek consultation for issue.

LIFE PHASES IN MEDICINE

Medical Students

Students enter medical school with similar mental health status to same-age peers. Their overall mental health declines in medical school. This may suggest that medical education itself contributes to student distress. A significant stressor from college to the first year of medical school is "not being the smartest" in their class. While some stress may enhance academic performance, high stress levels are associated with burnout, depression, and somatic distress. Major stressors for medical students are academic workload and volume of information, studying and time management, work–life conflicts, peer relationships, poor student guidance/support, evaluative pressures, finances, lack of time for oneself, responsibility, and the need to succeed.

Research on burnout prevalence rates among medical students ranges from 28% to 55% for high EE, 26% to 38% for high DP, and 27% to 84% for low PA. A 2009 national survey of U.S. medical students reports burnout strongly correlated in the first and second year with perceived level of dissatisfaction with support from staff and medical school faculty. During the third and fourth years, burnout was more closely associated with poor clerkship organization and exposure to cynical trainees. One episode of mistreatment by faculty or resident has been reported by 83%, with recurrent mistreatment as another contributing factor to burnout. Most commonly, the reported mistreatment is in the form of public humiliation from other staff, such as nurses, peers, and clinical faculty. Long hours studying, financial debt, interpersonal struggles, witnessing stressful clinical events, and lack of adequate sleep contribute to burnout. There are multiple potential ramifications of burnout for medical students, including poor academic performance, loss of empathy, negativity toward patients, impaired academic integrity, SUDs, and suicide. There is evidence that burnout is strongly associated with thoughts of leaving

Telegram: @medical_k

www.konkur.in

medical school. Medical students with burnout often don't seek care for fear of discrimination, stigma, and loss of confidentiality. Lotte Dyrbye and colleagues suggested that the reluctance to seek help is related to the misperception of being weak. Unfortunately, this may lead to maladaptive coping with excessive alcohol use. In a large national study of 2,682 medical students, students with burnout were more likely to report dishonest behavior and have less altruistic views toward society. Decreased empathy and professionalism associated with burnout continued in the transition from medical school to residency.

Rotenstein and colleagues did a systematic review and meta-analysis of 195 studies in 2016 based on medical students from 47 countries. Based on assessment modes, they estimated prevalence rates of depression of 27.2%, ranging from 9.3% to 55.9%. From 24 cross-sectional studies of medical students, they found prevalence rates of 11.1% expressing suicidal ideation. The Center for Disease Control and Prevention report in 2019 ranked suicide in the top three leading causes of death among teens and young adults, noting an increase of 36% among persons aged 20 to 24 years from 2000 to 2017. A 2019 report from the AMA's Council on Medical Education indicated that "medical students are three times more likely to commit suicide than the rest of the general population in their age range in other educational settings." Associated risk factors for suicidal ideation include depressive symptoms, burnout, psychological distress (anxiety, irritability, loss of control), living singly, having poor health and/or economic status, and family history of mental illness and suicide. The prevalence of depressive symptoms and suicidal ideation is significantly higher through medical school than in other postgraduate training. Excessive consumption of alcohol is common among U.S. medical students and strongly related to the distress experienced by learners. Younger age and being single are known risk factors for problematic alcohol use among students, similar to the general population. Educational debt was noted to increase alcohol consumption in a mass survey sent out in 2012 to all students listed in AMA Physician Masterfile; from 1995 to 2014, the average cost of private medical schools increased by 209% compared to an increase of 286% cost to attend public medical schools.

In their systematic review of 28 interventions designed to promote medical student wellness, Wasson and colleagues found that interventions involving the learning environment were associated with

Telegram: @medical_k

www.konkur.in

improved wellness among medical students. These include converting to a pass/fail grading system, available and easily accessible mental health programs, mind–body skills training programs, curriculum restructure with balancing between clinical and nonclinical learning environments, and implementation of formal faculty advisor/mentor programs. These and other studies suggest that addressing the environment of medical education and the culture of medicine is critical if we hope to improve the well-being of rising physicians. The AAMC's recommendations regarding health services for medical students remain relevant from 1992 for mental health and SUDs. Recommendations suggest providing all students with access to confidential counseling by mental health professionals, confidential policies protecting students' mental health records, and clear administrative mandates for evaluation and treatment. However, a lack of resources often prevents schools from implementing these guidelines. Access to community providers, long wait times, insurance and self-pay issues, concerns about future employability and licensure, and the scramble to orchestrate evaluations for medical leave and clearance for returns remain a challenge. Another barrier includes self-stigma, which describes the phenomenon whereby individuals have a loss of self-esteem and self-efficacy as they adopt and internalize the external social stigma of needing help or appearing weak. It has been long suggested that physicians stigmatize mental illness more than the general population. Furthermore, some learners may be on parents' health insurance plans with concerns about the privacy of receiving mental health treatment. Finances, time off, and co-pays pose another challenge for learners. Some researchers suggest incorporation of alcohol reduction programs, student debt reduction, wellness curricula, mindfulness programs, teaching cognitive reappraisal, and small group facilitated discussions. Ideally, well-being programs would be integrated into existing curricula with buy-in from students and faculty to maximize engagement and minimize further resentment toward overloaded schedules.

During the unprecedented era of the COVID-19 pandemic that emerged in February 2020, lockdown and quarantine were universally implemented by March 2020 to contain the spread of infection. Universities closed classrooms, and medical education shifted across the country to digital learning lectures for social distancing and safety, barring a student from in-person clinical work. Numerous studies have established the negative impact of social isolation on mental health. Before the COVID-19

Telegram: @medical_k

www.konkur.in

outbreak, several studies suggested a high prevalence of stress, anxiety, and burnout among medical students. The impact of the relatively rapid adaptations to revise course structures, new online requirements, social isolation, and reduced student–patient and student–faculty interactions created even more challenges for preclinical students. Third- and fourth-year students experienced disruptions in their clinical clerkships while navigating applications for residency training and virtual interviews.

Crises, whether a pandemic such as COVID-19, natural disasters such as Hurricane Katrina, school shootings, or a campus suicide, demand immediate response to provide safety to the community and restore normalcy (even if a “new normal”) as soon as possible. In the event of a suicide, it is critical to have a plan of action and a postvention team already in place. The AAMC has created a helpful toolkit for schools called “After a Suicide: A Toolkit for Medical Schools.” Assembling a crisis response team and creating a crisis response communication plan are critical first steps. The toolkit offers guidance on how to gather the facts, inform the emergency contact person/family, share the news, help medical students cope, and memorialize the deceased. In the case of a suicide of a learner, it is of utmost importance to identify whether there are other at-risk students or trainees and to ensure their safety. In addition, it is necessary to reach out to individuals who are known to be close to the deceased person, such as roommates, significant others, close friends, and academic mentors. It is important to provide psychoeducation about typical reactions to trauma, including disturbances in sleep, appetite, energy, and interest, and to emphasize the importance of self-care in returning to precrisis levels of well-being and available resources. Professional counselors and chaplains may offer group debriefings and a safe place to process the inevitable mix of emotions arising after such tragic events. Leadership typically allows and encourages their learners to take the time needed for emotional processing without penalty.

Mr. A was a 24-year-old Korean American who had just started his third year of medical school. He was a popular and well-liked student who had been active in the Christian fellowship. He was an excellent athlete and often played pickup basketball games with his peers. His classmates saw him as affable, kind, and funny. However, behind closed doors, Mr. A struggled with severe self-doubt and insecurities. Despite his high grades, he thought that his peers knew more than he did, and he questioned whether he could get into a competitive plastic surgery residency. Two weeks before the first step of his national board examinations, his girlfriend of 1 year broke up with him and started dating one of his close friends. Mr. A was devastated. The breakup added to his feeling that he was inferior to his peers. Mr. A had come from a high-achieving family, and he was expected to do the same. Despite evidence of significant mental illness in his family, it was never acknowledged or discussed. The day after Mr. A got his board scores back, he was found dead in his dorm by his roommate. He had hanged himself from his door frame. His roommate notified campus security, leading to the activation of the postvention response plan. The family was contacted immediately, and they expressly indicated that they did not want the cause of his death to be disclosed, which was honored. After the family was notified, the public affairs office of the medical center sent out an email to the entire medical community, alerting them to Mr. A's untimely death. In addition, the dean of student affairs emailed the medical student community, including medical school faculty, confirming that a medical student had died and the availability of staff to speak with any student wishing to do so. The same day, the postvention team set up shifts at the medical student dorm from 9 in the morning until 9 at night to provide psychological first aid for any students or staff. The counseling center contacted medical students who were known to have had suicidal thoughts in the past or who were being treated for severe depression to offer additional support. In addition, the counseling center posted flyers in the dorm announcing a support group for those students who were especially close to or distressed by Mr. A's death. The leader of the Christian fellowship also held a special session to help its members talk about the recent loss of Mr. A. The dean of students also met with medical school faculty who were involved in teaching Mr. A to provide support and review common reactions to a crisis so that

Telegram: @medical_k

www.konkur.in

they could be on the lookout for themselves and students exhibiting any symptoms. In addition, the dean stressed to the faculty that some students might need extensions on examinations or other accommodations. Meanwhile, the postvention team met daily to discuss the effectiveness of their efforts, determine whether any adjustments were necessary, and provide the necessary support to each other. Over the subsequent weeks and months, the medical school community resumed its usual functioning. However, the postvention team continued to meet to discuss improvements for future events.

Promoting Wellness

Well-being and wellness are often terms used interchangeably. Well-being is a state of being comfortable, healthy, or happy. Wellness includes a spectrum of domains that include social, physical, emotional, intellectual, spiritual, financial, and environmental. Resilience refers to the ability to rebound or grow from a stressful experience, often by connecting with others or with one's humanity or beauty rather than staying stuck in the stress response; resilience is believed to contribute positively to well-being and wellness. Over the past decade, there has been increasing awareness and recognition of mental health challenges faced by medical students, residents, and physicians and the importance of prevention. The AAMC, Institute of Medicine, and the Liaison Committee on Medical Education unanimously support and/or require policies and programs to promote well-being in medical school. The AAMC longitudinally tracks issues critical to medical education using student surveys. These voluntary surveys include the post–Medical College Admission Test survey, the Matriculating Student Questionnaire, the Medical School Year 2 Questionnaire, and the Medical School Graduation Questionnaire. Previous approaches to medical student mental health were largely reactive. Early initiatives relating to medical student mental health primarily focused on improving access to care, educating students on mental health issues, and addressing the stigma associated with treatment. In recent years, some medical schools have taken a top-down approach, incorporating into the curriculum basic education about personal mental health assessment, mindfulness strategies to build resilience, teaching devoted to managing and coping with errors in

Telegram: @medical_k

www.konkur.in

practice, gender- and racial-sensitive perspectives on the experience of being a learner and practitioner, and providing more resources and tutoring. Many medical schools have designed and implemented programs that promote optimization of learner well-being. For example, the University of Pittsburg School of Medicine addresses the challenges of access, privacy, and stigma with a dedicated mental health team. The medical school financially supports this team to provide care for their 560 medical students and 360 graduate students. A faculty psychiatrist receives 30% salary support, and a full-time master's level psychologist receives 100% salary support. This mental health team is further supported by the Student Health Advocacy Resource Program (SHARP), a confidential peer-counseling referral and advocacy service for medical students. Ten peer counselors provide guidance and assistance with life transitions, family stress, relationship difficulties, depression, anxiety, academic concerns, leaves of absence, and substance misuse. SHARP is organized by medical students and supervised by faculty from the psychiatry and medicine departments. There are other schoolwide initiatives for mental health and stress reduction for students at the University of Pittsburg. The Faculty and Students Together program helps students transition to medical school, be assigned faculty advisors, and observe how faculty balance work and life choices.

The Saint Louis University School of Medicine began an initiative in 2006. They developed a simple well-being model with three components. The first component was to mitigate unnecessary stressors and enhance the learning environment. The second was to teach students stress management skills and encourage the use of the available psychological and emotional support resources. The third component was to create more opportunities for students to find meaning in their work. This was followed 2 years later with interventions and changes in the learning curriculum and preclerkship environment. The grading system was changed to pass/fail, and a 10% decrease in hours for all curriculum courses and longitudinal electives and theme-based learning communities were instituted. Over the next decade, they found a noticeable reduction in depression and anxiety rates in the first-year class.

Well-being programs in medical education have been seen throughout the country. Components include mind–body skills, a longitudinal curriculum focusing on personal development with mentoring wellness activities, weekly 30-minute lectures on the neuroscience of yoga,

Telegram: @medical_k

www.konkur.in

relaxation and breathing exercises, resiliency mindfulness programs, and appointing faculty "wellness advisors." The University of San Diego implemented the Healer Education Assessment and Referral (HEAR) program to educate medical and pharmacy students, house staff, faculty, and trainees about burnout, depression, and suicide by providing confidential assessments. Other resources available to medical schools include free materials developed by the American Foundation for Suicide Prevention (afsp.org) to prevent burnout, depression, and suicide among health care learners.

Figure 30.8–1 depicts the various barriers, interventions, and outcomes at the medical school level, though the same infrastructure should be applied during postgraduate training. Wellness and well-being efforts cannot start and end at the medical school level. Training directors and employers must prioritize well-being at each phase of education and practice by measuring it, creating an infrastructure to address the barriers to well-being with adequate resources, and implementing strategies and tactics appropriate for the particular developmental level and specialty. Faculties who supervise and educate are instrumental in modeling self-care and a culture of support.

Physicians in Training

Residency and fellowship have long been thought to be stressful times in a physician's career. The literature is mixed regarding whether resident physicians begin residency with burnout. Most studies find that the rates of burnout significantly increase during the first year of residency. Interns with passive coping styles and struggles with perceived stress were more likely to have higher levels of emotional exhaustion and DP. Some contributing factors to burnout are long hours, financial hardship, sleep deprivation, and emotionally difficult situations with patients, families, and colleagues. Burnout symptoms contribute to more medical errors and decreased professionalism. In July 2003, citing a concern for patient safety, the American Council of Graduate Medical Education (ACGME) implemented a resident duty hour restriction of an 80-hour workweek for patient care and didactics. In 2011, after studies showed no improvement in burnout or self-reported medical errors, the ACGME instituted limited single-shift hours to less than 28 hours and a required 1 day off per week. The attention to burnout among residents is of significant interest in how professional identity and healthy habits are shaped during this critical

Telegram: @medical_k

www.konkur.in

time. The ACGME has made resident wellness a top priority, not only with work hour restrictions but also by alerting program directors of their role in assessing and promoting the wellness of their residents.

FIGURE 30.8–1. Flow diagram of various intervention avenues and outcomes.

Similar to entering medical students, studies show that medical residents are at higher risk for depressive disorders, depressed mood, and suicidal ideation than their peers in the general population. A meta-analysis showed prevalence rates of depressive symptoms among residents to be 28.8%, ranging from 20.9% to 43.2%, depending on screening instruments. This raises concern for developing greater long-term morbidity and risk for suicide even after training in these learners. The spotlight on suicide was elevated when, in 2014, two internal medicine interns committed suicide. Among residents in ACGME-accredited programs from 2000 to 2014, the leading cause of death was neoplastic disease, which raises the concern that trainees sacrifice

Telegram: @medical_k

www.konkur.in

medical care that might have discovered problems when still treatable. The second most prevalent cause of resident death was suicide. Suicide is the single most common reason for male physician mortality during training and the second most common reason for female physicians in training. A majority of suicides occurred during years 1 and 2 of training. Barriers to seeking help include time constraints and inconvenience, documentation and confidentiality concerns, cost, stigma, and future employability.

Strategies to prevent and respond to the emotional burdens associated with residency and fellowship training start with having an infrastructure dedicated to well-being, support, and mental health care. Deans of well-being and teams dedicated to measuring well-being and distress take the pulse of the community, encourage efforts that address drivers of distress and burnout, and build community and support. Examples include free and accessible mental health, academic success, and disability services; teams dedicated to the assessment and remediation of struggling trainees; peer support training and infrastructure to deploy peer counselors who are aware of resources; engagement of program directors and chiefs in promoting peer support; support groups; allyship groups; childcare, paternal leave, and lactation facility options; and having a crisis response plan and team in place.

www.konkur.in

Dr. E presented for consultation in the third year of his psychiatry residency for complaints of depression and burnout. He lamented that his passion for learning and zest for life had each atrophied and dried up since the beginning of his PGY-II year. He could not say for sure why he thought this descent had occurred, although he readily identified a couple of immediate possibilities: failure in his love life relative to his high expectations and experiencing himself as a cog within the greater wheel called profit-driven medical care. These factors left little protected time for his formerly passionate thirst for knowledge. He also owed more money than he could calculate to credit cards and student loan agencies—when would a day come that he could ever pay this debt or live in the expensive city of his training on such a thinly stretched salary? While he enjoyed basic invitations to know more about the human condition in sickness and health and the ubiquity of human suffering, he found himself directionless and listless in the bigger picture of his life. His prior experience in psychotherapy had soured, which left him in a hypocritical stance toward his patients and his work: how could he recommend and/or perform a procedure that had so wounded him?

Consultation over several sessions focused on several core concepts: the establishment of a supportive, mending therapeutic alliance; the restoration of hope; the normalization of Dr. E's plight relative to his stage of training and deep capacity for empathy; and the exploration of pharmacologic options to manage his mood and anxiety. Numerous treatment options were considered, including participation in a group therapy program for physicians. Over the course of the year, Dr. E made steady gains in his life and his mood. He broke up with his on-again, off-again lover with whom he had spent years in a passionate bad fit and worked on some searing emotional pain that stemmed from his family of origin, identifying his mother's history of alcoholism and his father's covert history of PTSD from Vietnam as significant drivers of his wish to become a psychiatrist. He reconnected with his brother in new and rewarding ways, fell in love with a fellow resident from the emergency medicine program, and refined a professional path focused on intensive inpatient hospital work with physicians in crisis.

Telegram: @medical_k

www.konkur.in

Early Career

The early career phase spans from medical school and postgraduate training to the first 5 years out of training. The transition from training to practice may be a particularly challenging time in trying to establish a professional identity and adjust to a new structure of work environment, uncompromising schedules, and learning the business aspects of medicine. Newly trained physicians may be reluctant to ask for help or demonstrate uncertainty, invoking tendencies to compare themselves to others, lack of belonging, and the experience of imposter syndrome. This phase coincides with the desire for romantic partnerships, community building, and starting a family. For single women, the reproductive complexities with their biologic phase in life pose alternative routes of in-vitro fertilization, surrogates, and adoption. These personal challenges are often superimposed on workplace expectations for productivity. Systematic factors of flexible hours, job share, mentorship, role models, and support networks are often lacking yet necessary for academic advancement. The AAMC has identified a “good work–life policy,” which includes paid leave offered to full- and part-time faculty, no required length of prior service to qualify for leave, 12 weeks of paid leave, and a 6-month total (paid and unpaid) leave. The Family and Medical Leave Act requires employers to provide 12 weeks of unpaid family leave once the employee has worked 12 months. However, the United States has no federal paid parental leave policy and only a minority of states offer paid parental leave. Consequently, parental leave time policies are inconsistent and often come with constraints under the discretion of the institutional and departmental leadership. Return to work following parental leave can be a difficult transition period with childcare availability, feeling pressure to return to work while on leave, makeup time with extra calls or clinic time, and feeling discriminated against. Many women lack access to lactation facilities and inadequate time for pumping breast milk.

Strategies to support physicians during their early career include identifying and responding to bias (especially women and minorities), mentorship, sponsorship, career and life coaching, implementing early and effective onboarding, and providing faculty development workshops on time management, self-compassion, and setting limits. Key initiatives include (1) support groups to normalize the stressors; (2) trained peer supporters: (3) training leaders to be authentically open to input, focused on the need for flexible schedules/telecommuting and advocating for

Telegram: @medical_k

www.konkur.in

staff's well-being and work–life integration; (4) developing enough cushion to allow for sick leave or parental leave; (5) making childcare leave and stop-the-clock policies opt-out versus opt-in; (6) having programs that reduce on-the-job stress (e.g., emergency sick child care programs, on-site child care, elder care, daycare hours in line with physician schedules); (7) having adequate lactation facilities and allowing time that is counted toward relative value units (RVUs) for breast pumping; (8) ensuring that promotion and tenure are the same for all faculty regardless of leave use; and (9) recognition and rewards for contributions to the team or department.

Telegram: @medical_k

www.konkur.in

Dr. A was a junior faculty member of a surgery department at an academic institution who presented to the psychiatry outpatient clinic after her husband urged her to seek treatment for possible postpartum depression. In the initial consultative appointment, 5 weeks after giving birth, she exhibited insomnia, tearfulness, loss of energy, low mood, anhedonia, and difficulty attaching to her twin babies. The latter made her feel shame and guilt, as she had desperately wanted to be pregnant yet now did not feel able or worthy of caring for her precious newborns, though she denied suicidal ideation. She explained how she dedicated her life to becoming a surgeon and delayed having children because there was never a right time. She and her physician spouse had been trying to conceive, but it was difficult. It felt strange not to be able to achieve this goal more easily when she had already achieved so much in her career. She assumed that her colleagues, mostly men whose wives carried out most of the domestic responsibilities, wouldn't relate to the level of stress she felt with this, and it would not be something she would feel comfortable discussing anyway. She prided herself on being tough and not complaining. Ultimately, with the second round of in vitro fertilization, she became pregnant. The pregnancy went okay after she figured out strategies to manage first-trimester nausea and vomiting (a particular challenge during her longer surgical cases), though she increasingly had symptoms of fatigue, insomnia, and free-floating anxiety. She had hoped to complete a book chapter and research manuscript before the end of her pregnancy but was struggling to manage her clinical responsibilities by the time she went into labor. Past history included symptoms of depression and anxiety in college during a time of interpersonal stress. She had responded to a combination of sertraline and cognitive behavioral therapy, but she attributed most of the benefit to the therapy. Subsequently, she tapered off the sertraline and found that a strategy of daily exercise, meditation, healthy eating, and strong organizational skills kept her reasonably stable throughout medical school and training. She was highly driven and very action oriented. Although medical school and surgery training were stressful, she excelled and loved being a surgeon.

After diagnosing postpartum depression, the psychiatrist recommended that she initiate sertraline, as she had done well with it previously, and it was known to be relatively safe with breastfeeding.

Telegram: @medical_k

www.konkur.in

She had partial improvement in depressive symptoms a few weeks after initiating sertraline, and over time, she felt more attached to the babies. Psychotherapy this time focused on allowing, accepting, and tolerating her emotions and imperfections with self-compassion, as well as the need to widen her support network. Her husband attended a few of these sessions, during which she began to acknowledge and communicate her needs, and they negotiated the sharing of domestic responsibilities. She was connected to a local peer mentor program and joined an online support group through Postpartum Support International. She was encouraged to extend the maternity leave to 4 months. When she returned to work, she talked with her Chair about options to remain on the tenure track via a “stop the clock” program at her institution, an idea shared by her peer mentor. The institution had lactation facilities; she was able to continue breastfeeding between surgical cases and, on clinic days, was given a reduced schedule to accommodate the breastfeeding. Over time, she found ways to integrate her personal needs and career goals rather than suffering in silence.

Midcareer

This has been defined by some as 11 to 20 years out of training with a general age group between the ages of 40 and 55 years. On a personal level, raising school-aged children and teenagers with social activities has its own set of developmental issues. Focus on child-rearing may overshadow attention to one’s partner, leading to separation or divorce. Many can get caught between raising children and caregiving to aging parents’ health issues. Balancing dual-career households with family can be difficult. Personal health issues may arise. The career trajectory for women may slow down compared to male counterparts.

Many of the solutions to supporting midcareer physicians are like early-career physicians. In addition, practices should find ways to lessen the burden of the EMR by providing adequate allied health staff support, optimizing the “right person for the right job,” and workflows. The AMA Steps Forward has many helpful modules directed at saving time and reducing the less rewarding aspects of clinical responsibilities. Departments and leaders should have zero tolerance for abusive behaviors at work. Institutions should facilitate and fund organizational

Telegram: @medical_k

www.konkur.in

science. Providing formal space for physician peer interactions, for example, physician lounges, and encouraging peer support groups and programs help diminish the isolation and exhaustion that can be felt during this very busy time in life. It is essential to encourage “rest and recharge” breaks and self-care and normalize help-seeking and mental health treatment. Midcareer is a time when physicians are often pulled in many directions, and burnout, depression, anxiety, and SUDs are common.

Telegram: @medical_k

www.konkur.in

Dr. L was a 50-year-old married sports medicine physician in a small, private group practice in a midsized town. In addition to a very active practice, he was the physician for a national sports team and engaged in his children's activities, such as helping to coach soccer and attending their games. A few years prior, his father, who lived nearby, was diagnosed with dementia, so he also began helping navigate his father's care. Just before the COVID-19 pandemic, the office manager for his private practice resigned, his father's dementia progressed, and his mother's health also started failing to the point that he needed to either look for an assisted living facility or have his parents move in with him and his wife. Knowing that his parents would resist moving to an assisted living facility, he and his wife began to work on a remodel to accommodate his parents. To further add to the stress level, his teenage daughter began showing signs of an eating disorder with excessive exercise and food restriction. Over time, the one glass of wine with dinner became two and was supplemented with a cocktail before dinner and sometimes before bed if he couldn't sleep. He became more irritable with his wife and kids. His office partner, Dr. E, observed him being impatient and less compassionate than usual with staff and patients and so asked him how he was doing, commiserating that she knew it was a stressful time with their practice and his life circumstances. Dr. L said he was fine but was just having a little difficulty sleeping. He said he would be ok if he just got a better night's sleep and asked Dr. E if she would prescribe some zolpidem because he didn't have time to see his primary care physician (in fact, he hadn't gone to his doctor in years). Dr. E sympathized with his dilemma but worried about the consequences of doing so in terms of her licensure, especially if there was a bad outcome with one of Dr. L's patients. She convinced Dr. L to make the time to be evaluated by his doctor. She wondered if she was obligated to report him but decided not to do so.

At the appointment with the internist, Dr. L was noted to have high blood pressure. The internist expressed concern about the alcohol use. She frankly discussed the duty to report if there were any concerns about impairment. However, they both agreed that the impact of his maladaptive drinking had not impaired Dr. L's functioning as a physician yet. She offered to connect him with another physician who was open about his experience with a PHP and mentored other physicians. She further proposed a "warm handoff" for Dr. L to meet

Telegram: @medical_k

www.konkur.in

briefly with the licensed social worker in their integrated behavioral health team. After meeting with the social worker, he began to acknowledge the realities of his stress level and maladaptive responses. He didn't want to threaten everything he had built, especially his involvement with the national sports team. He agreed to regular counseling sessions for accountability and to eliminate alcohol; he committed to seeking further treatment with a PHP program should he have difficulty changing these behaviors or managing his understandable stress level.

Late Career

Late-career physicians can be defined as those over 55 years of age. Work–life integration, a constantly changing health care environment with the requirement to master new technology, and providing quality patient care with increased regulation and decreased autonomy all impact career satisfaction. Possible cognitive and physical decline in one's own personal and spousal health may provide an impetus for early retirement. Physicians prefer gradual retirement with flexible and fewer hours, part-time employment, reduced on-call duties, and job share. The key to successful retirement is planning. In her chapter entitled "Late Career Solutions. Transitional Zone–Retire or Retread," Dr. Suzanne M. Conolly discussed the five Fs: fitness, family, friends, fun, and financial planning. These components cultivate a sense of well-being with the importance of being active with meaningful activities, that is, volunteer work, mentoring, teaching, writing, and community networking. Barriers to retirement planning include poor financial management, health insurance, and lack of interest or activities outside of medicine.

Telegram: @medical_k

www.konkur.in

Dr. B was a 60-year-old hospitalist and associate professor of medicine at an academic institution. A beloved teacher, she had mentored many students and trainees over the years. Patients appreciated her thoughtful approach to their care, and she remained dedicated to maintaining and expanding her skills and knowledge to keep abreast of new developments. She had served on many committees, often in leadership roles, including Division Chair. Together with her same-sex partner, she had raised three children who were now out of the house and pursuing their own careers. Other than recurrent, mild depression, stable on venlafaxine 75 mg daily, she remained relatively healthy for much of her career. She had seemingly managed to do it all. Yet, not long after her 60th birthday, she began noticing that she was progressively more emotionally exhausted, physically tired, lacking efficiency in her work, and overwhelmed. Feeling irritable and not enjoying her work, she felt increasingly annoyed with the requirements of the EMR and dealing with angry or opioid-seeking patients. She was frustrated with the realities of a much busier service, including greater numbers of agitated and violent patients, with a lack of support to go along with the realistic clinical demands. She thought about cutting back or retiring almost every day, though due to the cost of her children's undergraduate and graduate education and neglecting to attend to a financial plan, she didn't think she could afford to retire, which added a sense of being trapped. In the midst of this, she became ill with a flu-like illness, and in the course of the workup, lung cancer was incidentally discovered. Luckily it was found early, enabling a surgical cure. The medically required 6-week pause for surgery triggered some unexpected outcomes. First, her colleagues and friends showered her with kind words and offers of help and support. At the urging of her partner, who was aware of both her history of depression and recent symptoms of burnout, she agreed to meet with a psychiatrist. The psychiatrist offered an increase in the venlafaxine dose. However, Dr. A preferred to wait on making any medication changes now that she was away from work, which the psychiatrist agreed was reasonable. They continued to meet biweekly, during which time Dr. A began to reflect on how little time she devoted to past hobbies, such as playing piano and gardening, and the importance of taking time to be with friends or just having fun. She contemplated her mortality, values, and priorities. She appreciated that

Telegram: @medical_k

www.konkur.in

she valued the teaching and mentoring, though she had lost a sense of autonomy with the current demands at work. After meeting with a financial planner, she realized that she could afford to reduce her work hours and still manage financially. They worked out a plan of gradual reduction of work hours over the next 5 years. The prior symptoms of irritability and anxiety dissipated without the need for an increase in her antidepressant. Upon return to work, she maintained monthly visits with the psychiatrist to monitor the need to adjust her antidepressant medication. She talked with her department leadership about the clinical gaps, and although there were still problems, she also noted constructive efforts from the institution. With intention, she managed to reorganize enough to build her outside interests, reappraise how she viewed and approached her clinical work to allow meaning and purpose to flourish, and build in time for rest and recharge. She felt more in control of her schedule and choices and could see a path to a fulfilling retirement.

FUTURE DIRECTIONS

Much as the military has had to confront an epidemic of suicides since September 11, 2001, the medical profession is at its own tipping point. A window of opportunity exists now to expand upon the work of so many individuals, medical student mental health services, families of medical students or physicians who have died by suicide and are still grieving in isolation, and the pioneering work of the American Foundation for Suicide Prevention. If much of the mental duress that occurs during training stems from the emphasis on science over intuition, rational thought over feelings, and taking care of one's patients over taking care of one's self, then it makes sense that much of the risk of training comes from impossible expectations of omniscience, suppression of personal emotion in the name of patient care, and extinguishing of one's capacity to tend to physical, mental, and spiritual health.

As outlined in Tait Shanafelt's reflection on where physician well-being was and where it is going, health care professionals must cultivate human qualities (over deity or hero qualities) of vulnerability and growth mindset (over perfectionism), work–life integration (over no limits on work), self-compassion (in addition to self-care), community (over isolation), and meaning and purpose (over performance or frustration). Organizations

Telegram: @medical_k

www.konkur.in

must take action (over simple unawareness or simply being aware), focus on the needs of people (over just institutional or patient needs), be flexible (over rigidity), prevent distress and cultivate professional fulfillment (over ignoring distress or just responding after the events), emphasize alignment of organizational and professional values (over unfettered autonomy or carrots and sticks), create a shared responsibility (over blame or neglect), place value on investment (vs. return on investment or ignorance of economic impact), encourage physician and administrator collaboration (vs. functioning independently or with an adversarial relationship), and redesign the system to have sustainable workloads, provide coverage when physicians are ill, and incorporate appropriate breaks and rest. Commitment to developing leaders who value well-being, listening to input from health care professionals, optimizing team-based care, and developing and preserving a trusting environment will be essential to a healthy health care organization. Success will require an infrastructure with enough resources to support these organizational changes.

30.9 Computers in Psychiatry

JOHN LUO, M.D.

Computers in medicine were primarily used in large hospital systems that could afford them in the late 1950s. At Massachusetts General Hospital, Dr. Octo Barnett and his team developed a language known as Massachusetts General Hospital Utility Multi-Programming System, known as MUMPs or M. This language supported the lab system at the time and was the basis of the U.S. Veterans Administration VistA (Veterans Health Administration System and Technology Architecture). Early use of computers in mental health included the Eliza program written in the 1960s at the Massachusetts Institute of Technology Artificial Intelligence Laboratory by Joseph Weizenbaum. This program implemented the Turing test, a hypothetical test to determine whether a computer can think like a human. Eliza emulated a Rogerian therapist, asking you how you felt and then to elaborate on those feelings. These early uses of computing in medicine, much less in psychiatry, kept computer use in medicine on a large system level.

In the 1970s, computing became available more individually. These computers were primarily used by hobbyists and did not reach mainstream use. The International Business Machine (IBM) Personal Computer with MS-DOS (Microsoft Disk Operating System) earmarked the beginning use of computers in the workplace. Software packages handled more of the administrative aspects of health care, such as billing

Telegram: @medical_k

www.konkur.in

and accounts receivable. Data were saved on floppy disks, which evolved from the floppy 5.25-inch version with paper covers to the 3.5-inch version encased in hard plastic with a metal slider to reveal the media. Data also could be transmitted over dial-up modems, which sent basic billing files to clearing houses. Some providers began to use word processing documents to generate patient notes, but most practices were still on paper. Much of the slow adoption of computer use in medicine was related to the challenges in learning to use DOS commands.

The advent of the Microsoft Windows system in the mid-1980s began to change that paradigm. Initially, Windows was a graphical user interface built to work with DOS, making it easier for users to identify where their programs and files were stored and navigate the operating system. Windows software was much more intuitive to use, and personal computers began to proliferate in offices, along with the development of improved printing with laser printers and storage with hard drives with increasing storage capacity. Personal computers using the Apple Mac operating system, such as the Apple II+ and Macintosh, were mostly used at home for their graphics capabilities. There was a significant power disparity between personal computers used at home and the office compared to mainframe computers that large organizations such as hospitals used to manage data such as laboratory tests. Moore's Law is an observation by Gordon Moore in 1965 that the number of integrated circuits on microchips would double every 2 years. Increasingly faster and more capable computers and software development meant that computer technology began to play an integral role in daily life.

Online communities began to develop in the early 1980s with bulletin board systems, where users visited and shared messages that stayed on the host site, such as America Online, which provided online access and a destination to visit. In a parallel development, Tim Berners-Lee developed the World-Wide-Web in 1989 while at CERN, the European Particle Physics Laboratory. He wrote the first web client and server and set the foundation for the specifications of HTML (hypertext markup language), HTTP (hypertext transfer protocol), and URLs (uniform resource locator). Information exchange using web browsers such as Mosaic, developed by the National Center for Supercomputing Applications, which enabled the display of graphic images, helped spread the popularity of websites. Early organizational sites for information on the web, such as Yahoo.com, developed by Jerry Yang and David Filo at Stanford University, helped

Telegram: @medical_k

www.konkur.in

users find information in a growing online sea of information. Sergey Brin and Larry Page, also at Stanford University, developed a more efficient and effective search engine, Google.com, which dramatically facilitated Internet use. Information, including medical information, was becoming more accessible online and in hand.

EARLY INTERNET AND COMPUTERS

The internet as we know it today is a far cry from the early days. The Internet Archive Wayback Machine is an archive of old websites that preserves the early days of the Internet as far as the 1990s. Visiting some early websites illustrates that many were just sources of information that required manual updating. For example, this author wrote the American Psychiatric Association/Center for Mental Health Services Minority Fellowship webpage in HTML 1.0 using just Notepad, a basic Microsoft text editor. Early website pages linked to other pages both on the same site and external, hence creating the “web” of information.

Over time, the computing power of server computers increased along with higher-speed connections, and the Internet network increased its speed. Dial-up modems with initial speeds of 1,200 baud (one bit of information per second) were slowly supplanted by ISDN (integrated services digital network), capable of 64 kbits/second or 64,000 baud. In essence, ISDN lines were digital versions of the analog dial-up modems that ran over a hundred times faster. DSL (Digital Subscriber Line) delivered even higher speed internet over existing copper phone lines using a different frequency. Faster network speeds meant the Internet could be used to exchange more information than just text and pictures, including video and audio.

Along with increasing computing power, computing became much more portable. Early portable desktop computers such as the Commodore SX-64 eventually gave way to laptop computing. While not light, early laptop computers were significantly more portable than their early portable computer predecessors. The next level of computing was palmtop computing, such as the Apple Newton MessagePad and the Palm Pilot. These devices brought computing power into the palm of your hand, and when coupled with cellular capabilities, the smartphone was born.

The Palm Pilot was largely successful as a portable device due to its ease of use and well-designed user interface. Navigation involved using

Telegram: @medical_k

www.konkur.in

the stylus to tap on icons and scroll up and down. Input on the device was using letters via “Grafitti,” a single-stroke shorthand handwriting recognition system. A keyboard accessory made typing much easier and faster than using Graffiti. An infrared port could exchange information such as an address or note between devices. Software written for the Palm Pilot created many opportunities for medical applications. Many health providers took courses at the American Psychiatric Association annual meeting to learn how to use this device to access medical information.

Many consider drug reference software as the “holy grail” or “killer application” of the Palm Pilot and other mobile devices in health care. Gone was the need to find a Physicians Desk Reference or a textbook on medications. It was extremely convenient to find available dosages, indications, common side effects, pregnancy and black box warnings, and other information. However, the major strength was the ability to select medications and check the drug–drug interaction between them. Likewise, reference texts such as the DSM-IV and Washington Manual of Medical Therapeutics could be purchased and installed for reading using specialized applications. At the time, Internet access on these devices was unavailable, and there were not many health care–related websites online, so all health care content had to be installed or entered.

Physicians found other ways to use this portable device beyond storing and retrieving information. Electronic sign-out via the Palm Pilot was one way that two providers shared management of an inpatient service in a county hospital. Notes and tasks for each patient kept the care plan consistent and ensured laboratory results were followed up. Using a handheld database system, the consult service at UC Davis medical center likewise kept the continuity of care between the weekday team and the weekend on-call providers by managing patients using this database. Residents and attendings each carried their own Palm Pilot with the patients they were following and beamed via infrared updates to the ‘consult Palm Pilot’ for use by residents on call. A portable infrared printer also printed consult notes for the paper chart for full portability since desktop computers were not readily available. While this process nowadays does not sound so remarkable, at the time, charting was still done on paper, and orders were handwritten and entered manually by a unit secretary.

Telegram: @medical_k

www.konkur.in

Telemedicine was just beginning to take root with the use of dual ISDN lines and expensive camera systems. Hilty and colleagues wrote about patient satisfaction with telepsychiatry, even with the rather limited bandwidth. Concerns were abundant regarding the use of the technology, including worry about what to do in the event of a clinical emergency, technology failure, or the inability to properly assess the patient for movement disorders. However, patients were quite satisfied with telemedicine visits because, for many, it meant much easier access to care. For example, Lopez and colleagues described the use of telepsychiatry for deaf patients using American Sign Language to communicate over video. It was remarkably faster and more convenient for psychiatrists to see patients using telemedicine instead of driving from patient to patient for in-person visits. Patients in rural areas could see specialist providers unavailable in their local area. Primary care providers could also access psychiatric consultants to help manage their patients. There were many reasons why telemedicine did not take off at the time in the early 2000s, mostly related to the availability of technology such as expensive videoconference devices as well as access to the ISDN lines since dial-up Internet access from home and businesses provided speeds insufficient for good quality video referred to as the “last mile problem” in telecommunications.

IMPROVING TECHNOLOGIES

Over time, the speed and availability of the Internet improved. Dial-up modem access gave way to broadband access via DSL or cable modem with speeds measured in megabits per second (Mbps or 1,000,000 bits/second) compared to dial-up speeds of (kbps or 1,000 bits/second). Increased Internet access speeds helped develop better HTML standards to support additional website features, such as incorporating video, improved navigation elements, and database integrations. In turn, these improved features brought about website developments enabling the delivery of more than just health care information.

The relative privacy of searching for health information online made searching for health topics one of the more popular search terms. Online assessment tools for mental health began to proliferate on the Internet. For example, the PHQ-9 screening tool for depression is widely available on numerous websites such as Mental Health America. Online support

Telegram: @medical_k

www.konkur.in

groups for patients, such as DailyStrength.org, provided a community where patients with anxiety, depression, bipolar disorder, and schizophrenia could share their experiences. Patients felt less alone with their illness and received peer support. However, these forums were not moderated by health professionals, which meant that if someone posted thoughts of suicide, there may be delays in that person getting urgent assistance via a welfare check. The relative anonymity as well of an online profile also meant that sending a crisis evaluation team would be nearly impossible. TogetherAll.org has peer-to-peer support and registered mental health practitioners to monitor the safety and anonymity of members. These mental health practitioners can also provide online one-on-one sessions if needed. TogetherAll has a process of escalation if there are safety concerns, and their policy states that they will pass information to emergency responders. TogetherAll is freely available to all citizens in the United Kingdom, but in the United States, access is limited to universities and colleges that have arranged for services to augment student mental health services. PatientsLikeMe.com takes sharing to another level. On this website, patients share data such as symptoms and treatments used to manage those symptoms, including medications. Patients share their experiences with different medications, psychotherapy, lifestyle modifications, and treatment programs, as well as track their progress with those treatments.

More than a thousand health information and support websites are available to patients on the Internet, so it is unrealistic for any health care provider to have knowledge or access to all of them. When an online website influences their decision-making on whether to start a medication or undergo a procedure such as electroconvulsive therapy, it is helpful to ask to see from what site or article they are getting their information. Reviewing this information together will help them understand their concerns and provide direction as to what further education may be necessary. Larger health organizations often contract with patient education platforms such as X-Plain to integrate these educational materials into the electronic health record. Providers can add relevant information to the printed after-visit summary or send a link for viewing in the patient portal. Ultimately, it is a process of listening, validating their concerns, and using motivational interviewing skills to facilitate decision-making.

Telegram: @medical_k

www.konkur.in

One of the earliest forms of electronic communication has been electronic mail or email. In many ways, it is easier to use than just voice mail, which often is difficult to transcribe and not always accessible outside of the office. The American Medical Informatics Association Internet working group developed guidelines in 1989 for email communications with patients. Their recommendations included informing patients that email is not constantly monitored and is not to be used for urgent communication. They recommended that patients sign an affidavit recognizing these appropriate parameters for communication. Many of their recommendations still hold today. Joel Yager, MD, used email as an adjunct for communication with his patients with eating disorders in New Mexico. Many of his patients lived in rural communities and traveled long distances to see him; therefore, email was a convenient way to follow up on their progress and provide documentation for their medical records.

The Health Insurance Portability and Accountability Act (HIPAA), enacted in 1996, marked a major milestone regarding health information privacy in the United States. This law provided provisions to improve the effectiveness and efficiency of the health care system with national standards for electronic health care transactions, code sets, unique health identifiers, and, most significantly, security. The privacy rule sets standards for protecting individuals' medical records and other personally identifiable health information. It requires appropriate safeguards to protect the privacy of protected health information and limits appropriate disclosures of such information without the patient's authorization. Other elements include rights to copy the records, direct a covered entity to transmit this information to a third party, and correct this information. The security rule requires physical, administrative, and technical safeguards to ensure the confidentiality of health information. The enforcement rule highlights civil monetary penalties for breach of confidentiality and provisions for compliance and investigations. Any adoption of health information technology needs to ensure that the guidelines laid out in HIPAA are followed.

Communication with patients using email in a HIPAA-compliant manner was not a simple matter in the early days. End-to-end encryption has been considered the gold standard in ensuring that communication between provider and patient remains secure. The use of encryption software such as Pretty Good Privacy, developed by Philip Zimmerman, was initially cumbersome and required several steps. The first was to

Telegram: @medical_k

www.konkur.in

exchange public “keys,” which are the encryption rubric, so only the key owner could decode the message. Then the message text had to be copied into a separate security software application for encryption using the key. The now encrypted text could be copied into the email for sending to the recipient. The recipient would then use their key and password to decrypt and read the message. Nowadays, such encryption is managed in a variety of ways. Enterprise-level communication via email has built-in encryption invoked by a security code word in the subject of the email, thereby reducing the administrative burden on the sender and recipient with no exchange of keys nor use of a separate application. Companies such as ProtonMail and Tutanota provide secure email for individual practices via their Internet or web-based platform.

In this period, electronic health records also began to proliferate and develop. These are software applications designed to capture health data in a structured manner for ease of retrieval and organization. Early psychiatry adopters of computer use began with word processing or database software to manage health information. The advantages of electronic health records over paper include legibility, access by many simultaneously, and ease of analysis for population health. The Health Information Technology for Economic and Clinical Health (HITECH) Act in the United States in 2009 provided incentives for using electronic health records in clinical practice, known as “meaningful use.” Hospitals and individual providers could earn extra compensation from Medicare and Medicaid by meeting objectives in the electronic health record incentive program. Stage 1 involved data capture and sharing. Stage 2 involved advanced clinical processes such as drug–drug interaction and alerts regarding best practices. Stage 3 required improved clinical outcomes such as decreased falls or adverse events such as inappropriate dosing. Nowadays, without meeting these requirements, there are penalties via a reduction in reimbursement from Medicare and Medicaid.

Determining which health record system to use is a complex decision, requiring consideration of many factors. Documentation tools such as macros add standard text to help increase the speed of documentation. Not all providers are fast typists, so using voice recognition software or integrating medical transcription services may be a deciding factor. Electronic prescribing nowadays is a must since the reconciliation of medications is part of the meaningful use criteria and saves time over phone calls and sending facsimiles. Integration with billing, scheduling,

Telegram: @medical_k

www.konkur.in

and practice management software are key features. Likewise, integration of lab orders and results decreases time spent tracking down facsimiles or logging in separately into a web-based portal. Connections to a regional health information exchange may appropriately and securely share medical information electronically to improve health care quality, speed, safety, and cost. The ability to create a continuity of care document for ease of information exchange with other health care providers is another important feature of electronic health records. Other significant details include how the data or system is backed up and whether there is secured access remotely or online. An oft-overlooked feature is how the health record system manages users in the same medical record and addresses the need for users to enter and edit information without data loss and appropriate version control. A patient portal facilitates secured communication to providers and staff and is a must-have to decrease dependency on voicemail, email, and fax. Management of user access is often overlooked as a key feature of electronic health record systems, and it is part of the HIPAA requirement to ensure security and monitor access logs. To decide which of the above features are the highest priorities is certainly a challenge, and most vendors should have a training environment to try out the system for a test drive.

Like deciding which car to drive, an electronic health record system must be fairly intuitive. The user interface may be the most important feature of all. Navigation should be easy with both mouse and keyboard, and graphic visuals help orient the user to what function is used. Some developers will welcome requests for new or custom features, which they may build for minimal cost if that improves their system. Training demands and the ability to customize features are significant factors in selecting an electronic health record. Many health record systems offer mobile applications for the tablet or smartphone in additional to traditional desktop access. Information should be accessible and actionable no matter the provider's platform. The company's longevity may be the ultimate deciding factor because updates and maintenance become onerous tasks when the company becomes defunct.

HEALTH 2.0

A significant shift on the Internet has been the concept of Web 2.0, where new applications and sites began to harness collective intelligence and

Telegram: @medical_k

www.konkur.in

opinion. Wikipedia, an online encyclopedia where any web user can add and edit entries, is a good example of this paradigm. Real Simple Syndication (RSS) is a technology that allows people to not only link to a page but to subscribe, such that they are notified when there are changes. YouTube is another example where the site is a platform for users to upload any video content of their creation. In Web 1.0, there are hyperlinks to different sites, but with Web 2.0, the added element is interaction, engagement, and shared experiences. Health 2.0 is merely the application of these newfound principles to websites and services linked to health care. Prime examples of Health 2.0 sites were discussed earlier with patient support sites such as DailyStrength and PatientsLikeMe. These features of user-generated content to be shared online via various tools led the way for social media to become one of the more predominant features of online use.

At first, the general public's adoption of social media use was slow. Facebook was initially only for college students before opening to anyone over 13. Although Facebook is now considered the largest social media site, it was not always the most popular. MySpace was the first general social media site in popularity, but with the rising popularity of games such as Farmville on Facebook, the ability to post classifieds to sell products, chat features, and the addition of businesses on Facebook, it began to quickly become the main social media destination. The health care industry as a whole was slow to adopt the use of social media for professional purposes. The American Association for Directors of Psychiatric Residency Training created vignettes for discussion and exploration of resident physician views regarding appropriate professional versus personal use of social media in its Virtual Training Office.

The general public and health care providers' attitudes regarding social media use began to change. The initial recommendation to have separate professional versus personal accounts began to fade as people began to accept that both personal and professional online information became aggregated. This blurring of professional and personal use is best exemplified by how LinkedIn, a professional social media site, began to incorporate more features similar to Facebook with news feeds, hobbies, shared videos, likes, and messaging, while Facebook began to offer news and a marketplace for businesses. It also heralded the beginnings of how the convenience of using one login, such as Facebook, Google, or AppleID, to log into multiple websites began to override privacy concerns

Telegram: @medical_k

www.konkur.in

regarding information shared across these platforms. Linked accounts indicated one's interests, preferences, and purchasing tendencies thereby creating a digital information profile that commercial companies use to market goods and services. The value of convenience developed alongside the burgeoning "gig economy" where freelancers provide food delivery or transportation services.

Hospital systems began to develop a presence on social media primarily for marketing, extending the brand beyond the expected website to provide information. YouTube, X, formerly known as Twitter, and Facebook are popular platforms to tout the services available and message the public regarding expertise and quality recognized by U.S. News and World Report, Leapfrog group, and many others. Community outreach with online seminars linked to national health campaigns such as mental health awareness month provided hospitals and large groups a presence online, just as valuable as television and radio marketing. Health fairs, traditionally held in person, are shifting toward video conferencing to engage an audience beyond the local arena. Social media presence for health care agencies, health systems, providers, and companies is no longer novel or innovative but a must to engage the public or target audience.

Individual providers initially used professional social media to market their practice as an extension of their practice website; however, many are now using social media platforms such as Facebook and Yelp as primary ways to hang their virtual shingle. Links on these sites to curriculum vitae, blogs, and other social media platforms may lead to scheduling an appointment via a telephone call, email, or self-scheduling online. Voicing opinions on new research via X or retweeting other posts creates a professional presence and identity that serves many purposes. The ever-present #hashtag, popularized by X and now used universally across many social media platforms, helps the audience find providers with expertise in their area of interest, whether for patient care, research, or networking for future collaborations. Doximity, a professional network for providers, offers the ability to connect for ease of referrals and useful tools such as web-based electronic faxing and secured dialing that allow providers to keep mobile phone numbers private. In addition, Doximity provides individual providers the ability to rate hospital systems and residency programs in conjunction with U.S. News and World Report, as well as continuing medical education opportunities with articles and

Telegram: @medical_k

www.konkur.in

recorded webinars. Social media marketing of medical practices follows the natural trend of consumers who eschew the traditional white pages and guides such as Zagat for search engines and socially driven review sites such as Yelp.

Patients have benefitted tremendously from social media as a medium to share stories of life experiences beyond vacation photos, birthday parties, or gatherings. It has become a multimedia interconnected platform of photos and videos with linked comments and emoji reactions, where people share everything, including political views, favorite restaurants, and anything that comes to mind. Social media has bridged the communication gap that email, phone calls, and text messages could not with its broader community reach and engagement. Many social media users have shared their feelings with family and friends, which decreases isolation and loneliness. Searching on Facebook for “depression” has Facebook curated resources on how to take care of your emotional health or find health for a friend. Articles on depression from various websites are just a click away, and Facebook pages about depression are a collection of posts with comments from people regarding their experiences. People have found social media sites helpful in extending and improving relationships with those they already know and making connections to new people and groups. It is this extended yet separate sense of community that facilitates people to make announcements on Facebook that they are coming out or having suicidal thoughts. Many patients have been brought to the emergency room because they have written concerning posts about suicide, which has led Facebook to use Artificial Intelligence (AI) to review phrases in posts and comments for worrisome statements such as “had anyone heard from them?” In some ways, social media has created an extended community that oversees the well-being of its users besides their direct friends and family.

Just like any device or tool, social media has its detractions. The anonymous nature of creating a profile without the need for validation of the owner has fostered an opportunity for cyberbullying as well as “trolling,” which is a quite different concept than using the word when fishing. Internet trolling is when someone comments or responds to a post, usually in a confrontational way to evoke a strong emotional reaction, often for amusement. Trolling can be emotionally harmful, especially for young developing egos. Internet pranks, such as the

Telegram: @medical_k

www.konkur.in

#cutforbieber, can propagate through social media platforms, causing physical harm in addition to its emotional impact. Overuse of social media has led to problematic use that impacts psychosocial function, and well-being has led to social media addiction. A Healthy Minds Monthly poll by the American Psychiatric Association in January 2022 of 2,200 adults revealed that a third of Americans say social media does more harm than good for their mental health. It may be that asking about social media or video game use should be part of the standard regular new patient intake inquiry.

Social media and other online content also has another consequence. Together, they build an informational “picture” of a person online with the mosaic of social media posts, comments, likes, pictures, articles, videos, and anything else tagged about that person on the Internet. All this information creates a veritable Internet Rorschach test for others to decide if this person is a professional with whom they may visit in the future. Physician rating sites such as Healthgrades and Vitals summarize the prospective patient details such as medical school education, residency training, board certifications, office locations, and hospital privileges. They also rate the provider and office based on friendliness, wait times, cleanliness, and how the interaction went. More significantly, there is an opportunity for patients to post comments about the provider. Although a referral from a colleague or friend is still the most common way patients find their providers, the Internet and physician rating sites may soon become the norm. Issues arise when the reviews are not positive, as that stain on reputation online may deter future patients from considering that provider. Most sites provide little recourse for the provider regarding negative reviews as they say it threatens the integrity of their platform to be an open space. If the review uses profanity or appears to be bullying, sites will consider deleting negative comments. Some physician rating sites will offer a premium account, which offers the opportunity to have a higher profile spotlighted or marketed on the site, pushing down the negative reviews lower, akin to the last page of an Internet search. It may be tempting to have patients post positive reviews as a rebuttal; however, the ask itself is problematic as a boundary-crossing. There is a report of a New York City OB/GYN who sued a patient for false and defamatory reviews in 2018, which was successful in a court order to remove all online postings. This measure is quite costly regarding attorney fees, given that online physician rating sites are not yet the main source for

Telegram: @medical_k

www.konkur.in

patient referrals. Firms such as ReputationDefender offer to fix search results, remove personal data, and manage business reviews. These services also come at a significant cost that must be weighed to decide the service's value. Self-help tips include monitoring your name searches with alerts from Google, validating your profile on physician rating sites to fix errors, and creating your own website with links to desired sites to promote their search engine optimization.

In addition to the online reputation issue, social media and other online content also create a privacy risk to the provider. Search engine websites have indexed countless search terms, including people's names, so that they can save a search results list for future reference. People search engines such as TruePeopleSearch and Intellius take the Internet search further by linking other information such as court records, property records, and other publicly available databases. These search results identify significant details such as a home address, relatives, and age. While these details perhaps are not as alarming as social security numbers, credit cards, bank accounts, and other details for sale on the dark web, this readily available personal information poses a significant privacy risk. Scott McNealy, Sun Microsystems cofounder, is often quoted from a Fox Business interview as saying, "You have no privacy; get over it." Despite the truth of his statement, there are many ways to limit information exposed online. People Search Sites have opt-out options due to the privacy laws of states and the federal government. The Reputation Defender website also offers a self-help guide to removing personal information from the internet, such as providing the bare minimum of information in your profile and locking down privacy settings by limiting access to posts. Jumbo, an app available on both Apple and Android mobile operating systems, also ensures privacy by archiving old Facebook, Instagram, and Twitter posts; deleting your Google, Gmail, and YouTube search history; as well as notifying you if data such as credit cards, email passwords have been compromised. DeleteMe is another vendor that will remove private information from over 500 data brokers. Privacy is a relative commodity that requires active monitoring and a decision to actively prune the weeds of exposure or hire a gardener.

APPS AND ARTIFICIAL INTELLIGENCE

Telegram: @medical_k

www.konkur.in

The most recent wave of technology use in mental health has been the explosion of “apps” or applications for the smartphone. Social media use encouraged smartphone adoption as many posts are created on the fly and in real-time using these devices. The almost ubiquitous cellular signal availability and open wi-fi networks have made interacting with the Internet and each other with these devices an every day and all-day phenomenon. Indeed, leaving home without a smartphone is worse than leaving the house without keys. Apps such as maps are used daily for travel by foot or car as well as email, notes, and text messages. The COVID-19 pandemic has accelerated the use of telemedicine and apps for mental health due to the heightened need for services and increased access to mental health services that they provide. With so many apps available, the question of which ones to recommend to patients becomes a daunting task.

Many types of mental health apps are available in the Apple App Store and Google Play. Some are conduits to mental health providers, providing secure video conferencing, secured texting, or asynchronous communication. Other apps provide direct services using cognitive behavioral therapy approaches or have rating scales to provide the psychiatrist with status reports in-between visits. Reading reviews on the App Store or Google Play from users is not optimal as the prior user criterion for assessment is quite variable. The American Psychiatric Association has created an “App Evaluation Model,” a helpful framework for assessing whether an app is worthy of recommendation. The model implements several steps: access & background, privacy & safety, clinical foundation, usability, and therapeutic goal. The detailed questions asked are appropriate but may easily overwhelm those who intend to recommend them. The Argosy Foundation has funded Mindapps.org, an online database of apps reviewed using the APA framework. This site facilitates selecting apps for consideration with various filters such as cost, supported conditions, privacy, and features and is updated with new reviews by trained app raters. Ultimately, your patient will vote with their fingers as many apps are downloaded, but few are used regularly.

Artificial Intelligence in apps like chatbots is the next wave of behavioral health computing. Woebot and Wysa are examples of chatbots in production, using CBT, DBT, meditation, and motivational interviewing to help users build mental resilience and feel better. While most of the interaction is with the AI coach, there are links to human therapists when

Telegram: @medical_k

www.konkur.in

needed. The chatbots are not designed for crisis intervention or severe and persistent mental illness but are best used by the patient focused on wellness. They ask questions in a non-threatening tone and may include probing questions about local news events such as the COVID-19 outbreak and its impact on the user. Keywords such as “suicide” or “homicide” trigger safety protocols, including a human intervention or a call to 911 services. Chatbots are not poised to resolve the problem of not enough therapists, but certainly are a tool that may provide a bridge until a therapist is available.

A related product are digital therapeutics. Many of these are applications available on the smartphone and online via a web browser that treat serious conditions such as attention deficit hyperactivity disorder, depression, insomnia, and substance use disorders (SUD). Some of these are prescription based and therefore have been evaluated by the FDA and are reimbursed as products via pharmacy and medical benefits. They increase patient access to effective therapies and often extend the clinician’s ability to care for patients. Payors are involved as these solutions are scalable and cost-effective. Digital therapeutics are still in their infancy, but with the growing demand for mental health services, they will certainly grow and play a role soon.

CONCLUSION

The use of technology in psychiatric practice has grown slowly at first, but now adoption is at a more rapid pace. Traditional barriers used to be computing power, Internet access, and availability. Over time, desktop computers have given way to laptop computers and now smartphones and tablets with the continual development of smaller and more powerful central processing units, flash memory, and faster wireless Internet every year. Cloud computing and software as a service have also created an infrastructure where computing runs on the device and the network. Improved user interfaces and better multimedia graphics, along with a plethora of digital content online—websites, games, social media, and the like, have created a Matrix-like world where everything and everyone is connected. At first, the digital immigrants, who did not grow up with technology, were slow to embrace the digital world that digital natives, who grew up with technology, find incredibly necessary to their daily lives. It remains to be seen how growing up with technology changes the

Telegram: @medical_k

www.konkur.in

developing brain and how the preponderance of digital communication via text, social media, and email changes the value of direct human interaction. Will future generations have greater difficulty with nonverbal cues, or will they be better since AI-based avatars will help them determine what next steps to take? More significantly, will health care providers need to retrain much as factory workers and taxi drivers have done because technology has changed the need for their services with robots and automation? Health care has traditionally lagged behind in technology implementation due to privacy concerns and hefty regulations, but in the new future, it may be a different picture.

31 Psychiatric Emergencies

31.1 Suicide: Overview of Epidemiology, Risk and Protective Factors, Treatment, and Prevention

DANUTA WASSERMAN, M.D., PH.D., AND VLADIMIR CARLI, M.D., PH.D.

The problem of suicide cannot be limited to just one discipline, and the complexity of self-destruction transcends the psychiatric field. Suicide can be viewed from many perspectives like religious, philosophical, anthropologic, sociologic, ethical, psychological, and psychiatric/medical. A new body of literature stemming from research across numerous research disciplines informs a multidimensional understanding of suicide risk, which can be summed up by understanding suicide as a complex health outcome.

A stress-vulnerability model has been proposed to consider the complex interaction of several risks and protective factors in the development of the suicidal process. According to this model, a constitutional predisposition ("trait" or "diathesis") to suicidal behavior is developed through the influence of genetic factors and/or early prenatal, perinatal, and postnatal experiences, and determines the

Telegram: @medical_k

www.konkur.in

individual's suicidal threshold. Internal and external stressors interact with a diathesis and determine suicidal risk. Throughout the course of life, the resilience to stress and the suicidal threshold may be enhanced or diminished by the influence and interaction of different risk and protective factors, such as psychiatric or somatic illnesses, alcohol or drug use, traumas, coping, and problem-solving strategies, and social support. Furthermore, acute stress factors, such as relapse or exacerbation of illnesses, separation or losses, bullying, and economic problems, may act as triggers for suicidal behavior.

The development of suicidal behavior is a dynamic process. It may evolve from death wishes to suicidal ideation and then into suicide attempts and suicide. However, most suicidal processes do not end in death by suicide since death wishes and suicidal ideation fade away thanks to others' protective responses to suicidal communication, as well as treatment interventions. Nevertheless, if new life stressors occur, the suicidal process may be reactivated with fewer positive outcomes.

Given this complexity, suicide prevention requires a comprehensive and multidimensional approach targeting both public health and health care sectors. The health care strategy aims at identifying risk groups, improving diagnostics, treatment, and offering better rehabilitation for suicidal patients. Health care interventions can be selective and target subgroups displaying risk factors for suicide, or indicated, that is, targeting individuals with identified psychiatric disorders, who have severe suicidal ideation or have attempted suicide.

The public health approach utilizes universal and selective strategies that aim to increase awareness about the role of protective factors for mental health, improve support and attitudes toward individuals with mental illness or suicide risk, and promote measures to eliminate fears and misunderstandings that surround suicide. It also comprises strategies for promoting mental health, social welfare, and education policies. Both clinical treatment and community-based interventions have growing evidence for actions that can reduce suicide risk.

Telegram: @medical_k

www.konkur.in

Protective factors for suicide include cognitive flexibility, active coping strategies in difficult life situations, healthy lifestyles, active social networks, confidence, and a sense of personal value, as well as the ability to seek advice from others and help from the health care system.

This chapter focuses on the broad spectrum of psychopathology in suicidality and on treatment and preventive interventions used in the health care and public health sectors.

Universal public health interventions like restricting lethal means to suicide and school-based interventions are also shortly described.

EPIDEMIOLOGY

Suicide

Suicide occurs in all regions of the world and throughout the entire life span. According to the World Health Organization (WHO) 2019 estimates, with more than 700,000 deaths every year, suicide is among the leading causes of death worldwide. Indeed, suicide accounts for approximately 1.5% of all deaths, more than those due to breast cancer, war, and homicide. Suicide rates are likely to be even higher due to under-reporting, as not all countries report suicide mortality to the WHO. Furthermore, only 60 out of 194 Member States have good quality mortality registration data, and even in countries with good mortality statistics, suicides can be misclassified as accidents, homicides, or unknown causes of death.

In 2019, the global age-standardized suicide rate was around 9 per 100,000 population, even if large variations between different countries and regions are reported. The Eastern Mediterranean region showed the lowest suicide rate (6.01 per 100,000), while the highest rates were found in European (12.08 per 100,000), South East Asian (11.19 per 100,000) and African (10.28 per 100,000) regions. Within the same region, suicide rates can vary from one district to another. Therefore, it is important for tailored suicide prevention to survey local data from both population and clinical settings, as risk groups and risk factors can vary considerably at the

Telegram: @medical_k

www.konkur.in

local level. Moreover, in the same year, the global suicide rate for males (13.25 per 100,000) was more than double that of females (5.74 per 100,000).

Globally, suicides account for 57% of all violent deaths in men and 71% of all violent deaths in women. In high-income countries, 85% of violent deaths in both males and females are caused by suicide.

Among young people 15 to 29 years of age, suicide is the fourth leading cause of death globally, following road injury, tuberculosis, and interpersonal violence, accounting for more than 150,000 deaths per year.

Table 31.1–1.
Age-Standardized Suicide Rate by Sex in WHO Regions[a]

Year 2019	Age-Standardized Suicide Rate, Both Sexes (per 100,000)		
	Both Sexes	**Males**	**Females**
Africa	10.28	16.57	4.66
Americas	8.51	13.75	3.65
Eastern Mediterranean	6.01	8.51	3.29
Europe	12.08	19.94	4.69
South-East Asia	11.19	13.45	9.01
Western Pacific	7.65	10.33	15.13
Global	9.39	13.25	5.74

[a]Data from World Health Organization. Global Health Observatory. 2019. https://www.who.int/data/gho/data/indicators/indicator-details/GHO/age-standardized-suicide-rates-(per-100-000-population)?bookmarkId=5be1bd45-0345-4d38-b75f-3602374891ea.

Tables 31.1–1 and 31.1–2 show the number and suicide rates by sex and age group in all WHO regions.

Suicide rates for males are highest in the European Region, followed by the Regions of Africa and the Americas. Suicide rates for

Telegram: @medical_k

www.konkur.in

females are highest in Southeast Asia and Western Pacific Regions.

In Table 31.1–3, the absolute numbers, crude, and age-adjusted suicide rates per 100,000 persons in each state in the United States are shown. The age-adjusted suicide rate in the United States is 14.1 per 100,000 population. The highest age-adjusted suicide rates are in Wyoming (32.3), Montana (32.0), Alaska (30.8), New Mexico (25.0), and South Dakota (23.1), while the lowest are observed in the District of Columbia (6.2), New Jersey (7.1), New York (7.9), and Massachusetts (8.0).

Table 31.1–2.
Crude Suicide Rates by Age and Sex in WHO Regions[a]

	Crude Suicide Rates (per 100,000)					
Year 2019	5–14	15–19	20–24	25–49	50–69	70+
Africa	0.57	3.52	6.08	9.43	20.78	44.69
Males	0.85	5.21	10.03	15.67	32.31	72.21
Females	0.29	1.88	2.36	3.59	10.16	21.98
Americas	0.69	7.77	11.16	11.45	13.62	14.67
Males	0.79	10.89	17.95	18.28	21.98	28.10
Females	0.59	4.54	4.27	4.86	5.97	4.32
Eastern Mediterranean	0.50	5.93	9.63	8.77	7.47	8.92
Males	0.70	7.91	13.97	12.40	10.73	12.59
Females	0.29	3.81	5.04	4.77	3.88	17.47
Europe	0.57	7.11	12.60	18.44	18.62	22.33
Males	0.76	9.90	19.98	30.69	30.58	39.11
Females	0.37	4.16	4.78	6.08	7.90	11.24
South-East Asia	0.92	11.30	18.34	15.92	13.33	19.47
Males	0.85	8.35	18.02	20.21	17.42	25.65
Females	0.99	14.43	18.67	11.50	9.33	14.16
Western Pacific	0.38	3.65	6.93	8.03	12.94	32.82
Males	0.45	4.54	9.60	11.19	16.59	42.74

Global	0.64	7.02	11.61	12.05	14.25	24.53
Males	0.75	7.45	14.75	17.45	20.40	36.23
Females	0.53	6.57	8.38	6.57	8.33	15.38

[a]Data from Institute for Health Metrics and Evaluation. Global Burden of Disease Study 2019 (GBD 2019). GBD Results Tool. http://ghdx.healthdata.org/gbd-results-tool?params=gbd-api-2019-permalink/a7cb270a3838b12d7e28ca2e59fdd698.

Socio-Demographic Factors

Although 77% of suicides occur in low- and middle-income countries, the highest age-standardized suicide rate is found among high-income countries (10.9 per 100,000). In particular, suicide rates are highest among males in high-income (16.4 per 100,000) and low-income (15.2 per 100,000) countries. In contrast, the highest suicide rate among females is reported in lower-middle-income countries (7.11 per 100,000). Differences between genders in coping with stress and conflicts, patterns of alcohol consumption and help-

Telegram: @medical_k

www.konkur.in

seeking behaviors for mental disorders, as well as access to lethal methods of suicide, can explain regional and gender differences.

As shown in Table 31.1–2, suicide rates are highest both for males and females in persons aged 70 years and older in nearly all regions of the world. An exception is represented by South-East Asian females, where the suicide rates seem to peak in young adulthood.

Status of being unmarried, divorced, widowed, older adults, unemployed, immigrant, and having different sexual orientations are risk factors increasing the propensity for suicide. Moreover, individuals in the armed forces, veterans, prisoners, and indigenous people have an increased risk of suicide. Since Durkheim, religion, marriage, and parental responsibilities are known key factors that play a crucial role in controlling suicide impulses. Moreover, the impact of values, social-political trends, societal patterns of drug and alcohol use, and violence is also of great relevance.

Methods of Suicide

National-level data on suicide methods are limited, as many countries do not collect this information, especially in low-income areas of the world. In Europe, hanging (54.3% of male suicides and 35.6% of female suicides) is the most common suicide method. Among males, it is followed by the use of firearms (9.7%) and self-poisoning (8.6%), while, among females, other common suicide means are self-poisoning (24.7%) and jumping from high places (14.5%). Hanging and self-poisoning also appear to be the preferred suicide methods in Africa and Asia. Suicides by suffocation (59.2%), self-poisoning (17.7%), and firearms (13.8%) are predominant in Latin America and the Caribbean. In 2021, 55% of suicides in the US involved firearms. Suffocation (26%) and poisoning (12%) were other common means.

[a]CDC Wonder, Centers for Disease Control and Prevention. https://wonder.cdc.gov/
[b]Data suppressed due to confidentiality constraints (fewer than 10 persons per year).

It is estimated that self-poisoning with pesticides is responsible for approximately 20% of global suicides, and its prevalence is as high as 48.3% in low- and middle-income countries in the Western Pacific region. In some countries in Asia, jumping from high buildings is a

Telegram: @medical_k

www.konkur.in

common method of suicide. Since 1998, the use of barbeque charcoal, which produces highly toxic carbon monoxide gas, as a means for suicide has spread rapidly in many Asian countries.

Suicide Trends

Between 2000 and 2019, the global age-standardized suicide rate has fallen by 36%, with larger decreases in the European (47%) and Western Pacific (49%) regions. On the contrary, a 17% increase was reported for the Region of the Americas. According to CDC (Centers for Disease Control and Prevention), suicide rates in US increased by 37% between 2000–2018 and, after a 5% decrease between 2018–2020, they returned to their peak in 2021. The reasons for the observed decreasing suicide rates can be many. One likely explanation is the improvement of global health and the use of new treatment methods.

Attempted Suicide

There is a lack of systematic registration of attempted suicides across national levels. Data on suicide attempts typically derive from self-reported surveys in the general population or from hospital-based data of medically treated suicide attempts. Suicidal behavior tends to be rare during childhood and increases during adolescence and young adulthood. Both among adolescents and adults, suicide attempts are more frequent among females than among males. However, there is a wide variation in the attempt-to-suicide death ratio with respect to age, sex, region, and methods used.

Suicide attempts are known to be the single most important risk factor for completed suicide. In spite of this, there are very few countries that contain registries of medically treated suicide attempters.

In clinical work, the presumed continuum from suicidal ideation through suicide attempts to suicide completions can be a helpful model in understanding the suicidal process, risk detection, and treatment choices, even if this model cannot be applied to all suicides.

Telegram: @medical_k

www.konkur.in

RISK AND PROTECTIVE FACTORS FOR SUICIDE

According to the stress-vulnerability model, genetics and neurobiologic factors play an important role in the diathesis of suicide. Family and genetic studies show that the risk factors for suicide are both individual and familial. Suicidal behaviors aggregate in families, and a family history of suicidal behaviors is an independent risk factor for suicide attempts and death by suicide. The hereditability of suicidal behavior results from the contribution of multiple genes and genetic variants with small effect size, and it is at least partially independent of the hereditability of psychiatric disorders. To date, a large part of research on the genetics and neurobiology of suicide is focused on the study of the serotoninergic system, the hypothalamic–pituitary–adrenal (HPA) axis, and genetic and neurobiologic correlates of neuroplasticity. Other emerging areas of research involve the GABAergic neurotransmitter systems and inflammation parameters.

In the context of suicide, there is a growing body of evidence showing that exposure to childhood adversities can affect genes involved in crucial neural processes in the regulation of behavior through methylation and histone modification, which are supposed to induce behavioral deviations during the early development, and possibly later in life. This mechanism is called epigenetics. Childhood abuse and other detrimental environmental factors seem to target the epigenetic regulation of genes involved in the synthesis of neurotrophic factors and neurotransmission. On the contrary, family and school connectedness and support may act as a protective factor against suicide. Indeed, social relationships (e.g., social isolation, loneliness, sense of belonging, and social support) may play a major risk or protective role in the suicidal process, especially among adolescents and older people.

Impulsive and aggressive personality traits are largely recognized as suicide risk factors. Introverted, negativistic, perfectionistic, avoidant, dependent, and neurotic personalities are also associated with increased suicide risk. Other psychological characteristics, such

Telegram: @medical_k

www.konkur.in

as extroversion, curiosity, resilience, and self-esteem, seem to negatively correlate with suicidal thoughts and behaviors.

Increased suicidality is found to be associated with a wide range of health-risk behaviors, such as smoking, alcohol use, and sedentary behavior. On the contrary, healthy lifestyles such as being physically active and having a healthy diet may play a protective role against suicidality.

Finally, socioeconomic inequalities, such as high rates of unemployment, indebtedness, and job insecurity, as well as racism and discrimination toward ethnic and sexual minorities and people with mental health problems, are considered risk-conferring factors at community and societal levels. Conversely, country levels of social acceptance of people with mental health problems and availability of mental health treatments and services showed to negatively correlate with suicide rates in some countries.

PSYCHIATRIC DISORDERS AND SUICIDE

The presence of current and lifetime psychiatric diagnoses represents an important risk factor for suicide, even if the extent and the causal nature of this relationship are debated. Indeed, even if the majority of psychiatric patients do not die by suicide, an eightfold increased risk for suicide in psychiatric patients has been estimated using record linkage studies combining data on mental health service use and suicide deaths. Patients with psychotic disorders (risk ratio [RR] = 13.2) showed the highest risk, followed by mood disorders (RR = 12.3) and personality disorders (RR = 8.1). An increased risk for suicide was also found among patients with substance use disorders (RR = 4.4) and anxiety disorders (RR = 4.1). Considering these data, up to 21% of suicides may be prevented through the prevention and treatment of psychiatric disorders. Comorbidity between different psychiatric disorders, especially alcohol and substance use, largely increases the suicide risk. A suicide rate of 147 per 100,000 psychiatric inpatient years has been calculated, with a history of suicide attempts, depressive symptoms, suicidal ideation, and a

Telegram: @medical_k

www.konkur.in

family history of suicide being among the factors increasing the risk of inpatient suicide.

Depressive Disorders

Major depressive disorder (MDD) is strongly linked with suicide, especially when recurrent and long-term conditions are triggered by acute negative life events.

The clinical picture of MDD is characterized by symptoms like weight loss or gain, sleep disturbances, fatigue, concentration difficulties, changes in psychomotor capabilities, feelings of worthlessness, guilt, and recurrent thoughts of severe suicidal ideation with suicidal plans.

Patients diagnosed with persistent depressive disorder (dysthymia) complain of irrational patterns of negative thinking and chronic dysphoria.

The risk of suicide varies between the different subtypes of depression. Depressed suicidal patients have similar risk factors for suicide as patients with other psychiatric diagnoses, namely, living alone, being unmarried, unemployed, and especially having a history of previous suicide attempts. Furthermore, an increased risk of suicide was found among depressed patients with alcohol and/or substance use, anxiety symptoms, and personality disorders. Physical illnesses also increase the risk of suicide and attempted suicide in depressed patients, especially in the older adult population.

Affective temperaments like cyclothymic disorder and anxiousness are associated with both suicide attempts and suicide. Such temperaments, along with irritability and rapid mood switches, are important contributors to triggering suicidal acts. To prevent suicidality, treatment of depression with a combination of pharmacologic and psychological methods is recommended.

Bipolar Disorders

Bipolar disorders are separated from depressive disorders in the DSM-5 classification and are placed between the diagnostic class of depressive disorders and schizophrenia/other psychotic disorders in

Telegram: @medical_k

www.konkur.in

order to denote a bridge between those two diagnostic classes with respect to symptoms, family history of psychiatric disorders, and molecular genetic findings. Bipolar disorders constitute a high-risk group for suicide and attempted suicide. It is estimated that suicide accounts for up to 15% to 20% of deaths in people with bipolar disorders and that one-third to one-half of bipolar patients attempt suicide. The majority of deaths by suicide in this population occur when they are in a major depressive episode or in episodes with mixed features. Suicide during the manic phase is rare. The prevalence of suicide attempts is similar in both type I and type II bipolar disorders. However, younger age at illness onset and depressive polarity of both first illness episode and current or most recent episode significantly increase the suicidal risk. Other common risk factors are a family history of suicide and comorbidity with borderline personality disorder (BPD), anxiety disorder, and substance use disorders, especially alcohol use.

Effective pharmacologic treatment supported by psychological techniques is the primary strategy to prevent completed suicide.

Alcohol and Substance Use Disorders

Excessive alcohol and substance use, leading to significant impairment and distress, are well-recognized conditions for an increased risk of suicidal behaviors. Comorbidity with personality disorders magnifies the risk of suicide. Suicide mortality is highest among drug users, especially when opioid substances are involved, and lower, but still high, among persons with alcohol use disorders, as well as more prevalent among males compared to females.

Excessive alcohol and substance use increase sadness and feelings of despair, as well as aggression and impulsivity. Furthermore, it causes deterioration in cognitive capacity and flexibility to find constructive coping strategies. Finally, it might reduce the level of social integration. Suicidal alcohol users with a fairly good psychosocial coping abilities could make their suicide appear more astounding to their social networks. Good psychosocial functioning could potentially explain why they did not seek treatment or receive attention from significant others to motivate them for treatment.

Telegram: @medical_k

www.konkur.in

Triggers for suicidal behaviors in persons with alcohol and substance use disorders are losses of important relationships, work, economic security, and self-esteem. The more dependence the substance users experience in their relationships, the greater the risk that separation may push them into self-destructive acts.

Guidelines for the treatment of alcohol and substance use are published by the American Psychiatric Association (APA) and by the National Institute for Health and Care Excellence (NICE). The duration of treatment may vary, but it is important to use both pharmacologic and psychological treatments.

Decreasing the accessibility to alcohol both on a societal and individual level, as well as molding attitudes toward alcohol intake, show significant results in diminishing suicide, as described during the Perestroika period in the former USSR.

Anxiety Disorders

Anxiety as a risk factor for suicide has been neglected for a long time. There is a high comorbidity between mood and anxiety disorders, and severe anxiety and agitation strongly contribute to suicidal behaviors. There are many ways to assess the severity of anxiety, and it is important that suicidal psychiatric patients, especially those with mood disorders, substance use disorders, and psychotic states, are assessed for the presence of severe anxiety and treated for it.

Patients who suffer from severe anxiety may sometimes deny suicidal thoughts or suicidal intent and refuse hospitalization. It is recommended to document in the medical records the patient's refusal and level of anxiety and secure that outpatient treatment includes frequent follow-ups involving the family or social network whenever possible.

Schizophrenia and Other Psychotic Disorders

In the schizophrenic population, estimates show that approximately 5% to 10% die by suicide, and the risk is higher at illness onset. Already Bleuler drew clinicians' attention to the fact that the most serious of the schizophrenic symptoms is the suicidal drive.

Telegram: @medical_k

www.konkur.in

Moderate-to-severe depression is one of the most frequent features of schizophrenic patients who die by suicide.

Schizophrenics who die by suicide usually have poor treatment compliance, not seldom due to the side effects of antipsychotic medication like akathisia. Suicides often occur after abrupt discontinuation of medication due to negative attitudes toward medication and treatment. Poor treatment compliance, social isolation, and increased expectation of good performance from others and from patients themselves are risk factors for suicide in schizophrenics.

For a long time, there has been controversy surrounding the question of whether suicide in schizophrenia occurs during intense and frightening psychotic activity or during periods of remission. Studies found that command hallucinations are rare among completed suicides.

On the contrary, a good premorbid functioning, a higher level of education, or a higher intelligence quotient may predispose to suicide in younger schizophrenic patients, as they experience more disruption of performance and may have more difficulty accepting chronic illness and prospects of mental deterioration than older schizophrenic patients. Therefore, when giving information about the diagnosis, course of illness, and treatment, one should be aware that it is a risk situation for suicide.

Eating Disorders

Patients with eating disorders have an increased suicide risk. Thus suicide risk assessment should be included in a comprehensive clinical evaluation. High comorbidity of mental illnesses like MDD, bipolar disorder, anxiety disorders, and BPD among persons who are underweight as well as overweight is to a great extent responsible for the high suicide risk in all eating disorders. Treatment is often complicated and requires behavioral therapy combined with medication and supportive measures.

Low body mass index (BMI) and low serum cholesterol have been shown to be associated with a higher risk of attempted and completed suicide.

Telegram: @medical_k

www.konkur.in

Personality Disorders and Suicide

Personality disorders have been previously understudied in clinical and general population studies on suicidal behaviors. Nevertheless, it is estimated that more than half of individuals who died by suicide had at least one personality disorder, and a similar prevalence of personality disorders is found among psychiatric patients who died by suicide.

Persons diagnosed with Cluster B comprising borderline, antisocial, histrionic, and narcissistic personality disorders are characterized by poor impulse control, aggressivity, unstable identity, poor self-image, affective instability with proneness to experience, and strongly react to real or imagined environmental stresses and losses. Difficulties with interpersonal relationships, problem-solving, and the inability to plan and think about the future in positive terms increase the propensity for triggering suicidal behaviors. The highest suicide rate is found among people with BPD (10%). Furthermore, a history of a previous suicide attempt is reported in 50% to 90% of these patients.

Cluster C is characterized by a high level of anxiety and includes avoidant, dependent, and obsessive-compulsive subtypes. Few studies have investigated the suicide risk in these disorders. However, they may increase the suicidal risk when depression or other psychiatric disorders are present.

The study of suicide risk among Cluster A personality disorders has received little attention, even if some evidence exists for increased suicide risk for individuals with schizotypal personality.

Personality disorders contribute even more to the risk of suicidality when comorbid with other psychiatric diagnoses and in the presence of negative life events, especially those involving interpersonal distress and loss. Concurrence of psychiatric disorders with personality disorders is now recognized as a major risk factor in suicide and attempted suicide.

Somatic Disorders and Suicide

Studies performed in the United States, Australia, and Europe show an association between suicidal behaviors and severe or chronic

Telegram: @medical_k

www.konkur.in

somatic disorders.

The comorbidity of somatic disorders with psychiatric disorders, especially with MDD and personality disorders, substantially increases the risk of suicide. However, the increased risk persists even when adjusting for the presence of psychiatric disorders. Indeed, somatic disorders involve physical, psychological, and social repercussions. They imply stress, pain, sometimes handicaps, limited social performance, a decrease in the capability to work, and the increased need for help from others. Age and separation from loved ones, loneliness, hopelessness, helplessness, and social isolation are parameters of importance for suicide risk.

The suicidal situation and the suicidal propensity vary during the course of the somatic disorder and depend on the treatment outcomes and pain control, as well as on psychosocial comfort.

Cancer, HIV infection and AIDS, stroke, diabetes mellitus, epilepsy, Parkinson disease, trauma with subsequent brain damage, spinal cord injury, multiple sclerosis, Huntington disease (HD), and amyotrophic lateral sclerosis are associated with an elevated risk of suicide.

Older adult patients with chronic or incurable diseases need to have adequate somatic and psychiatric treatment, as well as good psychosocial care in times of shrinking economical resources. Different opinions on the distribution of economic resources can sometimes be associated with advocacy concerning euthanasia and assisted suicide.

Organizing home visits, case management, and regular telephone contacts with somatically ill and vulnerable older adults are effective preventive methods, as it diminishes isolation and provides the opportunity to detect risk factors and risk situations for suicide early.

SPECIAL POPULATIONS

Children and Adolescents

Poor Mental Health. Mental ill-health is among the leading causes of disability in young persons aged 5 to 14 years, ranking in second

Telegram: @medical_k

www.konkur.in

place in Europe and the Americas. The prevalence of mental health disorders among children aged 3 to 17 years in the United States is estimated to be 7.1% for anxiety, 7.4% for behavioral/conduct problems, and 3.2% for depression.

The results of the Saving and Empowering Young Lives in Europe (SEYLE) study showed that in a usual school class of teenagers, approximately 10% of young people display high-risk behaviors like excessive alcohol and illegal drug use, heavy smoking, truancy, etc. Thirty percent display unhealthy lifestyles like poor sleep and diet, physical inactivity, and excessive Internet/media use. Both of those groups have high levels of depression, anxiety, and suicidal behaviors. Approximately 12.5% of adolescents required qualified psychiatric and psychological help. However, experiences from the SEYLE study in Europe and the Columbia University TeenScreen program in the United States show that there is a fear of stigma when screening for mental health problems in schools, and both parents and adolescents show little trust in the mental health care systems. Therefore, the process of destigmatization of screening for mental disorders and increasing help-seeking behaviors is an important public health issue. SEYLE results show that younger adolescents are more likely to adhere to rules, procedures, and recommendations with higher attendance rates in the health care system for girls and for pupils victimized by peers. Suicidal behaviors also appear to be an important predictor of help-seeking and a predictor of referral to mental health care.

Risk for Suicide. A meta-analysis calculated a pooled suicide rate of 6.04 per 100,000 in 15 to 19 years adolescents, which is far higher than the rate found in 10- to 14-year-olds (0.93 per 100,000). Suicidal thoughts and behaviors at this age are also common, with a lifetime prevalence of about 30% for suicidal ideation and 4% to 10% for suicide attempts. For most adults, it is difficult to acknowledge the child's despair and suicidality. Caretakers, as well as parents, can deny serious childhood diagnoses due to frustrations and feelings of guilt when having difficulties handling a suicidal, depressed child or a suicidal child with serious conduct difficulties. Suicidal behavior in

Telegram: @medical_k

www.konkur.in

children and adolescents often occurs in the context of a poor family environment characterized by low perceived support, parent-child conflicts, and a lack of family cohesion. Parental suicide and psychopathology, particularly affective disorders and alcohol use, also increase the suicide risk in offspring. Suicidal children and adolescents have poor self-esteem and poor personal identity, are often truant, not seldom bullied, and have poor school grades, which leads to a sense of inadequacy. Impulsive-aggressive traits and impaired decision-making have also been described. Issues of gender identity are well recognized as risk factors for adolescent suicides. The presence of a mental health condition is associated with a 10 times higher risk of suicide death in young people, especially in cases of affective disorder, disruptive/conduct disorders, and substance use disorders. Attempted suicide is an important risk factor for future suicide.

Treatment. The treatment of suicidal children and adolescents should include the individual child and the entire family. Besides developing a safety plan, the aim is to improve coping styles and communication between the parents and the child. Psychosocial rehabilitation measures, including school consultation and academic remediation, are important.

The treatment of underlying psychiatric disorders requires psychotherapeutic and pharmacologic treatment when deemed necessary. Medications can play an important role in managing severe depression and reducing suicide risk when managed judiciously. When medication is used in the management of suicidal young persons, the family can get a false sense of security, as well as the fantasy that the problem has been solved, which may lower motivation to work through the problems in family and school situations.

Major advances have been made in effective treatment and care for youth at risk for suicide. Dialectical behavior therapy, cognitive-behavioral therapy (CBT), as well as a number of family-based therapies show evidence for reducing suicidal behavior in high-risk youth (e.g., attachment-based family therapy, family intervention for

Telegram: @medical_k

www.konkur.in

suicide prevention, Youth Nominated Support Team for Suicidal Adolescents). The common themes of these treatment approaches include the involvement of family to enhance positive communication and relationship dynamics, parent education and support, and treatment that goes beyond addressing the primary psychiatric condition to approaching suicide risk as to its own related but separate clinical target.

If the child or adolescent manifests psychosis, then hospitalization is required. Hospitalization may also be necessary in the case of extreme agitation, violence, or alcohol and drug use in the context of a disruptive home situation. If a young person perceives rejection in the family, a replacement home can be a solution during the period of treatment and rehabilitation.

Parent education using specialized resources—such as for parents of LGBTQ youth (Family Acceptance Program resources) or parents of bipolar or borderline personality disordered youth (Family Connections Program)—can be extremely helpful as well.

Older Adults

Risk Factors. In many regions of the world, older adults have the highest suicide rate compared to any other age group. The ratio of suicide attempts to suicide is very low among older adults, and therefore suicidal thoughts and plans in older persons should be taken seriously, given the increased fatality rate for attempts among older age populations. Decreased economical resources after retirement and placement into long-term care or residential care can increase the risk of suicide. Older adult suicides are characterized by high lethality methods, social isolation, and the presence of physical illnesses.

Diagnoses of MDD are the most common in older adult suicides, followed by a diagnosis of alcohol use and organic brain syndrome. Changes in sleep pattern, appetite changes, as well as somatic complaints or exacerbation of chronic concerns which stop an older adult from going out, can be a sign of depression. Symptoms of guilt, sadness, or anhedonia can be masked by somatic expressions. It is

Telegram: @medical_k

www.konkur.in

not seldom that cognitive functions are severely impaired, and depression can sometimes be misdiagnosed as dementia. Unconscious negative attitudes toward older adults may create a risk of not taking a suicidal risk in older persons seriously.

Evidence shows that dementia is not associated with an increased risk for suicide. However, the suicide risk can be higher in the period immediately after the diagnosis, especially in those of younger age, highly educated, and with preserved insight.

Treatment. The treatment of suicide risk in older adults benefits from focusing on aggressive identification and treatment of depression and enhancing social support. In cases of severe depression, when medication does not help, electroconvulsive therapy (ECT) can be recommended. In the treatment of older adults, drug-to-drug interactions are important to observe, as older adults often have multiple medications.

In talk therapy, it can be of value to focus on what the person has accomplished in life rather than talk about what may or may not lie ahead. Discussing suicidal ideation can be part of a process that puts one's life into perspective, and by acknowledging suicidal thoughts, the clinician can help the patient move away from the wish to die. Inclusion of family and other resources in the community should be encouraged in order to diminish loneliness and social isolation.

SUICIDE RISK ASSESSMENT

Even if suicide is regarded as a psychiatric domain, decisions regarding the level of suicide risk are made every day in all clinical specialties. Indeed, it is estimated that almost half of suicide victims had contact with primary care providers and one in five had contact with mental health services in the previous month. There are many obstacles when performing the suicide risk assessment due to the uniqueness of each individual possessing a unique set of risk factors. However, by engaging the patient in identifying drivers of suicide risk and reasons for living, it is possible to engage in a prevention-oriented suicide risk formulation. Foreseeable changes in the

Telegram: @medical_k

www.konkur.in

patient's life and environmental influences, which are likely to contribute to the outcome, are another key areas to engage the patient in safety planning for these foreseeable changes.

Clinical Interview

Suicide risk assessment is the most important instrument in clinical inquiry. This inquiry has an impact on the suicidal patients' communication, and to minimize the possibility of denial, it should be clear, empathetic, free from prior criticism, and focus on facts and patients' emotional and communication styles.

In a systematic clinical assessment of suicide risk, the presence of severe anxiety, MDD, use of alcohol or illicit substances, and previous suicide attempts should be covered. Personality type should be scrutinized. Intensive affective states characterized by severe anxiety, helplessness, hopelessness, rage, guilt, sleep problems, and impulsive behaviors are strong indicators of acute risk for suicide. Negative life events, such as bereavement, financial difficulties, and relationship problems, may act as precipitating factors. Indeed, disruption of social and occupational functioning is frequently reported among suicidal patients. Previous psychiatric disorders, suicide, or suicidal behaviors in the family should also be examined.

The recognition of direct and indirect suicidal communications is particularly important, and the clinician should explore if there is a suicide plan, its potential lethality, and the possible access to lethal means.

Repeated assessments are recommended to understand the mechanisms that generate the suicidal urge or impulse. Interview with the family or significant others is an important source of information. However, permission from the patient must be given, and it can sometimes take time to motivate the suicidal person to involve the family.

The evaluation of the social network and quality of family support should always be included when suicide risk assessment is done before temporary or final discharge from the hospital.

Psychometric Scales

Telegram: @medical_k

www.konkur.in

A set of scales can be used to complement clinical inquiry. The Ask Suicide-Screening Questions (ASQ), Suicide Intent Scale (SIS), Scale for Suicidal Ideation (SSI-C), the Beck Hopelessness Scale, and the Columbia Suicide Severity Rating Scale (C-SSRS) are used for screening and assessing the risk of suicide.

Some biologic and genetic markers have been described, but none of them has practical application for clinical suicide risk assessment at the present moment.

The final decision in the suicide risk assessment is always based on an intuitive judgment, and therefore the clinician should be aware of feelings toward a suicidal patient, which can contribute to a denial of suicide risk, a rigid approach to the patient, or even negative emotional states like ambivalence or hostility. Those feelings and behaviors are called countertransference.

MANAGEMENT OF THE SUICIDAL PATIENT

Hospitalization

Following the assessment of suicide risk, the first important decision to be taken is the choice between admission of the patient to a psychiatric ward or treatment in outpatient care. The decision does not depend only on the status of the patient but also on the quality of the available family support, availability of other community resources such as mobile crisis teams and respite centers, and the accessibility to qualified outpatient treatment.

Hospitalization is reserved for concerns about imminent safety risks, and most regions have a mechanism for involuntary treatment since it was traditionally felt that, in severe cases, hospitalization provides security if safety measures at the psychiatric ward are followed. In the management of the suicidal patient in the hospital, precautions are important in restricting access to means of suicide in the ward and establishing different degrees of freedom while maintaining an empathetic encounter. However, current advocacy and research support the use of least restrictive measures to support individuals through suicidal crises, and more evidence supports brief

Telegram: @medical_k

www.konkur.in

interventions like Safety Planning and other treatments such as CBT, DBT, CAMS, and other forms of therapy which engage the patient to not only stabilize but engage more deeply with effective treatment and reasons for living.

Suicide in the Ward

When a suicide or suicide attempt takes place in the psychiatric ward, it is important to give support to all patients. A regular suicide risk assessment should be carried out for patients who are at risk. In addition to the usual treatment, intensive psychosocial support should be given to work through the emotions and the possible identifications with the patient who died by suicide among patients in the same or neighboring unit. Also, the personnel at the ward should be given psychological support.

Treatment of Acute Suicidal Crisis

In the treatment of an acute suicidal crisis, it is important to focus on reducing anxiety, insomnia, depression, and psychotic symptoms. Collaboration with the family and significant others must be secured. Safety measures should also be considered in the home environment, and family members should be alerted of the increased risk of suicide after discharge from the hospital. The plan for follow-up treatment and establishing collaboration with rehabilitation units and community services for chronically suicidal patients, especially those with the diagnosis of substance use, schizophrenia, or other psychotic disorders, is recommended.

Finally, it is important to have proper documentation about communication between different departments, families, and social services and have a clear follow-up plan.

The patient and the family should also be informed that they need to seek psychiatric emergency services as soon as a new suicidal crisis arises. Brief intervention and follow-up contact are considered successful strategies for reducing future suicidal behaviors. It is aimed at identifying warning signs of suicide (SOS), promoting coping skills, increasing family and social support, and ultimately, engaging

Telegram: @medical_k

www.konkur.in

the individual in mental health care through follow-up contacts (e.g., telephone calls, postcards, e-mails, and other digital means).

Mood-Stabilizing Treatments

Lithium. Meta-analyses, reviews, and original studies show that long-term lithium treatment is associated with a substantial reduction in the risk of suicide and attempted suicide in patients with bipolar spectrum disorders. The analyses by the CDC show that mortality from overdoses of lithium is similar to the mortality from overdoses of new antidepressants and antipsychotic agents.

Ecologic studies also show that lower rates of suicide, as well as other violent behavior, are found in populations exposed to drinking water with a relatively high concentration of lithium salts. There is no plausible explanation for this finding, as the daily intake of lithium in drinking water is much lower than the dosages required for clinically effective treatment of mood disorders.

Other Mood Stabilizers. In bipolar depression, other mood stabilizers, such as anticonvulsants or second-generation antipsychotics, have beneficial effects on suicidal behavior. However, lithium is noted to be significantly superior in reducing suicidal behaviors and suicide death.

Antidepressants

Selective serotonin reuptake inhibitors (SSRIs) are nowadays widely used in the treatment of suicidal patients with MDD and related conditions. When choosing an antidepressant for a suicidal depressive patient, compounds with a sedative profile are preferable. Some experts have suggested that medications that increase drive may increase agitation, insomnia, and the risk of suicide. However, that risk is primarily theoretical.

Adverse outcomes in some patients during treatment with SSRI antidepressants like agitation, restlessness, irritability, dysphoria,

Telegram: @medical_k

www.konkur.in

anger, and insomnia can worsen the suicide risk in these patients. Due to those responses to serotonergic antidepressants, especially in some children and young adults below the age of 25 years, the Food and Drug Administration (FDA) and the European Medicine Agency (EMA) recommend continuous and competent monitoring of side effects. It should be noted that the data leading to these recommendations was on patients who reported suicidal ideation, not on actual deaths from suicide. Many experts, however, question the reality of this risk, particularly when compared to the very real risk of not treating a mood disorder.

Infusion of ketamine has shown promising results in reducing acute suicidal ideation. Nevertheless, further research is needed to assess its long-term safety and effectiveness in reducing suicide risk.

Antipsychotics

Suicidal symptoms in schizophrenic patients require, in addition to the standard treatment of schizophrenia with antipsychotics, an additional medication to control anxiety or agitation. Sedating antipsychotics are mostly used in these cases. When high dosages are required, attention must be paid to the risk of acute hypotension, particularly orthostatic. In some cases, to better control anxiety, benzodiazepines can be administered for a short period of time. Clozapine, although less used than many antipsychotics, has been shown to reduce suicide risk and is the only FDA-approved medication with that indication.

In the case of post-psychotic depression, additional treatment with antidepressants is recommended. If the suicidal symptoms are part of a depressive syndrome due to the side effect of neuroleptic treatment, the dosage should be reduced, if possible.

Anxiety Control

In controlling anxiety as a comorbid symptom of depression and in anxiety disorders, antidepressants are the preferred choice for acute and maintenance treatment. In cases where treatment response is

Telegram: @medical_k

www.konkur.in

not sufficient, adding short-term administration of benzodiazepines may be necessary.

Electroconvulsive Therapy (ECT)

Cases of depression with suicidality, which are difficult to treat by other means, can be treated by ECT, which has a rapid onset of action and relief of symptoms.

PSYCHOTHERAPY AND OTHER PSYCHOLOGICAL INTERVENTIONS

Treatment in the prevention of suicide requires a complex approach of psychosocial, psychotherapeutic, and psychopharmacologic interventions. Suicide cuts across the whole spectrum of psychiatric illnesses, and therefore therapists should be familiar with several therapeutic schools and strategies as they give valuable contributions to the treatment of suicidal persons. The choice of treatment depends on the condition of the patient. The combination of psychopharmacologic treatment with psychotherapy should always be taken into consideration as part of a complex treatment strategy.

Suicidal Statements

Suicidal communication, both verbal and nonverbal, must be taken seriously, independent of whether the clinician considers that the patient has a genuine wish to kill him/herself or if the purpose is to get attention. Suicidal communication always conveys an underlying sense of helplessness and hopelessness and a cry for help.

Risk of Suicide during Treatment

Treatment of suicidal patients is challenging, as the possibility of death by suicide is ever-present, independent of whether the treatment is pharmacologic or psychotherapeutic. Establishing an empathetic relationship with the patient when the threat that the patient might commit suicide is present can be difficult. This can be a discouraging condition to work under.

Telegram: @medical_k

www.konkur.in

Treatment of a suicidal person requires self-involvement and confrontation with one's own attitudes toward life and death.

In treating suicidal patients, one must allow the patient to feel suicidal and not minimize, reject, or deny the seriousness of their suicidal intent. Suicidal patients must be allowed to feel that their pain can be shared with another person. The challenge is to follow the patient and to understand, as well as to utilize psychotherapeutic methods without denying suicidality.

Transference and Countertransference

Suicidal patients have many different feelings toward their therapists and doctors, which in the psychotherapeutic literature are called transference. Therapists and doctors also have feelings toward their patients, which is called countertransference. Countertransference feelings toward suicidal persons can be empathetic but also ambivalent, aggressive, and even hostile. It implies an understanding of one's own attitudes and values, as well as the origins of suicidal patients' positive and negative feelings toward the clinician. A therapeutic alliance, which is important to establish, comprises elements of a real relationship between the therapist/doctor and the patient, as well as aspects derived from the patient's experiences of earlier relationships, which are transferred to the present treatment situation.

Long-Term Psychological Treatments

Two long-term–based treatments, CBT and dialectical behavioral therapy (DBT), show the strongest evidence of preventing suicidal behaviors.

There are also a sufficient number of studies of good quality showing promising results in the treatment of suicidal patients with family psychotherapy, developmental group therapy, psychodynamic therapy, and in-home interpersonal psychotherapy (IPT). IPT and psychodynamic approaches like transference-focused psychotherapy, mentalization-based treatment, and sequential Brief–Adlerian psychodynamic psychotherapy are supported by randomized

Telegram: @medical_k

www.konkur.in

controlled trials in which the psychodynamic approach was found to be effective in reducing suicidal behavior among patients with BPD. Other therapies like Collaborative Assessment and Management of Suicidality (CAMS) use a combination of therapeutic techniques from multiple previously studied interventions.

Brief Psychological Treatments

Brief psychosocial suicide preventive interventions with some empirical support are CBT-based interventions, contact interventions, a combination of those two approaches, and manual assisted cognitive behavioral therapy (MACT).

Psychosocial support and involvement of family, friends, and significant others after obtaining consent from the suicidal person is also recommended.

Supportive Telephone Calls and Letters

Treatments consisting of supportive telephone calls, SMS, or written contacts after discharge of the suicidal patient from the emergency department or hospital showed preventive effects. The use of new digital technology is promising, but more research is needed to evaluate its effectiveness. Involving community resources with the goal that the social intervention should give support to the patient for combatting loneliness and finding social networks, and in this way, enhancing a sense of meaning in their lives is essential.

LOSS SURVIVORS

The term suicide survivors usually refer to those who have lost a significant other to suicide. Since stigma has been diminishing, people with a history of suicide attempts also identify with the term “suicide survivor.” Therefore, it has become necessary to use more specific terminology, that is, suicide loss survivors and suicide attempt survivors. When a suicide occurs, the family and the surrounding people experience severe trauma and a range of reactions from shock, sense of unreality, sadness and grief reactions, anger, and

Telegram: @medical_k

www.konkur.in

feelings of abandonment and rejection. Suicide loss survivors experience a devastating event and desperately seek an explanation of what has happened. Often they make contact with the family doctor or doctor who treated the patient and who also is a survivor of the patient's suicide. It can be wise to ask an experienced colleague to help with advice on how to manage this situation. The doctor needs not only to work with their grief but also to assess the potential suicide risk in loss survivors, who have a higher risk for suicide.

The wide range of interventions targeting those bereaved by or exposed to suicide is called postvention. Support groups, grief counseling, outreach, and internet-based interventions have shown some effectiveness in reducing depression, anxiety, and distress, as well as increasing help-seeking behaviors.

The development of support groups can be considered an important step forward in working through the aftermath of suicide in a compassionate and supportive way, educating about grief, demystifying suicide, as well as eliminating excessive guilt, shame, and blaming. The WHO issued guidelines on how to form support groups, and national organizations of suicide survivors also offer resources and programs for those who have experienced suicide loss.

PUBLIC HEALTH PERSPECTIVE AND PREVENTION

Controlling the Environment

The fatality of suicide methods largely varies from that reported for medication overdose (1.5% to 4%) up to 90% reported for firearms. An analysis of state gun regulations demonstrated that increased state gun restrictions and lower gun ownership rates were associated with fewer firearm related suicides in both adults and the youth. The rationale behind the WHO recommendations to diminish access to suicide methods is to curb a sudden and strong impulse to end one's life. Controlling the access to suicide means is an effective universal suicide prevention strategy as shown in several studies on the

Telegram: @medical_k

www.konkur.in

restriction of access to firearms, pesticides, and charcoal, as well as on the detoxification of domestic gas and vehicle exhaust, placing barriers and safety nets at jumping sites, reducing access to medications, and controlling access to railroads and subways. Furthermore, it should be incorporated not only at the public health level but also at the clinical level.

Alcohol policies, such as the restriction on alcohol availability, increased alcohol pricing, and more severe drunk driving laws are associated with reduced suicides, especially in males.

One of history's most effective suicide prevention programs was observed in the second half of the 1980s in the former USSR during *Gorbachev's Perestroika* (restructuring), characterized not only by openness and freedom but also by the strict limitations on access to alcohol by cuts in the production and sale, primarily with the aim to improve the health of the population. Suicide for men decreased by 40% from the years 1984 to 1986 in comparison with 3% in 22 European countries during the same period. This decline occurred in all 15 republics of the former USSR. The sharp decrease in suicide applied to women as well. The largest decreases were observed among men in the workforce aged 25 to 54 years. No corresponding decline for this age group was noted in any country during the 20th century.

The Role of the Media in Suicide Prevention

Sensational and irresponsible reporting by different types of media may precipitate or induce suicidal acts through imitation or identification mechanisms in suicidal persons and even trigger suicide clusters. The WHO issued guidelines on media coverage, describing how the press and broadcasting media should report on suicide in order to avoid copycat effects. It is essential to avoid the description of suicide as courageous or desirable.

Furthermore, even if the impact of fictional portrayals of suicide is still to be ascertained, resources for filmmakers, stage, or screen artists were also released by the WHO.

Conversely, media may play a protective role against suicidality, the so-called Papageno effect, when providing positive coping examples

Telegram: @medical_k

www.konkur.in

or when providing educational materials.

School-Based Suicide Prevention

Children and young people spend many hours each day at school, which is a good arena for comprehensive suicide preventive work involving a continuum of activities from mental health promotion, screening and prevention to intervention (treatment), and postvention when a suicide occurs.

Overall school-based suicide prevention interventions are promising, and results from randomized controlled trials of classroom-based intervention programs in the United States, like SOS and Good Behavior Game (GBG), along with the SEYLE study in Europe, show that suicidality can be prevented.

The Youth Aware of Mental Health (YAM) program used in SEYLE aims at educating youth on mental health promotion and suicide prevention and promoting coping and help-seeking strategies through interactive discussions and role-plays, as well as through educational materials. Compared to the control group, the YAM program has reduced the incidence of suicide attempts and severe suicidal ideation with suicide plans by 50%. This effect is higher than effects noted in other successful public health interventions like bullying and bullying victimization (7% to 23%) and school-based interventions addressing smoking cessation (14%). Besides being perceived as stimulating by young people and adult instructors, YAM may be particularly effective due to the promotion of adaptive coping strategies, increased socialization and help-seeking, and decreasing violence/aggressive behaviors.

To secure both preventive aspects and treatment aspects for young people in schools, stakeholders must continuously build models for collaboration across the education and health care systems interface.

31.2 Suicide Treatment

Telegram: @medical_k

www.konkur.in

This chapter focuses on ways to identify individuals and groups at high risk for suicide and how to prevent death. Although the aspirational goal as clinicians may be to prevent *all* suicide attempts and deaths, in reality, we are not there yet—however, reducing attempts and deaths is both possible and attainable. Prediction is not equivalent to prevention, and as such, prediction is not necessary for prevention to be feasible. Research shows that almost half of suicide decedents had a visit to their primary care doctor in the month before their death. As such, the National Action Alliance for Suicide Prevention created a recommended standard of care for treating suicide in an effort to standardize care. This standard of care includes identification and assessment, safety planning, means reduction, and caring contacts. Ideally, this effort will also increase the number of patients receiving follow-up treatment once their suicide risk has been identified. However, suicide treatment encompasses a broad spectrum of patients. Whom are we treating? The attempter, the individual considering it, the family of the attempter or decedent, or even the public when the victim is prominent? A discussion of working with each of these groups follows.

SUICIDE-RISK ASSESSMENT

It cannot be stressed enough that every psychiatric evaluation must include a documented suicide-risk assessment. If there is no indication of prior suicide ideation, an attempt, or depression, this may be brief. Be certain you are not inadvertently signaling that you're looking for a negative answer, as in "You're not suicidal, are you"? Better to start with something like, "With all you've been through lately, have you started to wonder if you could go on"? followed by "Are you having any thoughts of ending your life"? and at some point in the conversation asking, "Through all of this, what has you kept going"? The inquiry proceeds stepwise until the physician feels reassured that the patient is in no need of more restrictive

Telegram: @medical_k

www.konkur.in

treatment. If the patient is psychotic and/or depressed, one needs to expand the assessment. “How depressed are you”? or “Does it ever get so bad that you wished you were dead”? or “That you ever thought about suicide”? “Have you ever felt suicidal at another time in your life”? “Have you ever attempted suicide”?

Any complete assessment must include “Any family history of suicide attempts or deaths”? If a patient responds affirmatively to “Have you now or ever felt you wished you were dead”? it is often helpful to ask “Are you concerned that you might harm yourself”? If the patient says “no” you then need to wonder if they are only saying “no,” because they think that’s what you want to hear. Asking other informants, such as the patient’s spouse or other family members accompanying the patient to your office or calling the patient’s family should you be suspicious that the patient may not have been forthcoming with you, is also helpful (assuming that the patient agrees).

However, proper interviewing techniques can help increase comfort of the patient, as well as the information they are willing to disclose. According to Shawn Shea (2009 a,b), the real suicidal intent of any patient is the combination of their stated intent, or what they directly tell you, their reflected intent, or the amount of suicidal thinking, planning, and actions that may reflect the intensity of their actual intent, as well as their withheld intent, or the suicidal intent withheld from the clinician either intentionally or subconsciously. Shea’s Chronological Assessment of Suicide Events (CASE) approach to interviewing utilizes four techniques including the behavioral incident, gentle assumption, symptom amplification, and denial of the specific to elicit truthful and comprehensive information about suicide, a historically sensitive and stigmatized topic.

When making a suicide-risk assessment, one must weigh risk factors and warning signs as well as protective factors, after gathering all the pertinent information. Risk factors are generally considered more distal indicators of suicide, while warning signs are more proximal. It is important to remember that suicide risk is dynamic, and can rapidly shift. Thus, it is important to include intervention strategies in any thorough risk assessment.

Telegram: @medical_k

www.konkur.in

Unfortunately, a recent meta-analysis of the last 50 years of research showed that no single risk factor predicted suicidal thoughts or behaviors much better than chance (Franklin et al., 2017), instead suicide risk is likely the confluence of many factors interacting simultaneously. However, there are several suicide measures available to help clinicians gather pertinent information regarding suicide history as well as scales that aid in risk determination. For example, the Self-Injurious Thoughts and Behaviors Interview (SITBI; Nock et al., 2007) is a comprehensive interview with strong psychometric properties that can be administered in both clinical and research settings. The Columbia Suicide Severity Rating Scale (C-SSRS, Posner et al., 2011), is also a clinician-administered interview with demonstrated psychometric properties. However, unlike the SITBI, the C-SSRS allows for the creation of an ideation intensity score and has triage and risk classifications. Additional suicide risk measures include the Beck Scale for Suicide Ideation (BSS; Beck & Steer, 1991), the Ask Suicide-Screening Questions (ASQ; Horowitz et al., 2008), and the Suicide Behavior Questionnaire—Revised (SBQ-R; Osman et al., 2001). The BSS has been widely used and has demonstrated predictive validity for suicide attempts and deaths by suicide (Brown, Jeglic, Henriques, & Beck, 2006), and the SBQ-R provides clinical cutoffs for use with both general and psychiatric inpatient populations (Osman et al., 2001). The ASQ was originally developed for use with pediatric populations (Horowitz et al., 2008) but has recently been expanded for use with adults (Horowitz et al., 2020).

Once you have completed a thorough history and evaluation, your assessment regarding the acuity of the situation determines what you do next. If you determine that suicide risk is greater than low, it is imperative a safety plan is completed (Stanley & Brown, 2012). A safety plan will identify warning signs and internal coping strategies for a patient, as well as various levels of external support including people and locations to provide distraction, people who will provide support, and professional support for times of crisis. For each person identified, telephone and contact information will be provided, so the patient has all the information in one place should a crisis arise. In

Telegram: @medical_k

www.konkur.in

addition, the final step of a safety plan will discuss means restriction, an integral step of any risk assessment. It is imperative the provider ask and document the patient's access to firearms, medications, and other lethal means, as well as discuss actions to mitigate danger when safety is a concern. Research shows that Safety Planning decreases suicidal behavior and increases treatment engagement for patients discharged from the ED (Stanley et al., 2018). For more information on Counseling on Access to Lethal Means (CALM), resources are available from the Suicide Prevention Resource Center at https://www.sprc.org/resources-programs/calm-counseling-access-lethal-means.

When determining a treatment plan for a patient, ideally the process should be collaborative, but it should always be patient-centered. More specifically, a treatment plan should be written based on the individual needs, resources, supports, and risk level of a patient. If a one-size fits all approach is used, patients might not have the ability to follow through with treatment, even with the best intentions, or worse, the plan sets the patient up for failure before they have even begun. In addition, a patient-centered treatment plan provides for the least restrictive environment possible for a patients' determined level of risk, such as an intensive outpatient program or partial hospitalization, if traditional outpatient would not be enough. If concerned about liability, the clinician can carefully document their rationale, as well as steps taken to mitigate potential risk (e.g., Safety Plan, means restriction, increased visits, communication with family, crisis hotlines, consultation with other clinicians, suicide-specific treatment, etc.). Clinicians can also increase communication with suicidal patients until the risk subsides. Research shows that "Caring Contact" or follow-up calls, emails, postcards, etc. reduced the rate of suicide behaviors after people were discharged from inpatient psychiatry or emergency department treatment (Luxton et al., 2013). Finally, inpatient hospitalization remains an option, but should be reserved for when there is a serious concern for safety, and your patient is at an imminent risk of harm.

THE TREATMENT OF SUICIDE

Telegram: @medical_k

www.konkur.in

The Biologic Treatment of Suicide

There are several biologic treatments with research support for the reduction of suicide symptoms. For example, there is a large body of research support from meta-analyses and other studies showing that lithium reduces the risk of both suicide death and attempt in patients diagnosed with bipolar disorder. In addition, the antipsychotic drug clozapine has also been shown to have a protective effect on suicide death in patients diagnosed with schizophrenia. Other biologic treatments include electroconvulsive therapy (ECT) and transcranial magnetic stimulation (TMS). While ECT has not been studied as extensively as a treatment for suicide, research does support ECT as a treatment for depression. A meta-analysis of RCTs showed ECT as a valid treatment of both severe and treatment-resistant depression. Other neurostimulation techniques, including TMS are gaining popularity because they are less invasive, have fewer side effects, and do not require anesthesia, but there is less available research into their efficacy with suicidal patients.

Psychotherapy

Ellis and Goldston, guest editors for a special series, “Working with a Suicidal Client—Not Business as Usual,” noted that “until recently, suicide literature focused on risk factors and assessment, and treatment focused on the “underlying DSM-5 disease” in which suicide is seen merely as a symptom of another disease such as depression, psychosis, etc., and on prevention.” However, there is evidence of success for psychotherapies that specifically target suicide risk. An example of this is dialectical behavior therapy (DBT) for borderline personality disorder (BPD). Although DBT has come to be regarded as the gold standard for treating BPD, there are studies showing it may be equally valuable in reducing suicidal behaviors for patients with other psychiatric disorders as well. In addition to DBT, there are other therapeutic approaches that appear to be helpful for suicidal patients. One of them is mindfulness. As Luoma and Villatte (2012) point out, experiential avoidance, the tendency to avoid or escape from unwanted psychological experiences, may produce

Telegram: @medical_k

www.konkur.in

harmful consequences like suicidal behaviors. Mindfulness and psychological acceptance may serve as a means to target experiential avoidance, thereby decreasing the risk of suicide. This approach directs treatment of suicide not solely as a symptom of disease but as the primary target of therapeutic efforts. Similarly, mindfulness is a key feature that overlaps the four psychological processes in acceptance and commitment therapy (ACT).

CBT is another highly valued treatment for suicidal behaviors. A 2012 article in *The Behavior Therapist,* indicates that suicidal behavior should be viewed as the primary problem rather than merely viewing this behavior as a symptom of a psychiatric disorder. The authors target specific cognitions and behaviors which fuel suicidal behavior. They detail *Cognitive Therapy for Suicidal Patients* (CBT-SP; Wenzel, Brown, & Beck, 2009), an approximately 10-session program divided into early, intermediate, and late stages of treatment. Results from Brown et al.'s (2005) RCT showed that participants in the cognitive therapy group had a 50% reduction in reattempts when compared to participants receiving usual care.

Another suicide-specific treatment is David Jobes' Collaborative Assessment and Management of Suicidality (CAMS; Jobes, 2016). CAMS is a therapeutic framework for working with suicidal clients, regardless of the theoretical orientation of the therapist. It is a patient-centered approach guided by the principle that the patient is the expert in their own suicidal experience. Utilization of a Suicide Status Form (SSF) keeps suicide a focus of treatment. A distinctive aspect of CAMS is that the first session of treatment incorporates a thorough assessment of history and risk, which becomes part of the case formulation. Because of this patient-centered approach, a CAMS clinician is uniquely situated to be able to simultaneously build rapport with their client while also gathering pertinent risk assessment information. Several RCTs have shown strong research support for CAMS specifically for reducing suicidal ideation, but not necessarily attempts or death as of yet.

Role of the Hospital

Telegram: @medical_k

www.konkur.in

When the patient reports intense ideation, the therapist is unsure of intent, or the patient reaches a severity that the therapist feels hospitalization is necessary to protect them, then hospitalization is required as a last resort. Although this sounds simple and straightforward, as discussed earlier, this is a complex situation, even when the patient and family agree. Since the therapist generally is not the decider of who gets admitted, the therapist will need to provide a convincing reason for “Why now in”? Assuming that hospital staff agree to keep the patient, they may or may not want your input in helping decide what level of care is required: closed or open unit, single or double room, frequency of observation, etc.?

Presumably, you (the therapist) and the hospitalist will work together on this. Before your patient can be safely discharged, however, virtually the same question must be asked by the attending, namely “Why now out”? What has changed to indicate that the patient is now safe? The mere fact that they have been in the hospital for a few days in itself is insufficient evidence. How has his improved outlook been documented? Just because they are taking medicine and attending groups is not sufficient evidence by itself. What do staff and family report? Such evidence must inform the discharge plan.

For the treatment of suicide while hospitalized, postadmission cognitive therapy (PACT), combined with enhanced treatment as usual has shown clinically significant reductions in depression, hopelessness, suicide ideation, and post-traumatic stress symptomology when compared to enhanced treatment as usual (Ghahramanlou-Holloway et al., 2020). PACT is six, 60 to 90 minutes sessions, adapted from Brown et al.’s Cognitive Therapy for the Prevention of Suicide Attempts (2005) for use in an inpatient setting. When longer-term inpatient hospitalization is an option, research shows that patients treated with an inpatient adaptation of CAMS showed greater improvement in measures of suicide ideation and suicide cognition (Ellis et al., 2015). In addition, patients treated with CAMS showed greater improvement on measures of suicide ideation, depression, well-being, and disability than patients receiving treatment as usual (TAU), even after controlling for severity of suicide ideation and previous attempts at admission. Furthermore, these

Telegram: @medical_k

www.konkur.in

gains were durable at 6 months post-treatment (Ellis, Rufino, & Allen, 2017).

The Patient Who Survives an Attempt or "Person with Lived Experience"

Suicide remains a leading cause of death, with psychiatric patients at an elevated risk. A patient who indicates suicidal ideation or who has just attempted suicide represents a psychiatric emergency; individuals who have attempted and those planning an attempt comprise the majority of the psychiatric emergencies managed by clinicians, aside from pharmacologic and general medical emergency situations. Traditionally, having serious thoughts of suicide was seen as a "symptom" of a disease, not a disease per se, and conventional wisdom has dictated that it is the disease that needs to be treated, not one of its symptoms. Over time, there has been a shift in the conceptualization of suicide from a model where it was considered a symptom that would decrease if the overarching disorder was treated, to the current conceptualization where it is the target of treatment.

DBT, a treatment specifically designed for patients with BPD also appears useful in some other impulsive psychiatric conditions such as nonsuicidal self-injurious behavior as well. Similarly, lithium, a treatment for stabilizing bipolar patients, appears to be useful in other conditions. Antipsychotics are commonly used for nonpsychotic agitation, and so forth. The most common condition associated with suicide is depression, and the psychotherapies and pharmacotherapies which address this are all part of the arsenal employed to decrease the risk of a suicide attempt or death. Unfortunately, "suicide attempter" has become almost a pejorative label, and such individuals too often are treated dismissively and peremptorily by emergency personnel, as though the attempt is merely a way to control or manipulate others. Certainly, most emergency rooms (ERs) are understaffed with stressed-out personnel who too often view attempters as unnecessary burdens which may stem from staff's own discomfort, anxiety, and lack of knowledge. However, a recent follow-up study revealed that from a total of 65,784 patients seen in ERs in Canada, during a median follow-up period of

Telegram: @medical_k

www.konkur.in

5.3 years, 4,176 had died, including 976 (23.4%) by suicide (Finkelstein et al., 2015). This is hardly a low-risk subpopulation. In fact, immediately following discharge from the hospital is the highest risk period for death by suicide. A meta-analysis of 100 studies examining the postdischarge suicide rate from mental health facilities revealed a pooled rate of 484 per 100,000 person-years, significantly higher than the 2016 global suicide rate of 10.5 per 100,000. This rate increased dramatically when the samples were limited to three months from the time of discharge (1,132 per 100,000 person-years) or patients who were admitted to the hospital for suicidality (2,078 per 100,000 person-years) (Chung et al., 2017). However, research continues to show evidence of more effective treatments and clinical tools as discussed in this chapter.

Helping Significant Others When a Suicide Occurs

Foremost among "others" is the decedent's family. Assuming that they desire help, they may be referred to a local "SOS" (Survivors of Suicide Loss) group near them. Both the American Foundation for Suicide Prevention (AFSP—headquartered in New York) and the American Association of Suicidology (AAS—headquartered in Washington, DC) can provide a geographic directory for such groups. SOS groups are *not* designed for those with lived experienced, since SOS groups exist to support individuals bereaved by suicide. Some SOS groups are reluctant to have family members attend meetings immediately after their loved one's death, as it can be too overwhelming. Meetings are generally conducted by other survivors, rather than mental health professionals, on the principle that they "know" and empathize with what the families are suffering better than the professionals. This certainly does not mean that the treating professional's role ceases following a patient's death. Attending the funeral, meeting with the family to offer condolences, and discussing with them whatever is possible within the bounds of confidentiality is generally perceived by grieving families as helpful. Following a patient's suicide, many mental health professionals are reluctant to have any contact with the decedent's family—often because they feel so guilty or are so frightened of litigation that they wish to terminate

Telegram: @medical_k

www.konkur.in

all contact. However, such contact may actually diminish such an outcome and be comforting to the family.

The mental health provider is a survivor, as well. Approximately 20% of psychologists and 50% of psychiatrists report having lost a patient to suicide (Ruskin et al., 2004). Because having one's patient die by suicide is so traumatic for therapists, they often seek help for themselves. Institutional review boards which routinely conduct suicide reviews, postmortems, or "root-cause" reviews are generally designed with the institution's needs in mind, not necessarily the clinician's, so that therapy and support for the involved provider can be extremely helpful. Ellis, Schwartz, and Rufino (2018) discuss the importance of candid communication with supervisees and trainees when discussing loss or struggle. Specifically, having struggle normalized by respected mentors, and that seeking consultation or help does not equate to weakness or incompetence can be an invaluable lesson for colleagues and trainees alike. Additional resources for clinician survivors are also available from AAS.

"Significant others" also include classmates, coworkers, and friends of the victim, and mental health professionals may become involved in assisting and supporting them, as well. There are a number of postvention programs to assist schools in handling some of the emotional distress produced by a schoolmate's suicide. The AFSP has a postvention toolkit (2018) available to schools at no cost. These suggestions include the recommendation that schools should avoid permanent memorials to decedents, for instance, and other similar steps to avoid "contagion risk" resulting in additional suicides. Similarly, AFSP has toolkits customized for medical schools, residency programs, and veterinary medicine schools and clinics. In addition, there are published guidelines for the media to help them present suicide information in ways that do not engender "copycat" suicides.

Suicide and Malpractice. What standard of care applies to patient suicide? Conventional wisdom holds that "the psychiatrist isn't expected to predict all suicides," only to properly appraise the "risk" of it and to determine how "foreseeable" the risk is. Although correct in

Telegram: @medical_k

www.konkur.in

theory, it is more accurate to conclude, “it all depends on the judge and the jury.” Most psychiatrists will have at least one suicide in their careers. The great majority of these do not proceed to litigation. Psychiatry residents, unfortunately, not uncommonly have patients who die by suicide. Then, if litigation ensues, it is generally against the institution and the attending physician as well as the resident. The resident is often called as a witness but not held financially accountable. This is of small comfort to the resident because they have less capacity for perspective to fall back on and less confidence —hence, the critical need for support programs, lawsuit or not.

How does the prudent psychiatrist keep risk at a minimum? The medical record will generally be decisive in court proceedings; so it behooves clinicians to absolutely ensure that the record accurately reflects the evaluation, diagnosis, the suicide-risk assessment, treatment plan, course, results, etc. Any contact with the patients’ family to corroborate the diagnosis and explain the treatment should be documented. The inquiry about available means for suicide (e.g., guns in the home, potentially lethal medications, etc.) should be detailed. If there is reason to believe that the patient might be suicidal, were they asked about it at every visit and was this documented in the chart? Did the therapist ask about past history and family history of suicide? Did they ensure that the doses and types of medicine prescribed were reasonably safe, effective, etc.? Were the number of pills prescribed and their doses excessive or insufficient for the situation? A good relationship between the provider and the patient’s family may be the most critical factor in terms of avoiding lawsuits after a death.

Special Populations

Military. For both active duty and, to a lesser extent retired, military personnel have increased rates of attempts and completions. A recent study by Rudd et al. (2015), compared brief CBT in patients with previous attempts or ideation with intent to act. Half the participants received CBT while the other half received TAU. Results revealed the CBT subjects were 60% less likely to attempt than the

Telegram: @medical_k

www.konkur.in

subjects who received TAU. Suicide in military and veteran populations is researched extensively through the Department of Defense Military Suicide Research Consortium (MSRC), an effort led by Dr. Thomas Joiner at Florida State University and Dr. Peter Gutierrez at the Rocky Mountain Mental Illness Research, Education, and Clinical Center at the Denver VAMC. More information about their work can be found at msrc.fsu.edu.

Adolescents. Depression in adolescents is less likely to manifest the same symptoms as in adults. Verbal or even physical aggression is just as apt to be seen as sadness, tearfulness, etc. Giving prized possessions away or changes in behavior (becoming unruly, uncooperative, abruptly starting to use drugs or alcohol) may be all that the parents note as changed. Similarly, a drop in grades in a student who has always done well may be all that is observed by the parents. More “moodiness” or more sleep irregularity are common symptoms but not as common in adolescence as to be poor markers for depression. Suicide is the second leading cause of death in children and adolescents, so a thorough assessment of suicide risk should be completed when indicated, regardless of age. Similar to adults, this can include interviews and screening instruments such as the ASQ. If suicide is indicated, suicide-specific treatment should be implemented. CAMS-4Kids and CAMS-4Teens are age-appropriate adaptations of CAMS (see Jobes et al., 2019). This treatment utilizes an adapted SSF but also incorporates parent/caregiver involvement to optimize success.

The Older Adults. The geriatric population has more deaths by suicide than any other age group. In 2019, older adults comprised 16.5% of the population, but accounted for 19.3% of the suicide deaths (Drapeau & McIntosh, 2020). Risk factors prominent in the geriatric population include mood disorders, hopelessness, cognitive rigidity, physical illness and pain, isolation through loss of friends and family, particularly a spouse, work problems coping with retirement, and use of lethal means (Maris, 2019). Research on suicide prevention in the geriatric population has proposed four main drivers

Telegram: @medical_k

www.konkur.in

to decrease suicide in this demographic: (1) early detection, (2) general health promotion, (3) evidence-based mental healthcare, and (4) increased social connectedness (Conwell, 2014).

The Publicly Shamed. Shame, a risk factor for suicide, is further exacerbated when the shame is made public. Defrocked clergy, disbarred attorneys, delicensed physicians, and other prominent and respected individuals, who have become publicly shamed due to fair or unfair reasons (e.g., online shaming; criminal charges; financial "mischief," etc.) are anecdotally reported to have suicide rates higher than any other subgroup within the year following their exposure.

Victim-Precipitated Suicide. Also known as suicide-by-cop, victim-precipitated suicide is a method of killing oneself that engenders pain not only to the decedent's friends and family but also to an innocent person. The unfortunate police officer who is confronted by a stranger who appears to be homicidal and who shoots and kills that stranger thinking their own life or some third party is in danger also ends up becoming a victim. Jumping to one's death in front of a passing train or car leaves a similar painful legacy for innocent second parties.

ACKNOWLEDGMENT

The author wishes to express her appreciation to Drs. Tom Ellis and Christine Moutier for comments on an earlier version of this chapter.

31.3 Other Psychiatric Emergencies

ROBERT T. COBB, M.D., AND KATHERINE CAMFIELD, M.D., M.P.H.

The Community Mental Health Centers Act of 1963 established Emergency Psychiatry as one of the five essential services mandated for all federally funded community mental health centers nationwide. This legislation ultimately helped establish Emergency Psychiatry as a subspecialty through the increased recognition of its importance to the health care delivery system. Recently, legislative impacts have continued to expand psychiatric emergency services (PES) and led to a rise in advanced training programs. Along with providing further historical background of the field, this chapter will discuss frequently encountered PES diagnoses and how to prioritize care. Recent advances in management, both pharmacologic and nonpharmacologic strategies, also are highlighted. This edition of the chapter includes updated references and new subject material, in addition to the most relevant information from the previous version.

HISTORY

Emergency psychiatry originated in the Russo-Japanese War (1904 to 1905). Psychiatrists in the Imperial Russian Army championed treating psychiatric emergencies at the front lines. Healthy components of personality were strengthened, esprit de corps was encouraged, and soldiers returned to action as soon as they were

Telegram: @medical_k

www.konkur.in

stabilized and reconstituted. This countered the effects of stigmatization, secondary gain, and avoidable iatrogenic effects of longer-term military therapies that entail the removal of soldiers from the front lines. With this approach, the Italians found that 60% of what would be defined as post-traumatic stress disorder remitted. American military psychiatrists did not at first adopt this technique; only 18% of U.S. psychiatric casualties returned to action in 1943. A year later, when crisis-oriented therapy was introduced using abreaction, ventilation, and social support, as many as 85% returned to fighting. It is apparent that brief crisis-oriented approaches at times of emotional crisis can not only restore functioning but also reinforce and help develop healthy coping styles that protect against future stresses. Crisis intervention approaches have been incorporated into psychiatric practice and extended to the civilian populations over the years and now serve as an important arm of mental health care services available to patient populations.

Several major forces converged in the 1950s and 1960s that gave rise to the field of emergency psychiatry as it is known today. With the beginning of deinstitutionalization in the mid-1950s, and the emergence of emergency medicine as a medical specialty, hospital emergency departments began to see an increase in the number of chronically ill psychiatric patients who were being admitted for assessment and treatment. These patients were generally seen in the medical emergency department by a psychiatrist who acted as a consultant and with recommendations for either referral to an outpatient clinic or a psychiatric hospitalization. With the passage of the Community Mental Health Centers Act of 1963, which mandated 24-hour emergency services, the PES was created as a specialized program with its own staff and designated clinical area. The PES evaluated and treated patients suffering from acute psychopathology with the goal of providing treatment at the least restrictive level of care.

The American Association for Emergency Psychiatry was founded in the 1980s for psychiatrists with a special interest in emergency psychiatry. Other programs for providing emergency psychiatric care

Telegram: @medical_k

www.konkur.in

have since evolved, including crisis hospitalization programs, crisis residences, and mobile crisis teams.

The passage of the Emergency Medical Treatment and Labor Act (EMTALA) in 1986 made it illegal for hospitals to refuse emergency medical care to patients, which included psychiatric emergencies. Although this law was enacted to help prevent refusal of care for patients who are unable to pay and prevent “patient dumping,” it also developed a system where patients would remain in emergency departments for extended periods of time awaiting placement. Thus, it became imperative for psychiatrists to be present in the emergency department for both initial evaluations of psychiatric emergencies and re-evaluation assessments to decompress emergency department patient volumes.

The most recent major policy shift affecting PES came in 2010 with the passage of the Affordable Care Act (ACA). With millions of more Americans receiving health insurance and the expansion of Medicaid, the hope was that there would be decreased utilization of emergency department resources. The overall impact of the ACA on emergency psychiatric care is still unclear, but the need for these services definitely has not waned with the continued growth of PES as a specialty with advanced training programs.

A psychiatrist working in a PES must have an in-depth knowledge of psychiatry, substance-related illnesses, medicine, neurology, and the available community resources and advanced training programs aim toward the development of these specialty skills and knowledge.

In emergency psychiatric care, as with emergency medicine, prioritization of specific patient needs is essential to safe and effective health care delivery.

The priorities and goals of an emergency psychiatric assessment are as follows:

- To control aggressive behavior in order to protect other patients, the PES staff, and the patient from him- or herself.
- To rule out any etiology for a patient’s behavior that might be life-threatening or may increase medical morbidity.

Telegram: @medical_k

www.konkur.in

- To facilitate a thorough clinical evaluation and an appropriate longitudinal plan.

First Priority

The first priority is to ensure that the PES environment is safe for clinical evaluation. Clinical personnel should be trained in the management of aggressive behavior and have a working understanding of their clinical responsibilities and institutional policies and procedures. Various formal training programs have been designed to ensure that providers are trained accordingly in management strategies. These programs serve to mitigate the risk of injury to patients and clinical personnel and are essential to providing a secure and safe environment for patient care.

Certain environmental variables should be modified to decrease the potential for violence. These include, but are not limited to: shortening waiting times, offering the patient drink or food, and decreasing environmental stimuli. Providing the patient with a comfortable chair in a quiet area or the opportunity to lie down is also effective in mitigating the risk of worsening agitation. Early identification of potentially dangerous pathology and early intervention can markedly decrease negative outcomes due to behavioral escalation, and a skilled practitioner should be able to intervene safely and appropriately.

It is important to understand that the physical structure of the PES is also crucial to facilitating a safe environment for patient care. Having shatterproof windows in the doors of interview rooms provides privacy but allows an interview to be observed. In addition, security cameras can allow for observation of clinical providers and ensure another layer of safety. Cameras can also provide the patient with a sense that their behavior is being monitored. Posting rules visible to patients within the PES can be useful in making it clear that violence will not be tolerated and has consequences is another useful strategy.

Safety and security can be further enhanced by:

1. weapons screening prior to entry of the secured area;
2. rooms in which the examiner cannot easily be trapped;

Telegram: @medical_k

www.konkur.in

3. a choice of open or enclosed interviewing areas;
4. an alarm system to call for help, preferably a panic button in every room; and
5. adequate personnel to respond if help is needed, including trained security personnel.

If a person is brought in detained by the police with a history of a very recent assault, then it may be necessary to examine the patient in handcuffs or possibly in physical restraints, if the agitation or threats of violence persist. If the patient is acutely agitated and threatening, then it may be necessary to administer medication to help them regain control before beginning a complete interview. Interventions for calming the agitated and aggressive patient are discussed later in this chapter.

Second Priority

The second priority in managing emergent psychiatric pathology is to rule out a medical etiology for the patient's behavior. The incidence of patients presenting with psychiatric illness who have a medical etiology for their symptoms varies quite dramatically based on age and complexity of known medical history. Medical examinations of psychiatric patients in the emergency department are often limited in scope, and psychiatrists and emergency department physicians may have different viewpoints on the utility of laboratory screening. Therefore, psychiatrists must maintain a high index of suspicion for underlying medical problems and may need to initiate further studies than those that are recommended by emergency medicine guidelines.

Clinical history, signs, and symptoms that are suggestive of a medical etiology include:

- patients older than 40 years or younger than 12 years with no previous psychiatric history
- acute onset (hours to weeks)
- fluctuating course
- altered state of consciousness

Telegram: @medical_k

www.konkur.in

- visual or olfactory hallucinations
- abnormal vital signs
- disorientation
- known medical illness or neurologic symptoms
- memory impairment
- complex medication regimen
- a history of alcohol or drug use
- atypical or unique psychiatric symptomatology

When medical conditions are suspected as the cause of the patient's symptoms, a physical examination and an appropriate medical workup should be completed, if possible. Initial diagnostic studies should include a complete blood count with differential, a complete metabolic panel (including electrolytes, blood urea nitrogen, creatinine, liver function studies, glucose), thyroid hormone level, an electrocardiogram, and urine drug screen, urinalysis, blood alcohol level, and neuroimaging when indicated. Medication blood levels should be obtained if applicable, for example, valproic acid, lithium, or carbamazepine. An ammonia level should be obtained for patients taking valproic acid. If the initial diagnostic studies are negative, but the clinician still suspects an underlying medical etiology, then additional tests can be completed once the patient is admitted to the hospital. Various medical illnesses that present with psychiatric signs and symptoms are listed in Tables 31.3–1 through 31.3–4.

Third Priority

Facilitating appropriate treatment and disposition through a comprehensive psychiatric evaluation is the third priority. The patient interview should always be regarded as a therapeutic opportunity. Patients in the PES are frequently in distress and should be given the opportunity to express their concerns and ventilate their affect. An open-ended question will usually elicit the primary reason for the visit and potentially aid in rapport development. Even if the staff has already obtained an initial history, it is still important to let the patient talk for a few minutes without interruption. Closed-ended questions should be reserved for the end of the interview or for those patients

Telegram: @medical_k

www.konkur.in

who are unable to adequately provide a meaningful and coherent history. Reassurance should be given frequently, and some clinicians may prefer to avoid long silences during the interview to ensure efficiency in the provision of care.

The emergency evaluation varies in length and may, on occasion, exceed several hours. Ideally, the evaluation should include:

- identifying information: age, gender identity, preferred pronoun, ethnicity, marital status, and source of referral
- chief complaint
- history of present illness
- past psychiatric history
- substance use history
- medical history
- social history
- educational, occupational, and military history
- legal history
- family history
- review of systems, if indicated
- physical examination, if indicated (breast, genital, pelvic, or rectal examinations should not be done)
- mental status examination, including a cognitive screen

It is essential that suicidal and homicidal ideations are assessed thoroughly. A structured suicide and violence risk assessment should be performed and documented during the course of the examination. The most common liability in the PES is failure to hospitalize a patient who is at significant risk of violence to themself and/or others. If a decision is made to allow for discharge from the PES and not hospitalize, a thorough record of the clinical determination should be documented. This includes protective factors, risk factors, and the overall risk stratification of the patient for the potential for harm to self or others. While there is not a “gold standard” for documenting the clinical decision, it is important to have documentation reflect one’s

Telegram: @medical_k

www.konkur.in

decision should an unfortunate adverse event occur. Additionally, with a recent focus on decreasing the risk of suicide by the Joint Commission, the Behavioral Health Care and Human Services National Patient Safety Goals created minimum standards of care to help ensure patient safety due to suicide. As policies and guidelines are heterogeneous among institutions, it is important for clinicians to understand and practice within institutional policies.

Obtaining a comprehensive history in a PES can be challenging as patients who are psychotic or agitated may provide unreliable or

Telegram: @medical_k

www.konkur.in

inconsistent histories. This is especially true if the patient is mute, cognitively impaired, or agitated. In these situations, it becomes even more important to utilize collateral sources of information, including significant others, family, therapists, neighbors, police, or paramedics. Managed care companies may have significant clinical information and may be able to provide useful patient data and history. Previous hospital records, if available, should be reviewed, and important information should be summarized in the final assessment.

PRINCIPLES OF TREATMENT

Overview

Treatment in the PES usually focuses on behavioral and symptom management related to psychiatric pathology once other medical pathology has been ruled out and/or treated appropriately. Patients often have multiple confounding clinical problems. These include psychosis, depression, substance intoxication or withdrawal, extreme psychosocial stresses, and overlapping character pathology. Furthermore, psychosis and depression have an extensive differential (Tables 31.3–2 through 31.3–4). Given the complexity of patients presenting for care, making a definitive diagnosis may be difficult in the limited amount of time available to the PES clinician. Beginning diagnosis-specific treatment may be problematic unless continuity of care can be coordinated and assured with the next provider. The focus of the PES intervention should be acute stabilization and safety with subsequent longitudinal planning based on the outcomes of initial interventions.

The Initial Evaluation

Treatment should ideally begin at the time of the initial evaluation. The initial interview should serve to elicit important diagnostic information but is also an important therapeutic tool, if approached correctly. While the goal of the interview is to gather information about the present illness, past psychiatric and medical history, family history of mental illness, social history, and drug or alcohol use, it can serve

Telegram: @medical_k

www.konkur.in

as an important vehicle in establishing rapport and ensuring a patient is aware of their specific treatment plan.

Ideally, the interview should take place in a quiet, comfortable setting with both the patient and the clinician seated. However, often the intervention may take place in a less than ideal setting. In these instances, at minimum, the clinician should have an unimpeded exit in case of patient behavioral escalation. If the patient is seen after the medical evaluation, then it is important to remove unnecessary intravenous needles and ask the patient to sit up on the stretcher. This helps restore the patient's autonomy and improve the physician-patient alliance. The physician should always introduce themselves and address the patient by utilizing the patient's preferred pronouns formally to ensure a patient's sense of dignity.

The interview should begin with nonspecific, less intrusive questions. Only after the patient begins to show some comfort with the interviewer should the physician start questioning them about the specific details of the present illness. Questions should be open-ended. The physician should be flexible in their approach to the interview as each patient presents a unique set of circumstances, behavioral triggers, stressors, and life experiences that will influence the diagnostic evaluation.

When interviewing an acutely disturbed patient, it is frequently necessary to structure the interview by asking straightforward questions. If the patient begins to ramble, then the interviewer should indicate that they understand what the patient is saying while helping them to be redirected in providing important content. When patients have disordered perceptions, it is important not to attempt to correct the misperceptions but to clarify how the patient experiences them. The clinician should avoid the temptation to use logic to convince the patient that they are wrong. Such an approach makes the patient more defensive and can lead to escalation with the potential for dangerousness. The interview should be geared toward fact-gathering and establishing a baseline understanding of psychopathologic-related impairments.

Establishing emotional contact with the patient to help identify the patient's feelings will help build the treatment alliance. Even a

Telegram: @medical_k

www.konkur.in

psychotic patient's feelings are not unique, and the interviewer should be capable of identifying and empathizing with them. A patient's need to protect their sense of integrity and self-control may initially make them reluctant to engage in the interview. If patients are resistant to the idea of talking, then it is useful to elicit their feelings about the situation and try to understand the patient's discomfort with being in a PES and not knowing what may happen to them. Sometimes it may be better to drop a particular subject and come back to it later in the interview when the patient is more at ease. It is of great importance to understand that the patient is experiencing a significant loss of autonomy in requiring an assessment in the psychiatric emergency room setting. Individuals react differently to their circumstances depending on the level of impairment and previous life experiences. Impulse control is often compromised and is often a reflection of the normative human response to stress. The innate "fight or flight" response based on sympathetic nervous system drive can be elevated in PES patients, especially those who do not want assistance with their underlying psychopathology. The goal of the interview should be to develop rapport with the patient and aid in their understanding of the unique set of circumstances that have led to the clinical intervention. It is also important to understand that the clinician may be in a position of perceived power by the patient. As a result, the goal should be to have the patient understand that you are an advocate and there to help aid in the recovery process.

When psychotic patients do not respond to questioning, the interviewer should use whatever data are available to make a meaningful connection with the patient. This may include the patient's words, expressions, appearance, or behavior, as well as a physician's feelings. Comments should be as specific as possible in order to provide some structure to an interview that has little to no momentum —"I don't know what Jesus says to us" or "I see you are in a bathrobe. I gather you were brought to the hospital unexpectedly." By attempting to develop rapport in understanding the patient's experiences, a clinician can have a significant impact on developing a therapeutic alliance and improving patient outcomes.

Telegram: @medical_k

www.konkur.in

Of all patients, the most difficult to evaluate is the hostile, paranoid patient. If a patient is frightening, then the physician should not ignore their own fear. Even the most impaired patients can quickly sense a physician's discomfort and may become frightened, resulting in reactive behavior. This may, in turn, lead to a violent episode. At times, however, the physician may have to acknowledge their fears to the patient, "The way you are looking at me is scary like you are on the verge of striking out. I won't be able to give you my full attention if I am afraid." If the physician remains professionally confident and does not avert their eyes, then the patient is reassured. The patient's anxiety can be further ameliorated if the interview is conducted with the door open, thus allowing for a sense of safety for the patient. If the patient engenders a level of anxiety in the clinician such that it interferes with the evaluation, then the clinician should request another clinician to interview the patient or interview the patient with another staff member present in the interview room. It is often difficult for clinicians to understand their limitations in engaging with patients, but ensuring your safety and the safety of others is paramount in the PES. Termination of a clinical assessment may be necessary and is not usually a function of poor training.

It is important to be extremely tactful with paranoid patients because they are vulnerable to being easily humiliated and made to feel guilty for their actions and thoughts. The clinician should never become involved in how the patient's beliefs are distorted. If the physician tries to determine what is real and what is not, then they will be experienced as a prosecutor, and the patient may become more argumentative and defensive. By identifying a patient's thought distortions in their delusional belief system, especially those that are paranoid in nature, a clinician may become incorporated into the delusional construct and disrupt rapport development.

Frequently, paranoid patients who are angry begin with a tirade of accusations about being mistreated. The physician may have to interrupt these tirades and ask the patient, "How can I help you?" in an attempt to develop a supportive therapeutic alliance. With the hostile, paranoid patient, the physician should always keep a professional distance by not becoming too friendly, avoiding jokes,

Telegram: @medical_k

www.konkur.in

and avoiding parental reassurance as patients can quickly escalate on the basis of external stimuli or a misperception of circumstances. Occasionally, highly paranoid patients can make the interviewer feel defensive and foolish by twisting the meaning of the interviewer's words, making it impossible to sustain any direction in the interview. Under these circumstances, it is advisable to alter the course of the interview and attempt to process with the patient their conduct. If meaningful contact cannot be made, then the interview should be terminated, reassuring the patient of concern for their safety and ensuring that they are aware of the clinician's role as an advocate and care provider.

When patients are unable or unwilling to provide clinical information, significant others should be contacted (e.g., spouse, relatives, immediate family, or previous treating physicians) to obtain collateral information. Whenever possible, consent to contact others should be obtained. Written consent is preferable to verbal consent. In potentially life-threatening situations such as suicidal ideation or gestures, homicidal ideation or threats, or an inability to communicate, the emergency takes precedence over confidentiality, and significant others should be contacted even without consent. In these cases, the clinician should carefully document in the medical record the reasons for breaking confidentiality.

An important aspect of the interview is its termination. Although there is considerable pressure on the clinician to work rapidly, the interview should be structured to make the patient feel validated and that they has been given sufficient time to present their story. Allowing a patient an opportunity to present information independent of the structured interview can often deescalate a tense interaction, and the clinician should validate the experience of the patient. The clinician should give a summary of their understanding of the patient's problem, followed by recommendations for further care.

Difficult Patients

Difficult patients encompass a wide category of diagnoses. A common theme with these patients is their ability to induce extremely negative reactions in PES staff and clinicians. Most often, patients

Telegram: @medical_k

www.konkur.in

with personality disorder-trait specified (PD-TS) or formal personality disorder (particularly borderline personality disorder), those who repeatedly present for care, and those with addiction-related behaviors which might be demanding, manipulative, and entitled may fit this category. Difficult patient populations often demand immediate attention, have a poor frustration tolerance, and relate to others in a negativistic manner. As a result, clinicians may feel anxiety, ambivalent anger and rage, and even fear. It is essential to remain objective and ensure appropriate professional responses to the patient. The clinician's responses to challenging patient populations can have a significant impact on treatment and outcome.

Because of the wide diagnostic variability with difficult patients, similarly, diverse clinical presentations may be seen in the PES. Patients may come voluntarily or may be brought in by police for disruptive or violent behavior. Those with borderline traits or personalities may present with suicidal ideation, suicidal gestures, suicide attempts, homicidal ideation or gestures (and rarely attempts), drug abuse, brief psychotic episodes, and impulsive behavior, often precipitated by interpersonal conflicts. Patients with antisocial personality disorders often use the emergency service for the purpose of secondary gain, such as obtaining medication, avoiding legal issues, or using the prospect of hospitalization to escape from some psychosocial predicament.

The management of these challenging populations is similar, beginning with a clear understanding of acceptable behavior and firm but supportive limit setting by the clinician. An effective strategy to accomplish this is clearly stating that certain behavior is unacceptable and the reasons why it is unacceptable. The patient should be offered two therapeutic alternatives. For example, *you cannot keep punching the walls because your behavior is scaring other patients, and you could injure yourself. Therefore, you can take some medication or lie down in a quiet room until you feel more in control.* It is important to understand, especially in dealing with patients who are involuntarily being observed, that a loss of autonomy can precipitate untoward behaviors. In providing a patient with alternatives to maladaptive behaviors and allowing them to make decisions about their own care,

Telegram: @medical_k

www.konkur.in

a clinician can potentially deescalate a tense situation. Threatening the patient with punitive consequences will exacerbate the negative behavior and may lead to further acting out behaviors. Medication such as benzodiazepines or antipsychotics may be useful in reducing the patient's agitation, which is discussed further in this chapter. Effective communication between staff members, clinicians, and the patient is essential, as these patients may be manipulative or try to divide the PES staff. The strategies discussed earlier in dealing with agitated and aggressive patients are effective in dealing with difficult patients. These patients may require more time for an evaluation in order to discharge their affect, regain control of their behavior, and realistically discuss their options. Effective interpersonal intervention may avert hospitalization. A primary diagnosis of adjustment disorder, mood disorder, or brief psychosis will show that the decision to involuntarily hospitalize a patient is based on an illness rather than a pattern of maladaptive behavior. However, involuntary commitment may be necessary for patients with unremitting homicidal or suicidal ideation to ensure safety.

Pharmacologic Management of Psychiatric Emergencies

In the PES, a high priority is given to the pharmacologic treatment of agitated patients to reduce the incidence of patient and staff injuries and to reduce the patient's psychological discomfort. Management of agitation and aggression is complex because these nonspecific symptoms can occur in a wide variety of clinical conditions. These may include delirium, dementia, alcohol and drug intoxication or withdrawal, personality disorders, and psychosis secondary to primary psychotic illnesses. At times, patients are so agitated that they are unable to cooperate with a psychiatric or medical evaluation and are incapable of providing any relevant information.

Pharmacologic management may initially serve as the primary therapy or as an adjunct to a verbal intervention. Clinically significant agitation may be defined as abnormal and excessive verbal or physical aggression, purposeless motor behaviors, heightened arousal, and significant disruption of the patient's functioning.

Typical behaviors of clinically significant agitation include:

Telegram: @medical_k

www.konkur.in

- explosive and/or unpredictable anger
- intimidating behavior
- restlessness, pacing, or excessive movement
- physical and/or verbal self-abusiveness
- demeaning or hostile verbal behavior
- uncooperative or demanding behavior or resistance to care
- impulsive or impatient behavior
- low tolerance for pain or frustration

The goal of pharmacologic intervention is to calm the patient without sedation so that they can participate in the evaluation and treatment plan. Whenever possible, the patient should be given the option of the route of administration as this can facilitate their sense of having some measure of control. The use of oral liquid or dissolving tablets is the least invasive pharmacologic intervention and allows the patient to have a feeling of control and participation in treatment.

The most frequently used medication strategies consist of benzodiazepines, second-generation antipsychotic medication alone or in combination with a benzodiazepine, and haloperidol alone or in combination with a benzodiazepine. The most commonly used benzodiazepine is lorazepam.

Studies of the pharmacologic treatment of agitation in a busy PES are methodologically challenging. A treatment algorithm for the management of acute agitation or aggression based on the extant literature is as follows:

- Agitation due to a primary psychiatric illness
  - Orally disintegrating or liquid risperidone (2 mg) or orally disintegrating olanzapine (5 to 10 mg) is a first-line intervention for agitation.
  - An oral benzodiazepine can be added if deemed necessary and should be done so before adding additional antipsychotic doses.
  - For severe agitation secondary to psychosis when oral medications are not possible, IM ziprasidone (20 mg) that can

Telegram: @medical_k

www.konkur.in

be supplemented with IM lorazepam (2 mg) is first-line to limit the potential for side effects.
    - Second-line recommendations for severe agitation secondary to psychosis are IM haloperidol (5 mg) and IM lorazepam (2 mg), or IM olanzapine (5 to 10 mg). *Lorazepam should not be used in combination with olanzapine because of the risk of cardiorespiratory depression.*
- Agitation due to stimulant intoxication OR alcohol withdrawal
    - Benzodiazepines are first line, such as Lorazepam 1 to 2 mg or diazepam 5 to 10 mg.
    - Oral medications should be attempted prior to IM or IV medications when possible.
- Agitation due to alcohol or other CNS depressant intoxication
    - Haloperidol (2 to 10 mg) has been shown to be safe and has low concern for additional respiratory compromise, therefore is a first-line treatment.
    - Second-generation antipsychotics (either PO or IM) are the best alternatives, if needed.
    - Benzodiazepines should be avoided due to the risk of respiratory depression.

Medication may be given every hour, up to three or four doses every 24 hours, though most patients will respond to a single dose of medication. The most common side effects of antipsychotic medications are dystonic reactions that can be effectively treated with IM benztropine (2 mg). Akathisia may develop with the use of highly potent agents and should be monitored. Management is with PO beta-blockers such as propranolol, and patient management can be optimized with the concomitant use of benzodiazepines. The most common side effects of benzodiazepines are sedation and ataxia.

Pharmacologic management of agitation in children and adolescents in the PES setting is a complex and difficult task for the psychiatric provider. Although the number of atypical antipsychotics FDA approved for use in children has increased, the use of these medications is complicated by the indications varying based on age and diagnosis. However, in emergency situations, a consensus of

Telegram: @medical_k

www.konkur.in

PES medical directors responded that risperidone or lorazepam are their preferred medications.

Unfortunately, there are also no outcome studies or formal guidelines for treating agitated pregnant patients. In general, clinicians should use the minimal amount of medication necessary to reduce agitation and aggression in these two groups of patients and work collaboratively with specialty services to ensure consensus care as a treatment team. It is important to weigh the risks of acute agitation with that of a one-time dose of an antipsychotic or benzodiazepines. Mood stabilizers are not typically helpful in the rapid resolution of agitation symptoms.

Management of Agitation and Aggression

Agitation is a nonspecific symptom that occurs across all medical and psychiatric diagnoses. Untreated agitation can escalate to violence. Managing agitation in the emergency setting is complicated by the need to make clinical decisions on the basis of relatively incomplete psychiatric and medical assessments and histories. Severe agitation may make it impossible to obtain an initial medical history, complete a medical examination, or collect screening laboratory studies. Once agitation subsides and the patient is more cooperative, a complete medical history and evaluation should be performed as medical illness can precipitate violent and aggressive behavior. The differential diagnosis for violence is summarized in Table 31.3–5.

Interventions for agitation should be conceptualized as hierarchal, beginning with the least restrictive and least intrusive interventions and only using the most restrictive interventions when all other treatment approaches have been exhausted. The core clinical strategy for managing agitation is the use of interpersonal strategies that emphasize verbal deescalation interventional techniques. It is important for the clinician to reduce the patient's anxiety and fear by maintaining a humane and respectful disposition. A patient who is treated with honesty, dignity, and respect is likely to respond with reciprocity if there is retained reality testing. Affect management is central to any effective aggression management technique. It involves acknowledging the patient's affect, validating it when appropriate, and encouraging the patient to talk about their feelings. Attempting to use logic and rational thought with a patient who is effectually dysregulated may lead to a further increase in agitation. An emotionally distraught patient requires an active response from the clinician. The use of active listening techniques, such as paraphrasing to the patient a brief encapsulated form of their statements, helps convey that the clinician is attempting to understand what the patient is experiencing. It is important to be honest and unambiguous. Verbal deescalation techniques require time and are often sufficient to reduce agitation and eliminate the risk of violence. Offering food or drink may also help facilitate a therapeutic alliance and reduce a patient's agitation. Management of aggressive patients may be compromised when the clinician inadvertently evokes feelings of fear, anger, or rejection. This can generate thoughts of retaliation aimed toward the clinician. If identified, the clinician should stop the interview and ask another staff member to continue with the therapeutic intervention.

Patients with a history of documented or witnessed assaultive behaviors should be provided a significant amount of space by all clinical providers. A general rule of thumb is to keep at minimum two quick steps or at least two-legs lengths distance from the patient. Personal space can be visualized as an oval zone extending 4 to 6 ft all around. If the patient is standing, then the clinician should stand. If the patient is sitting, then the clinician should also sit down, preferably

Telegram: @medical_k

www.konkur.in

at the same level as the patient. The clinician should never stand over the patient during the interview as this may further escalate patients and places the clinician in a compromised position for potential harm. If the patient is pacing, then the clinician can walk with the patient but at a much slower pace. The clinician should take a posture that makes them appear small and thus less threatening. This can be done by holding the hands at waist level with palms up and open. This posture ensures the patient, especially if paranoid, does not misperceive the intentions of the clinician and ensures that there are no syringes or other devices of perceived harm in the practitioner's hands. Assuming the "Thinker" stance (one forearm crosses the chest, and the opposite elbow rests on it with the index finger on the cheek or chin) is also an effective technique. In this position, the patient's content can be validated by affect but also ensure the practitioner is ready for any unexpected behaviors by the patient. Some patients may not respond or only partially respond to verbal intervention and will require psychotropic medication to aid in behavioral management.

When both interpersonal and pharmacologic interventions fail to reduce agitation, and the patient remains uncooperative with treatment efforts, a show of force with five or more staff and/or security guards may encourage the patient to cooperate with treatment. The presence of additional staff supporting the clinician conveys to the patient that their aggressive impulses are not appropriate in the given circumstances and will need to be controlled. A show of force should not be implemented in a way that threatens or humiliates the patient but serves as a vehicle for ensuring the safety of the patient, patient peers, and staff.

When less restrictive interventions fail to reduce a patient's agitation, physical restraints may be necessary to prevent imminent harm to the patient, patient peers, or staff. Prevention of serious disruption of the treatment setting, prevention of bodily harm, and/or prevention of significant damage to property is the goal, and restraints should be considered a last resort in the PES setting. Recent evidence suggests that the acute symptoms and presentation characteristics in a PES clinical encounter are more likely to be

Telegram: @medical_k

www.konkur.in

associated with restraint/seclusion than the patient's underlying disease process or demographics. A careful approach to every patient is warranted, especially if there is a history of impaired impulse control or assaultive behaviors. PES providers should always be prepared for behavioral escalation. Once the decision is made to restrain a patient, the restraint process should be implemented immediately and without negotiation. Rigorous attention to the patient's safety is paramount as restraints are contraindicated in the patient with an unstable medical condition such as infection, cardiac illness, body temperature instability, metabolic illness, pregnancy, or orthopedic problems. In addition, patients with delirium or dementia may experience worsening symptoms secondary to the sensory isolation induced by restraints and seclusion. In all restraint episodes, documentation should clearly outline the behavior requiring restraints, the interventions that were made to reduce the patient's agitation prior to restraints, and all interventional efforts to remove the patient from restraints. While a patient is in restraints, continuous monitoring of the patient should occur to prevent injury with 15-minute checks of extremities to insure adequate circulation, adequate hydration, and limb exercise. All clinical efforts should focus on removing the patient from restraints as quickly as is clinically possible. All clinicians should review and thoroughly understand the restraint guidelines, policies, and procedures of their respective institutions.

A PES should have written policies and procedures that are understood and practiced by all clinical staff. Patients should be evaluated and treated in areas that have adequate space, appropriate lighting and alarm systems, and the ready availability of security officers. Interviewing rooms should have multiple exits and a minimum of materials and furniture that could be used as weapons. As a clinician, it is important to understand your physical and psychological limitations in dealing with the unpredictability of a psychiatric emergency setting. Ensuring the safety of patients and staff is the first priority and will mitigate the risk of a potential secondary emergency. Be aware of your surroundings, communicate effectively, and utilize resources available on site.

Telegram: @medical_k

www.konkur.in

PSYCHIATRIC EMERGENCIES RESULTING FROM SUBSTANCE INTOXICATION

Intoxicated patients tend to evoke negative responses from hospital staff, which in turn may further agitate an intoxicated patient. As with all difficult patients, personal feelings should not be allowed to influence professional judgment and clinical care. Utilization of all available resources is the standard of care to ensure safety, as intoxicated patients can be unpredictable. Security forces, though seldom needed, should be alerted before interviewing an intoxicated patient. If possible, the interview should be conducted in a large comfortable room. The clinician should assume a tolerant, nonthreatening manner and be prepared for potential verbal insults and physical threats. Offering food, coffee, or juice may also be helpful, as well as other strategies for intervention with aggressive patients.

Consideration of patient needs longitudinally will require an understanding of each patient's level of intoxication or potential for withdrawal, medical comorbidities, emotional and psychiatric comorbidities, acceptance or rejection of treatment, relapse potential, and availability of a supportive environment. Due to the heterogeneity of institutional resources, it is important for each provider to become familiar with available resources, both within the care setting and within the community. Resources such as The Patient Placement Criteria developed by the American Society of Addiction Medicine can be very helpful for determining the level of aftercare for patients with substance-related pathology.

Stimulant Intoxication

Sympathomimetics substances, also known as stimulants, which include cocaine and amphetamine salts, also are relatively short-acting substances with rapid effects when snorted, smoked, or used intravenously (IV). Symptoms of acute stimulant intoxication include a heightened sense of well-being, increased sense of alertness, decreased anxiety, reduced social inhibitions, increased talkativeness, and poor judgment manifested by loss of money,

Telegram: @medical_k

www.konkur.in

sexual indiscretion, and potentially illegal activities. Patient symptoms usually resolve within 48 hours. Stimulant intoxication may also present with grandiosity, psychomotor agitation, paranoid ideation, formication (sensation of insects crawling on the skin), bizarre behavior (such as sorting objects into various groups), stereotyped movements of the mouth and the tongue (such as teeth grinding, lip biting, and skin picking), tactile or visual hallucinations, and distorted perceptions. Delusional states, especially paranoia, can also occur.

Physical findings include tachycardia or bradycardia, hypertension or hypotension, hyperthermia, dilated pupils, perspiration or chills, hyperreflexia, nausea, and vomiting. Patients may have evidence of weight loss, muscular weakness, respiratory depression, chest pain, or cardiac arrhythmias. Intoxication can lead to confusion, seizures, or coma. Patients who abuse stimulants IV are at risk for numerous medical conditions, including endocarditis, tetanus, hepatitis, abscesses (MRSA), and AIDS. Urine and serum drug screens provide corroboration of the diagnosis and should be part of the PES intervention, if suspected or if there is a need for determination of diagnosis based on readily available information.

Treatment should include placing the patient in a quiet room away from the general traffic of the PES as external stimuli may exacerbate the physiologic effects of sympathomimetics. Explaining the treatment in simple language coupled with reassurance to the patient that the effects of the stimulant will subside may aid in providing comfort. Because the patient should not be left alone, family members or friends can be included in the treatment to provide further reassurance and support, if safe to do so. Strategies discussed earlier in this section for managing aggressive patients should be utilized. If interpersonal interventions fail to relieve the patient's agitation, a benzodiazepine can be administered to calm it. If the patient does not respond or is delusional, extremely agitated, or combative, then an antipsychotic medication with or without a benzodiazepine can be given as per the medication algorithm discussed earlier. The patient should be discharged to the care of family or friends with a follow-up outpatient appointment for the next day in a drug treatment program, if possible.

Telegram: @medical_k

www.konkur.in

Hospitalization should be considered if:

- the psychosis does not remit and affects the ability to negotiate their needs.
- the patient has a polysubstance abuse problem and requires detoxification.
- the patient has no family or other support system, and appropriate housing or shelter cannot be arranged.
- the patient has protracted cognitive impairment.
- the patient has serious associated medical problems.

Alcohol Intoxication

Patients who are intoxicated with alcohol in the PES may be self-referred or brought in by police, friends, or relatives because of self-destructive, disruptive, or violent behavior. It has been estimated that more than one-half of murderers and their victims are intoxicated at the time of the act. In addition, approximately one-quarter of deaths by suicide in the United States involves alcohol.

Blood alcohol levels usually correlate with the clinical presentation of the alcohol-intoxicated patient:

- 30 mg/dL: attention difficulties and/or mild euphoria
- 50 mg/dL: coordination problems and/or unsteadiness
- 100 mg/dL: impaired memory and/or ataxia
- 200 mg/dL: confusion and/or stupor
- >400 mg/dL: seizure, coma, respiratory arrest, and/or death

Chronic alcohol use disorder patients will have a higher tolerance to the effects of alcohol, so blood levels of alcohol will not always correlate with the clinical presentation. Blood alcohol levels should always be obtained in the assumed intoxicated individual. Alcohol is metabolized at the rate of about 1 oz per hour or 10 to 30 mg per hour in patients with healthy hepatic functioning.

Symptoms of alcohol intoxication include aggressive or inappropriate behavior, mood lability, impaired judgment, slow or slurred speech, incoordination, unsteady gait, and nystagmus. Objective physical findings of intoxication may include autonomic

Telegram: @medical_k

www.konkur.in

instability; tremulousness; nausea and vomiting; transient visual, tactile, or auditory hallucinations or illusions; psychomotor agitation; and anxiety. Progression to withdrawal may be rapid in chronic and heavy users of alcohol, and symptoms should be monitored closely in patients with complicated use histories. At a minimum, vital signs and neurologic function checks should occur every 4 hours for patients at high risk for withdrawal.

Medical complications are common in chronic use of alcohol. These include but are not limited to: gastrointestinal bleeding, gastritis, stomach or duodenal ulcers, cirrhosis, pancreatitis, vitamin deficiencies, cardiomyopathy, peripheral neuropathy, and malnutrition. In an acute presentation, patients may have sunburn exposure and subdural hematoma from head trauma, thus making an exploration of patients' recollection of events prior to arrival imperative. Duration of use, quantity used, and timeline of the most recent exposure must also be explored. Other drugs may also have been ingested, thus further complicating the clinical picture. Death may occur from aspiration of vomitus or respiratory depression, if not clinically identified.

The first treatment priority is to protect the acutely intoxicated patient from harming him- or herself or others and to identify medical problems that require immediate attention. A patient may be hyper- or hypoglycemic, bleeding internally, hypertensive, have end-stage cirrhosis, a cardiac arrhythmia, pneumonitis, hematoma(s), or one of the alcohol-related syndromes such as alcohol-induced persisting amnestic disorder or Wernicke encephalopathy. A person may appear obtunded by alcohol, but clouding of consciousness from hyper/hypoglycemia, blood loss, or a subdural hematoma may be the cause. Clouded consciousness in the clinical presentation of a negligible serum alcohol level is concerning for medical pathology warranting intervention. The patient's vital signs should be obtained every 15 minutes if possible, and depending on the patient's medical history and physical examination, appropriate laboratory studies should be obtained. If control of agitation is required, then the use of antipsychotics should be used, as described earlier in this section. Benzodiazepines should be avoided, if possible due to the increased

Telegram: @medical_k

www.konkur.in

risk of respiratory depression. Patients may require a higher level of care than may be offered in the PES setting, and emergency medical personnel should be involved in care as acute intoxication, especially in the context of the potential for withdrawal, can be a medical emergency.

Disposition should be to home with family, if available, or other community placement if the patient presents no immediate danger and has no acute medical problems. The patient should be given a follow-up appointment in an outpatient program and referral to alcoholics anonymous (AA). Many facilities offer on-site substance use counselors, which may be beneficial in aiding in longitudinal planning as well.

Benzodiazepine, Sedative, and Hypnotic Intoxication

Benzodiazepine, sedative, or hypnotic intoxication is marked by impaired judgment, loquacity, mood lability, dreamlike feelings, and a disinhibiting of sexual and aggressive impulses. Slurred speech, incoordination, unsteady gait, lateral nystagmus, areflexia, muscle hypotonicity, hypotension, and hypothermia are common physical findings.

Management of benzodiazepine, sedative or hypnotic intoxication is a complex medical intervention best left to clinicians who have experience in treating such cases. These patients should be treated in the medical emergency department with continuous monitoring of vital signs and immediate availability of airway protection interventions. Barbiturate overdose, in particular, is a medical emergency. Most patients require admission to a medical intensive care unit for continued evaluation and treatment. Patients may require management for a comorbid psychiatric illness, but intervention should be deferred until medical stability is ensured.

Opioid Intoxication

Symptoms of opioid intoxication include drowsiness, slurred speech, and potentially coma. Physical findings include decreased respiration, blue lips, blue or pale skin, pinpoint pupils (if brain damage has

Telegram: @medical_k

www.konkur.in

occurred, usually secondary to anoxia, pupils may be dilated, or meperidine can cause mydriasis), hyperemic nasal mucosa, recent needle marks, pulmonary edema, cardiac arrhythmias, or seizure.

Death is secondary to pulmonary or cerebral edema.

If a patient is unstable due to the direct physiologic effects of opioids, then the signs and symptoms are rapidly reversed by the administration of a narcotic antagonist, for example, naloxone. Formulations of naloxone include injectable, auto-injectable, and nasal spray. Symptoms of opioid intoxication may be complicated by varying levels of intoxication or withdrawal from other drugs. Therefore, patients should have urine and serum drug screens. Because of the life-threatening risk or its potential medical complications, opioid intoxication or overdose should be treated in the medical emergency department with continuous monitoring of vital signs and immediate availability of airway protection interventions. Patients may require management of a comorbid psychiatric illness, but intervention should be deferred until medical stability is ensured.

Cannabis Intoxication

Cannabinoids include substances such as hashish, bhang, marijuana, and purified Δ9-tetrahydrocannabinol (THC). Abusers commonly use cannabinoids with other substances, particularly alcohol and cocaine. The most common methods of use are smoking and oral consumption. Drug effects develop within 20 to 30 minutes. There has been an increasing prevalence of the use of cannabinoids due to recent legalization in various jurisdictions. Providers should always inquire about use independent of legality as cannabinoids may directly influence the psychiatric phenotype of the patient in the PES.

Clinical findings of acute intoxication include:

- Impaired motor coordination
- Euphoria
- Anxiety
- The sensation of slowed time
- Impaired judgment

Telegram: @medical_k

www.konkur.in

- Social withdrawal

Within 2 hours of cannabis use, the patient may develop the following:

- Conjunctival injection
- Increased appetite
- Dry mouth
- Tachycardia

Marijuana intoxication usually will not be the primary reason for evaluation in the PES unless an adverse reaction to the drug occurs. Treatment involves reassurance and a calm environment. Symptoms will usually clear within 4 to 8 hours. If the patient's anxiety or panic becomes severe, then a benzodiazepine can be given. Paranoid delusions are rare but may require antipsychotic medication. If a psychotic reaction lasts more than a few days, then the patient should be evaluated for a comorbid psychiatric illness.

It is important to note that patients may have exposure to synthetic cannabinoid products in presenting to the PES. Patients may endorse the use of "marijuana" use only, but synthetic cannabinoids have seen recent increases in incidence rates in the emergency setting. Patients may present with symptoms similar to naturally occurring cannabinoids but can develop severe tachycardia, hypertension, marked restlessness, agitation, anxiousness, nausea with emesis, mydriasis, somnolence, hallucinations, the elevation of blood glucose, hypokalemia, and even seizures. Patients may require supportive medical interventions to ensure stability, and physicians may need to treat symptomatically underlying psychopathology, especially when agitation and psychosis are salient features. If the presentation of a patient is inconsistent with the use of cannabinoids alone, clinicians should ensure thorough screening for other substances, including synthetic cannabinoids. Toxicology testing, whether urine or serum, may have limitations in its utility as synthetic compounds are not regularly part of commercially produced screening tests. Patients should be monitored closely, and if a psychotic reaction lasts more

Telegram: @medical_k

www.konkur.in

than a few days, the patient should be evaluated for a major psychiatric illness.

Hallucinogen Intoxication

Hallucinogens include the following:

- Lysergic acid diethylamide (LSD)
- Psilocybin ("magic mushrooms")
- Dimethyltryptamine (DMT)
- Peyote
- Dimethoxy methylamphetamine (DOM or "STP")
- Mescaline
- Phencyclidine (PCP)
- Ketamine
- Methylenedioxymethamphetamine (MDMA, "Ecstasy," or "X")

Hallucinogens cause no known withdrawal symptoms. Unfortunately, drugs are often mixed, adulterated, and sold under a different name and, therefore, clinicians can never be certain what hallucinogen was ingested on the basis of a patient's provided history. Therefore, serum and urine screens must be obtained. Pre-existing psychiatric or medical illness or premorbid personality disorders may intensify hallucinogenic symptoms as the effects of substances are not homogenous among users. The symptom complex present in the clinical setting is often multifactorial and the result of drug–drug interactions and the dose ingested. The duration of action and rate of onset of symptoms is also heterogeneous. Additionally, a user's premorbid personality, expectations, and social setting can directly affect the behavioral phenotype and described effects. Hallucinosis typically lasts 16 hours to 2 or 3 days.

Symptoms include perceptual, emotional, and cognitive changes. Patients may see colorful mobile displays of geometric designs or complex human or animal forms. Colors appear more intense, and fixed objects undulate and flow. The patient has a greater sensitivity to touch and an altered sense of taste and smell. Synesthesia may occur (an overflow of one sensory modality into another; for instance,

Telegram: @medical_k

www.konkur.in

the patient “hears” colors or “sees” music). Other perceptual changes include depersonalization, derealization, and body image distortions in which body parts seem to grow, shrink, or disappear.

Emotional presentations range from euphoria, elation, and bliss to tension and anxiety and may culminate in a panic attack. The patient may laugh or cry for prolonged periods of time. Cognitive changes include loosening of associations with unusual content, illogical and fantasy-laden thought sequences, paranoid grandiosity, and, less commonly, persecutory delusions. Physical findings include hypertension, hypothermia, dilated pupils, tachycardia, sweating, palpitations, tremors, blurred vision, incoordination, and hyperreflexia.

Hallucinogen intoxication usually will not present to the PES unless an adverse reaction to the drug occurs or a patient places themselves in imminent danger due to impaired judgment and is brought in by a concerned family member or agency. The primary intervention involves reassuring the patient that the drug’s effects will subside within several hours. It is helpful to remind the patient that the hallucinogen has produced their extraordinary ideas and feelings and that the drug effects will soon dissipate. When possible, friends and family members can help alleviate the patient’s anxiety by maintaining a continuous dialogue in a supportive, nonthreatening environment. Because closing the eyes can intensify the hallucinogenic state, the patient should sit up or walk. Clinicians should try to avoid pharmacologic intervention. If the patient’s anxiety becomes overwhelming, then a benzodiazepine can be given. Severely agitated patients may require an antipsychotic agent.

Phencyclidine Intoxication

Originally marketed as an anesthetic agent, phencyclidine (PCP) was taken off the market because of the psychotic reaction experienced by patients postoperatively. PCP, commonly called “angel dust,” is an illegal drug often sold to consumers under many names and may be sold as “crack” or “LSD” (it is neither). The drug may be taken orally, inhaled, snorted, or injected IV. PCP presents a confusing clinical picture with diverse psychological, physiologic, and behavioral effects and may mimic schizophrenia. PCP highlights the importance and

Telegram: @medical_k

www.konkur.in

utility of urine and serum drug screening in complicated patient presentations.

Patients can become extremely violent when intoxicated with this illicit substance. It can create a significant paranoid psychosis resulting in harm to others and, when taken in sufficient amounts, can produce death from respiratory failure, cardiac arrhythmias, and adrenergic crisis. Clinical findings are diverse and can include calmness to the point of sleep, agitation, hostility, disorientation, emotional lability, a sense of slowed time, out-of-body feelings, unpredictability, impaired judgment, hallucinations, assaultive behavior, and paranoid ideation. Because of the amnestic quality of PCP, patients will often not remember how they behaved while intoxicated.

Clinical signs and symptoms tend to correlate with PCP blood levels and include vertical and horizontal nystagmus, ataxia, loss of pain response, drooling, nausea, and mild pulse and blood pressure elevation at low doses. Higher blood levels include catatonia, rigidity, myoclonus, fever, elevated pulse and blood pressure, hyperreflexia, and elevated creatinine phosphokinase secondary to muscle trauma. PCP intoxication can proceed to death as the dose increases.

Patients with mild to moderate intoxication should improve with supportive care. The patient will require supervision in a nonstimulating environment that should include protection from self-injury. If symptoms remit and there is no cognitive impairment after 12 hours, then the patient can be discharged from the PES. Moderate to severe intoxication will require supportive care in an emergency department or medical inpatient unit with special attention to respiratory and cardiac function. It is often important to obtain serum creatinine kinase levels, especially in the context of significant abnormalities in vital signs. Patients may require IV fluids to ensure that renal damage does not ensure when creatinine kinase levels are markedly elevated. Vital signs need to be monitored for laryngeal stridor and/or respiratory depression. Restraints should be avoided to avoid the increased risk of rhabdomyolysis and resultant acute renal failure.

Telegram: @medical_k

www.konkur.in

The preferred method of physical restraint for combative patients is total body immobilization by rolling the patient in a sheet. Sedation with a benzodiazepine may be required for anxiety, agitation, or harmful behavior. An antipsychotic may be given for psychosis.

Inhalant Use

Inhalants can cause irreversible damage. They can cause death by suffocation, aspiration vomitus, or myocardial infarction. Patients who abuse inhalants sniff aerosols, cleaning solutions, nail polish remover, lighter fluids, paint thinner and other petroleum products, or glue containing toluene. Intoxication occurs within 5 minutes and ceases in 1 to 2 hours.

Clinical findings include belligerent or assaultive behavior, apathy, impaired judgment, and impaired social and occupational functioning. Physical findings include dizziness, nystagmus, slurred speech, unsteady gait, depressed reflexes, tremors, blurred vision, diplopia, stupor, coma, rash around the nose and mouth, breath odors, residue on the face, hands, and clothing, redness and swelling of the eyes, and irritation of the throat, lungs, and nose. Major medical problems associated with inhalant abuse include cardiac arrhythmias, hypoxia, hepatitis, renal failure, bone marrow suppression, impaired pulmonary functioning, and skeletal muscle weakness. Death can result from central nervous system depression, cardiac arrhythmias, bronchospasm, and ventricular fibrillation.

Care is mainly supportive. Patients should be kept in an environment with minimal stimulation. Clothes smelling of solvents should be removed, and solvents on skin or hair should be washed away with mild soap and water. Marked agitation should be controlled with antipsychotic medication as benzodiazepines may potentiate the effects of inhalants. Hospitalization may be warranted. However, chronic inhalant users often have polysubstance involvement and clinicians should carefully screen for other substances and treat accordingly.

Telegram: @medical_k

www.konkur.in

PSYCHIATRIC EMERGENCIES RESULTING FROM SUBSTANCE WITHDRAWAL

Withdrawal from Alcohol

Alcohol withdrawal is a medical emergency. If left untreated, it may lead to death. Clinical signs of alcohol withdrawal include disorientation, fluctuating attentiveness, and intermittent agitation, commonly violent in nature. Physical findings include tachycardia, sweating, hypertension, nausea, vomiting, tremulousness, hyperreflexia, orthostatic hypotension, and, occasionally, generalized seizures. Patients in withdrawal are usually depressed, irritable, and anxious and may experience illusions or transient visual, tactile, olfactory, and auditory hallucinations. Hallucinations are usually frightening—the patient sees and feels mice or lice crawling on the skin or sees animals, especially snakes. Alcohol withdrawal can be complicated by seizures or delirium tremens. Delirium tremens is the most severe form of ethanol withdrawal. It can manifest clinically with an altered level of consciousness and/or global confusion coupled with autonomic hyperactivity (specifically the sympathetic nervous system), which can lead to cardiovascular damage or failure.

Death occurs in 4% to 20% of cases from complications such as hyperthermia, aspiration, or vascular collapse. The onset of complicated withdrawal is usually 2 to 10 days after cessation or decreases in alcohol use and may last hours to days. Symptoms of uncomplicated alcohol withdrawal peak 24 to 48 hours after the last drink and subside within 5 to 7 days, even without treatment. Irritability and insomnia may last for 10 days or more. Withdrawal is more severe in patients with previous episodes of withdrawal or medical illnesses.

Alcohol withdrawal symptoms are generally effectively treated with benzodiazepines. Chlordiazepoxide (25 to 100 mg every 4 to 6 hours and as needed) provides for smoother detoxification given its long half-life. Lorazepam (1 to 2 mg orally or intramuscularly every 6 hours and as needed) is preferred when IM medication is necessary, or patients have markedly impaired liver function. Lorazepam is safer for

Telegram: @medical_k

www.konkur.in

patients with hepatic disease or brain damage due to renal excretion and a shorter half-life. An antipsychotic, as recommended earlier in this section, could be used for patients with hallucinations. Pulse, blood pressure, and temperature must be monitored every 30 minutes in the PES. One hundred milligrams of thiamine is given IM to address expected vitamin deficiency. Delirium tremens or a seizure is a medical emergency and must be treated in the medical emergency department in a monitored setting. If a patient has a documented or verbalized history of alcohol withdrawal-related pathology, it is considered a medical emergency, and patients will require monitoring and potential hospital admission, independent of any comorbid primary psychiatric pathology.

Withdrawal from Benzodiazepines, Sedatives, and Hypnotics

Withdrawal from benzodiazepines, sedatives, and hypnotics is similar to alcohol withdrawal. Physical findings include tremors, increased pulse and respiration, hyperthermia, loss of appetite, nausea and vomiting, postural hypotension, hypertension, seizures, and delirium. Patients who abuse sedatives are at risk for infections and hepatitis.

Withdrawal from short-acting agents will have an onset 12 to 24 hours after the last dose, peaking between 24 and 72 hours. Withdrawal symptoms with longer-acting agents peak 5 to 8 days after the last dose. The older adults or patients with hepatic disease may develop symptoms more slowly because of decreased drug metabolism.

There are several pharmacologic options for withdrawing a patient from benzodiazepines, sedative, and hypnotic drugs.

- One method is to gradually withdraw the agent of dependency.
- Substitute the dependent agent with phenobarbital or a longer-acting benzodiazepine and taper. For short half-life benzodiazepines, treatment would be with a longer-acting drug such as clonazepam or chlordiazepoxide.
- In cases of barbiturate or other mixed sedative/hypnotics, a phenobarbital taper can be used, as this will allow for safer detoxification because it produces few changes in blood levels

Telegram: @medical_k

www.konkur.in

between doses, it has observable signs of toxicity, and intoxication does not produce euphoria. A phenobarbital taper is done as follows:

1. Administer a 200-mg test dose of pentobarbital orally and assess neurologic status after 1 hour. Pentobarbital can be converted to phenobarbital, which has a longer half-life with fewer variations in blood level (100 mg of pentobarbital is equivalent to 30 mg of phenobarbital).
2. If the patient is asleep but arousable, then no treatment is required. If the patient is drowsy with slurred speech, coarse nystagmus, or ataxia, then the patient's estimated pentobarbital requirement is 400 to 600 mg per 24 hours.
3. If the patient is comfortable with only fine lateral nystagmus, then the 24-hour pentobarbital dose is 800 mg.
4. If the pentobarbital has no effect, then the 24-hour pentobarbital dose is estimated at 1,200 mg or more.

Patients who are withdrawn from sedative-hypnotics should be admitted to the hospital for the withdrawal protocol because this is a life-threatening condition. Clinicians should also familiarize themselves with the dose equivalents of benzodiazepines and other sedative drugs.

Some common benzodiazepine dose equivalents are:

- Alprazolam (Xanax) 0.5 mg
- Chlordiazepoxide (Librium) 10 mg
- Clonazepam (Klonopin) 0.25 mg
- Diazepam (Valium) 5 mg
- Lorazepam (Ativan) 1 mg
- Oxazepam (Serax) 15 mg

Withdrawal from Opiates

Patients' opioid use disorders may present to the PES requesting detoxification or, more commonly, present in withdrawal requesting relief. In addition, patients may have significant mood symptoms that may potentiate the untoward effects of withdrawal. Cessation of

Telegram: @medical_k

www.konkur.in

opiates, while uncomfortable, is not life-threatening. Opioid withdrawal is precipitated by the abrupt cessation of opioid administration. When heroin, morphine, or short-acting prescription opioid use is discontinued, withdrawal symptoms can appear within 6 to 8 hours, peak within 36 to 72 hours, and last for 7 to 10 days. Meperidine withdrawal may not begin until 1 to 3 days after the last dose, with symptoms dissipating after 10 to 14 days. Fentanyl, one of the most potent opioids, has both faster onset and resolution of withdrawal symptoms, with onset from 2 to 5 hours, peak within 8 to 12 hours, and resolution within 4 to 5 days.

Withdrawal symptoms from opioid use include nausea, vomiting, diarrhea, dilated pupils, muscle aches and pains, insomnia, lacrimation (tearing eyes), flu-like weakness, rhinorrhea (running nose), piloerection, sweating, flushing, abdominal cramps, increased temperature, yawning, and semen ejaculation. These symptoms can be managed with nonopioid adjunct medications. For example, ondansetron can be given for nausea, dicyclomine for gastrointestinal cramping, and ibuprofen for body aches. Although opioid withdrawal is not considered life-threatening, patients who are dehydrated or debilitated could potentially have life-threatening complications. Seizures and delirium tremens do not occur.

Recently it has become more common for the management of potential opiate withdrawal actively in the PES setting. Buprenorphine (with or without naloxone) is a partial *u*-opioid agonist that has been shown to alleviate acute opioid withdrawal symptoms and be an effective long-term treatment for opioid use disorder. Although sedation can occur, it does not have the same risk for respiratory depression as other opioids. It is considered safe to initiate in the emergency department and can help bridge patients to outpatient addiction treatment. One caveat is that patients must already be experiencing withdrawal symptoms prior to initiating buprenorphine, as it may precipitate withdrawal. Induction dosing of buprenorphine is variable depending on the severity of the withdrawal, typically with a maximum dose of 32 mg per day.

Patients can also be referred to methadone maintenance or drug rehabilitation program for further evaluation and treatment, but

Telegram: @medical_k

www.konkur.in

clinicians should not initiate methadone management in the emergency setting. However, if a patient is in established treatment for opioids with methadone, efforts should be made to continue care. This includes contacting current providers once consent is obtained to prevent a lapse in care, if possible.

Withdrawal from Cocaine and Amphetamines

Withdrawal from amphetamines and cocaine produces dysphoria, hypersomnia or insomnia, increased appetite, apathy and lack of energy, muscle aches, chills, depressed mood, anxiety, irritability, and vivid and unpleasant dreams. Patients will have a heterogeneous presentation in sympathomimetic withdrawal and may be agitated or have psychomotor retardation. Drug cravings may be intense. Suicidal thoughts can occur, and in some cases, patients may experience paranoia or hallucinations. The severity of the symptoms will depend on the potency of the stimulant of use. With amphetamines, these symptoms commonly occur 3 or 4 days after a decrease or cessation of heavy amphetamine use. The depression can last for months, although symptoms may last only 8 to 48 hours, with milder symptoms persisting for several weeks.

There is no standardized detoxification regimen for stimulants. Usually, after several nights of sleep, the dysphoria and suicidal ideation resolve. A calming environment can decrease agitation, and clinicians should avoid a confrontational approach. Quiet time, food, and sleep are the best interventions. However, while in PES care, the patient has to be carefully evaluated for suicide risk and may require inpatient hospitalization. Many of these patients do not regularly use the health care system, and clinicians should always maintain a high index of suspicion for undiagnosed and/or untreated medical diseases. Because these patients are at high risk for relapse, an inpatient rehabilitation program should be considered. Given that antidepressants have a delayed onset of action, their use is of no value in substance-induced mood disorders in the PES. If the patient is discharged home, then it is preferable to have family or another supportive individual accompany the patient home from the PES.

Telegram: @medical_k

www.konkur.in

Withdrawal from Inhalants

Chronic, heavy use of inhalants has been reported to precipitate withdrawal symptoms within a few hours to several days after cessation of use. These symptoms include tremulousness, anxiety, inattention, diaphoresis, diarrhea, restlessness, and insomnia. Withdrawal symptoms can be treated with benzodiazepines. Whether there is an actual withdrawal state from inhalants is controversial

OTHER PES-RELATED ISSUES

Domestic Abuse

Domestic abuse refers to a behavior pattern in which a person repeatedly inflicts physical injury, pain, fear, or mental anguish on another member of the household. The abuse may be imposed through physical, psychological, sexual, or economic means. Neglect occurs when a care provider fails to provide the basic necessities for living to a dependent individual. Given the marked prevalence of the problem and the difficulty of identifying domestic abuse and neglect, clinicians should maintain a high index of suspicion. Knowing the signs that suggest domestic violence can help the clinician to determine the necessary intervention. Although men are less likely to have a history of abuse than women, they are more likely to be attacked by their partners with knives, guns, or household objects and suffer serious injury or death.

Treating a patient's physical injuries is the first priority. It must then be determined whether the patient's significant other (or another household member) caused the injuries. The clinician should obtain a history of the current relationship, as well as a history of the previous types of abuse. Victims of abuse often will give inconsistent explanations for their injury. Frequently, the abused adult patient may minimize the pain suffered from the attack and impede investigating the abuse or claim that the abuser did not really mean any harm. Issues such as whether the patient should report the abuse and whether the patient should seek placement other than their home are complicated and require a great deal of patience and skill on behalf of

Telegram: @medical_k

www.konkur.in

the clinician. If a patient has a pattern of injuries sustained by an abuser, it is advised to separate them from the abuser if possible and consider long-term treatment to aid in recovery. Whether or not to seek further social services and legal aid also factors into the intervention. Mandatory reporting guidelines can vary between jurisdictions; therefore, it is very important to be familiar with local laws and reporting guidelines. Treatment options may include psychotherapy, special abuse programs, and self-help and advocacy groups. Knowledge of available community resources is important for PES staff to ensure appropriate care.

Elder Abuse

Older adult patients can be victims of various types of abuse: passive neglect, physical abuse, and emotional or sexual abuse. The most common form of abuse is neglect, although physical abuse and financial exploitations are also common. The clinician's high index of suspicion is a critical component in making the diagnosis. The first priority is always to treat the physical consequences of the abuse or neglect. An older adult patient may minimize the problem, appear afraid of the caregiver, and express fears about returning home. Patients should be asked about being hit, being physically harmed in the past, or being deprived of care or necessities such as food and clothing, if any suspicions arise in clinical care. Signs of neglect in an elder person may include malnourishment, dehydration, poor hygiene, or pressure sores. The misuse of drugs, including overdosing, underdosing, or inability to obtain prescribed medications, may also reflect abuse. Sometimes additional evidence of neglect can be obtained from the person(s) bringing the patient to the emergency department. They may have first-hand knowledge of the patient's domicile and can comment on the level of cleanliness, the functioning of utilities, and the adequacy of medical appliances such as walkers and commodes.

Risk factors for those that perpetrate elder or dependent abuse include substance abuse (especially alcohol), psychiatric illness, psychosocial stressors, emotional and financial dependency, history of abuse themselves, social isolation, inexperience in caregiving, and

Telegram: @medical_k

www.konkur.in

misinformation as to how to provide care. In addition, there are risk factors specific to institutional care settings. Staffing shortages and provider burnout, lack of oversight, and lack of sympathy for residents have all been shown to increase the potential for elder abuse.

Interventions for those providing care to elders may include reducing the stress on the family by expressing empathy and providing support to the caregiver. Identifying interpersonal conflicts that underlie the abuse may also help alleviate tension in the family. Treatment for a patient, the abuser, and another family member will occur outside the hospital, but the clinician must inform the family of appropriate community resources and make appropriate referrals. If elder abuse is suspected, mandated reporting laws require a concerned clinician to report findings to the appropriate authorities. Clinicians should be familiar with the local statutes concerning this issue and the available mechanisms for reporting suspected abuse.

Child Abuse

The majority of child abuse cases reported annually are related to neglect, with smaller proportions related to physical abuse, sexual abuse, and emotional mistreatment. Because child abuse is underreported, the clinician should always maintain a high index of suspicion. Risk factors associated with child abuse include a single-parent household, especially if the father is the sole caretaker, children between 3 and 12 years of age, behavioral problems, large family size, and poverty. Of all of the risk factors, poverty is most strongly associated with abuse and neglect. Caretaker factors that have been associated with or have contributed to child abuse and neglect include younger age, poverty, personal history of abuse, large family size, unplanned pregnancies, illicit drug abuse and alcohol use, inadequate parenting skills, low–birth-weight babies, and social isolation.

The interview of a child who may be a victim of abuse requires a compassionate and sensitive approach, which assures the child that they are in no way at fault. The most successful interviews occur when the child is interviewed alone. The clinician should sit at the child's eye level, explain the purpose of the interview, use open-

Telegram: @medical_k

www.konkur.in

ended questions when possible, and not display shock or horror at the child's descriptions. Depending on the outcome of the interview, the clinician has numerous options for treatment, including hospitalization, outpatient treatment and family therapy, contacting the state or city social welfare agencies, and, depending on the state legal statutes, contacting legal authorities. Medication may be considered to treat underlying psychopathology but not to treat reactive emotional states. If underlying mental illness is discovered, the use of child and adolescent psychiatrists is optimal to ensure appropriate longitudinal care by specialized providers.

Rape

Rape is a major psychiatric emergency. Due to social stigma, taboo, or fear of retaliation by the offender, the victim will often not immediately report rape or wish to report it at all. However, a victim who is not managed properly may develop enduring patterns of psychological and sexual dysfunction. Thus, the treatment of a patient for known or suspected rape is complicated. The accompanying fear of future violence and death at the hands of a known perpetrator and of contracting sexually transmitted diseases are also difficult acute stressors in the context of rape. For women, there is the additional fear of becoming pregnant. The management of the rape victim involves medical, mental health, and forensic interventions that may be initiated in the PES. However, the primary goal of the assessment for a victim of rape is to restore psychological safety by providing information, correcting misattributions, restoring and supporting effective coping, and ensuring social support. A respectful, compassionate, and sensitive approach is necessary to forge a therapeutic relationship with victims.

Helping the patient recognize that they are in the hospital and are safe can restore psychological safety. Because patients may be sensitive to power and control issues, a common respectful approach will help develop this sense of safety. Patients who react to the trauma with dissociative symptoms may appear calm and unaffected by their ordeal yet have a high risk of developing post-traumatic stress disorder. Once a sense of safety is achieved, it is essential to

Telegram: @medical_k

www.konkur.in

provide information to the rape victim about their current medical status. Addressing fears of future health problems, including pregnancy, sexually transmitted diseases, and HIV infection, is paramount and will aid in reducing anxiety. Information must also be given about the legal system, the responsibility of the police, and the need for evidence collection. Clinicians should acknowledge the patient's fears of being touched and undergoing vaginal and rectal examinations and discuss the potential for these examinations to trigger flashbacks or intrusive thoughts of the rape or sexual assault. The presence of a trusted family member or friend may help the patient to cope with the examination. Victims of rape or sexual assault commonly blame themselves for what happened and may have persistent fears of being out in public and perceiving being out alone as dangerous. Helping the patient to recognize the potentially impairing nature of sexual trauma may decrease anxiety, guilt, and anger. Education about common reactions to rape, such as irritability, hypervigilance, and problems with sexual intimacy, is important to share with the patient once a therapeutic relationship has been established. Discussing sleep problems, intrusive thoughts, nightmares, avoidance, and numbing may also aid in restoring psychological stability and allay fears that they are crazy or have lost control. Ongoing counseling and psychotherapy should be recommended for all sexual abuse victims. Facility-specific services may be available, and it is important for the PES provider to be familiar with all potential resources to help patients longitudinally with sexual trauma.

PSYCHOSOCIAL ISSUES IN THE PES

Homelessness

Homelessness has become an increasingly difficult social stressor for many in the United States. Additionally, many urban homeless are chronically mentally ill. PES and social services personnel are frequently called on to provide aid to homeless persons after medical care has been rendered in the emergency department. Although the

Telegram: @medical_k

www.konkur.in

typical “street person” is difficult to characterize, these patient populations may suffer from one or more psychiatric illnesses, including schizophrenia, substance use disorders, neurocognitive disorders, and personality disorders. Because of the extensive biopsychosocial pathology seen in the homeless, numerous resources must be devoted to their evaluation and treatment. Recent novel care programs in various jurisdictions have aided in providing longitudinal community-based care to mitigate the potential use of scarce hospital-based resources. Awareness of these services is crucial for a PES physician.

It is often difficult to engage homeless populations. Homeless individuals, especially those with severe mental illness, may not trust or actively seek to avoid contact with the medical or social service systems. If the clinician cannot develop a rapport with the patient, it is not generally an effect of poor training. In these instances, other PES staff members may be utilized to try to establish a relationship with the patient in order to assess their needs. The clinician’s initial task is to determine what the patient requires (shelter, medical attention, or antipsychotic medication), especially when self-presenting. However, police or other agencies may bring in homeless patients for care, and the chief complaint may be obscure or often nonexistent.

Helping the patient to clean up and offering food and drink may be the best ways to engage the patient and learn about their psychiatric and social needs. As a general rule, all homeless persons should be at minimum screened for any medical illness. Some people may have unidentified illnesses due to head trauma or nutritional deficiencies. If possible, these patients should be hospitalized for further evaluation.

When mental health care is rendered, and medication is utilized, it is less likely the patient will continue to take medication following discharge from the PES unless a more structured living situation can be arranged. The mentally ill homeless person is commonly resistant to a meaningful change in lifestyle unless the patient is actively and accurately describing their needs. A caring, nonthreatening clinician may be able to place the patient into the mental health care system to meet needs. Linking a patient to a drop-in center or day hospital may be worthwhile, if possible, and many urban facilities may offer

Telegram: @medical_k

www.konkur.in

specialized programs in providing assistance. Working with the patient and targeting specific identified goals can potentially develop a positive therapeutic alliance and allow a homeless patient to receive necessary services longitudinally.

High Utilizers of Service

Patients may utilize psychiatric emergency care services for inappropriate secondary gain. Beginning with symptoms, patients may complain of urgent needs that are ripe with unrealistic expectations and wishes for immediate relief. Patients may relate in a generally negativistic manner and are often regarded by staff as demanding and/or manipulative. These patients' desires and demands are usually quite different from their clinical needs on assessment and can create intense frustration on the part of both the patient and the treatment team. High utilizers of resources have a paucity of supportive interpersonal networks as they tend to interact within their social environments in much the same way they do in the PES, leaving available resources exhausted and depleted.

Managing these patients requires a flexible approach. The patient's autonomy should be supported, but each emergency visit should be viewed as an opportunity to encourage both the patient's engagement and participation in treatment. In addition, every effort should be made to enhance the patient's understanding of what the PES provides and the limitations of service. Some of these patients may ultimately develop a positive transference to the PES that will help them maintain a relatively consistent level of functioning. While the optimal goal would be to have them engaged in an outpatient program, their relationship with the PES may keep some patients under the protective mantle of a single health care facility and ensure appropriate and safe longitudinal care. A partial hospital or intensive outpatient program is an effective, relatively stabilizing disposition and should be encouraged by PES staff. However, the availability of such resources may be limited, and the care in many instances rests on PES providers.

Perhaps the most difficult aspect in managing any patient whose expectations are unmet is the clinician's own discomfort. Because

Telegram: @medical_k

www.konkur.in

these patients may be manipulative, uncooperative, and ambivalently help-rejecting, the clinician must be aware that the patient's style is likely a reflection of interpersonal deficits. The deficit is usually the result of early-life developmental exposures having little to do with the clinician. Such an understanding should help the provider resist being drawn into the transference struggle and instead help them to respond empathically despite provocation. In addition, a supportive approach combined with operant shaping strategies that set limits on demanding or inappropriate behavior can be effective when interacting with this population.

LEGAL ISSUES IN EMERGENCY PSYCHIATRY

Relevant legal issues in the PES include confidentiality and release of information, duty to warn and/or protect, informed consent and right to refuse treatment, competency, and involuntary commitment. An overarching concern for all of these issues is the need for adequate documentation in the medical record. The chart is a legal document; therefore, a court can subpoena a medical record. This is the most important piece of evidence in most malpractice cases. Charting should include an accurate assessment of the patient and all procedures, interventions, treatments, and plans for continued care. All chart entries should be accurately timed, dated, written legibly, and signed. Fraudulent documentation or "doctoring" the chart is a very serious legal offense.

Confidentiality

Since the time of Hippocrates, information shared between a doctor and a patient has been considered confidential. Accordingly, the American Psychiatric Association has established ethical codes addressing confidentiality. A physician is ethically and legally obligated to maintain the privacy of all information shared by the patient in a clinical doctor-patient setting. This "privileged" information belongs to the patient and can be shared with others only if the patient gives their permission to release the information or if the court system demands it. There are, however, several clinical situations in

Telegram: @medical_k

www.konkur.in

which confidentiality is waived. These include situations of child/dependent/elder abuse or neglect, competency hearings, court-ordered psychiatric assessments, danger to self, danger to others, expressed intent to commit a crime, and communication with other treatment providers involved in the care of the patient.

Duty to Warn

For the PES physician, the duty to warn is of particular significance. If a physician determines that there is a substantial risk of harm to another person if no intervention is made, then they are legally obligated to warn the person at risk. It is imperative for the psychiatrist to determine whether the information provided is a credible threat. Vague statements about thoughts of harm should not be taken at face value as a legitimate threat. However, after further questioning and clarification, if a threat with intent to harm others is elucidated, it is the responsibility of the clinician to make an effort to warn the threatened individual. Obtaining information from family, friends, and other treatment providers will often help clarify the credibility of a threat as well. When available, medical records of prior psychiatric treatments or the patient's managed care company's clinical database can also provide pertinent clinical information related to historical threats. The medical record should accurately detail the patient's statements and all follow-up information obtained, including the physician's opinion on the credibility, or lack thereof, of any threat. The record should justify the clinical action taken by the doctor and should include any specific plans expressed by the patient, capacity to carry out the plan, prior history of violent behavior or aggression, access to weapons, current mental status examination, and a current psychiatric differential diagnosis. The clinician should also document any consultation with colleagues, supervisors, administrators, or other authorities. If the threat is deemed credible or the clinician is unsure, then the patient should be admitted to a psychiatric unit for further evaluation as imminent danger to others is a viable justification for inpatient care.

Evaluation of Capacity and Competency

Telegram: @medical_k

www.konkur.in

Clinical capacity is broadly defined as the ability of a patient to make informed decisions and consent to receive medical treatment as assessed by any physician. Similarly, competency is a patient's legal capacity to engage in the decision-making process regarding their medical care. A patient's incompetence, however, may be determined only by a judge who is often supplemented with a physician's capacity evaluation. By law, all adults are presumed competent unless otherwise determined by a court of law. In a psychiatric emergency, waiting for a judgment from a court is rarely practical.

In assessing a patient's decision-making capacity, a patient must be able to:

1. understand the basic information necessary to make a decision;
2. understand alternative treatment strategies available;
3. appreciate the consequences of treatment and of no treatment; and
4. integrate all of the relevant information to make a consistent decision on their own behalf.

Aside from these four criteria, the standard for capacity may also vary on the risks to benefit ratio of the proposed treatment. A high benefit with a low-risk procedure may carry a higher standard of capacity to refuse and a lower standard of capacity to accept the treatment.

Competency is situation-specific, but a patient may also be assessed for global incompetence. A patient may be competent to consent to treatment and still suffer from major mental illness. A patient who is delirious, floridly psychotic, demented, or who is acutely intoxicated or withdrawing from drugs is likely not competent to make decisions concerning their treatment. In these cases, a surrogate decision-maker, usually a family member acting in the best interest of the patient, may decide on the patient's behalf. Additionally, facility-specific risk management services may be available for consultation to ensure practice within institutional guidelines.

Telegram: @medical_k

www.konkur.in

Competency is a medicolegal determination and should not be used to coerce a patient into treatment, even if the physician feels it is in the best interest of the patient. If found competent for decision-making capacity, a patient has the legal right to determine their own treatment independent of the physician's recommendations for care. Accurate and timely documentation, including a mental status examination in the medical record, is mandatory in mental health cases regarding patient competency, especially when the patient refuses the recommended treatment.

Informed Consent

Physicians often equate informed consent with a person giving permission to participate in a clinical research trial. The concept of informed consent, however, is relevant to all clinical settings, especially the PES. The doctrine of informed consent mandates that a patient must voluntarily give permission to receive or deny medical or psychiatric treatment. However, in order to provide consent, the patient must be deemed competent to make medical decisions on their own behalf (see "Evaluation of Capacity and Competency" previously) and be free of any coercion. A key component of informed consent is that adequate information must be provided to the patient or surrogate decision-maker. In some states, the amount of information needed for an average individual to make a decision on a proposed treatment is required (materiality standard). However, in other states, the amount of information required depends on the needs of the specific individual. Typically, the information for informed consent includes the patient's diagnosis, nature of the treatment proposed, treatment risks, benefits, and alternatives, if available, likely outcome with or without the proposed treatment, and the unpredictability of some treatment outcomes.

The medical record should document informed consent granted for treatment given or why treatment was necessary despite a patient's refusal. In some instances with patients who have chronic psychiatric conditions, a court-appointed delegate might be designated to provide consent on the patient's behalf. This is a legal determination and not one made by a psychiatrist. In children, parents generally

Telegram: @medical_k

www.konkur.in

have the right to treatment decisions except in the case of emancipated minors. The age and nature of treatment where parental authorization is required vary from state to state.

There are four circumstances in which a psychiatrist may treat a patient without first obtaining informed consent from the patient.

1. The patient is incompetent (a legal determination).
2. Emergency care is necessary to prevent serious risks to the patient or others.
3. There is a therapeutic waiver, where a competent patient designates the physician to make treatment choices for them.
4. Therapeutic privilege allows the physician to withhold information from the patient if it poses a threat to the patient or would impair their ability to make a competent decision.

Whenever informed consent is not obtained, precise and thorough documentation of the clinical circumstances should be placed in the medical record in the form of a legible, dated, and timed progress note.

Involuntary Commitment

Psychiatrists are in a unique position of having an ethical and legal responsibility to care for patients against their will if they meet specific criteria. Depriving an individual of their civil liberties is often a difficult decision, as patients may not have the insight into their actions and repercussions of behaviors due to an underlying mental illness. Although each state has its own involuntary commitment procedures, virtually all include criteria related to dangerousness to self, dangerousness to others, or an inability to care for oneself as a result of a mental illness. A patient may demonstrate symptoms consistent with severe mental illness, but if they are not deemed at imminent risk of harm to self or others and able to utilize resources for self-care, then they generally cannot be placed into involuntary psychiatric care. Family members, friends, police, or physicians can petition for the patient to be evaluated and allow a certified mental health professional to determine the safety of the patient's behavior in most

Telegram: @medical_k

www.konkur.in

jurisdictions. If deemed dangerous, the patient may then be hospitalized for a few days to a week, depending on the state mental health laws. Within a designated time period, the patient must have their specific case reviewed by a mental health court to determine whether a release is appropriate or detainment for longer treatment is warranted. It is important to emphasize that mental illness is necessary but not the only criteria sufficient for involuntary psychiatric hospitalization. Behaviors consistent with concern for safety or inability to care for self must be provided to ensure appropriate detainment. Homelessness, for example, does not justify forced hospitalization.

CONCLUSION

This section has reviewed some of the unique challenges that present to clinicians working within PES. Although emergency psychiatry is challenging for clinicians, it is also very rewarding and a critical component of the mental health delivery system. As services expand, so do programs for advanced training in the specialty of emergency psychiatry. As is the case in all emergency department settings, the need for a focused, thoughtful initial evaluation is the key to clinical success. Unlike an outpatient service, time pressures are essential to effective and efficient health care delivery. The PES clinician must be able to complete a biopsychosocial assessment, formulate a differential diagnosis, and make treatment or placement decisions, often in a few hours or less. The primary focus is on patient and staff safety with concomitant initiation of appropriate treatment. The importance of concise, accurate charting which accurately reflects clinical evidence is critical. It is unlikely that the PES clinician will be following the patient long-term, and the medical record will be the enduring material supporting placement decisions and must contain the supporting clinical information. Accurate dating and timing of all notes are particularly important in the PES, as this may impact legal issues (such as involuntary commitment) and clinical issues (such as medication dosing). Maintaining a high index of suspicion for medical illness will minimize the potential mortality

Telegram: @medical_k

www.konkur.in

and morbidity of PES patients. Managing violence is of particular importance to ensure the safety of patients and staff. Thus, all patients presenting to the PES should be considered potentially violent. This "universal precaution" mentality will help mitigate dangerous situations from developing. PES staff must be familiar with the array of social resources available in the community, including shelters, drug and alcohol treatment services, and community mental health services. These are vital to running an effective PES. PES staff must also be familiar with the legal aspects of providing the standard of care in a psychiatric emergency setting.

32 Psychotherapies

32.1 Psychotherapy Integration

ADAM M. BRENNER, M.D., AND AMY S. BRENNER, M.S.W., L.C.S.W.

The term eclecticism has long been used to identify the practice of blending ideas or techniques from various schools of psychological thought in order to provide a more multifaceted, targeted treatment for patients. Although the field of clinical mental health is vast, and there exists many schools of thought on practice, technique, and aims, the one commonality all schools share is the desire to help patients improve their state. The ideas of eclecticism, currently known as integration, sought to further this idea by increasing the ability to be effective treaters, using the manner, time frame, and logistics already in place for the patient.

As the idea of treating the brain through talk therapy evolved, so did the idea that one's own particular talk therapy was superior to the next. Beginning with Freud, psychoanalytic thought held sway till it began to be challenged in the 1950s by behavioral therapy. From there, an increasing number of theoretical orientations proliferated, and partisan allegiance began to further separate clinicians into an array of "name brand" therapies. Trainees were indoctrinated by

Telegram: @medical_k

www.konkur.in

teachers expert in a particular school and graduated believing, "*The way I practice is better than the way you practice, and my patients get better faster, or change more deeply, or recover more completely.*"

While this rivalry among schools led to a proliferation of theories and therapies, there was little evidence that any one of them worked better than another. The factors that most therapies have in common, such as alliance, positive regard, empathy, and emotional relief, are the factors that researchers find contribute the most to positive outcomes for patients. Only 10% to 15% of outcome differences in the research literature are attributable to varying techniques. Further, in the promotion of their new brands of therapy, experts were prone to overstate what was unique, and many commonalities were given new jargon. As one of our mentors used to remark, many "advances" in psychotherapy were simply "old wine, new bottle." (K. Altshuler, personal communication, multiple.) As for the actual added value of the specific techniques, the sum of psychotherapy research and clinical experience made clear that no one theoretical school could help every patient.

In treating something as complex as the human brain and mind, psychotherapy practitioners found both limitations to their orientations and overstatements of the effectiveness of the same. Frustrated with what appeared to be clinical failures, some clinicians reexamined their professional identities and began to reach out to other therapeutic schools to see what was there. Consequently, some practitioners began to carefully choose techniques outside of the approaches they were originally trained in, blending these with their original school of thought. As one eclectic proponent, Arnold Lazarus, put it, while remaining grounded in one's original training, one should "borrow, purchase, pilfer, and import" other techniques from other schools of thought. A particularly significant milestone in the development of these efforts came when like-minded practitioners launched the Society for the Exploration of Psychotherapy Integration in 1983. In 1991, the society began publishing the Journal of Psychotherapy Integration.

Telegram: @medical_k

www.konkur.in

Unfortunately, the monotheoretical communities often responded as if affronted by these “eclectics.” (One of the ironies to keep in mind about the current “pure forms” of therapy is that they were often created as a blend of theories and techniques from the major thinkers of the time.) It was suggested that deviation from the pure form of an established school of psychotherapy was evidence that the therapist was either poorly trained, indecisive, or disorganized.

When the authors trained in the 1990s, this had progressed to the point that the term “eclectic” became almost derogatory. As a result, the term “integration” slowly replaced it. And yet, eclecticism/integration is not syncretism. Syncretism implies a hodgepodge of quickly gathered methods without attention to a grounding in good practice or the evidence base. This can indeed imply poor training and focus. The goal of the integration of therapeutic approaches does not imply a blind acceptance that all theories and all techniques work. Theories and techniques must be grounded in an evidence base and operate within the established guidelines of responsible clinical practice.

Norcross has identified several barriers to therapy integration beyond partisan bias. The obstacles begin with training—most clinicians are schooled in one idea about psychotherapy, sometimes two. Being immersed in these ideas would, of course, lead new practitioners to a partiality toward that school of thought. In addition, psychotherapy as a field lacks a common language with which to describe, teach, and supervise integrative ideas—by contrast, the jargon of individual schools can be impressive. The use of such jargon can, of course, also serve competitive and narcissistic aims. Finally, there is the question of whether psychotherapies that are grounded in different theories of human nature may be ultimately philosophically incompatible.

Nonetheless, many clinicians have gone about integrating therapeutic techniques and ideas over the course of their careers, whether they choose to disclose this to their peers or not. Below we discuss the four major ideas regarding psychotherapy integration: the common factors approach, technical eclecticism, assimilative integration, and theoretical integration. Additionally, we will examine

Telegram: @medical_k

www.konkur.in

more recent proposals, including pluralism and differential psychotherapeutics. Each has a distinct way of viewing integration, all with the idea that flexibility and thought outside a monotheoretical view can lead to better patient outcomes.

Telegram: @medical_k

www.konkur.in

Mrs. E is a 47-year-old woman. She is coming to therapy because she has been feeling “overwhelmed” for the past few months. She works as an accountant in her own business from home. She is married, and her husband also works full-time as an EMT. They have 3 children, 2 boys, 16 and 11, and a 13-year-old daughter. The boys have chronic medical conditions that lead to significant expenses.

Mrs. E reports that she initially started having trouble sleeping, with early waking around 3 AM and trouble returning to sleep. She has been taking over-the-counter Benadryl, but this has only led to feeling groggy upon early waking, but not helping with prolonging sleep. She then feels “draggy” during the day, has bouts of rumination about her inability to get enough done, and has some anxiety around the chaos she feels her household is in and also regarding various accounts she is dealing with at work. She reports this negativity is making her cry almost every day and feel “less resilient” than she has felt in the past. She is alarmed that she can’t enjoy anything in her life and ashamed that she has had thoughts of wishing her life was over “so I can be at peace.” She has gotten some response to antidepressant medication, and her psychiatrist suggests the addition of psychotherapy as the next step.

Mrs. E’s business has taken off recently, which helps with the financial strain of healthcare expenses but causes a new set of problems. She was always able to be a very hands-on mother to her children but now has found she has less time available for all her tasks. She says, “I feel disgusted with my inefficiency and sloppiness. Taking care of the kids isn’t rocket science, but I have kept dropping the ball and letting things fall through the cracks.”

Childrearing has been very rewarding, and she has some sadness that as the children have aged, they have needed her less emotionally. She reports they are doing well and feels much of her concerns are her own feelings about the change in her role, less about any specific complaints from the children.

Telegram: @medical_k

www.konkur.in

Mrs. E reports no substance use other than an occasional glass of wine with meals when she and her husband go out to eat. She is neatly dressed, with a normal range of affect that is most often sad and anxious. She is well-spoken and has some insight into her ongoing issues.

Her husband works as an EMT and has rotational shifts throughout the week. So, though he is very helpful, this help is not regular or reliable. He is troubled by his work, with increased pressure and secondary trauma from the scenes he is called to. His shift changes make it difficult to be together, but they both work hard to make that happen. His work has provided financial stability for them as she has built her business, and he has been looking forward to cutting back. Mrs. E feels that their relationship has suffered as her work has become greater, and she has wanted more help at home. She feels he is disappointed in her, but she has avoided discussing this. She is angry that he seems more distant and withdrawn.

She reports being very religious and engaged in her church. She has been on a number of mission trips to Mexico and Central America over the years, and these have been rewarding. However, in the last few years, she has experienced a crisis in her faith and the teachings of her church, especially as her daughter has matured. The culture of the church and its teachings have not aligned with how she wants her daughter to perceive herself, and this has been difficult.

She was raised in a very religious household, the eldest of three sisters. Their father was very exacting, expecting “perfection,” as she reports. He was never satisfied with their best, always feeling more could be done to be better, and his tone was often angry, sarcastic, and demeaning. Mrs. E’s mother never chastised her particularly but never spoke up to the father either. She wonders if her mother was intimidated or depressed herself. One of her younger sisters is completely estranged from the family, and the other is living with the parents following years of ups and downs in relationships and an ongoing alcohol use problem. Mrs. E is “a dutiful daughter” but tries to keep her

Telegram: @medical_k

www.konkur.in

distance from her parents and limits interactions with them. She is especially careful to keep their influence on her children to a minimum.

She reports feeling similarly in college. She was overwhelmed with doing well and getting perfect grades. At times she found the work too much and would resort to “disordered eating” to make herself feel better. When asked about this, she reports that she would often forgo eating to “have some control” over her life–deciding when she had done enough work to be “rewarded” with food. One of her roommates reported this to a college resident assistant, and she was seen by the college counseling service for help with this. She reports that the counseling was helpful in some aspects but finds that this type of thinking and behavior about food has returned. One of the drivers for appearing in treatment is to minimize such behavior in the future.

COMMON FACTORS APPROACH TO INTEGRATION

One of the most well-established findings in psychotherapy research is the importance of the “common factors.” This refers to those elements which the whole variety of therapies share. Yet, we believe they are still underemphasized in the scholarly literature and in training programs.

Why this relative lack of enthusiasm? Perhaps the reason lies in the matter of prior investment on the part of the therapist. Learning the theory, formulations, and interventions of any specific therapy requires hundreds of hours of study, practice, and supervision. After all that work, therapists can be forgiven for wanting to believe that those specific techniques are at the center of the treatment’s benefit.

Brown et al. argue that therapists should pay much more attention to common factors and that this is an ethical requirement. They begin with the idea that ethics guidelines call for the use of evidence-based therapy, but if the evidence argues that it is common factors that are most important, perhaps we should be talking about

Telegram: @medical_k

www.konkur.in

evidence-supported therapies instead. Instead of assessing whether there is an evidence base for the specific therapy applied to the patient's specific problem, the ethical practitioner can fulfill their duty by practicing any reasonable approach with a strong emphasis on maximizing the common factors.

What exactly are the common factors? There is no universally accepted answer to this question. Different authors have proposed different lists, and no one can claim that theirs is definitive.

For example, Frank's "Persuasion and Healing" did much to draw the field's attention to common factors. Frank's list included: an emotionally charged confiding relationship; hope; placebo effects; healing setting; mutually accepted belief system; therapeutic ritual; warm and inspiring therapist; catharsis and practice of new behaviors; therapeutic suggestions; and interpersonal healing. More recently, Feinstein et al. argue for the following: (1) Patient characteristics; (2) Hawthorne effect; (3) Hope; (4) The therapeutic alliance; (5) Therapist characteristics and behaviors; (6) Impact of external life events.

However, rather than attempt to exhaustively review the many proposed collations, we will instead focus on those common factors which, in our reading, find the greatest consensus in the literature. These are (1) Empathy; (2) Expectations or hope; and (3) Alliance.

Empathy is a complex construct, and much happens when a patient experiences true empathy from the therapist. There are cognitive, affective, and interpersonal aspects. The therapist actively listens and imagines what the patient is feeling, based on all that the therapist has learned about the human experience from her own personal history, from psychological theory, from narrative art and entertainment, and from prior patients. Along with this cognitive work, the therapist allows herself to resonate affectively with the patient's feelings. She may be moved directly by the patient's expression of emotion or may have associated it with her own emotional experiences. She creates space within herself to feel with the patient. The final piece of the picture is the therapist's attitude of compassion and acceptance of the patient's feelings and the effort to communicate this to the patient with tact and kindness. As the reader

Telegram: @medical_k

www.konkur.in

can see, calling something a “common factor” does not imply that it is automatic or lacks effort and skill.

Empathy is so powerful because we are social animals with a powerful biologic system of pair-bond attachment. Human beings are not designed to be alone with their distress. A secure attachment is an absolutely crucial element in child development. And loneliness in adults is a toxic stress that contributes to much psychiatric morbidity.

Experiencing empathy creates at least two very powerful therapeutic effects. First, the patient feels that they matter. This is the root of the Hawthorne effect—the gift of sustained attention. Second, many patients come to therapy believing that their experience is unacceptable. They often feel shame in addition to whatever the primary problem is. Empathy is a powerful antidote to shame. Knowing that the listener understands my experience and doesn’t recoil from me is innately therapeutic. This is all-encompassed in what Wampold et al. refer to as the “real relationship.” Their review of the literature suggests a Cohen-d effect size of 0.63 for empathy, in the medium range.

Once an empathic connection has been made, therapists of all stripes convey to the patient that they have some manner of making sense of the problem and a treatment approach that they believe will help. The impact of this step is not limited to psychotherapeutic interventions, but extends across all of medicine. It is the root of the placebo effect and is both widespread and powerful. Having brought their distress to an expert, the expert’s expression of confidence can feel transformative. (Contemporary anthropologists argue that the development of a penchant for identifying and learning from experts was a pivotal step in the move from biologic to cultural evolution.) What had been a source of despair now pivots to an expectation of healing and a feeling of hope.

This leads us directly to the therapeutic alliance, perhaps the best studied of the common factors. The therapeutic alliance is the condition created by a patient and a therapist who agree on goals, pursue tasks together toward these ends, and work in the context of a warm interpersonal bond. The presence of a strong therapeutic alliance is one of the best predictors of success in therapy.

Telegram: @medical_k

www.konkur.in

From the perspective of any one psychotherapeutic approach, this seems obvious. To a psychoanalyst, of course, the therapy will depend on the patient and therapist pursuing the goals and tasks of an analytic therapy. Perhaps less intuitive is that it doesn't seem to matter what the specific goals and tasks are. It may be to explore the transference, practice mindfulness in the face of painful feeling, correct maladaptive cognitions, or any number of other possibilities. What matters is the experience of working together.

We have all become more aware of the problem of burnout in our helping professions. While the degree of stress is an important element, the literature also demonstrates the power of teamwork and alignment of the mission. A physician who feels they are part of a team rowing in tandem, aimed at a shared and worthy goal, is less likely to become burned out by stress. This is similar to the effect of the therapeutic alliance. Feeling that one is contributing to a joint project with members you trust is a powerful antidote to feelings of demoralization and worthlessness.

There is an irony in how the positive expectations and productive alliance rest on the pair's confidence in the specific therapy they are commencing together. We are unlikely to generate the full effect of the common factors if we were to meet with a patient without the scaffolding of a specific theory and its accompanying technical maneuvers.

What, then, does a common factors approach to integration look like when put into practice? Perhaps like supportive psychotherapy. We might suggest that much of what is called supportive therapy is actually psychotherapy integration with an emphasis on common factors. Welton and Crocker, in their recent overview of supportive therapy, note that the "common elements become the primary target of therapy" and that supportive therapy then overlaps and borrows specific techniques from other schools.

Feedback informed treatment is another approach that attempts to put an emphasis on common factors into concrete practice. Its advocates argue that regular formal measure and review of the therapeutic alliance should be built into the treatment. The aim is to create a "culture of feedback" with a particular emphasis on the

Telegram: @medical_k

www.konkur.in

patient's view of the alliance, which is generally a better predictor of success than the therapist's.

The therapist prioritizes making sure that Mrs. E feels empathically listened to. The therapist comments, "I can hear how overwhelmed you feel. You work so hard but you're still not sure you're doing enough or doing it well enough. And then you feel ashamed at how depressed you've become." As a result, Mrs. E feels understood, accepted, and no longer alone with her problem. The therapist says, "I believe therapy can help you," which is both an evidence-based prognosis and also meant to foster hope. The therapist then focuses on what Mrs. E's goals are and what to work on first. Together they decide to focus on maintaining healthy eating habits, identifying activities that relieve stress, and talking about what kinds of support she most needs. After just a month in therapy, Mrs. E reports improvement in all domains.

TECHNICAL ECLECTICISM

Technical eclecticism is the form of integration that is probably the most used, and least discussed. It flows from the techniques, not the theories. Technical eclecticism uses data, both from the literature and from clinical practice, to choose the best therapeutic options for a patient, options that have been shown to work in the past. Practitioners don't necessarily champion the particular theories behind each technique, but rather are able to see beyond the theory and value the particular techniques from various theoretical sources. Practitioners also tend to use techniques that already exist, as opposed to creating grand new theories and techniques. This practice is grounded in what has worked in the past and translating that into what hopefully will work now.

Wakefield points out that becoming well-versed in many theoretical frameworks is not realistic. The difficulty in cost and time of training

Telegram: @medical_k

www.konkur.in

argue against such a quest. Nor is referring a patient to multiple practitioners a realistic way of practice. Psychotherapies occur within the limitations of available providers who are affordable or covered by insurance, not to mention the difficulty in forming multiple new alliances for a patient-changing practitioners.

As a result, many practitioners have used some form of technical eclecticism in their practice. These are often clinicians who have run up against the limits of what a monotheoretical approach has to offer. Interestingly, they tend not to be found in academic settings, where there is often relatively little support for ideas regarding integration. Each eclectic clinician has found on his/her own that there are great commonalities in practice techniques across the different schools, and these interventions work the same, no matter what vocabulary one uses. Unfortunately, eclectic clinicians often move under the radar, lest they offend the assumptions of theoretical purity. One of the authors recalls being asked about her therapeutic orientation at a job interview. When she declared an eclectic mindset, she experienced a disdainful silence and awkward end to the meeting.

There have been several noteworthy attempts to systematize what eclectic therapists do spontaneously. The work of Lazarus et al. on multimodal therapy is a prominent example. They argue that using empirically supported techniques will be more useful in treating patients than trying to use theories of psychopathology to lead the treatment. Multimodal therapy begins with an assessment of patients on a wide spectrum of function—behavior, affect, sensory, imagery, cognition, interpersonal, and drug/biologic. This is called a modality profile and represented by the acronym BASIC ID. A clinician working in multimodal therapy appreciates the common factors, such as the therapy relationship, as a valuable driver of change. Consistent with the general flexibility of the approach, the therapist's way of relating to the patient should be based on what the patient responds best to—the therapist is "trying to be an authentic chameleon." Regarding therapeutic technique, the MMT clinician will be free to draw from any method that has demonstrated efficacy and is appropriate to the problem at hand. However, proponents of the approach do not generally include psychodynamic interventions

Telegram: @medical_k

www.konkur.in

related to transference within their scope. While multimodal therapy draws on techniques that have demonstrated efficacy independently, there is little rigorous controlled research to support the overall approach.

Systematic treatment selection (STS) also de-emphasizes theories of etiology and tries to provide an alternative approach to structuring eclectic intervention. STS is built around a set of principles to help guide the choice of technique. For example, careful attention should be paid to the alliance, and the need to repair ruptures with empathy and flexibility. Additionally, the characteristics of the patient should guide technique. They reasonably suggest that greater impairment of the patient should be met with greater intensity of treatment. Patients who are highly resistant to therapy should be met with less directive approaches, while those who are less resistant may find comfort in being directed. Similarly, focusing on behavioral change and symptom reduction is recommended for patients who externalize, while insight and relational learning may be preferred for those who internalize. A small but intriguing research base suggests that matching characteristics of the patient to the technique may enhance outcomes.

Telegram: @medical_k

www.konkur.in

Mrs. E's therapist prioritizes forming an alliance that engages the patient in shared work. The therapist observes that Mrs. E tends to internalize her difficulties and is very open to exploring new ways to think about her experience and relationships. This exploration makes clear that Mrs. E is grieving several losses. She conveys her sadness about her withdrawal from the church that she was raised in. She expresses her bitterness about the need to keep her children from their grandparents, lest her father's toxicity harms them as well. Her therapist moves from an exploratory to a more problem-solving stance. They discuss how to set effective limits with her father when the family is together, and practice this in role play. Appreciating Mrs. E's longing for spiritual support, her therapist helped her examine the anxieties that prevented her from trying different churches and denominations. As these were connected to a fear that she would be rejected by the pastor and congregation, Mrs. E and her therapist began to use an approach of gradual exposure and guided relaxation to overcome these inhibitions. Mrs. E was appreciative that her therapist was willing to try different approaches to her different problems, and this deepening trust allowed them to return to an exploratory approach to the long-standing issues around food and body image.

ASSIMILATIVE APPROACH TO INTEGRATION

In this mode, the clinician works from a theoretical and technical foundation of one distinct and established school of therapy and adds elements from other therapies onto that framework. It should not be surprising that this would be a common mode of integration. Generally, clinicians are trained in programs that teach distinct schools of therapy. The practice of integration does not usually begin with a therapist who is an empty receptacle acquiring a variety of eclectic techniques. Nor is it likely that most practicing integrationist therapists begin with construction of an integrated theoretical model.

Telegram: @medical_k

www.konkur.in

In a study of experts in psychotherapy integration, three-quarters reported that though they drew on multiple orientations or schools of therapy, they considered one to be primary. As Wachtel points out, “All proponents of integration start from somewhere, and how they look at the end is in good part shaped by where they started.” This is consistent with an assimilative approach.

Therapists often become open to integration when they find themselves up against the limits of their chosen therapeutic style. That experience of “limits” can take a number of different forms.

First, there are those times when a new problem surfaces that the current form of therapy is not as well suited for. For example, a patient may be deep in a psychodynamic therapy to explore difficulties with intimate relationships when they reveal that they are also suffering from an obsessive-compulsive disorder. The therapist feels the dynamic therapy has been valuable but believes that CBT is a better, more evidence-based approach to severe OCD symptoms. Similarly, the therapist may learn of a substance use disorder that might be best managed with motivational interviewing. Rather than refer the patient to another therapist, an assimilative approach would be to add some CBT-based management of compulsions or motivational interviewing for addiction into the current treatment.

Another kind of limit, however, is the experience of simply being stuck. Consider again a clinician working from a psychodynamic foundation. The patient and the therapist understand their shared work to be an exploration of the patient’s mind and an exploration of the therapist–patient relationship, in the service of developing insight into unconscious conflicts, and implicit relational patterns. There are several ways that exploratory work that seemed to be progressing can become stuck. One way is when the exploratory process seems to still be moving along well, but deepening insight is not leading to symptomatic or behavioral change in the patient’s life. Another way is when the exploration itself has become stalled. Perhaps the transference is too volatile to productively discuss, or perhaps the patient’s symptoms (such as anxiety) become too painful to tolerate. The assimilative therapist may decide that these are times when a

Telegram: @medical_k

www.konkur.in

more directive or symptom-focused approach is necessary to break the impasse.

On the flip side, let's imagine a CBT therapist who finds that the patient is unable to adhere to the planned homework because any such expectation from the therapist evokes intense feelings of resentment and defiance. The therapist may suggest a brief exploration of the relational origin of this paralyzing reaction as a means to clear the space for a return to a working alliance focused on exposure-based tasks.

This kind of work is clearly not easy to do—it requires all the usual skills of the dynamic or CBT therapist and also the judgment of when to switch tracks. This is the critical issue. For example, our psychodynamic clinician could err in either direction. They might incorporate a more directive technique unnecessarily and enable the patient's avoidance of a crucial, but painful, emotional experience. Or they might continue to explore the symptom's meaning while the patient requests a more direct approach and simply repeat and reinforce an experience of a rigid authority more interested in "following the rules" than being of actual help. A psychodynamic purist may suggest that in the latter case, the solution is more exploration of this experience, but when the patient drops out of treatment in frustration, exploration generally diminishes markedly.

In their writing, Stricker and Gold have attempted to define an assimilative psychodynamic psychotherapy (APP) and ground it in a three-tiered model of mental function ([1] Behaviors/relationships; [2] Conscious cognitions and emotions; [3] Unconscious conflicts and self/object representations). They retain the core dynamic emphasis on exploration and insight but incorporate techniques of exposure and cognitive learning as indicated. The therapy may begin with either exploratory or more directive methods, depending on what the patient prefers, which "tier" is most prominent in the presentation, and what kind of interventions the patient can tolerate. Their default mode will remain exploratory but they note that sometimes people "need to learn new skills and to unlearn maladaptive skills in order to change." They argue that more active work on symptoms can be

Telegram: @medical_k

www.konkur.in

synergistic with exploration; by providing relief from acute distress new areas of potential exploration become accessible.

Castonguay and colleagues have described an approach that uses CBT as its foundation but acknowledges its limitations. In their view, CBT remains too focused on the individual's cognition, and doesn't sufficiently emphasize interpersonal factors and the value of deepening emotional experience (contrasted with controlling it). As a result, they created a program where therapists did an hour of CBT followed by an hour of interpersonal emotional processing (IEP) therapy. It is worth noting that the IEP hour is a fairly rigid and directive version of dynamic work. The authors report preliminary data that didn't show particular gains compared with CBT alone except in secondary analysis for patients with dismissive attachment style. It is hard to draw much inference from this work to a more organically integrated approach where the clinician utilizes the interpersonal/emotional focus within the framework of a CBT hour.

Proponents of assimilation can argue that they are providing patients with the "best of both worlds" the benefits of the core mode of therapy while addressing the gaps in its utility or the limits of its reach. Critics might suggest that the result will actually be a watered-down version of the foundational theory and that switching approaches when faced with an impasse prevents the clinician from learning how to deepen their work and turn such challenging periods into opportunities for therapeutic growth.

Telegram: @medical_k

www.konkur.in

Mrs. E begins treatment with a psychodynamic psychotherapist. The focus is on the roots of her perfectionism and self-criticism about her role as a mother. They make connections to her father's harsh standards and also to her own sadness that her children are growing more emotionally independent. Together they wonder if this sadness is related to her determination to never have her children experience her as she did her own mother—distant and emotionally removed. Some of these themes of judgment and closeness come up in the therapeutic relationship and are used to deepen their understanding. After several months, Mrs. E feels much less depressed and overall is functioning very well.

However, her eating symptoms have not gotten any better. Insight into their meaning is not leading to change. Mrs. E's therapist suggests that they continue dynamic therapy, which has proven so productive, but that they devote some time each session to using a CBT approach to her eating. They map out how thoughts of inadequacy trigger ruminations about her weight. Mrs. E begins recording all her food-related thoughts, emotions, and behaviors. Overevaluation of appearance and weight is identified as a core problem and strategies for minimizing her dysfunctional eating behaviors are developed.

Mrs. E's eating symptoms improve, but she and her therapist find that directly addressing these issues also opens up new areas of exploration in her therapy. She begins to report a recurring dream about her body and her associations lead to anxieties about physical intimacy that have never surfaced before. The psychodynamic work deepens.

THEORETICAL INTEGRATION

Instead of focusing on what therapies have in common, or how to modify existing therapeutic techniques toward integration, some authors have proposed that we begin our efforts at integration with

Telegram: @medical_k

www.konkur.in

an underlying theory of psychotherapy. They have asked, can we construct a theoretical model that embraces the entire range of psychotherapy strategies? There is an obvious appeal to this approach that makes it something of a “holy grail” of therapy integration.

Integration that begins at the theoretical underpinnings—what is our theory of psychopathology and of healing/change—would have the potential to streamline education and training, focus research efforts, and provide consistent standards of practice. In this section, we will review some of the more prominent efforts.

Wachtel’s “Integrative Relational Therapy” in some ways straddles the categories of assimilative and theoretical integration. It is assimilative in that Wachtel was trained in psychoanalytic psychotherapy and builds upon the long traditions of psychodynamic formulation and technique—ego psychology, self-psychology, and relational psychoanalysis. Yet it is also a theoretical integration, because there is not just addition of techniques from outside the dynamic tradition, but also a reworking of the dynamic model termed “cyclical psychodynamics.”

As in traditional psychodynamics, the patient is seen as having internal conflict—wishes/longings that pull in opposing directions or provoke the internal experience of threat and anxiety. However, Wachtel’s emphasis is equally on behavior—how does the patient act in the world, or fail to act, that provokes responses from others that actually confirm the anxiety? Insight into internal conflict is not enough to undo these “vicious circles.” The therapist and patient must focus on learning new behaviors that carry significant anxiety. This means working with the patient on a process of gradual exposure and desensitization.

One of Wachtel’s most important contributions is the idea that “exposure” is not a technique limited to behavior and that it is equally applicable to disturbing thoughts. He argues that it is a core concept that helps unify behavioral and psychoanalytic approaches. The psychodynamic technique of clarification and interpretation also results in the patient learning that something feared will not be catastrophic. “Exposure” to disturbing ideas about the self and

Telegram: @medical_k

www.konkur.in

important relationships is uncomfortable, but if done gradually and with tact, not intolerable.

Eubanks and Goldfried similarly argue that there are principles of change that cut across different therapies. These extend beyond what are generally studied as “common factors,” as they begin with fostering hope and strengthening the alliance, but also include increasing insight, corrective emotional experience, and improvements in reality testing. As Wachtel reframes exposure for internal experience, the authors reframe insight to encompass action, arguing that patients are often unconscious of what is incompetent about their behavior and must move to “conscious incompetence” in order to change. The principle of corrective emotional experience is intriguing. It is the place where learning theory and relational psychodynamics can come together. It is also problematic, as the question of whether the therapist allows corrective emotional experience to occur spontaneously versus intentionally providing a prescribed experience is one that depends on the theory.

Prochaska and DiClemente’s Transtheoretical Model (TTM) is an attempt to create a comprehensive structure that could contain all therapy approaches. They propose to describe the processes of psychotherapy using four dimensions: processes of change, stages of change, pros and cons of change, and levels of change. Levels of change attempt to locate and define the problem by specifying whether the target is a symptom, a cognition, an intrapersonal conflict, an interpersonal conflict, or a family/systems conflict. Next, we can assess the readiness to change. The TTM outlines a continuum that progresses through precontemplation, contemplation, preparation, action, and maintenance. Describing the pros and cons of change captures the decision from the patient’s unique individual perspective. Finally, the processes of change define the range of techniques and interventions and intend to pair these to specific levels of readiness. These include consciousness raising, self-liberation, social liberation, counterconditioning, stimulus control, self-reevaluation, environmental reevaluation, contingency

Telegram: @medical_k

www.konkur.in

management, helping relationships, and dramatic relief/emotional arousal.

The model's creators have attempted to define where specific psychotherapies are most relevant and useful given the intersections of levels and stages of readiness, but this is not a strength of their work. The model's strength lies in its tested efficacy for specific maladaptive behaviors—most commonly involving substance use disorders and general health promotion (e.g., smoking cessation). In these circumstances, there is substantial evidence that matching change processes (interventions) to the stages of change (readiness) increases the effectiveness of the therapy.

Unfortunately, the paradigm was designed for the kinds of difficulties that are binary in nature—either the patient will quit smoking or they will not. It is much harder to apply the model to the typical complexity of mental health disorders, and not surprisingly, there is only very preliminary evidence of value.

Prochaska and DiClemente's levels of change are echoed in the "levels of meaning" that Wakefield and colleagues propose. They argue that psychotherapy integration is crucial not only because every therapy doesn't work for every individual but because different treatments target very different levels of meaning. The levels of meaning they propose are biology, neuroscience, behaviorism, cognitive, psychodynamic, family systems, and culture.

The first two levels are largely targeted by pharmacologic and neurostimulation interventions. Behaviorism focuses on difficulties in learning and reinforcement. Cognitive therapy aims at conscious beliefs that motivate action, while psychodynamics addresses meanings outside of consciousness that can only be activated associatively. Family systems therapies focus on the implicit rules and roles in our intimate relationships, and culture brings into focus the ways that social context shape identity and the presentation of symptoms. Embracing the idea that there are different levels of meaning seems to be an essential first step in creating a theory that can encompass all therapies. The authors, unfortunately, but understandably, are not able to provide similar clarity regarding the implications for technique—should we continue the pursuit of

Telegram: @medical_k

www.konkur.in

integrated technique or use different therapies in a “stepped care” model?

We do not think that any of these authors have fully succeeded in their quest for theoretical integration—the “grail” is not yet in our grasp. This does not mean that it is impossible, nor does it mean that the efforts have not been valuable. The journey of a quest can be transformative regardless of whether the final object is yet attained.

During their initial consultation, Mrs. E’s therapist notes that she is very motivated to address her depression. They decide to begin by understanding the ways that Mrs. E’s depression is currently being sustained and focus on her marital relationship. She describes that she has not directly discussed her need for more help at home because she is afraid of how her husband will react. Unfortunately, in the absence of communication, Mrs. E has nonetheless experienced her husband as disappointed. She wonders if her hurt and anger in response have contributed to the growing distance between them. Her therapist calls this a “vicious circle,” which Mrs. E finds very helpful. Together they decide to continue to explore Mrs. E’s feelings and their origins in her family while also taking small steps in tolerating the anxiety of talking directly with her husband about her own needs and disappointments. She notes that it would be nice if he felt the same responsibility for the household that she did, for example. Mrs. E and her therapist find that behavioral steps work synergistically with allowing herself more “exposure” to her own mixed feelings in her marriage.

OTHER RECENT APPROACHES TO INTEGRATION: PLURALISM, STEPPED CARE, AND DIFFERENTIAL PSYCHOTHERAPEUTICS

Cooper and McLeod have proposed an approach they call “pluralism,” grounded in the observation that many very different

Telegram: @medical_k

www.konkur.in

kinds of therapy have proven helpful to different patients or the same patient at different times. They note that these different therapies can consist of very different models to explain the cause of psychological distress and the mechanisms of change.

Pluralism means accepting that these different models may all hold some truth, some piece of the complexity of human life, but that attempts to resolve them into one comprehensive theoretical model of pathology/cure have been unsuccessful. But further, Cooper and McLeod believe such a resolution is unnecessary. Instead, they advise us to move away from theory and into three “domains” that are more pragmatic: goals, tasks, and methods.

“Goals” refers to the big picture of what the patient and therapist are trying to accomplish through therapy. Goals can include “to gain more insight into myself ” or “to cope more successfully with stress at work.” Tasks are more discrete and focused. They are specific action items in the larger project of therapy, in the same way, that “sorting through the closets” and “taking out the trash” are steps toward the larger goal of making one’s home feel livable. A partial list of therapy tasks would include: talking openly; expressing/letting go of emotion; finding and analyzing information; exploring meaning; problem-solving; changing behavior; enhancing self-care.

Cooper and McLeod do note that these are conjectural, and there is a need to develop an empirically grounded “taxonomy of therapeutic tasks” through qualitative research.

Once the task is defined, an appropriate method is applied. The available methods are all the techniques of the various schools of therapy that the therapist is able to offer. Pluralism pragmatically accepts that no therapist can be expected to offer every possible method to pursue each task. Thus far, it may be very hard to distinguish pluralism from technical eclecticism. One especially strong emphasis of pluralism is that respect for the patient’s agenda and preferences are prioritized. As a result, the choice of each of the three domains is negotiated in collaboration with the patient. (This is called “metatherapeutic dialogue.”) This should occur at the beginning of therapy and again as tasks are completed, new ones are decided on, and methods are chosen.

Telegram: @medical_k

www.konkur.in

We should note here that the term “pluralism” means something quite different in contemporary psychoanalytic thinking. While some essentials of psychoanalytic technique have been preserved—free association, interpretation of the unconscious, working within the transference—there are great differences among the proliferating psychoanalytic schools in their theories of psychopathology and cure. Theoretical models include foci on drives, defenses, internalized relationships (object relations), formation of the self, or intersubjective relationships. Instead of the atheoretical emphasis on tasks and methods of Cooper and McLeod, psychoanalytic pluralists tend to focus on which theoretical frame of reference to apply to best explain the clinical moment.

A very different approach to the different needs of patients at different clinical moments is taken by the advocates of “stepped care.” Markowitz and Milrod, for example, argue against eclectic treatment. They suggest it is confusing to patients and that therapist adherence to specific therapies has been shown to be useful. Instead, they would have us develop an evidence base for conducting sequential algorithms for psychotherapies, similar to those we have for psychopharmacology. They suspect that changes in psychotherapy type should occur more often and be driven by having time-limited treatments with outcome measures/monitoring.

Cabaniss and Holoshitz propose a process called Differential Psychotherapeutics to guide changes in therapy type. They begin from the perspective that no one kind of therapy fits all patients and that the strongest evidence available is for discrete, not integrated, therapies. The challenge is then to have a systematic approach to “prescribing” when and what to change. There are four steps to the Differential Psychotherapeutics cycle: learning, thinking, matching, and discussing. “Learning” covers all the usual components of an initial psychotherapy assessment—establishing the current problem, obtaining the patient’s life story, and identifying internal and external resources. “Thinking” means a preliminary jargon-free formulation—what is wrong, why is it happening, and what needs to change. Cabaniss and Holoshitz acknowledge that we cannot think about “why” without some theoretical framework, but no one theory can

Telegram: @medical_k

www.konkur.in

explain everything. “Matching” means generating the possible fits between the formulation and the potential therapies. Although no therapist will be able to offer all treatments, we are expected to become knowledgeable about the frameworks so we can think with patients about the options.

The choice of “match” focuses on using the evidence base when possible and always keeping the patient’s safety and preferences as central concerns. The final step is the discussion of one’s thinking and recommendations with the patient. The differential psychotherapeutics cycle is to be used at the beginning of the treatment but at other key points as well—if there is an impasse, the patient’s goals change, or the patient’s circumstances, symptoms, level of function, etc., change.

Telegram: @medical_k

www.konkur.in

Mrs. E presents initially to a therapist who believes that patients often need more than one kind of therapy and that the choice of modalities should be openly discussed and decided on with the patient. The therapist suggests that both the depressive and eating symptoms are rooted in distorted cognitions—some about self-worth and perfection, others about food and body image. She suggests beginning with a trial of CBT, and the patient enthusiastically agrees. Mrs. E's eating symptoms respond very well and are soon in remission, but her depressive thinking proves more complicated. Her harsh self-criticism proves resistant to improvement. In fact, Mrs. E often hears the therapist's encouragement to work on symptoms as actually a veiled and sarcastic criticism of her lack of progress. Whenever the therapist notices this, Mrs. E is reminded of some painful childhood experiences of her father. More and more of their time is spent on this kind of exchange. The therapist tells Mrs. E that psychodynamic therapy would be indicated for this kind of problem and notes that the patient seems spontaneously drawn to this approach. The therapist primarily does CBT and has much less experience in a psychodynamic approach. She explains this to the patient and offers to do this work with her or to refer her to a colleague who specializes in this approach. Mrs. E decides that her growing trust and connection with her current therapist outweigh any disadvantage in relative expertise in the modality. They begin a new course of dynamic therapy together.

FUTURE DIRECTIONS

Even today, very few training programs teach an "integrated" approach to psychotherapy—one might be lucky to be exposed to multiple approaches as monotheories. The Accreditation Council of Graduate Medical Education (ACGME) only requires psychiatry residents to become "competent" in supportive, psychodynamic, and cognitive-behavioral psychotherapies. Each of these components

Telegram: @medical_k

www.konkur.in

tends to be taught by practitioners of that school and often remains siloed clinically and educationally. One of the reasons for this is the relative lack of academics who focus on integration. More integrationists tend to be found in clinical practice, where clinicians often see a wide range of patients and feel the need to expand the range of their techniques to assist them.

For integration to grow further, training programs need to be more proactive in including the topic in their curricula. While it is, of course, important to learn the basics first, being exposed to ideas from other schools of thought, as well as opportunities to observe the fluidity of integrationist thinking and practice, would go a long way toward normalizing the practice.

Having supervisors who can discuss a more integrated approach for specific patients would also be of great benefit.

Graduating psychiatrists who are interested in, or at least curious about, the integration will also lead to an increase in practitioners who identify as integrationists. The ability to be fully oneself with one's practice will boost not only individual identity but also the identity of the integration practice ideas as a whole.

The more accepted the practice is, the more funding will become available for research of techniques and the creation of a more robust evidence base. Most research in psychotherapy, in general, is still woefully underfunded and confounding, as distinct approaches are pitted against each other in trials that rarely demonstrate a significant difference in efficacy. Research in integration instead offers the opportunity to focus on interventions and change processes that cut across schools of therapy.

The fluidity of thinking in integration may foster a more patient-centered way of thinking about care, as opposed to a theory-oriented focus. The focus can be less reliant on rigid DSM-V diagnoses and focus more on the various concerns, goals, and needs of a patient. Indeed, many of the most challenging patients we see, termed treatment-resistant, do not present with only one DSM-V diagnosis—they arrive at treatment with distress that represents the "integration" of many strains of psychopathology. The complexity of each person—when viewed through the various lenses of

Telegram: @medical_k

www.konkur.in

personality/temperament, child development, and the social determinants of mental health—is very difficult to capture within any one theory of psychotherapy.

This patient-centered focus may allow for more multicultural sensitivity. In viewing a patient's cultural context, race, sexuality, biology, beliefs, biases, and abilities as part of the whole, various techniques drawn from different schools of therapy may be valuable in order to reach each facet of a patient's needs and their interaction within society. Wakefield argues that the "moral imperative" we as practitioners have in helping the most patients possible is only possible with an integrated, multitheoretical approach. This makes for a more complete recovery and a more resilient sense of healing.

At the core of all treatments is the therapist's desire to help. The ability to offer aid to the diverse problems a patient brings to treatment can have a positive effect on the challenge of retaining our mental health workforce. The more help one can be, the more rewarding the work is, and the greater the desire and capacity to remain in the profession. Though burnout is a complex issue, the ability to create a robust and flexible clinical identity can go a long way toward retention and career satisfaction in the mental health field.

The flexibility of integrative treatment, which evolves as the patient's illness and recovery evolves, not only encourages us to remain hopeful about the most difficult mental health issues. Integrative approaches also provide a path toward rethinking the partisanship that has limited the help each clinician can offer their patient.

32.2 Supportive Psychotherapy

JOHN BATTAGLIA, M.D.

The science of psychotherapy, the “talking cure,” was developed by Freud based on his topographical and structural theories of the mind in the early 1900s. Freudian psychoanalysis became the *sine qua non* for treating neuroses and spread rapidly throughout the industrialized world. Fidelity to the psychoanalytic technique was seen as essential for treatment success, and therapy practice that strayed from classical psychoanalysis was disavowed. Despite this worldwide popularity, practicing therapists began to realize that many neuroses, as well as more serious mental illnesses, were not helped by psychoanalysis. Also, therapists noticed some patients improved even when psychoanalytic practice guidelines were not strictly followed. In one of the earliest papers to address improvement in psychoanalysis from something other than insight, Edward Glover proposed that inexact interpretations sometimes led to symptom improvement by repression and displacement, thereby reducing anxiety.

Franz Alexander was trained in the classical Freudian technique. However, he recognized that many patients were unable to tolerate

Telegram: @medical_k

www.konkur.in

the stress of relatively unstructured therapy sessions and needed more guidance from the therapist. He outlined the need for the therapist to be flexible and use shifting tactics to accommodate the patient. He advised modifications from the standard psychoanalytic technique, including changing the frequency of sessions, using directives in the interview, helping the patient address real-life problems, and modulating the transference to make the sessions more tolerable for the patient. These modifications of the psychoanalytic technique comprise the fundamentals for what we now define as supportive psychotherapy. The therapeutic modulation of the transference, specifically maintaining a positive transference, is now considered the cornerstone of supportive psychotherapy. These supportive techniques were not developed from a theoretical perspective. Rather, they sprung from the keen observations of Alexander in response to what patients needed from the therapist in order for healing to occur.

Alexander realized that people had transformative, life-changing experiences from relationships outside of therapy and questioned the degree to which insight was necessary for change. While classical psychoanalysis emphasized insight as the curative force in therapy, he realized that the process of obtaining comfort from the therapist also provided a curative effect. This process–that of the patient overcoming painful experience in therapy (either from addressing their difficult emotions or experiencing turbulence in the transference) in the context of an accepting, nurturant therapist–was labeled the corrective emotional experience by Alexander. The concept of the correctional emotional experience as a fundamental healing component in supportive psychotherapy remains cogent today.

Over the next several decades, a number of therapists began recognizing that supportive elements in psychotherapy were not only acceptable but necessary in many cases, especially with more seriously ill patients. Also, therapists were naturally “drifting” into using supportive techniques even with traditional psychoanalysis. These changes did not occur without controversy, and there was a considerable professional argument that supportive techniques were

Telegram: @medical_k

www.konkur.in

causing the infidelity of psychoanalytic therapy in a damaging way. In fact, many psychoanalysts did not consider supportive types of therapy as valid psychotherapy, epitomized by this quip from Crown, “if it is supportive, it cannot be psychotherapy; if it is psychotherapy, it cannot be supportive.”

At the heart of the controversy with supportive psychotherapy was the notion that patients might improve and display symptom improvement. However, had they really “changed”? Many psychoanalysts argued that supportive psychotherapy helped relieve symptoms but did not change the person in any fundamental way. The concept of *structural* change, that is, change of personality in a permanent way versus *behavioral* change (symptom resolution), was put to the test in perhaps what was the most ambitious psychotherapy study ever conducted. An extensive longitudinal study that spanned 23 years was developed by the Menninger Institute Psychotherapy Project in the 1950s to compare classical psychoanalysis (several days a week on the couch) to psychoanalytic psychotherapy (weekly “upright” psychoanalytic sessions face to face). A supportive psychotherapy arm was added as a control condition. The results were quite unexpected in that there were no significant differences among the three types of psychotherapy. The researchers noted that supportive elements were found in both psychoanalysis and psychoanalytic psychotherapy and that these elements accounted for many of the observed changes. Also, they concluded that change did not occur in proportion to insight, and thinking of change as “structural” as opposed to “behavioral” was not a useful concept.

Although supportive psychotherapy lacked an underlying theoretical model, the practice techniques and strategies became standard among therapists of many different persuasions. The widespread effectiveness of supportive techniques in therapy could not be denied, and eventually, the term “supportive psychotherapy” became accepted as a separate, bona fide therapy. The first textbook on supportive psychotherapy was published by Werman in 1984, and at least a dozen others have followed since. Supportive

Telegram: @medical_k

www.konkur.in

psychotherapy skills are now listed as core requirements for psychiatry residency training in the United States.

RESEARCH

The Menninger Psychotherapy Research Project epitomized what would become a default standard practice for research on supportive psychotherapy, and that is, supportive psychotherapy has often been studied as a “treatment as usual” or “comparison” condition when other types of therapy were being examined. Despite this lack of concerted investigational focus on supportive psychotherapy, it often performs well in psychotherapy research even when compared to treatments that are the areas of interest for the academic institutions studying them. For example, Klein and associates investigated behavior therapy versus imipramine treatment for specific phobias and added supportive psychotherapy as a control arm of the study. Therapists trained in the behavior therapy techniques followed a highly structured, manualized protocol that included relaxation training, systemic desensitization in imagination, in vivo desensitization homework assignments, and assertiveness training (including modeling, role-playing, behavioral rehearsal, and in vivo homework). The supportive therapists were instructed to be empathic, nondirective, and nonjudgmental, encourage the ventilation of feelings, and allow discussion of life problems. The results were surprising and showed that both behavior therapy and supportive psychotherapy were highly effective, with no significant differences between them. The authors pointed out that supportive psychotherapy performed beyond their expectations.

McIntosh and associates conducted a randomized, controlled study looking at cognitive behavioral therapy versus interpersonal therapy for anorexia nervosa, and nonspecific supportive clinical management was added as a third arm to mimic treatment as usual in the community. The cognitive-behavioral and interpersonal therapy arms of the study included highly structured treatment manuals, which were followed by therapists trained in the techniques. The cognitive behavioral protocol included

Telegram: @medical_k

www.konkur.in

psychoeducation, motivational assessment, cognitive behavioral skills training (including thought restructuring and homework), relapse prevention, and recovery strategies. In the interpersonal therapy arm, the patient's life events, interpersonal relationships, and eating problems were assessed, and links between them were examined. Problem areas in domains of grief, role transitions, interpersonal disputes, and deficits were identified, and their links with depressive symptoms were examined. In the nonspecific supportive clinical practice, patients were provided education and support about their eating disorder, and therapists provided praise, reassurance, and advice. The researchers fully expected the two specialized psychotherapies would be superior. However, the patients who received the nonspecific supportive clinical management had outcomes as good or better on most measures. The authors of the study were surprised by these results and noted that supportive management techniques likely best provided the important nonspecific factors of psychotherapy, such as the therapeutic alliance, empathy, and positive regard.

Rutledge and associates looked at cognitive behavioral versus supportive psychotherapy in nurse-delivered telemedicine treatment for chronic back pain. The cognitive behavioral arm was highly structured and followed a manualized protocol that included the treatment rationale, pain education, patient activity log monitoring, relaxation training, monitoring of sleep hygiene, sexual activity and exercise, homework assignments, and examination of pain cognitions, cognitive distortions, and pain behaviors. In the supportive psychotherapy condition, the patients were provided a self-help book on back pain, and the nurses were instructed to employ active listening techniques following Rogerian principles. Both cognitive behavioral and supportive psychotherapy was moderately effective in reducing pain, with no significant differences between them.

These three studies spanning nearly four decades, epitomize the research frequently conducted on supportive psychotherapy. It is often used as a control/comparison condition for more rigorous and specialized treatments under study. It is usually equally efficacious to

Telegram: @medical_k

www.konkur.in

other psychotherapies. Finally, it requires little training or expertise. Supportive psychotherapy techniques are easily adaptable for practitioners outside of psychiatry, including nurses and family practitioners. Supportive psychotherapy research has shown effectiveness for a variety of psychiatric and medical conditions, including schizophrenia, bipolar disorder, depression, anxiety disorders, personality disorders, substance use disorders, eating disorders, perinatal stress, breast cancer, ovarian cancer, diabetes, leukemia, heart disease, chronic bronchitis, emphysema, inflammatory bowel disease, back pain, and for hemodialysis patients.

CLINICAL ISSUES, STRATEGIES, AND TECHNIQUES

A key component for successful, supportive psychotherapy is to maintain a positive therapeutic alliance. Negative transference is handled by the therapist actively providing comfort, reassurance, and "repairing" the disruption in the therapeutic alliance as opposed to interpretation. A number of studies have supported the view that a positive therapeutic alliance is most strongly correlated with therapy treatment success, regardless of the type of therapy utilized (cognitive behavioral, interpersonal, psychodynamic, other), patient characteristics, or country. A recent study by Leibovich and associates showed that supportive techniques acted as mediating factors for therapy success in the treatment of depression by strengthening the therapeutic alliance and subsequently decreasing symptoms.

In supportive psychotherapy, the therapist not only engages in maintaining a positive therapeutic alliance, but also in modulating the pacing of the sessions, the anxiety of the patient, and the degree to which the patient should "open up" versus "cover-up." Contrary to more exploratory or provocative therapies, it is the job of the supportive therapist to proactively guide the patient throughout the session so they can adequately cope with their psychic pain. First

Telegram: @medical_k

www.konkur.in

and foremost, the supportive therapist helps the patient develop coping skills and methods for soothing themselves when feeling bad. This will lay the groundwork for calming in later sessions when the patient addresses difficult feelings and lower the degree to which the patient may “act out” as a result of a painful therapy session (“acting out” is unconsciously acting on the painful emotion outside the psychotherapeutic session, often in a physical way, and often with adverse consequences). Time management of the sessions is also an important ingredient for the therapist to actively monitor. Enough time must be conserved at the end of each session in order to help the patient cope with the material that was worked on, as well as to prepare for possible ripple effects of emotions that might arise later after the session has ended.

The style of the supportive psychotherapist can be described as conversational. That is, the therapist is able to use emotion in their voice much the same as when talking with friends. They do not mimic a “blank slate,” stare, or subject the patient to long, anxiety-provoking silences. This conversational style, when used in a comforting manner, helps the patient feel more at ease with the therapist, less like an alienated “subject,” and helps form a positive therapeutic alliance. Many, if not most, supportive therapy strategies are aimed at helping the patient feel less anxiety and safe in the therapeutic environment.

There are many supportive psychotherapy techniques, limited only by the creativity of the therapist. Providing *encouragement, hope, reassurance*, and *praise* are common supportive techniques that help the patient’s self-esteem. Over time the patient is sometimes able to incorporate some of the comfort and understanding of the therapist into their own self-acceptance. In psychoanalytic terms, the therapist is “lending ego,” and the patient develops a more positive self-image by introjection of the therapist. This process falls within the theoretical perspective of the correctional emotional experience as described by Franz Alexander so many years ago.

Psychoeducation (teaching the patient about their symptoms), *coping skills training,* and helping the patient find ways to soothe themselves are also mainstays of supportive therapy. When teaching

Telegram: @medical_k

www.konkur.in

self-soothing techniques, it is useful for the therapist to overtly label the process "self-soothing," as this concept is foreign to many patients and increases their awareness that they can be a curative force for their own suffering rather than rely on external supports. This also reduces their tendency to act out when experiencing difficult emotions. These techniques are all most effective when practiced while maintaining a positive therapeutic alliance.

Explaining behavior can greatly benefit the patient to feel less alienated and also contribute to a positive therapeutic alliance. By explaining behavior, the therapist helps the patient understand that they are acting in ways that make sense to their particular situation, even if seemingly "crazy" or unhealthy. This *normalizes* their behavior, thereby reducing stigma and helping improve self-esteem.

The use of *storytelling* and *metaphor* are powerful techniques that often can have a lasting impact when used in ways most cogent to the patient's situation. Storytelling and metaphor are sometimes more palatable for the patient because these techniques seem less directed toward them and, therefore, less confrontative. This allows the patient to listen less defensively, and the images from the story or metaphor then have more enduring effects. For example, a patient might become anxious or defensively reactive if directly told they were self-sabotaging. However, they would hear it more easily if told a story about a person who would "shoot themselves in the foot" with their behavior.

The technique of *confrontation* is therapeutically holding a mirror to the patient's behavior, so they may see how their own patterns contribute to their suffering. Contrary to lay usage, confrontation by the therapist does not involve any kind of anger or stern demeanor and is most effective with employed in a nurturant, accepting manner of the therapist. Confrontation is a powerful and useful supportive therapy technique and can only be used with a strong therapeutic alliance. The stronger the therapeutic alliance, the better the patient is able to tolerate confrontation.

There is a wide range for the number of sessions needed to perform supportive psychotherapy, dependent upon both the nature of the stressors present and the degree of psychopathology in the

Telegram: @medical_k

www.konkur.in

patient. Supportive psychotherapy is sometimes conducted over just a few sessions to help patients with adjustment disorders, while at other times can be utilized over the lifetime of the patient. Patients with primitive personality disorders or major mental illnesses are seen as having significant mental “defects” causing chronic symptoms as opposed to having neurotic “defenses.” With this perspective, some patients will require ongoing supportive psychotherapy on a chronic basis, much as patients with brittle diabetes will need continual, ongoing endocrinologist care to maintain their medical health. Thus, a specific process of termination in supportive psychotherapy is sometimes not necessary. When the termination process is indicated, the therapist provides the patient ample opportunity to express their feelings about it as well as review what insights or learning from the therapy may be taken forward with them.

Supportive psychotherapy can be an intense, intimate process, and some patients will internalize their positive experience with the therapist and utilize the interpersonal gains well beyond termination. For patients with significant losses in their lives, successful termination with a nurturant, supportive psychotherapist can be a corrective emotional experience.

We live in an era in which psychoanalysis is no longer the dominant paradigm of psychiatric treatment. Analytic training institutes are not the prevailing institution that they were before the revolution of psychopharmacology beginning in the 1960s. There has been a differentiation and proliferation of various short-term symptom-targeted treatments, many of which are derivatives of psychoanalytic theories, ideas, processes, and practices. Nevertheless, psychoanalysis continues to evolve and thrive as a robust contemporary discipline. It is an effective treatment for many of the psychic ills that bring patients into consulting rooms, clinics, and hospitals.

Unfortunately, because of past problems, including the rigidity with which it was once practiced, there continues to be an erroneous idea that psychoanalysis still represents a “one size fits all” treatment. This is a misconception as psychoanalytic treatment is deeply individualized to the patient, to the person’s specific life history and circumstances, and to their unique subjectivity, modes of thinking, fantasies, affects, and actions. Despite differences among analysts, there are core values to which most would subscribe and that this chapter will describe.

This chapter will detail what constitutes psychoanalysis as a treatment and explore its derivative psychotherapies, including various forms of psychodynamic or psychoanalytic psychotherapy. Our goal is to convey something about the psychoanalytic sensibility and the attention to interpersonal and psychological processes that are applicable not just to these individual outpatient treatments but also can be applied to many domains of the psychiatrist’s work across diverse patient populations and treatment settings. As Nancy McWilliams writes, “Most fundamentally, psychoanalytic practitioners take seriously the evidence that the sources of much of our behavior, feelings, and thoughts are not conscious. There is a dynamic organization to how we unconsciously register experience, an organization that prompts analysts to refer to *the unconscious.”*

What in nonconscious sources of thought, feeling, and behavior might lead someone to seek psychoanalytic treatment? Consider these three cases:

Telegram: @medical_k

www.konkur.in

A 30-year-old man who gets engaged, appearing enthusiastic as he tells family and friends. Almost immediately, he begins to have panic attacks and nightmares about death. Seeking treatment for the panic attacks, he gives a history that his father died soon after he was born. In his early childhood, his mother endlessly repeated stories of their lives as newlyweds before his unexpected and untimely death. It becomes clear that there is a set of *affects* that the patient is not immediately aware of, involving an emotional recollection and re-experiencing of fears in his early childhood mind that linked the marriage of his parents with his father's sudden unexpected demise. The man makes no conscious connection between his current symptoms and his childhood experience.

A woman in her mid-20s who repeatedly goes to various physicians is convinced that she has an undiagnosed illness that would explain her chronic pain. Following a comprehensive evaluation and physical exam, she is told, "there is nothing wrong with you." The woman feels angry and dismissed, believing herself to be rejected by yet another purported caretaker. This replicates the neglect she experienced from her alcoholic mother as a child during her mother's binges. There is a particular *object relationship* that is not yet conscious. This is how she experiences herself in relation to the internal representation of an important other that profoundly shapes how she views these emotionally charged encounters with physicians.

Telegram: @medical_k

www.konkur.in

A financially successful screenwriter who has worked mostly by himself accepts a leadership position for a theatre organization, only to become angry and depressed at his inability to feel appreciated at work. He goes to great lengths to avoid chance encounters with the very people who selected him, afraid that if an interaction does not go well, he will feel ignored and disrespected, leading to an angry outburst that might ruin his increasingly public reputation. This man is not consciously aware of the impact of his unmet childhood need for mirroring and validation that plays out over and over again in his adult life.

All of these examples reflect unconscious aspects of an individual's psychological functioning that can lead to suffering, inhibitions, and restrictions in personal growth. This chapter will explain how it is that psychoanalysis and psychodynamic psychotherapy affect change, in part, by identifying such unconscious processes. In contemporary psychoanalytic thinking, there has been a shift away from the noun of Freud's early writing: "*the* unconscious" as if it is a concrete place in the mind or a "second mind." There is now an emphasis on the unconscious as an adjective, describing an important aspect of various mental processes that can render them problematic.

We acknowledge that this is an enormous subject. It includes the rich history and the extensive set of practices that constitute a treatment for psychopathology, a set of theories and working models of the mind, and the various derivative psychotherapies based on those theories and practices.

The field has come a long way since Freud. Multiple schools now exist that focus on different models of the mind and different lenses through which to examine particular problems in living as well as types of psychopathology. Some of these models overlap. There are also points of tension that are constantly being renegotiated in an effort to clarify, reconsider, or integrate contested viewpoints. This has led to a modern psychoanalytic landscape known for ambiguity

Telegram: @medical_k

www.konkur.in

and plurality of views that can be deeply enriching as well as confusing, disorienting, and frustrating for the beginner and even seasoned practitioners.

Psychoanalytic training takes years, following an already lengthy postgraduate education, which can limit its appeal to practitioners and availability to patients. Psychoanalytic treatments are focused on individual *meaning* and facilitate in the patient a gradual elaboration and expansion of their inner worlds. This fosters a greater capacity of awareness and ability to observe, reflect on, and understand the multidetermined associations and sources of thoughts, feelings, and behaviors. The enormous richness and complexity of the field cannot be conveyed in one chapter; however, we hope to provide a solid foothold for the reader to venture a climb through the fundamental concepts of the psychoanalytic models of mind as well as the clinical process.

Telegram: @medical_k

www.konkur.in

The emergence of psychoanalysis, as created by Freud in the late 1800s, was a direct outgrowth of the treatment of neurotic patients at that time by physicians in general practice—the use of hypnosis for hysteria. Freud's friend and older colleague, the Viennese internist Josef Breuer, set the stage in 1881 with his serendipitous discovery that a patient's symptoms disappeared as a consequence of their verbal expression under a hypnotic trance. This was the famous case of Fraulein Anna O., who resides in the annals of psychoanalysis for having given it its impetus as well as its lasting name, the "talking cure" or, as she jokingly referred to it, "chimney sweeping." When Freud heard of the success of the technique in 1882, he was just completing his medical training with an assignment at Vienna's Allgemeine Krankenhaus, under the direction of Theodor Meynert. Struck by Breuer's compelling account, he spent the year from 1885 to 1886 studying hypnosis at the Salpêtrière in Paris with the French neurologist Jean-Martin Charcot. The latter's direct demonstration that with hypnosis, he could both elicit and abolish hysterical symptoms so captured Freud's imagination that it became a major turning point in his thinking. In his practice in the late 1880s, Freud used hypnosis to enable patients to suppress or deny their symptoms while under its influence. More important to Freud's subsequent thinking, however, was the use of hypnosis in retracing the history of symptoms.

When Freud returned to Vienna and subsequently established his medical practice, he had no success in treating hysterical patients with the more typical methods of the day, such as hydrotherapy, electrotherapy, and rest cures. He then decided to draw on the profound influences of Breuer and Charcot. The hypnotic method at that time was used strictly for psychic catharsis, attempting to gain access to patients' reminiscences that they could not remember under any other conditions. The particular method was a form of cathartic therapy borrowed from Breuer.

Telegram: @medical_k

www.konkur.in

In their collaborative work on hysteria in the mid-1890s (Studies in Hysteria), Breuer and Freud discussed their theory that the symptoms represented repressed ideas that had not reached consciousness and were a transformation or "conversion." They suggested that hypnotic treatment was effective because of the discharge of affect previously attached to the repressed mental acts, called "abreaction." A major requisite for the cathartic method, which was contingent on that theoretical position, was that the patient could be hypnotized and thus be enabled to revert to the psychological state in which their morbid symptoms had appeared for the first time. Their clinical experience and observations suggested to them that the patient's memories, thoughts, and impulses that were no longer conscious could enter the mind under hypnosis and that when recounted to the physician, especially under circumstances of intense emotion, the symptoms would disappear automatically. It was consistent with the theory that hysteria was the result of traumatic experiences, usually sexual in nature, whereby large quantities of affect that had been barred from consciousness appeared in disguised form as symptoms. Freud poignantly noted that "hysterics suffer from reminiscences."

Following Breuer's precedent with Anna O., Freud used the cathartic method (in conjunction with hypnosis) in 1889 to locate the traumatic origin of the hysterical symptomatology of Frau Emmy von N. In describing the case, Freud anticipated his later thesis, which speculated that inhibited sexuality played a role in the etiology of her illness. Freud grew dissatisfied with hypnosis because he was not able to hypnotize all his patients who suffered from hysteria. He was also frustrated by the transitory effects of hypnosis that seemed to last only as long as the patient's contact with the physician. He began to suspect that the therapeutic effects depended more on the relationship between patient and doctor than on the technique per se. His suspicions were prompted by a striking incident in which one of his female patients threw her arms around him on waking from a hypnotic trance. (Breuer had earlier reported a similar incident.) As a

Telegram: @medical_k

www.konkur.in

result, Freud turned his thinking in the direction of the physician–patient relationship itself and, with that, the origins of his eventual discovery of transference. It was not until his use of hypnosis failed in the case of Fräulein von R. in 1892 that Freud felt obliged to experiment with modifications of the original hypnotic–cathartic method. The physician, Hippolyte Bernheim of the Nancy School, an adversary of Charcot, influenced the technical direction that Freud took. Freud's decision to give up the hypnotic–cathartic method was largely based on Bernheim's observation that the events recalled during hypnosis (in a hypnoid state) could be re-evoked by patients in states of consciousness when prompted by leading questions and urgings of the physician. Basing his concentration method on that premise, Freud developed a strategy in which he requested the patient to lie on a couch with eyes closed, then concentrate on a particular symptom and attempt to recall past memories; Freud would place his hands on the patient's forehead as a physical way of facilitating the memory process.

Through his work with the same recalcitrant patient Fräulein von R., Freud discovered the method that is identified with the true creation of psychoanalysis—free association. Freud soon realized that his interruptions of the patient and his constant prodding for additional details hindered the spontaneous flow of the patient's thoughts. A simple remark by Fräulein von R., namely that she did not know what to say because she was not sure what Freud wanted to hear, sparked his realization of the undesirable effects of censorship and direction by the analyst. He began to instruct his patients to express even the most irrelevant, unpleasant, or trivial material. The method of free association is thus the gradual consequence of experimentation with technique—from hypnosis and the cathartic method to a concentration method, to an approach almost antithetical to the original suggestive methods. As a new technique, free association was (1) unlike hypnosis, which required patient suggestibility; (2) unlike catharsis, which focused on the release of affects only;

Telegram: @medical_k

www.konkur.in

and (3) unlike the concentration method, which prodded, directed, and interrupted the patient.

In altering his therapeutic technique, Freud realized that a "different though not contradictory conception of the therapeutic process" was warranted. With the new emphasis on the removal of amnesia and the recovery of repressed memories, he observed that the same instinctive forces that brought about repression to obliterate pathogenic material from consciousness continued to exert force—resistance—against full disclosure through free association. Moreover, unexpected feelings toward the analyst—transference—provided additional resistance to treatment. The persistence of repression with free association brought to the fore those two concepts, the unconscious and transference, which remain the critical constructs of modern psychoanalysis.

The first section of this chapter will describe core concepts of psychoanalytic models of the mind, including unconscious process, motivation, conflict, defense, transference, countertransference, and fantasy. The second section will focus on core concepts of clinical process, including the psychoanalytic frame of treatment, mechanisms of therapeutic action, and resistance. Through the description of these core concepts of mind and treatment process, the various "major tradition" or psychoanalytic schools will be reflected in the evolution of these bedrock concepts.

For example, our discussion of unconscious process and motivation will reflect Freud's initial discoveries and formulations of the topographical model of the mind as well as his emphasis on the way that the mind grapples with physiologic needs. The concepts of defense and internal conflict reflect developments in ego psychology which became paradigmatic of psychoanalysis during its heyday in American psychiatry from the 1940s to 1960s. We will discuss what continues to be useful as well as what is potentially problematic about these early models. We will consider findings from modern

Telegram: @medical_k

www.konkur.in

neuroscience that may shed light on their scientific validity as well as the limits of such an enterprise.

Transference and unconscious fantasy, while Freud's discoveries, were greatly elaborated and developed by object relations theorists, including Melanie Klein, Wilfred Bion, Ronald Fairbairn, and D.W. Winnicott. Countertransference became a focus of contemporary relational psychoanalysts and intersubjectivists. This chapter will then explore various derivatives of psychoanalysis, including psychodynamic psychotherapy and several evidence-based, manualized treatments that have emerged under the umbrella of psychodynamic psychotherapy. Some of these manualized treatments were developed by psychoanalysts looking to integrate aspects of the aforementioned schools. For example, transference-focused psychotherapy for personality disorders features a useful integration of object relations theory and ego psychology as developed by Otto Kernberg and others. Lastly, we will look at how specific psychodynamic therapies and psychoanalytic concepts can be variously applied to major DSM-5-TR syndromes.

CORE CONCEPTS OF PSYCHOANALYTIC MODELS OF MIND

Motivation and Unconscious Process

Why do human beings do the things that they do? When a person does something that causes them to suffer, it may or may not be pathologic. The behavior may lead them into treatment with the hope of understanding how it is that they do something repeatedly that causes pain to them or to people with whom they are in relationships. As noted by George Vaillant, "Over the short haul, neurotic defenses make the user suffer; immature defenses make the observer suffer." Part of the clinician's work is to understand the "why" or what is *motivating* the behavior or set of choices that the individual makes. We can take this deeper and ask such questions about not just behavior but the feelings themselves. That is, we can

Telegram: @medical_k

www.konkur.in

question the motivation(s) underlying a particular experience of an affect, or even an experience of the self.

Freud started theorizing a metapsychology of motivation using the concept of drive. Contemporary psychoanalysis uses this theoretical concept less, but it is worthwhile to consider why this was a starting point for Freud and for psychoanalytic psychology. For Freud, the drive is “the psychical representative of the stimuli originating from within the organism and reaching the mind, as a measure of the demand made upon the mind for work in consequence of its connection with the body.” A drive is a *frontier concept* between body and mind, an unconscious representative of physiologic needs in the mind, and therefore a way of thinking about the pressure that the body places on the mind for the mind to “do work.”

We can distinguish the concept from instinct, an unconditioned behavior pattern prompting reproductive success, in its emphasis on psychological representation. People can feel driven toward certain feelings and behaviors on the basis of biologic imperatives. This was an idea that, while it seems obvious to us now, was threatening to the culturally sanctioned ways of viewing human thought and behavior in Freud’s time. Humans are motivated to satiate biologic needs like hunger, thirst, and sexual expression. We now understand this is also true for attachment needs.

At times those needs come into conflict with what is allowable or available in the external or cultural environment. In circumstances when the expression of a physiologic need is restricted, the mind must negotiate with the mental representation of the need to find the maximum allowable expression of the need in order to obtain gratification. This “drive satisfaction” is the maximum possible reduction in physiologic tension and all within the limits of what is acceptable to the person’s (more or less conscious) sense of self and the internalized limits imposed on the self from parents or wider society.

Freud also thought that this was a key function of dreams, allowing “wishful hallucination” to keep the dreamer asleep; take a common example of dreaming, one is drinking water only to wake up parched with thirst. The role of dreams in analytic therapy is now known to be

Telegram: @medical_k

www.konkur.in

more complex and nuanced than simple wish-fulfillment, as will be explored later in this chapter, but we can see how Freud was grappling with ways that the mind is forced to reckon with the desire-filled demands of the body. It was in that grappling that the original theoretical ideas, as well as the nature of the clinical practice of psychoanalysis, was born.

Dreams reflect both the inner struggles of the mind and the world at large.

> A patient described the change from a typical “anxiety dream,” that is, being back in college and discovering he had not attended a class all semester and it was the day of the final. During the height of the COVID pandemic, he noted the dream had changed to being on campus with no one wearing a mask, crowds of people walking towards him, and him not having a mask. “Did COVID change how we dream” (NYT Brooke Jarvis, 11/3/2021).

A person’s motive for their behavior may not be immediately apparent, observable, or understood. Much of the clinical work in psychotherapy, irrespective of the specific psychopathologic syndrome, is to identify and elaborate causal links between thoughts, affects, and behavior, as well as their situational contexts and historical antecedents. It is when motivation is not conscious to the patient that achieving change is most difficult. They may feel at a loss for how to modify their behavior or feel that a behavior is purely “automatic” that they “can’t help it,” or have no motivation to modify that behavior. A person can feel “lived by” one’s impulses and desires rather than feel themselves to be the experiencing agent who desires the object of the impulse. This can obscure the person’s awareness of the reasons for such impulses.

When a person comes to see the function that a particular choice serves in the maintenance of their psychological equilibrium or identifies the “hidden gratification,” the behavior becomes mutable as the true cost/benefit analysis of the action becomes clearer. As

Telegram: @medical_k

www.konkur.in

explored in the following section on mechanisms of therapeutic change, making such “hidden gratifications” or motives conscious is one of the ways that analysis may lead to change over time. This is rarely an immediate change.

A patient with dependent personality traits has somatization, which worsens in the setting of relationship conflict. Over the course of analytic treatment, this patient becomes aware of the physical symptom as a “safe” expression of aggression towards, and control of, their partner, upon whom they are dependent. The dependency is unconsciously anxiety-producing with fears of abandonment. The physical symptoms keep the partner involved but at the cost of suffering to both individuals. The awareness of this mental mechanism allows the person to reflect on the physical symptoms rather than succumb to them.

The evolution of the history of psychoanalytic thought involves the tendency of different psychoanalytic theories or schools to posit one or two supposedly supraordinate motivational systems to which other motivations are considered subordinate or derivative expressions. Freud initially posited a dual instinct of sexuality (libido) and a “self-preservative” instinct. He would ultimately revise his thinking, and in his second dual-instinct model, he assumed a primary sexual and a primary aggressive drive. The various psychoanalytic schools would, in turn, shift the emphasis, partially due to reactions against and desires to correct earlier models when it was felt certain core motivations had been de-emphasized.

For example, contemporary psychoanalysts, informed by infant observational research, consider attachment needs to be a primary motivational system. This is reflected in the perspective of object relations theorists and relational psychoanalysts. This perspective emphasizes *relational needs* (such as the need for a sense of self-coherence found in an understanding other) as a primary motivation as opposed to drive discharge or expression.

Telegram: @medical_k

www.konkur.in

One of the strengths of the psychoanalytic approach is that it explores and includes, but is not limited by, the conscious subjectivity of the patient. The analytic therapist listens intently on multiple levels, not just to the conscious verbal output of the patient but also to what may lie behind that content. This has also been called listening *from surface to depth*. Psychoanalysts contend not just with the words the patient is saying but what is latent in the manner in which a narrative is communicated, as well as what may be left out. Analysts listen for the "affective music."

Defense and Conflict

The motivation for using a defense is the avoidance of unpleasant affect. Different psychological defenses may be adaptive or maladaptive at this task in the short term (Table 32.3–1). Defenses, which may have conscious elements but are largely unconscious, may exact a long-term price for that short-term gain of comfort. A person's typical relied-upon defenses become part of their character, or what Wilhelm Reich first described as "character armor." One person may be very adept at dealing with painful situations by finding the humor in them without disregarding the difficulty. This helps the person stay engaged with the unfolding events and those who are involved along with them in a shared experience. We would describe this as a "mature" defense since it improves the ability to cope or adapt to difficulty without avoiding or distorting reality. This is in contrast to the less mature defense of denial.

A middle-aged patient diagnosed with severe coronary artery disease reacts with, "This can't be right. I'm as healthy as a horse." Instead of pursuing the recommended evaluation and treatment recommendation, the person does nothing, leading to a bad outcome.

The immature defenses are more reality-distorting, meaning they get rid of a negative affect at the cost of the person's ability to

Telegram: @medical_k

www.konkur.in

adequately negotiate with reality. Thus, immature defenses are usually, therefore, more costly over the long term. The kinds of negative feelings that are defended against include negative feelings about the self, loss of love or approval from significant others, or painful realities like mortality or loss of a loved one, as well as the inability to achieve desired goals.

Psychoanalytic theory about defense was heavily elaborated by the ego psychologists who made particular use of Freud's *structural model of the mind* with its emphasis on wish, defense, and internal compromise. In the original metapsychology, the defenses were initiated "against the threat of the drives." Defense analysis became the predominant focus of ego psychology that dominated American psychiatry from the 1940s to 1970s.

www.konkur.in

Table 32.3–1.
Defense Mechanisms

Telegram: @medical_k

www.konkur.in

Mature Defenses

- Suppression: consciously putting a disturbing experience out of mind
- Altruism: vicarious but instinctively gratifying service to others
- Humor: overt expression of normally unacceptable feelings without unpleasant effect
- Sublimation: attenuated expression of drives in alternative fields without adverse consequences
- Anticipation: realistic planning for inevitable discomfort

Neurotic Defenses

- Repression: involuntary forgetting of a painful feeling or experience
- Controlling: manipulation of external events to avoid unconscious anxiety
- Displacement: transferring an experienced feeling from one person to another or something else
- Reaction formation: expression of unacceptable impulses as directly opposite attitudes and behaviors
- Intellectualization: replacing of feelings with facts and details
- Rationalization: inventing a convincing, but usually false, reason why one is *not* bothered
- Isolation of affect: separating a painful idea or event from feelings associated with it
- Undoing: ritualistically “removing” an offensive act, sometimes by atoning for it, or in thought by immediately “taking back” an assertion

Immature Defenses

- Splitting: experiencing oneself and others as all good or all bad
- Idealization: seeing oneself or others as all-powerful, ideal, or God-like
- Devaluation: depreciating others
- Projection: attributing unacceptable impulses or ideas to others
- Projective identification: causing others to experience one’s unacceptable feelings. One then fears or tries to control the unacceptable behavior in the other person

Telegram: @medical_k

www.konkur.in

- Acting out: direct expression of an unconscious wish or impulse in order to avoid being conscious of the affect and thoughts that accompany it
- Omnipotent control: a fantasy of total control of another perceived to be hostile, usually as a result of projective identification
- Passive aggression: expressing anger indirectly and passively
- Intermediate denial: refusal to acknowledge painful realities

Psychotic Defenses

- Psychotic denial: the obliteration of external reality
- Delusional projection: inner conflicts are externalized and given tangible reality—minimal reality testing
- Schizoid fantasy: withdrawal from conflict into social isolation and fantasizing

Adapted from Muskin PR, Haase EK. Personality disorders. In: Noble J, Greene HL. *Textbook of Primary Care Medicine*. 3rd ed. Mosby, Inc.; 2001:458–464.

A useful aphorism of Freud is that the "child is the father of the man." Conceptually this is how the developmentally young mind of the child copes with intense bodily wishes and feelings of frustration when its wishes are denied. Eventually, a child learns to delay gratification. This occurs as the child internalizes parental prohibitions and expectations as well as positive early feelings of mastery, accomplishment, and the synergy of good feelings about oneself alongside parental pride. The intensity of the internal "No!" that the child takes on can have a harsh, punitive quality. This impacts how the child's mind will treat itself even years later as it comes to measure itself against that internal standard. That standard exists in a psychological structure that Freud, in his structural model, called the *superego*.

This was differentiated from the *ego* and the *id*. It is worth noting that these terms entered popular culture long ago. The concepts are nearly universally well-known and equated with the Freudian model of the mind; however, these labels were not quite the actual terms used by Freud. This results somewhat from the translation by James

Telegram: @medical_k

www.konkur.in

Strachey from the original German in an effort to give these ideas the scientific sheen of latinate terms. The words Freud used were the “Ich,” the “Es,” and the “Uber-Es,” which can more directly be translated to the “I” (or *ego*), the “It” (the *id*), and the “Over-I” (*superego*). The plain language that he used is evocative and inclusive of ordinary meanings and invites one to see these different “agencies” of the mind from the subjective conscious perspective of the “I.”

From this perspective, it is one’s “I” that feels itself to be looking out at the world (through sense perception) and goes about mediating the interactions between the first-person, agentic self, and external reality. The structure that would come to be called *the ego* in ego psychology, and is said to be the mediator between wishes and desires (often unconscious, sometimes repressed, and therefore said to be located in the “it” or *the id*) and external reality. With the term “Over-I,” one can imagine the perspective of the small child’s self looking up at the towering authority that sets the rules and metes out punishment, but that also represents the wished-for ideal standard of a person that one hopes to grow into.

These three entities are not locations in the brain nor are they expected to correspond to any one neuroanatomical structure. Instead, they describe aspects of developmentally achieved psychological structures that are reflected in clinical phenomena, especially when it comes to internal conflict.

What does this look like in practice?

Telegram: @medical_k

www.konkur.in

A premedical student is eager to please and help others. He holds to rigid standards that are also projected in the form of judgment upon others for not being adequately selfless. The student feels guilt for this judgment upon others as well as guilt for not living up to an idealized standard of morality informed by a religious upbringing that provided a sense of belonging and early models of moral authority. Seeking treatment for anxiety, the student is aware of feeling overly deferent and uncomfortable around authority figures. Aware that he feels compelled to be deferent, he has an inkling of an “irrational” motivation. He explores his feelings in relationships through an analytic treatment. This allows him to reflect on a growing awareness that, while his family instilled a sense of hope for him to achieve, they also found many opportunities to communicate an imperative not to achieve too much, lest he surpass them and no longer be someone to whom they could relate. These mixed messages around the dangers of achievement were a constant during his adolescence. Eventually, this patient takes on the role of monitoring himself lest he goes too far, restricting his interests and doubting his capacities. He develops a chronic sense of dysphoria and frustration, accompanied by guilt whenever he spends his time exploring personal interests.

We can say that this patient is experiencing a conflict between his nascent adult sense of self (separate from his family with his own interests and capacities) and harsh superego restrictions upon his achievement. This can lead to less-than-fulfilling life choices. He chooses not to be a doctor, despite having outstanding grades and accomplishments, and instead chooses to work in an ancillary capacity supporting other healthcare workers. He avoids situations that might lead him to feel angry at authority figures. His choice of a career that is more supportive and from the sidelines is an example of a *compromise formation* that partially, but only incompletely, satisfies both sides of an inner conflict. Through treatment, he

Telegram: @medical_k

www.konkur.in

develops a growing awareness of what each side of his conflict feels like and what are their historical determinants. Ultimately, he develops a greater sense of agency in making choices that are informed by a growing awareness of what he wants for himself, as an autonomous adult. This may include making new and different, but hopefully more satisfying, compromises.

Transference and Fantasy

Transference is one of the concepts most associated with psychoanalysis, which is logical as it is an important and ubiquitous psychological phenomenon. “Transference is of central importance in psychoanalysis because it demonstrates vividly that the past lives within the present and exerts a powerful force upon it. While transference is a universal feature of mental life, its role within the analytic situation provides a unique experience for the patient, one that provides the greatest leverage for therapeutic gain.” Alessandra Lemma defines transference as reflective of “the human predisposition to see current interpersonal experience through the largely unconscious lens of selected forms of past experience” but importantly adds, “it is not a photocopy of the patient’s childhood.”

When the psychoanalytic patient develops an attachment relationship to their analyst, the quality and nature of that attachment will contain elements of past relationships. These elements are then revealed and explored in the treatment. This process occurs through feelings, thoughts, and fantasies about the analyst, or what is known as *the transference*.

Telegram: @medical_k

www.konkur.in

A patient arrives late for a session and talks about the fear they have disappointed their analyst with their lateness and “wasted your time.” Associating to the concern, they remember the manner in which their depressive mother never seemed to care when they were around as a child. This patient arrives at an understanding that the worry conceals the wish to be important enough that the analyst would be disappointed when they didn’t show up to a session on time.

It can be useful to understand transference through the lens of object relations theory. Freud coined the term transference, recognizing the impact of past relationships on the lived experience with the analyst. He focused on the idea of transference being a misreading or a distortion of current experience because of expectations formed in past relationships. Transference has come to be a more capacious concept and is seen as a working ground for interpersonal growth, not merely a distortion. The classical analytic literature indicates that an analysis is used to promote a “transference regression” or to establish a “transference neurosis” that is based on infantile wishes and conflicts that can then be worked through.

More modern psychoanalytic theories such as object relations, self-psychology, and intersubjectivity offer broader approaches to understanding the nature of transference in a psychoanalytic treatment. The elaboration of the transference in treatment allows a patient to understand the meanings inherent in their expectations of others’ minds, including expectations about how another person will respond to the wishes and feelings of the patient. When responses from the analyst do not correspond exactly to what the individual expected in their early relationships, the potential for new forms of relationships begins.

Inasmuch as transference relates to early childhood relationships, common types of transferences may be characterized as a *paternal* or *maternal*, or even *sibling transference*. A series of transferences

Telegram: @medical_k

www.konkur.in

develop according to the stage of treatment. The transferences reflect particular relationship conflicts occurring in the person's outside life and/or situations arising with the analyst that recall dynamics from the person's early family life.

We can say that relationship schemas, or expectations, about the other's mind and their responses are represented in *fantasies*. The fantasies may be initially unconscious and come to consciousness via the treatment. In a fantasy, we are relating in our mind to another person or feel that we are being treated by another person in a highly specific way. Fantasies are *affective narratives* and usually take the form of *who is doing what to whom and why?* This contributes to the affective intensity of the transference experience, that is, in a *positive transference*, the individual generally feels cared for, attended to, loved, and helped. They feel that the analyst is interested and curious and is doing something for their benefit. This experience contains derivates (fantasies laden with specific memory traces, feelings, and imaginings) related to earlier helpful, caring figures in the person's life.

If the person experienced deprivation in their nuclear family but was aided and taken care of by trusted others (teachers, guidance counselors, or other relatives), this would play out in a variety of transferences. The analyst might expect the patient to alternately experience a *positive transference* associated with a precarious longing as well as a *negative transference* as if confirming the feared reality of neglect from parents. The greater the overall impairment in ego function and personality organization, which is usually a result of serious deprivation and outright trauma in childhood, the more prone a person is to predominantly negative transferences, which may be experienced as concrete reality. That is to say, they lose the "as-if" quality most advantageous to an ability to reflect on transference and to integrate insights about it into the personality over time. Such negative transferences are often hostile and paranoid in nature, accompanying a sense of being exploited or harmed. For more examples of such negative transferences as seen in borderline personality organization (BPO), refer to the transference-focused psychotherapy section of this chapter.

www.konkur.in

Countertransference and Intersubjectivity

Countertransference is one of the core concepts that has been most fruitfully elaborated after Freud's lifetime and has benefited particularly from theoretical developments in self-psychology and intersubjectivity. As psychoanalysis has developed over time, the analyst's participation in, and contribution to, analytic process and outcome has also evolved. The earlier view of them as being an objective, outside observer and interpreter of the patient's mind has evolved to greater recognition and inclusion of the analyst's own emotional life and responses as fundamental aspects of psychoanalytic understanding. The so-called *relational turn in psychoanalysis* is also regarded as a shift from the predominantly "one-person psychology" of the classical ego psychological model to the "two-person psychology" of intersubjectivity.

The original understanding of countertransference was that of the analyst's potentially idiosyncratic or personal response to a patient's transference. This was generally seen as a possible obstacle to treatment and something for the analyst to be aware of and work through in their own analysis. When Freud recognized that patients developed loving feelings towards their analysts as attachment figures that recapitulated feelings towards parents or other love objects, he saw the potential vulnerabilities this could lead to in the analyst. The analyst might feel gratified by these expressions of strong feelings in patients that appear to be directed toward the person of the analyst rather than the transference figure. This experience could set the stage for boundary crossings, as happened with early analysts in Freud's inner circle. For example, Carl Jung began an intimate, boundary-violating relationship with patient Sabina Spielrein. One of Josef Breuer's patients developed a delusional pregnancy in conjunction with an erotic transference prompting Breuer, frightened by this, to immediately terminate the treatment. This might be understood as Breuer's *acting out of the countertransference*. While those are dramatic examples, we now understand how these and the more subtle and productive

Telegram: @medical_k

www.konkur.in

manifestations of countertransference are a critical part of psychoanalytic work.

As a result of the frequency and concomitant affective intensity of analytic treatment, analysts come to be immersed in their patients' minds in a way that no other treatment can replicate. As analysts become attuned to their own reveries with patients, they hone an ability to use their associations, pattern-recognitions, and feelings to better understand patient material and behavior. The felt resonances of bodily affect and thought content often tell an analyst a great deal about the inner workings of their patients' minds. The epistemic status of countertransference data as "knowledge" about the patient is a complex issue. Rich theorizing about countertransference comes together in several strands under the header of relational psychoanalysis or intersubjectivity.

This includes the theory of self-psychology of Heinz Kohut and his understanding of narcissism. The works of Bion and Ogden are often cited in understanding how an analyst's own reverie in sessions allows for a more nuanced understanding of the unique analyst–analysand dyad. Robert Stolorow and Steven Mitchell each, in their own ways, integrate the infant observational research of Daniel Stern. Stern described "interaffectivity," or the mutual sharing of affect states as seen in the mother–infant pair, as an important potential forerunner of the analytic intersubjective process. It is the mother's responsiveness to the infant's recurrent affect states and internalization of those patterns that play a major role in the infant's developing affect- and self-regulatory capacities. Stolorow explains, "the child becomes vulnerable to self-fragmentation because his affect states have not been met with the requisite responsiveness from the caregiving surround and cannot become integrated into the organization of his self-experience." Defenses against affect become necessary to preserve a brittle self-structure from the experience of *fragmentation* that lies at the root of narcissistic problems, including narcissistic rage. As Stolorow describes, Kohut's "discovery of the developmental importance of phase-appropriate mirroring of grandiose-exhibitionistic experiences points to the critical role of

Telegram: @medical_k

www.konkur.in

attuned responsiveness in the integration of affect states involving pride, expansiveness, efficacy, and pleasurable excitement."

Intersubjectivists tend to see transference not as distortion, projection, or displacement but rather as an organizing activity of the self. In turn, this has implications for countertransference to be understood not as a pathologic response to an individual's "distorted" experience of the analyst but as a necessary part of being involved, responsive, and engaging with a patient's subjectivity.

Stephen Mitchell outlines a useful framework for describing and situating the intersubjective process in clinical work in a way that both incorporates other aspects of psychoanalytic theory and helps us see what is uniquely intersubjective about this way of working. He describes an "interactional hierarchy" of four modes of interaction between the analyst and the patient that are of increasing organizational sophistication. These modes are (1) nonreflective behavior; (2) affective permeability; (3) self-other configurations; and (4) intersubjectivity. These are different "levels" of relationality as well as different lenses that organize a clinical moment. In any given interaction, one may be in the foreground while others operate in the background.

Nonreflective Behavior. This refers to the level of action involving two people or *what* is being done to *whom*. This behavioral dimension was seen as central to John Bowlby's attachment theory and later infant observation that examined the behavioral microinteractions between child and mother, activities such as smiling, clinging, crying, and turning to or turning away from the other. This kind of careful tracking of mutual but "presymbolic" or prereflective behavior is a surface-level "way in" to an understanding of complex processes of mutual regulation.

Affective Permeability. This refers to the properties of affect that enable it to resonate from person to person, particularly with regard to intense affects like anxiety, euphoria, or rage. Humans are built for sharing affect, and Mitchell notes that at this level of affective permeability, questions like "who started it and who did what to

Telegram: @medical_k

www.konkur.in

whom? tend to be meaningless when intense affective connections are involved, as in strong sexual attraction, terror, rage, or joyous exhilaration." This level of analysis is often helpful in understanding the interpenetrability of transference–countertransference experiences and how the analyst's own feelings can be used as a window into the patient's affects, even dissociated ones.

Self-Other Configurations. This describes the level of object relations, where the complexities of *symbolic representations* of self and other can be understood. These are the internal object relations or object dyads of W.R.D. Fairbairn and Otto Kernberg's work, where a specific representation of self is linked to a specific representation of another by an affect state. For example, at any given moment, the patient may feel themselves a child in relation to a parent with the attendant affects, fantasies, and associative memories, which may then get played out in the therapeutic dyad. It is at this level that we can understand the contribution of Heinrich Racker's distinction between *complementary* and *concordant countertransference*.

If the patient is experiencing themselves as a child seeking understanding and advice from a caring parent, and the analyst feels themselves pulled into just such a parental attitude towards the patient, this would be considered a *complementary countertransference*. In other words, the analyst's own experience resonates with the object representation from the patient's internal object world. The analyst may also note the ways in which they are *not* resonating with the patient's experience in the transference.

A *concordant countertransference* is an identification with the affective experience of the patient—feeling what the patient is feeling—which may indicate empathic immersion in the experience of the patient but may also alert the observant analyst to a potential blind spot. For example, if the analyst is having personal problems with their spouse, and a patient is complaining of feeling disappointed and criticized by their spouse, this analyst would want to be aware of how their own personal feelings might be stimulated in such a way as to lead them to be more inclined to believe they knew exactly

Telegram: @medical_k

www.konkur.in

what the patient was experiencing. This can help the analyst maintain a neutral position with respect to the patient's conflicts.

Intersubjectivity. This recognizes that both persons in the dyad are complex, self-reflective subjectivities, or subjects "in their own right." Each will have ways of mutually regulating with others through behavior and affective resonances. Each has an internal object world that will be at play in the therapeutic encounter. Each can strive to understand the complex intentionality of mind at play, with the caveat that the psychoanalytic frame requires a degree of asymmetry between patient and analyst that is unavoidable in order for it to be clear that it is the patient who is there to be helped.

An early example in the psychoanalytic history of asymmetry in the therapeutic encounter being disregarded was in the work of Sandor Ferenczi. He experimented with "mutual analysis," in which the analyst also free-associated to the patient and discussed his own feelings and conflicts. It is easy to imagine how this could create a sense of impingement on the patient, who may feel pulled to "take care of" the clinician, with pathologic consequences. While an extreme example of a disregarded practice, it highlights the importance of asymmetry in the roles of analyst and patient, even in this contemporary era of intersubjective exploration. This asymmetry is constituted of the relative anonymity of the analyst, clear role expectations for the patient to freely associate, and the need for the attention of both parties in the room to be focused on the problems, feelings, and conflicts of the individual seeking help.

Intersubjectivity, especially as developed in the work of feminist psychoanalysts, was a necessary corrective to the dangers of a view of the analyst as a silent, all-knowing authority who has unique possession of knowledge of the patient's unconscious. However important a corrective provided by the postmodernist deconstruction of the analyst's authority, it is precisely the asymmetry of the clinical encounter that creates conditions for a safe playground of the mind in which two subjectivities work together for the benefit of the patient.

Telegram: @medical_k

www.konkur.in

CORE CONCEPTS OF CLINICAL PROCESS

The Psychoanalytic Frame

The "frame of psychoanalytic treatment" or *psychoanalytic frame* refers to the contractual conditions that comprise the psychoanalytic situation, including but not limited to meeting times, location of sessions, payment, and use of the couch. Psychoanalytic sessions are typically 45 to 50 minutes in duration and take place three to five times per week. During the sessions, the patient is encouraged to *free associate* or to speak as freely as possible about their thoughts as they come into mind, regardless of how illogical or disconnected the thoughts may seem. Freud referred to this as the *fundamental rule* of psychoanalysis. He believed that through free association, patients could bring repressed material into conscious awareness. The psychoanalyst responds to the patient's free associations by asking questions to facilitate the deepening of the material and through the use of interpretations. In the course of free association, patients will, often out of their conscious awareness, show signs of avoiding discussion of certain topics, expression of affects, or to the analytic procedure itself. Freud termed this phenomenon *resistance*.

Psychoanalysts of all orientations tend to agree that a critical part of the analytic process should be devoted to making the patient aware of their resistances and to help the patient view these resistances as obstacles to the analysis that must be understood and overcome. Eventually, the patient will produce material that contains overt or covert references to their thoughts and feelings about the psychoanalyst. This material is derived from a combination of the patient's current perceptions of the analyst as well as past wishes, experiences, and relationships (particularly with significant figures such as parents) that the patient has experienced, which is known as *transference*. Transference analysis is at the heart of psychoanalytic technique and what distinguishes psychoanalysis from all other forms of psychotherapy.

Aside from the fundamental rule and the expectation that communication can be in any form except through physical contact

Telegram: @medical_k

www.konkur.in

or violence, analysands are otherwise subjected to few rules. Most of the rules governing the analytic situation apply to the psychoanalyst, who generally maintains a stance of anonymity in keeping with the "rule of abstinence." According to Laplanche and Pontalis, the "[the analyst] should refuse to satisfy the patient's demands and to fulfill the roles which the patient tends to impose upon him" in order to ensure that "the patient finds as few substitutive satisfactions for his symptoms as possible." In addition to abstinence, the analyst attempts to maintain an analytic space in which the patient feels sufficiently safe and free to share their intimate thoughts and to fully engage in the analytic process. These aspects of the treatment frame are essential for preserving the analytic space from both internal and external influence, as described by Casement in 2013:

> "The consulting room space gives privacy and protection from intrusion by others; the set times, kept specifically for each patient, provide reliability and continuity; the professional ethic offers a guaranteed confidentiality and nonexploitation of the patient; and the relative anonymity of the analyst aims to keep to a minimum the impact upon the patient of knowing personal details about him/her… The analytic space also offers a freedom from the intrusive pressures (influence, reassurance, advice, or moral judgment) that could arise from any personal or theoretical predisposition of the analyst." (Excerpted from Casement P. *Learning from the Patient.* Guilford Press; 1985:340.)

The analytic situation has been referred to as a "transitional space" in which the patient, facilitated by their analyst, can "regress in the service of progression" (as described by Balint and Sandler in 2018), test out new ideas, and challenge old ones. Winnicott referred to the analytic space as a "holding environment" and emphasized the analyst's role in ensuring the patient can feel safe and "contained" even when in the midst of a severe regression. Schafer believed that the analytic attitude of "gentleness, undemandingness, open-mindedness, flexibility, patience, tentativeness, spontaneity, and individuality, and willingness to go along" was also crucial to maintaining an atmosphere of safety in the analytic situation.

Traditionally, patients in psychoanalytic treatment are invited to lie recumbent on a psychoanalytic couch facing away from the psychoanalyst. This technique was believed to allow analysands

Telegram: @medical_k

www.konkur.in

greater access to their unconscious minds by freeing them from inhibitions related to censoring or judging thoughts that they may experience when they see their analysts face-to-face. Over the years, at times out of necessity, such as during the COVID-19 pandemic, analysts have made modifications to the standard analytic technique, including but not limited to allowing patients to sit up or meeting with patients via telephone or video chat to accommodate for special circumstances. Such changes are known as “parameters of technique” and can be employed either temporarily or on a longer-term basis. When working in an analytic treatment, changes to the frame or shifts in parameters are always to be explored with the patient in order to understand the meanings that such changes generate.

Mechanisms of Therapeutic Action

Each major school of psychoanalysis has a theory of *therapeutic action* or idea of how psychoanalysis works to produce a therapeutic benefit that is based upon its own unique model of the mind and the associated theory of technique. Contemporary theories of therapeutic action tend to emphasize the role of interpretation and of the function of the therapeutic relationship in producing change. Though there are limited studies to support certain techniques being associated with specific outcomes, clinical data seem to suggest that there are multiple modes of therapeutic action.

Prior to the establishment of psychoanalysis proper, Freud’s and Breuer’s rudimentary theory of therapeutic action was that patients suffering from hysteria could be cured via *catharsis*—that the recovery of traumatic memories and discharge of their associated affects could remove symptoms of hysteria.

Freud went on to propose the topographic model, which emphasized: “making the unconscious conscious” as the primary mode of therapeutic action. According to this model, neurosis was attributable to repressed childhood wishes and the analyst’s role of interpreting the patient’s resistance to the analytic process. In addition, the patient’s transference(s) toward the analyst was critical

Telegram: @medical_k

www.konkur.in

to lifting the repression, providing the patient with insight, and thus effecting the cure. With his shift to the structural model, Freud amended his psychoanalytic technique to center around interpreting the patient's conflicts within and between the id, ego, superego, and reality but continued to focus on the patient's acquisition of insight as the primary mode of therapeutic action. Freud believed that the key to this process was through the patient's improving their capacity for regulating drives and strengthening ego capacities.

Ego psychologists continued to emphasize the role of interpretation and insight in their work. Some of those theorists deviated from the original Freudian theory to postulate the superego as being the site of therapeutic action or transference interpretation as being the primary mechanism for therapeutic change. Ideas about the role of the therapeutic relationship as the driver of therapeutic action also gained traction. Franz Alexander introduced the concept of patients experiencing a "corrective emotional experience" in the treatment. This was controversial at the time but paved the way for ego psychologists who focused on the "therapeutic alliance." They included both transferential and nontransferential aspects of the therapeutic relationship as a force for mutative change. Hans Loewald emphasized the role of the analyst as a "new object" for the patient, not dissimilar to a parent, who assists the patient in integrating their ego, self, and relationships with others.

These ideas informed Object Relations theorists who hypothesized that object relations are activated in the patient–therapist relationship. For them, the therapeutic action derives from using the analytic situation to better understand internalized relationship schemas, including in the "here and now" of the clinical moment, with the analyst functioning as a new object. Melanie Klein and her followers in the Object Relations school emphasized the role of the patient's transference and the analyst's countertransference in this endeavor.

The school of Self-Psychology, derived from Heinz Kohut's work with patients suffering from disorders of the self, views psychoanalysis through a developmental lens focusing especially on the consolidation of the sense of self and problems when this aspect

Telegram: @medical_k

www.konkur.in

of development goes awry. In this model of the mind, patients develop disturbances in their sense of self-cohesion, self-esteem, and capacity for investment in ideals and goals when their primary childhood caretakers did not adequately provide the child with certain crucial functions, known as *self-object functions*.

Examples of these functions include *mirroring*, which consists of validating the child's need for exhibitionism and accomplishments, and the *idealized parental imago*, in which an idealized caregiver provides adequate strength and calm needed for the child to develop affect regulation. According to Self Psychologists, previously arrested development is reactivated in the analytic setting, with the analyst serving important *self-object functions* that the patient felt were missing in childhood so that the weakened self can be repaired. Kohut believed that central to therapeutic action is the examination of *empathic failures* in the treatment, that is, moments of disruption in the analyst–patient relationship, and an understanding of what is essential for their repair. Empathy is thought to play an important role in facilitating therapeutic change.

Modern-day psychoanalysts have also looked to neuroscience research in an attempt to elucidate potential mechanisms for therapeutic action. An fMRI study looked at the neurologic effect of verbal labeling of affective stimuli. There was increased activity in the right ventrolateral prefrontal cortex and diminished amygdala and limbic responses to negative emotional images. This indirectly suggests that there is therapeutic value in making the unconscious conscious. Identifying an unconscious affect and labeling it, making it conscious, appears to cause an appreciable change in neurologic functioning.

Similarly, psychotherapy research suggests that the strength of the therapeutic alliance, regardless of the therapeutic approach, is correlated with treatment outcome. Contemporary psychoanalysts Glen Gabbard and Drew Westen suggest that there are multiple modes of therapeutic action. These include, but are not limited to, the role of interpretation, the role of the analyst–patient relationship, and various other strategies that work together to, per Auchincloss and Samberg, "change unconscious associative neural networks that

Telegram: @medical_k

www.konkur.in

represent problematic emotions, defenses, and interpersonal patterns, as well as conscious patterns of thought, affect, and motivation." More empirical research is needed to help characterize the mechanisms for therapeutic action.

DERIVATIVES OF PSYCHOANALYSIS

Psychodynamic Psychotherapy

Psychoanalytic theory and treatments were the primary approaches to care taught and used in mental health training for many years. By the mid-1980s, psychoanalytic approaches were increasingly being marginalized as a treatment. This is in large part due to limited research on psychoanalytic treatments, given how difficult these treatments are to manualize and systematically study. Training practitioners of psychoanalysis is a lengthy and difficult process, and criticism grew that psychoanalysis was not tailored to specific DSM disorders. In the late 1980s, Barbara Milrod et al. developed a psychodynamic formulation for panic disorder and used this to create a symptom-focused manual of psychodynamic psychotherapy that could be used in both training and research. This treatment model has since been adapted for the treatment of depression and post-traumatic stress disorder. It provided one of the first systematically studied manualized dynamic treatments that demonstrated efficacy.

In many ways, this created a foundation for other manuals to be developed using key principles of psychoanalytic treatment. These treatments could then be tailored to treat a broader range of issues since patients do not typically present with a single disorder. Luborsky developed a psychodynamic treatment manual that could be used in research based on data from the psychotherapy research project of the Menninger Foundation. A set of core conflictual relationship themes (CCRT) was developed, underlying key psychopathologic syndromes and presenting problems such as anxiety and depression.

These approaches can collectively be referred to as problem-focused psychodynamic psychotherapies (PrFPP). In PrFPP, the

Telegram: @medical_k

www.konkur.in

therapist is more active and focused and provides more psychoeducation than in traditional psychoanalytic treatments. The treatment approach aims to address core dynamics (core conflictual themes), trauma, and adverse developmental events as they contribute to various difficulties. The usual psychodynamic approaches to transference and countertransference and interpretation of conflicts and feelings in response to separation from the therapist are employed.

Psychodynamic therapy, especially as it has been operationalized in order to study and teach, can be seen as consisting of essential building blocks. Summers and Barber outline five building blocks: therapeutic alliance, core psychodynamic problem, psychodynamic formulation, strategies for facilitating change, and termination.

The *therapeutic alliance* has been the subject of much examination, as an essential common factor in therapeutic efficacy. It refers to a collaborative, here-and-now working alliance between patient and clinician. Each person has an understanding of tasks that must be performed, a sense of an attachment bond, and a notion of working towards shared goals. The therapeutic alliance is sometimes thought of as the “unobjectionable positive transference” and does not, therefore, require interpretation. Rather, it provides a fulcrum upon which productive therapeutic work takes place, which may include the elaboration of transference feelings and fantasies which are related to but can be distinguished from the so-called “real relationship” with the therapist.

The *core psychodynamic problem* refers to one of several frequently presenting problems with common underlying patterns that are typically well-suited to psychodynamic treatment. Summers and Barber refer to six core psychodynamic problems, including depression, obsessionality, fear of abandonment, low self-esteem, panic anxiety, and trauma. These are similar to the CCRT, which recognize these common patterns as the basis for the empirically supported psychodynamic therapy developed by Lester Luborsky. In the early (diagnostic and induction) phases of treatment, the forging of a working alliance and the identification of core problems will lend themselves to developing a psychodynamic formulation.

Telegram: @medical_k

www.konkur.in

A *psychodynamic formulation* is a synthesis of data gathered from the patient encounter. It includes working hypotheses of factors leading to the development of core problems within the context of individual character vulnerability and strengths, historical events, nondynamic predisposing factors, and life stressors that help explain the patient's central conflicts. In other words, it is an integrated understanding of the patient's inner mental life, with a focus on unconscious aspects that may explain how patients came to feel and behave as they do and how their symptoms developed. A formulation will offer a degree of predictability about the expected course of treatment, including prognosis, strategies for facilitating change, probable transference manifestations, and resistance to change. The heart of the treatment, or the so-called mid-phase, is where the *working through* of these conflicts takes place through the use of psychodynamic psychotherapy techniques, including empathic listening, facilitating emotional exploration, and the sequence of clarification, confrontation, and interpretation.

The eventual *termination* of treatment is itself seen as a critical phase allowing the patient to work through feelings related to separation and autonomy as well as consolidation of gains and reflection on unresolved conflicts and disappointments.

Evidence Base for Psychodynamic Psychotherapies. Randomized controlled trials (RCTs) are considered gold-standard evidence of effectiveness in medicine. To the extent that DSM psychiatric diagnoses are able to be reliable diagnoses, despite limitations regarding heterogeneity and comorbidity, RCTs have enabled treatments to be evaluated for effectiveness in reducing symptoms as expressed descriptively in DSM. Over the last 20 years, research into the effectiveness of psychodynamic treatments has caught up to other modalities.

Leichsenring et al. conducted a systemic review finding 39 RCTs demonstrating the efficaciousness of psychodynamic therapies for major depressive disorder, social anxiety disorder, panic disorder, borderline and other personality disorders, somatoform pain disorder, and anorexia nervosa, with "possible efficaciousness"

Telegram: @medical_k

www.konkur.in

(because of only one RCT) in dysthymia, generalized anxiety disorder, and complicated grief. A recent Cochrane Report by Abbas and colleagues found psychodynamic treatment to be efficacious in common mental disorders. Effects were also found to be stable or even increased in follow-up assessments. This may point to specific strengths of psychodynamic approaches, which attempt to address psychological structure, enable personal growth, and thereby are particularly positioned to “keep working” over time.

There are important controversies, caveats, and limitations when discussing effectiveness research into psychoanalysis and psychodynamic treatments. The settings in which psychotherapy RCTs take place are generally quite different from real clinical situations, which limits their generalizability. Some argue that psychoanalytic interventions are competing in research trials where the outcome measures are not necessarily the same as the overarching goals of psychoanalysis and are more suited to those goals targeted by medical intervention. That is, we must question the real-life significance of changes on the symptom questionnaires typically used in RCTs to evaluate the outcome. A common criticism of psychotherapy research in general (inclusive of CBT, IPT, and others) is that we may find manualized treatments targeting the scales of measurement rather than the underlying pathologic process.

We can also think more broadly about what it means to invite “science” into the debate about the validity of psychoanalytic interventions. Some psychoanalysts argue that psychoanalysis should not be considered a science and it is, therefore, meaningless to evaluate it by those standards. This argument sidesteps the critical concern: if any therapy is to be a treatment for psychological problems, we have a responsibility to ensure that it works. As Alessandra Lemma puts it, “if psychoanalysis only claimed to be a philosophy, experimental validation would not be an issue.” In the chapter sections below on specific problem-focused treatments, the relevant clinical trials supportive of their efficacy will be discussed.

Telegram: @medical_k

www.konkur.in

Psychodynamic Treatment of Panic. Panic-focused psychodynamic psychotherapy (PFPP) was developed by Milrod and colleagues as one of the first rigorously tested short-term symptom-focused psychodynamic treatments. The treatment emphasizes core psychodynamic conflicts and meanings of symptoms involved in panic disorder and has since been extended to address a range of DSM-5 anxiety disorders. It has demonstrated efficacy in RCTs as a 12-week, 24-session psychotherapy and has been studied in comparison to CBT and applied relaxation training. The psychodynamic view includes the necessity of uncovering previously unconscious meanings of symptoms in contrast with the "atheoretical" and acontextual DSM definition of "out of the blue" panic disorder phenomena. Core psychodynamic conflicts addressed in the treatment include difficulties with separation and autonomy, particularly in light of early attachment difficulties and fearful dependency on caregivers, with recognition and management of anger and perceived dangers of sexual excitement.

Defense mechanisms such as denial, reaction formation, and undoing are employed in an unconscious effort to reduce the threat from such feelings, fantasies, and conflictual wishes related to separation, anger, and the perceived threat to the sense of safety in core attachment relationships. Milrod and colleagues note that other DSM-5 anxiety disorders have psychodynamic constellations and core conflicts that overlap in varying degrees with those typically found in patients with panic disorder. They note that patients with anxiety disorders are prone to viewing themselves as inadequate and ineffectual, which reinforces dependency fears and the need to squelch feelings that they perceive would be disruptive to those essential safety relationships.

In generalized anxiety disorder, patients may maintain a state of internal hypervigilance in an effort to prevent the conscious emergence of "prohibited" fantasies that could arise if they were to relax. Worries about certain life stressors or somatic concerns can also function as defenses against unacceptable feelings and fantasies. The time-limited nature of the psychotherapy paradigm also permits panic patients to re-experience their difficulties with

Telegram: @medical_k

www.konkur.in

separation and autonomy directly with the therapist. This enables them to better understand underlying fantasies and renders them less “magical” and frightening. Patient reaction to termination is addressed for at least the final eight sessions of the treatment.

Psychodynamic Psychotherapy for Major Depressive Disorder. Dynamic Interpersonal Therapy (DIT) (not to be confused with Interpersonal Therapy or IPT developed by Klerman and Weissman) is another form of short-term psychodynamic psychotherapy. DIT is a 16-session dynamically oriented intervention informed by attachment and mentalization theory which owes much to conceptualizations of dynamic therapy advanced by Luborsky and Crits-Christoph, and Otto Kernberg. DIT focuses on how dysfunctional thoughts and beliefs in relationships cause depression. DIT aims to help patients improve their ability to cope with current attachment-related interpersonal challenges by better understanding their subjective reactions to them as threats. It makes implicit anxieties and concerns explicit and improves patients’ ability to reflect on their own and others’ thoughts and feelings. DIT helps patients understand the connection between their presenting symptoms and their relationships by identifying a core, nonconscious, repetitive pattern of relating. This pattern, termed the interpersonal affective focus, becomes the therapy’s central focus, and the therapist works on the conscious cost of such repetitive patterns. DIT primarily targets the assumed dynamic origins of depressive symptoms. Secondarily it fosters enhanced interpersonal functioning through an improved capacity to reflect on the individual’s own states of mind as well as those of others.

There are RCTs and meta-analyses examining the efficacy of a variety of psychodynamic and short-term psychodynamic therapies on efficacy for MDD. Leichsenring conducted a meta-analysis of seven studies comparing short-term dynamic therapy to CBT and found no significant differences between them in outcome scores or response rates. A 2013 meta-analysis by Barber and colleagues suggested that dynamic treatments were as therapeutically effective as alternative treatments at the end of active treatment and at short-

Telegram: @medical_k

www.konkur.in

and long-term follow-up and were more effective than control conditions.

Transference-Focused Psychotherapy for Borderline Personality Disorder

Transference-Focused Psychotherapy (TFP) is an evidence-based treatment for borderline and narcissistic personality disorders. TFP is a modification of a psychodynamic approach to treating personality pathology with a strong emphasis on contracting, setting goals, and the employment of limit-setting. It is a particular application of psychodynamic therapy for BPO, not just the DSM-5-TR diagnosis, as will be further explained shortly. It was developed and tested as a twice-weekly psychotherapy, typically of at least a one- to two-year duration. TFP relies on an ego psychological and object relations framework initially derived from the work of Melanie Klein and most recently elaborated by Otto Kernberg. This came about in part from the challenges of treating patients that did not improve using a classical psychoanalytic frame. Their treatment required modifications based on the borderline patients' characteristically distorted senses of self and others, which would inevitably get played out in the relationship with the therapist or analyst.

In the TFP model, the diagnostic assessment focuses less on DSM descriptive criteria of personality disorders and more on the assessment of an axis called *level of personality organization*. This assessment reflects the severity of the personality pathology and aligns more with the alternate DSM-5 model for personality disorders that can be found in the DSM-5 appendix section III, written by Oldham and colleagues. One of the limitations of the current DSM diagnosis is the high degree of comorbidity among categorical diagnoses of personality disorders. There is an advantage to focusing on core features of personality pathology that cut across categorical diagnoses.

BPO is a broader construct than borderline personality disorder (BPD) proper. It reflects deficits in six intimately related domains of personality that are present in BPD but also in many of the major

Telegram: @medical_k

www.konkur.in

personality disorder diagnoses. The domains of assessment in the structural interview include reality testing, aggression, defenses, identity diffusion, object relations, and superego pathology. One can refer to the STIPO-R, a validated semistructured interview that assesses each of these domains and has been used extensively in personality disorder research.

The core therapeutic target of long-term TFP is considered to be *identity diffusion*, though the six domains are deeply interrelated. In keeping with the emphasis on identity diffusion as a core feature of personality disorder, achieving a more consolidated or integrated identity (or cohesive self-structure) is a major goal of the treatment. Identity diffusion is a lack of integration of a coherent sense of self, especially in relation to others. It is evidenced by nonreflective, contradictory, and incoherently oscillating experiences of self. Identity pathology may be reflected in the inability to pursue consistent goals in career or in relationships. Tastes, values, and opinions may be highly inconsistent and shift easily according to the social environment.

Identity diffusion is also characterized by a predominance of subjective feelings of emptiness, free-floating anxiety, and chronic dysphoria. In contrast, normal identity formation is understood as an expression of an adaptive, flexible, and stable organization of component object relations. This is a process called identity consolidation, whereas pathology of formation is understood in terms of rigid and distorted organization of component internal object relations. Patients with neurotic personality organization have a consolidated identity, while those with borderline organization do not. As discussed earlier in the section “defense and conflict,” psychological defenses can be thought of as generally unconscious strategies for managing difficult affects.

Key in the TFP model is that borderline patients use a predominance of splitting-based defense mechanisms, which means that they separate (split) idealized from persecutory components of their experience. Any individual may use a mix of characteristic defenses, some more mature, such as intellectualization, rationalization, humor, and sublimation; some less mature such as

Telegram: @medical_k

www.konkur.in

denial, projection, and projective identification. The more an individual patient relies on splitting-based mechanisms, the more severe the personality pathology. This is because splitting-based defense mechanisms may function to remove painful feelings from awareness but at the expense of a clear sense of reality, especially in the interpersonal domain.

The domain of assessment of an individual's *object relations* involves an understanding of the person's functioning in their intimate relationships. The most straightforward way of describing an *internal object relation* is as a mental representation of self-connected to a mental representation of another person linked by an affect. Representations are mental constructs that are vulnerable to alteration by the individual and thus may not reflect reality. Object relations are an internal representational system that emerges in childhood in the context of attachment relationships and is fundamental to how personality is structured. Object relations inform the quality of our relationships in adulthood.

This concept is closely linked with unconscious fantasy, as these are deeply embedded, stereotypically reproduced relationship schemas that contain aspects of an "affective narrative" of the self's relation to the other at a given moment. *Object dyads are* a single specific internal representation of self, connected to the representation of someone else (the other) linked by an affect. A negative object dyad might occur in an individual with a personality disorder whose self-representation is of being weak, vulnerable, and sick. This self-representation is connected to a representation of the other as exploitative but needed, linked by a negative affect of suspicion, rage, and helplessness. A positive object dyad would be a comfortable sense of oneself as longing and dependent but perceiving the other as caring and idealized, linked by an affect of love and sense of being cared for. These dyads are activated repeatedly in interpersonal situations and may fluctuate rapidly. This is seen in the classic "flip" in the borderline patient who may idealize their significant other or their therapist one minute and then devalue or hate them the next.

Telegram: @medical_k

www.konkur.in

The last three domains are reality testing, aggression, and superego pathology. In regards to *reality testing*, the greater the use of splitting-based defenses, and the more distorted and stereotyped the patient's internal object relations, the more impaired the capacity for social reality testing. The hallmark distinguishing this experience from psychosis is that it depends on affect activation in an interpersonal context, rather than being a persistent state in the person. Along with affect management, reality testing is important to specifically assess how the patient manages aggression. The more severe, or low-level, borderline patients are likely to have more prominent paranoid and antisocial personality traits; their object relations are more highly suffused with aggression. The more severe the personality pathology, the more disturbed the domain of moral structure or superego formation. Low-level BPO patients, such as the severely narcissistic and antisocial, will use others for their own gain without a sense of guilt or remorse.

Much of the work in the twice-weekly treatment proceeds according to principles of dynamic therapy technique outlined throughout the chapter, including the clarification of internal conflict and the confrontation and linking of defenses to the object dyads that emerge in treatment. Patients with borderline character structure often have trouble recognizing internal conflict, instead perceiving a conflict as problem between themselves and another person, that is, they project one side of their own conflict while enacting the other. Dissociative defenses (splitting) are empathically addressed and object relationships are interpreted. Over time this leads to greater degrees of integration in the personality, improvement in consolidation of identity, and improvements in reflective functioning.

Mentalization-Based Treatment of Borderline Personality Disorder

Bateman and Fonagy have developed a manualized treatment for patients with BPD with a focus on increasing mentalization. Their approach was initially studied in a partial hospitalization setting with patients randomized to a Mentalization-Based Treatment (MBT)

Telegram: @medical_k

www.konkur.in

versus a treatment-as-usual group. Patients in the MBT group showed a statistically significant reduction in depressive symptoms, suicidal and self-injurious behaviors, number of inpatient hospitalization days, and better social and interpersonal functioning. The improvement began after 6 months of treatment and was maintained following termination of treatment at 18 months. Follow-up evaluations suggested that the patients who received the MBT intervention continued to experience significant improvement relative to the control group after the treatment had ended. MBT has since been adapted to the outpatient setting consisting of one group and one individual psychotherapy session per week and can be administered by any mental health practitioner trained in MBT and supervised by experts.

According to MBT theory, mentalization is a capacity that is typically gradually acquired in the first few years of life in the setting of secure child and caregiver attachments. It entails “making sense of the actions of oneself and others on the basis of intentional mental states, such as desires, feelings, and beliefs.” Prior to the development of capacity for mentalization, children are thought to experience the world in terms of psychic equivalence. In this experience, the internal and external worlds are equivalent. In pretend mode, the mental state exists independent of external reality but separate from the rest of the child’s mental state. A playful, attentive, and sensitive caregiver who respects the thoughts, feelings, and wishes of the child as significant, while also not being on the same order as physical reality helps the child modify the psychic equivalent and pretend modes of functioning. This style of parenting eventually allows the child to develop the capacity for organizing and recognizing their internal states as internal states.

When this process goes awry, as in the case of early neglect or physical maltreatment, the child’s internal experience remains unlabeled, chaotic, and uncontained. A child who does not receive adequate mirroring of their current state is likely to internalize the caregiver’s actual state as their own self-structure. When a caregiver exhibits primarily negative affects of rage, hatred, or fear, the child takes in the image of themself as frightening or unmanageable. The

Telegram: @medical_k

www.konkur.in

child then must externalize this painful, persecutory image in order to achieve a coherent self-representation. This sets the stage for the affect dysregulation and impaired interpersonal functioning that characterizes conditions such as BPD.

Important features of this treatment include the “mentalizing stance” of the therapist. The treatment focuses on the here and now rather than on the past. The relatively safe, secure base of the attachment relationship to the therapist provides a relational context in which it is safe to explore the mind of the other and to find one’s own mind within it.

CONCLUSION

Psychoanalysis has evolved from its early days, historically rooted in hypnosis and the treatment of conversion phenomena, to a robust and flexible discipline of depth psychological psychotherapies. Different “schools” of psychoanalysis emphasize different supraordinate motivational systems or models of mind. Ego Psychology focuses on internal conflict and compromise formation. Object Relations schools emphasize relationship schemas and paved the way for attachment research. Self-Psychology focuses on the development of self-esteem and self-cohesion and the ways that these are often disrupted in narcissistic disorders. Relational Psychoanalysis and Intersubjectivity emphasize the “two-person psychology” of the patient–therapist dyad as a corrective to outdated models, which tended to ignore the analyst’s own mind in working with their patients.

Readers of this chapter should now be familiar with the distinctive features of psychoanalysis and psychoanalytic therapy that underpin their effectiveness. These distinctive features include a focus on affect; examination of characteristic avoidances (defenses); identification of recurrent themes in thought, feeling, and behavior (enactments and repetitions); use of a developmental lens; a focus on interpersonal relationships (attachment and object relations); a focus on the therapeutic relationship in particular (transference and countertransference); and an exploration of fantasy life. This last

Telegram: @medical_k

www.konkur.in

feature, exploration of fantasy life, refers to a privileging of developmentally determined personal meanings that emerge through a sustained focus on the patient's inner world. By making such affects, avoidances, repetitions, relational themes, and fantasies conscious, their connection to symptoms can be worked through and clarified in a process that leads to enduring psychological structural change.

ACKNOWLEDGMENT

This chapter represents a major update and revision of previous chapters in this series, most recently by Dr. Silvia Karasu from the last edition. We have included a brief section of the last chapter that outlines Freud's early work.

32.4 Psychoanalytic Treatment of Anxiety, Obsessive-Compulsive and Trauma-Related Disorders

ERIC M. PLAKUN, M.D.

Since the history of psychoanalysis extends back over 100 years, its conceptualization of psychiatric disorders has evolved over time,

Telegram: @medical_k

www.konkur.in

extending and correcting but remaining consistent with Sigmund Freud's earliest formulations of the importance of the unconscious, mental representations, transference, countertransference, resistance, and defenses. The reader is referred elsewhere in this volume for a description of the history and theory of psychoanalysis. This clinically focused section endeavors to make accessible a psychoanalytic way of understanding and treating patients with anxiety and several related disorders, and to put theory and clinical practice into ordinary language.

Although psychoanalysis is a theory of the mind and of human development, as well as a specific form of treatment developed by Freud for treating "psychoneuroses," the adjective "psychoanalytic" refers to more than these. Today its more usual form in psychiatry is as the word "psychodynamic." This term refers both to a less intensive form of individual therapy based on psychoanalytic theory and to an entire way of looking at things that happen in the minds of (and between) patients and clinicians, but also within (and between) families, groups, and systems, and to a way of understanding, formulating, integrating, and responding to them. Psychodynamic psychiatry is the interface between psychoanalysis and psychiatry. A psychodynamic approach to anxiety and related disorders includes both a specific form of psychotherapy used to treat patients and a way of integrating the overall treatment plan of patients with these disorders. For example, and as illustrated later, this might include a specific way of conducting the psychopharmacologic treatment of anxiety and other disorders that has been called "psychodynamic psychopharmacology."

THEORETICAL ISSUES

Two Types of Anxiety

When Freud initially studied the affective state known as anxiety in the 19th century based on his observations of himself and patients and the relevant neuroscience of his time, he concluded that anxiety was a physiologic phenomenon resulting from blocked discharge of

Telegram: @medical_k

www.konkur.in

a form of psychic energy that he referred to as libido. Thirty years later, in “Inhibitions, Symptoms and Anxiety,” Freud modified this view, as he would others, to differentiate between *primary anxiety* and *signal anxiety.*

Primary anxiety is associated with an overwhelming, inchoate experience of total disintegration and is thought to have origins in the earliest threats to the cohesiveness of an individual at or shortly after birth. It implies no capacity to think about or respond to whatever the overwhelming stimulus may be.

Signal anxiety is a warning of potential danger or of a potential threat to equilibrium. It warns that primary anxiety may not be far off and leads an individual toward thought and action. In psychodynamic thinking, signal anxiety is seen as a symptom of a deeper problem rather than necessarily as a specific focus of clinical attention, just as the dashboard “check engine” warning light in a motor vehicle is a warning to deal with some hidden but discoverable danger, not a warning to turn off the light. In both cases, there is an underlying problem that has led to the signal, and the solution lies in the direction of dealing with the underlying problem.

In psychoanalytic structural theory, structures like the ego, id, and superego are used to understand internal mental processes. Viewed through the lens of structural theory, signal anxiety is the ego’s response to sexual and aggressive drives originating in the id that are in conflict with the moral standards of the superego. Humans are never far from conflict between their wish to gratify id impulses immediately and the superego’s demands for adherence to standards of behavior that require delay in acting on impulses. Signal anxiety is ubiquitous and part of ordinary human functioning. Indeed, anxiety is the price humans pay for civilization. However, some individuals suffer from marked signal anxiety in ways distressing enough to come to clinical attention.

Psychoanalytic theory includes recognition of a predictable progression of developmental issues that emerge in the course of human life. Signal anxiety may occur in response to conflicts that emerge as the developmental sequence unfolds, including but not limited to conflicts about loss of the self, separation from an

Telegram: @medical_k

www.konkur.in

attachment figure who is loved and needed (separation anxiety), loss of the love of an attachment figure who is loved and needed, fear of massive retaliation by a powerful rival for the love of an attachment figure who is claimed by the powerful rival (castration anxiety within the Oedipus complex), loss of control, dependency, aggression, fears of sexual impulses, and others. Signal (or even primary) anxiety may also emerge from severe adverse experiences of loss, neglect, deprivation, trauma, or abuse.

Nosologic Issues

DSM-5-TR anxiety disorders are listed according to age of onset, and include separation anxiety disorder, selective mutism, specific phobia, social anxiety disorder, panic disorder, agoraphobia, generalized anxiety disorder (GAD), substance/medication-induced anxiety disorder, anxiety disorder due to another medical condition, other specific anxiety disorder, and unspecified anxiety disorder. This chapter will focus on the psychoanalytic psychotherapy of three of these: specific phobia, panic disorder, and GAD. In the transition from DSM-IV to DSM-5, two anxiety disorders were relocated to other chapters—obsessive-compulsive and related disorders like body dysmorphic disorder, and trauma and stressor-related disorders. This chapter on psychoanalytic treatment of DSM-5-TR anxiety disorders will also address obsessive-compulsive disorder (OCD) and posttraumatic stress disorder (PTSD).

Although disorders will be discussed as separate entities, there is often comorbidity among anxiety disorders and between anxiety and other disorders. Except for research purposes, psychoanalytic therapists do not generally join what is arguably a false assumption of psychiatry that most or even many patients will present with a single disorder that will respond to a specific evidence-based treatment of that disorder. Studies like the STAR*D for depression have shown that the vast majority of patients present with multiple comorbid conditions despite the “one disease-one treatment” models of psychopathology that predominate in the field.

Telegram: @medical_k

www.konkur.in

Indeed, increasing recognition of the ubiquity of comorbidity set the stage for replicated factor analyses of patients' symptoms, leading to the elucidation of a single psychopathology or "p" factor that underlies most mental disorders. Concurrently, some cognitive behavioral therapy researchers have demonstrated the efficacy of transdiagnostic "unified protocol" therapies for anxiety disorders that target neuroticism and other underlying factors rather than disorder-specific anxiety symptoms. Psychoanalysis and psychodynamic therapy are arguably the original transdiagnostic therapies and are often indicated in the presence of complex comorbid conditions.

While psychiatry groups a series of disorders together as anxiety disorders, anxiety is often part of these disorders in different ways that are meaningful to a psychodynamic psychiatrist. Although some direct experience of a form of anxiety is part of GAD and panic disorder, other anxiety disorders may come to clinical attention because of efforts to avoid anxiety, as in agoraphobia to avoid the risk of exposure to sources of anxiety, other phobias in which anxiety is limited by limiting the risk of exposure to the phobic stimulus to a degree that may compromise functioning, or when obsessions and compulsions in OCD may serve to ward off the experience of anxiety, or because of symptoms beyond anxiety (as in avoidance, re-experiencing, negative alterations in cognition, or hyperarousal phenomena in PTSD).

These distinctions are meaningful to a psychodynamic psychiatrist. Signal anxiety is an affect, whereas phobic avoidance, obsessions and compulsions, and re-experiencing phenomena are symptoms that may be associated with anxiety (e.g., a flashback in PTSD) or with its relief (e.g., counting rituals that ward off anxiety in OCD). Psychodynamic psychiatrists are generally less interested in eliminating a symptom or affect than in helping a patient to discover and then take charge of what lies hidden beneath. What is the conflict hidden beneath the affect of generalized (signal) anxiety? What is the meaning of the symptom of phobic avoidance or of a counting ritual? Psychodynamic treatment understands symptoms and affects like signal anxiety as the visible phenomenologic tip of an iceberg that really goes much deeper than a surface view suggests

Telegram: @medical_k

www.konkur.in

—the “check engine” light suggesting the need to look beyond the dashboard to discover the problem.

The Unconscious and Psychotherapeutic Technique

Elsewhere in this volume, the evolution of psychoanalysis is addressed, including its move from a topographical model to a structural model, to an object relations–ego psychological model, and more recently to an intersubjective-relational model. For the current chapter, the model used will be based on the notion that psychoanalytic or psychodynamic psychotherapy of any disorder presupposes that there is a relationship between the disorder and the functioning of the dynamic unconscious. This point of view is based on the notion that much of the behavior of any individual is governed by forces outside conscious awareness. Unconscious processes are active and make significant contributions to psychiatric disorders, including anxiety disorders. Although a patient may be aware of anxiety or of behavioral symptoms that cause distress, the conflicts or other meanings that underlie these may well remain out of awareness, although they are potentially discoverable —and discovery can lead to mastery. These conflicts and the issues associated with them are repressed or kept out of conscious awareness by defense mechanisms.

From this perspective, the task of psychodynamic therapy is to bring into conscious awareness and under conscious control these unconscious conflicts and other meanings that are signaled by anxiety or encoded as nonverbal communications in behavioral symptoms. Making the unconscious conscious is a significant challenge, but psychodynamic therapists understand that there is a range of ways to do this.

Psychodynamic therapists conceptualize three parts of the therapeutic relationship. The *real relationship* always exists and is based on the reality elements of two individuals involved in the therapy situation, including age, gender, ethnicity, and personality features, among others. The *transference relationship* also always exists and is based on life experiences from the patient’s past that

Telegram: @medical_k

www.konkur.in

are projected onto the therapist (and the therapist's transference to the patient or countertransference based on the therapist's own life history). The third part of the therapeutic relationship, the *therapeutic alliance,* exists only if it is negotiated between therapist and patient, and this negotiation is an essential early step in treatment.

Psychodynamic therapists negotiate an agreement to explore the patient's mental life, encouraging patients to *free associate,* that is, verbalize their thoughts and feelings freely as they arise in sessions, including thoughts and feelings about the therapist. Psychodynamic therapists recognize that a patient's fantasies, dreams, fleeting thoughts, slips of speech, and habitual or unusual behaviors offer opportunities for therapist and patient to discover clues about unconscious motives, fantasies, and conflicts that can illuminate and make sense of the patient's disorder. These discoveries make therapeutic work possible in order for the patient to acknowledge, bear, and put into perspective these issues. From a psychodynamic perspective, the therapeutic alliance includes an agreement for both parties to be committed to the task of therapy, especially when this is most in question, as in periods of regression or amplification of the transference or countertransference.

Psychodynamic therapists understand that, in addition to the wish to change that brings them to treatment, patients, like other people, are fundamentally ambivalent, and thus also fear change and prefer the familiar. This is partly because patients' symptoms are not only problems but also represent the best solutions patients have been able to find for challenges they face in life. Patients may pay a high price for their solutions, but their symptoms are nevertheless solutions.

Hence, it is understood that patients will inevitably bring to the treatment a reluctance to change which is known as *resistance.* Given the request that patients free associate, resistance may take the form of conscious censorship or unconscious repression of thoughts, fantasies, or feelings. It is important to emphasize that not all parts of resistance are conscious or entirely under the patient's control. While resistance is motivated and powerful, attention to the patient's (and therapist's) associations allows it to be discovered and

Telegram: @medical_k

www.konkur.in

brought into conscious awareness. In psychodynamic therapy, bringing the patient's resistances into conscious awareness is generally a necessary step before change can occur.

Psychodynamic therapists work with a focus on transference and countertransference as an inevitable therapeutic phenomenon. Transference and countertransference are important opportunities to learn more about what a patient is struggling with, to engage relevant issues in the here and now of the therapy relationship, to deepen the work, and to help a patient to move toward change.

In psychodynamic psychotherapy, the therapist maintains a stance of *technical neutrality* rather than being directive or self-disclosing. Technical neutrality should not be misconstrued as being cold and distant. It is in fact a warm, empathic, and nonjudgmental listening stance with evenly hovering attention and responsiveness. Patients who meet with a therapist operating from a stance of technical neutrality will react to the therapist in ways shaped substantially by past relationships that have influenced their experience of others. The psychodynamic therapist strives to accept whatever the patient brings to the sessions, including distorted perceptions of the therapist based on past relationships, that is, the transference, while striving to renounce ambition and desire about how the patient's life should be or what choices the patient should make. The psychodynamic therapist expects that central experiences from the patient's life history will inevitably be recreated in the transference to the therapist.

For example, it is likely a patient with a history of early sexual trauma perpetrated by a relative will come to experience the therapist at different times as like the abuser or like another relative who failed to stop the abuse or even as the victim of abuse. Psychodynamic therapists try to accept the transferences that are offered, including unpleasant negative transferences, without refusing them or trying to talk the patient out of them. This is because they recognize that this is the way a patient's problems come to life in the therapeutic relationship. Transference is the vehicle for "exposure and response prevention" in psychodynamic therapy.

Telegram: @medical_k

www.konkur.in

Because therapists are also human beings, they will have a range of reactions to a patient. Some of these will be the reactions anyone would have to a patient acting in that particular way, whereas others may be more uniquely related to the therapist's character as shaped by their life history.

For example, a therapist who was unable to protect their own younger sibling from abuse may respond to the aforementioned patient's transference to the therapist as an abuser with guilt and a wish to talk the patient out of the transference through reassurance about how professional and kind he is. This kind of situation, in which a patient's transference engages the therapist's character and life history in a way that creates a reciprocal countertransference that the therapist cannot endure, leading to action that refuses to accept the transference, is called an *enactment.*

Enactments are ubiquitous therapeutic phenomena. In fact, the difference between beginning and experienced therapists is better characterized by the experienced therapist's ability to detect, analyze, and utilize enactments to deepen the work, rather than entirely eliminate them. To be sure, enactments are a slippery slope, but, as in skiing on a slippery slope, the task is not to avoid sliding down at all, but rather to develop skill in maneuvering and maintaining one's balance and control while sliding down the slippery slope. It is partly because of the inevitability of countertransference enactments that it is so valuable for psychodynamic therapists to undergo psychoanalysis or psychodynamic therapy themselves so that they become aware of their blind spots, character styles, and countertransference vulnerabilities.

In this chapter, case examples are deeply disguised and/or composites of several patients. The case examples are offered to illustrate theory and technique. They are not offered as single-case proofs of the efficacy of psychodynamic psychotherapy. Although a review of the evidence base for psychodynamic psychotherapy is beyond the scope of the current chapter, there are over 300 studies demonstrating the efficacy of psychodynamic therapy, including its efficacy in treatment of specific disorders, complex comorbid

Telegram: @medical_k

www.konkur.in

disorders, and including studies that demonstrate the “noninferiority” or “equivalency” of psychodynamic therapy to other forms of therapy.

SPECIFIC PHOBIA

In phobic disorders, the affect of signal anxiety is evoked in response to a particular phobic stimulus. Avoiding the stimulus often eliminates anxiety, but the price paid to be free of anxiety may be high, seriously compromising social or role functioning. Psychodynamic therapists approach phobias by exploring the unconscious meaning of the phobic stimulus to the individual as revealed by associated feelings, memories, dreams, and fantasies. As these emerge in the transference relationship, there is an opportunity to engage them and to work through the resistances and the associated issues and conflicts. The following case example illustrates treatment of a woman with a specific phobia.

Telegram: @medical_k

www.konkur.in

D, a woman in her 40s, had a long history of a specific phobia about driving over bridges. Over the course of years, she had been treated for this phobia with benzodiazepines and then, with good effect, exposure and response prevention. After the sudden death of her father, D's phobia returned worse than ever, making it nearly impossible to commute to work. This time behavioral treatment did not seem to help. D was referred to a psychodynamic therapist, who worked with her to explore and elaborate the details of her phobia, which was most anxiety-producing when it involved bridges with open sides. Associated with her anxiety was a sense of dread that she would be swept off the side of the bridge and fall to her death. She could sometimes force herself to cross them, but there was a horrible swirling knot in the pit of her stomach the entire way across. Having someone else in the car helped, but only if they agreed to hold her hand while they drove across the bridge.

The therapist explored D's relationship with her father, given that his death seemed to have made the phobia worse. D had been very attached to her father, who seemed more loving and tender toward her than her aloof mother, but, despite his warmth, her father was often absent. She had not really grieved his sudden death because of how much her widowed mother needed D to be her solid support.

At one point in a session, when the therapist asked if she had ever previously felt the kind of feeling in the pit of her stomach that was associated with driving over bridges, D recalled a memory from a family vacation when she was 13 years old. With her father, she had climbed a steep and exposed fire tower. Going up had been exciting and the view was exhilarating, but when she tried to climb down D became terrified by the steep pitch and small steps and felt the same horrible, swirling knot in the pit of her stomach that was now associated with crossing bridges. D froze and asked her father to hold her hand during the descent, but he declined, saying she had to make it down on her own, then turned away from her and descended. He did not stop

Telegram: @medical_k

www.konkur.in

when she called him. Alone at the top, D was terrified, but she had no choice but to make her way down alone. She sat on the steps and slid down one at a time, all the while terrified she would slip off a step and fall to the bottom, where her family was gathered waiting and joking about her timidity. When she got down her father laughingly commented that he knew she could get down on her own one way or another.

In the next phase of her therapy, driving over bridges became somewhat easier while therapeutic work was done around the earlier experience at the fire tower that caused the same knot in her stomach, the same fear of being swept into space and falling, and the same sense of shame and humiliation for being laughed at for not being able to do what others could do easily. These feelings were also associated with a painful sense of abandonment and ridicule from the father she needed and loved. She had never spoken to him again about the incident. A great deal emerged in the therapy about her longing for her father and the way his absence in her life and tendency to ridicule and tease her had hurt her. She felt that there was something that made her less interesting to him than her older brother, with whom he spent more time. As these feelings emerged, with them came intense grief over her father's death. Now she would never have him with her again, and the hope of understanding why he had acted so uncaringly on the tower, or that he would apologize for it, was gone forever. As she grieved in and outside the sessions, D's bridge phobia diminished further.

After about 6 months of weekly therapy, D felt ready to think about ending therapy, so she and her therapist set a termination date a couple of months in the future. In the termination phase of their work, D began to have more trouble commuting over bridges again. This led to an opportunity to address the ways in which the loss of her therapist was presenting D with another abandonment. Termination was another occasion in which she would feel all alone and in danger of being swept into the void. During the termination phase, abandonment and dependency issues were explored in the transference. D's symptoms

Telegram: @medical_k

www.konkur.in

subsided again by the time of termination. At a 2-year follow-up she was free of the bridge phobia.

D's phobia about bridges was revealed to be a translation into a symptom of a humiliating memory of an experience of abandonment by her beloved but belittling father, whose death could not be fully grieved until she gained access to issues in their relationship that had been frozen in time in her symptom. In this instance, the "anxiety disorder," that is, D's phobia, and the signal anxiety associated with driving over bridges, concealed issues of unresolved grief and loss. The therapy provided an opportunity to discover this and to grieve the relevant losses.

PANIC DISORDER

Psychodynamic therapists view panic attacks as a form of signal anxiety triggered by unconscious, unresolved past conflicts often involving aggression, anger, separation, and dependency. By following affects, by listening to the patient's wishes, dreams, and fantasies, and by carefully exploring the patient's life history for therapeutic stories that illuminate the meaning of the panic attacks, as well as by attending carefully to the triggering context of panic attacks, a psychodynamic therapist joins the patient in a search for unconscious past conflicts related to panic. These conflicts are brought into awareness and under the patient's conscious control by engaging these issues as they arise in the transference relationship.

A specific form of psychodynamic therapy has been developed and studied for panic disorder. A randomized, controlled trial compared a manualized, twice-weekly, 24-session therapy called panic-focused psychoanalytic psychotherapy (PFPP) to twice-weekly, manualized, applied relaxation training. PFPP was found to be efficacious in patients with panic disorder.

PFPP is conducted in three phases. Phase 1 focuses on acute panic. The therapist works with the patient to uncover unconscious meanings of panic to achieve relief from panic attacks. PFPP

Telegram: @medical_k

www.konkur.in

therapists explore the circumstances and feelings surrounding the onset of panic, the personal meaning the patient assigns to panic symptoms, and the feelings and mental content of panic attacks. Conflicts involving separation, autonomy, and suppressed anger are frequently discovered. Within phase 1 some panic relief is typical, together with a reduction in any associated agoraphobia.

Phase 2 of PFPP focuses on lessening vulnerability to panic through the understanding and alteration of core unconscious conflicts. These are addressed as they arise in the transference and are shown to be ubiquitous in the patient's life. Responses expected in phase 2 include improved relationships, less conflicted and anxious experiences of separation, anger, and sexuality, and reduced recurrences of panic.

Phase 3 of PFPP occurs during the last third of the sessions and focuses on termination. Conflicts—for example, those about separation or anger about losing the relationship with the therapist—are re-experienced directly within the transference. Although there may be a temporary recrudescence of symptoms during termination, as if the patient were saying, "If you let the treatment end and abandon me, then all my symptoms will return," this allows consolidation of gains in the termination phase through transference work on the central separation, anger, and autonomy issues associated with panic. Patients generally emerge with a new ability to manage separation and anger and to function autonomously.

Patients with panic disorder who responded to 12 to 14 weeks of PFPP maintained their gains 12 months later at the same rate as those who responded to 12 to 14 sessions of cognitive-behavioral therapy or applied relaxation training.

GENERALIZED ANXIETY DISORDER

For a psychodynamic therapist, even GAD, in which (signal) anxiety seems to be ubiquitous and without specific content, would be approached with curiosity about and a search for whatever pieces of context may emerge in the course of exploration of a patient's fantasies, fleeting thoughts, dreams, and other clues from the

Telegram: @medical_k

www.konkur.in

unconscious that may emerge as associations to the affect of anxiety are followed and explored. Treatment is oriented toward discovering the unconscious fantasies that illuminate the conflicts associated with anxiety, some of which may involve fears of separation from attachment figures, fears of loss, fears of castration or other loss of agency, or fears of sexual impulses. The therapist approaches the patient with no preconceived notion about what these conflicts are, although with knowledge of potentially conflictual issues in human development. The following case example illustrates psychodynamic therapy with a patient with GAD.

Telegram: @medical_k

www.konkur.in

B, a 28-year-old man with a history of GAD, had alcohol use disorder now in remission and regularly attended Alcoholics Anonymous (AA) meetings. Because of their sexual side effects, B was unwilling to take selective serotonin reuptake inhibitors (SSRI), while serotonin norepinephrine reuptake inhibitors and buspirone had been ineffective, and gabapentin was too sedating. Clonazepam was effective, but B's peers in AA urged him to give up benzodiazepines. Partly because of these pressures, B sought weekly psychodynamic therapy with a psychiatrist, who suggested that they begin tapering clonazepam in light of B's history of alcohol use disorder. B balked at this idea, worried that he would become more anxious. The therapist suggested that it might be useful to bring his anxiety to sessions if their task really was going to be to learn more about it. B agreed to the plan after some reflection.

B's anxiety increased as the dose of clonazepam decreased. He complained that his male therapist was unempathic, forcing B to suffer with anxiety while the therapist did nothing. As the treatment unfolded, the therapist learned B had been especially close to his mother, who, with B, had been the target of criticism from his often absent, short-tempered, mean-spirited, alcoholic father. B's mother had surgery and chemotherapy for breast cancer when B was 14 years old. It was shortly after this that B's anxiety symptoms began.

When clonazepam was discontinued, B experienced an increase in anxiety and had an outburst of anger at the therapist for making B suffer so much. The therapist quietly accepted B's anger at him, empathically noting that he had asked B to endure anxiety while leaving him alone and on his own most of the week. When he pointed out that he and B might want to be curious about the way he was finding in the therapist someone like his absent and sadistic father, B thought this made sense and began to trust the therapist more. Over time B stated his appreciation that the therapist could endure and understand his anger without retaliation. B also realized that the therapist was sticking to a

Telegram: @medical_k

www.konkur.in

treatment plan they had agreed to at the outset. As the alliance deepened, B struggled to put words to his experience of anxiety. B spoke more of his attachment to his mother and to the way he would cling to her to support her, pressing himself against her ample bosom, while his father would rage at them both while drunk, sometimes suggesting that B's clinging to her was unnatural and inspired by lust.

B reported a dream in one session in which he watched passively, frozen with fear and guilt and unable to move, as a man murdered and dismembered a naked woman. B's associations to the dream led to painful memories of his mother's disfiguring cancer surgery and to his guilt about his inability to stop his father from angrily criticizing her before or after the surgery. B then added there was another part of the dream he had left out because of shame; B had been sexually aroused during the dream. B suddenly reported an intrusive thought that upset him—a thought that the breast cancer had come because he had been unable to protect his mother—and because he had been aroused by her breasts. B wept for the first time in the therapy. Over time therapist and patient explored the dream and his intrusive thoughts, learning that B guiltily felt as if he were the cause of his mother's illness and disfiguring surgery. It felt as if she had become ill as retribution for his failure to protect her from his father's rages, but also as retribution for his attraction to his mother's breasts. He spoke of the way his father's drunken accusation of lust toward his mother had actually been partly right. B feared, too, that he would be disfigured because of a disease or accident, perhaps by castration, for what he had done to his mother. It was not easy for B to explore these feelings, but as he did his anxiety diminished.

By the end of B's treatment, it was evident that what had appeared initially to be GAD without context had actually been the surface presentation of unconscious psychological conflicts around attraction to his mother, guilt about her disfiguring illness, and fear of his father.

Telegram: @medical_k

www.konkur.in

These conflicts were revealed in the course of B's therapy, with resolution of his symptoms.

POSTTRAUMATIC STRESS DISORDER

In PTSD, a patient has experienced something horrifying that is out of the range of ordinary human experience. The experience of anxiety during the traumatic event may approach that of primary anxiety. The clinical presentation of PTSD includes more than anxiety, with a range of symptoms that carry discoverable meaning.

Freud's early theoretical formulations dealt with the horror of actual but repressed sexual trauma as the cause of neurosis as he came across patients whose unfolding unconscious conflicts led to descriptions of childhood sexual abuse by adults. Freud later moved away from theoretical formulations based on the notion of actual seduction of children by adults to formulations based on the notion that such seductions were wished for and feared fantasies of patients. There is no simple resolution of such matters. Some patients have experienced early sexual trauma, whereas others may struggle with such "seduction" within the realm of fantasy.

Patients with PTSD have experienced actual sexual or other kinds of trauma. Psychodynamic therapists recognize that patients with PTSD are likely to struggle with difficulty trusting authority figures, given that past abusers may well have been untrustworthy authority figures. Psychodynamic therapists negotiate an alliance within which patients are encouraged to explore the details of their experience of abuse and the associated affects as they are able to bear them.

Psychodynamic therapists also anticipate that patients with PTSD will likely mobilize in their transference relationships with therapists aspects of the past abusive relationship. Thus, psychodynamic therapists understand they may be experienced within the transference as the abuser, as the helpless victim of abuse in response to the patient's sadism, or as the passive witness or bystander, like the other parent in an abusive family who seems to the child like someone who ought to know about and put a stop to the abuse—unless they are sanctioning it. These are often

Telegram: @medical_k

www.konkur.in

particularly difficult transferences for clinicians to endure because therapists are motivated primarily by the wish to be healers and helpers. Such transferences may evoke powerful countertransference reactions in the therapist—and enactments in therapy.

The following case illustrates psychodynamic therapy with a patient with PTSD.

Telegram: @medical_k

www.konkur.in

M, a 33-year-old woman, was employed by a domineering male boss who singled her out at work as the target of his anger, publicly humiliating her over the slightest failures. Her efforts to report him to superiors were ignored as his behavior was minimized. After a frightening sexual approach by him that she successfully rebuffed, she became symptomatic, with re-experiencing phenomena, negatively altered cognitions, hyperarousal, and intrusive memories of the abuse by him. She quit her job, felt unable to follow advice from friends to take legal action against her boss, and sought outpatient treatment. M was initially treated by a psychiatrist who prescribed medications for her symptoms and urged her to file a complaint against her boss. Although M felt unable to file a complaint because of her unhelpful past experience with her boss' supervisor, her psychiatrist urged her to do so because it might protect other employees, but she continued to refuse. When she experienced significant side effects, M stopped the SSRI he had prescribed. Her psychiatrist pressured her to try another medication, but this one, too, was associated with intolerable side effects. Unhappy, M ended her treatment, but, when symptoms persisted, began work with a new psychiatrist, although with considerable trepidation that she would have another bad treatment experience.

M began psychodynamic therapy with the new psychiatrist. She quickly felt comfortable with her new psychiatrist when he helped her see that her previous treatment experience had unwittingly recreated the experience of abuse by a domineering authority figure as the well-meaning first psychiatrist had badgered her about making a formal complaint, she did not feel ready to file and pressured her to take pills associated with intolerable side effects. The alliance was off to a good start, with a strong positive transference attachment.

Soon, though, M started to miss or come late to sessions. Although still symptomatic, she came to a session with a decision to end the therapy. Taken aback, the therapist pressured her to

Telegram: @medical_k

www.konkur.in

continue the therapy, and M reacted with anxiety, anger, and a flashback to the experience of abuse by her boss. The therapist realized he was in an enactment, noticing to himself that the abusive relationship had once again been recreated, this time between them. Now it was the new psychiatrist who was experienced as domineering and pressuring her to do something she did not want to do but had trouble resisting. Aware of the enactment, the therapist noted to the patient that they had unwittingly recreated the abusive scenario. The psychiatrist suggested that they slow down to take stock of what was happening between them that would lead to another repetition of a now-familiar pattern. The therapist noted that a choice to end the work was hers to make, but he thought that they were in the midst of important work and thought there was more to understand about her wish to flee, if she were up for the learning that might unfold. M agreed to continue the work.

With difficulty, M revealed that she had been troubled by somatic sensations she had avoided revealing. For some weeks, about as long as the lateness and missed sessions had been occurring, she had been having strange, confusing, and sometimes arousing genital sensations before and during the sessions. She realized with fear and disgust that she was feeling attracted to him. In further work it became apparent that becoming sexual with the therapist was not just something she feared, but also something she guiltily desired. This led to the patient's revelation of an experience of date rape by an 18-year-old man when she was 14 years old. Although she had never really forgotten this incident, it was an "unthought known" in her mind, something she tried not to think about or tried to make unimportant on the rare occasions when she did acknowledge it to herself.

As the experience of date rape was explored, it emerged that it was not her first terrifying experience of being forced to do something that she did not fully want to do by a domineering man. Her father, too, had been frightening when angry, although usually loving and never sexually inappropriate. As the

Telegram: @medical_k

www.konkur.in

exploration continued, M reported discomfort and a feeling that bringing the memory of the date rape to the therapy felt like being invited to reveal more than she wanted to. When she complained that the therapist was pressing her to reveal things that made her uncomfortable, he realized that this was true and that he was again in an enactment. He apologized for pressuring her, noting he could see he was pressing her to keep going beyond the point that felt safe in a way that replicated her traumatic experiences with men. After the apology, M guiltily revealed that the experience of date rape, as terrifying as it genuinely was, was also associated with sexual pleasure. M wondered if she were to blame if that was the case. Over the remainder of the therapy, work was done exploring her conflicted and guilty sexuality as her PTSD symptoms subsided. When she felt strong enough, M decided to file a complaint against her former boss.

M presented with symptoms of PTSD in response to a recent experience at work that had important connections with an earlier instance of sexual abuse and with her relationship with her father. The first abuse experience was recreated in her work life and then, repeatedly, in enactments in therapeutic relationships, until the underlying fears and wishes were brought to consciousness, explored in the transference, and worked through over the course of several repetitions. Both therapist and patient recognized their own roles in recreating the problem.

OBSESSIVE-COMPULSIVE DISORDER

OCD is a disorder in which signal anxiety may be present (as when intrusive obsessions are associated with anxiety), although other patients with OCD ward off anxiety through compulsive rituals, expending huge amounts of energy through their symptoms to control and contain anxiety about unacceptable thoughts, risks, or impulses.

Telegram: @medical_k

www.konkur.in

From a psychodynamic perspective, OCD is thought to have its origins in an individual's earliest struggles to achieve a capacity for autonomous functioning in the period of toilet training. During this period, a child is encouraged, lovingly and otherwise, to give up a form of dependence on parents and to take charge of their own excretory functions. This creates the potential for a complicated struggle about control in the form of complying with or defying parental expectations. Defiance is a way of refusing to grow up, whereas complying and accepting change, though a kind of surrender, is ultimately in the service of achieving greater autonomy. A psychodynamic therapist approaches a patient with OCD by searching for hidden meaning encoded in the obsessions and compulsions, with anxiety often emerging as the meaning of the symptoms becomes apparent.

Telegram: @medical_k

www.konkur.in

P, a passive, emotionally vacant, exceedingly polite, apologetic, and quiet man in his 30s, sought psychodynamic psychotherapy for OCD because he was having difficulty functioning at work and in relationships. P reported counting rituals and compulsive behaviors that filled hours. Among his bedtime and cleanliness rituals were a need to keep shoes shined and properly hung on shoetrees or aligned in closets, and behaviors to verify that knives were safely locked up. In sessions, he often droned on endlessly about emotionally empty details of his work life. The therapist became drowsy at one point as he struggled to remain attentive to P, who noticed this and, with uncharacteristic affect in his voice, asked, “Doctor, excuse me, but are you listening?” To this the therapist replied, “No, I guess not. Are you?” P seemed taken aback, and then characteristically apologized for having been boring.

This incident led to a direct discussion between them about the way P’s obsessive, circumstantial, and emotionally empty recounting of details was a form of resistance and one in which his therapist had joined him by becoming drowsy in the session. This was a sign their work was in trouble. Were they going to do the work of therapy together or not?

In subsequent sessions, P made efforts to speak more about the origin of his symptoms, which began with a ritual of kissing each of his parents goodnight nine times lest he be unable to sleep. On one occasion, while explaining this, P made a slip of speech about having to kiss his father nine times, instead substituting the word “kick” for “kiss.” The therapist asked P if he had noticed the slip. P insisted he could not have made such a mistake, escalated his protests about this for a minute or two as he became sadder, then began crying. While weeping, P accused the therapist of pretending there had been a slip of speech to make him look bad, and then, with an outburst of anger, recalled the hurt and injury he had felt when the therapist had become drowsy in the session.

Telegram: @medical_k

www.konkur.in

Surprised at the intensity of his feelings, P recalled when his need to kiss his parents goodnight in a ritualized way had begun. It was after he had gotten and then lost a new puppy. His controlling and intrusive father had kicked P's beloved new puppy after the latter had a series of toileting accidents in the house. P was filled with authentic sadness as he recalled his revulsion and rage at his father and the way he had later comforted his dog when alone. P recalled having repeatedly unfolded and refolded the blade of his jack-knife to show his dog his weapon and swore to his dog that he would use it on his father if the latter ever tried to hurt him again. Soon after the kicking incident, P's father decided he had had enough of this messy puppy and sent the dog away while P was at school. P was bereft for a while but settled into an affectless, timid, apologetic, and passive way of being.

P responded to what he had learned about his compulsions by actively trying to suppress them and becoming more anxious. As his anxiety was explored, memories emerged of P's earlier struggle with his parents around toileting before the puppy came into his life, when he had received regular enemas from his father to control the frequency of bowel movements. Despite loving his father, P was also enraged at him for taking his dog away without even a chance to say goodbye and for the intrusive and terrifying experience of the enemas, while he was also furious at his mother for not stopping his father. P also felt humiliated that he had experienced this kind of intrusion into his body and that he had let his dog be given away by his father after swearing that he would protect the puppy from his father.

The meaning of P's specific rituals about knives and shoes became apparent in the course of his therapy as a result of his reaction to his therapist's entry into an enactment in becoming drowsy and as a result of a slip of speech that revealed aggression hidden beneath passivity and compliance. P's compulsive need to be sure that no knife blades were exposed related to the way such

Telegram: @medical_k

www.konkur.in

blades signified the threat of a terrifying assault on his father or an equally terrifying failure to protect the puppy that he loved but lost. Similarly, P's compulsive need to put shoes properly and safely on shoetrees was linked to an effort to put away the memory of and prevent any recurrence of his beloved lost puppy being kicked and injured by a shod foot. After these were clarified and P tried to control his rituals, signal anxiety emerged, and with it the recovery of memories of an earlier struggle with his parents about intrusive control of his toileting behavior.

PSYCHODYNAMIC PSYCHOPHARMACOLOGY IN THE TREATMENT OF ANXIETY DISORDERS

In addition to psychodynamic therapy as a treatment of anxiety disorders, a psychodynamic perspective informs psychopharmacologic treatment of anxiety as well as other disorders. If anxiety is a signal, then a psychodynamic psychiatrist will wonder what the advantage is of medicating it away rather than bringing the relevant conflicts into consciousness. The psychodynamic psychopharmacologist will hold this point of view in mind while formulating a treatment plan and selecting drugs and dosages. Using medications to achieve optimal capacity to do the work of therapy is a goal of psychodynamic psychopharmacology.

Psychodynamic psychiatrists attend carefully to the meaning of medications when they treat patients with anxiety and other disorders. They recognize that the way medications are prescribed and their intended and unintended effects will have important meaning for patients, whether or not there is concurrent therapy, and whether or not any such therapy is provided by the psychodynamic psychiatrist or another clinician. Psychiatrists practicing psychodynamic psychopharmacology pay attention not only to *what* to prescribe but also to *how* to prescribe. An example of this was part of the case of B, who presented with a GAD. His therapist's stance about reducing benzodiazepines so that B could bring his

Telegram: @medical_k

www.konkur.in

anxiety to the sessions led to the emergence of feelings that opened up an understanding of hidden issues in B's life.

The meaning of medications may not be the same to patients as to therapists. Psychiatrists who practice psychodynamic psychopharmacology recognize that their wish to help patients with medications may not be perceived simply as help by patients. The prescription of an SSRI to reduce anxiety may be perceived by a patient who develops sexual side effects as an intentional interference with sexual functioning. Prescription of medications, then, becomes an area in which psychiatrists may step into countertransference enactments. This was illustrated in the case of M, the woman with PTSD, whose first psychiatrist's well-intended efforts to medicate her PTSD symptoms was experienced as a replication of abuse by an intrusive and controlling boss. Her new psychiatrist's eventual recognition of this recurring between them helped strengthen their alliance and created a precedent for examining and learning from other enactments as her treatment unfolded.

There is evidence of the power of meaning effects of medication. One double-blind placebo-controlled study suggests that a patient's readiness to change is more predictive of response of panic disorder to a benzodiazepine than whether the patient is receiving an active drug or placebo. Similarly, there is evidence the quality of the therapeutic alliance may be more important for psychopharmacologic treatment outcome than medication effects. A large, multicenter, National Institute of Mental Health–supported study found that, in psychopharmacologic treatment, patients had the greatest reduction in symptoms when a strong alliance was paired with an active drug. Patients receiving placebo who had strong therapeutic alliances with their doctors had greater symptom reduction than patients with poor therapeutic alliances receiving an active drug. These studies support a basic premise of psychodynamic psychopharmacology that symbolic aspects of medications, that is, their meanings, may be as potent as the biologically active ingredients and should not be neglected in the care of patients.

32.5 Intensive Short-Term Psychodynamic Psychotherapies

MANUEL TRUJILLO, M.D.

The terms Short-Term Dynamic Psychotherapies (STDPs) and Intensive Short-Term Dynamic Psychotherapies (ISTDPs) denote a robust corpus of theories, clinical practices, and therapeutic techniques deriving from psychoanalysis, as discovered, developed, and formalized by Sigmund Freud at the end of the 19th century and the first third of the 20th century. Those short-term therapy systems that include the label psychodynamic in their self-definition usually wish to signal a strong adherence to the classical psychoanalytic metapsychology and a very extensive inclusion in their therapeutic armamentarium, of essential psychoanalytic techniques, such as the utilization of transference concepts and transference interpretations, and the use of the unconscious and of unconscious mental functions to understand the causal underpinnings of psychic conflict and to frame the development of the psychopathology of common psychiatric disorders. Finally, most of the currently active systems of STDPs use the interpretation of impulses, sexual and aggressive feelings, loss and abandonment, and shame and guilt as key therapeutic interventions.

The growth of psychotherapy in general and of dynamic psychotherapies derived from the psychoanalytic framework, in particular, represents a landmark achievement in the history of psychiatry. Most impressive is the capacity of the STDP field to meet the challenging standards of contemporary biomedical research paradigms by producing high-quality treatment research studies evaluating the therapy outcomes obtained in well-defined patient populations suffering from various psychiatric disorders such as

Telegram: @medical_k

www.konkur.in

anxiety, depressive disorders, personality disorders, and others that, together, represent a vast majority of the large and growing suffering and disability burden imposed by psychiatric disorders on most societies.

Probably because of these advances, and despite growing and spirited competition from many other biomedical and psychosocial interventions, more people are treated with psychodynamic approaches than ever before in history. Those who are treated achieve clinical results at least comparable to those treated with alternative psychological/psychosocial or biomedical approaches. In the cases complicated by the presence of significant personality pathology or substantive psychosocial problems, traumatic experiences, and psychosocial crises, the results achieved by psychodynamic psychotherapies are often superior to the clinical outcomes delivered through standard clinical management, including the use of psychotropic medications.

Since the methodologically sound meta-analysis conducted in the 1970s by Mary Lee Smith, Gene V. Glass, and Thomas I. Miller, which concluded that 75% of patients treated with psychotherapy were better off at termination and follow-up than the untreated controls, many rigorous research studies have demonstrated the efficacy and effectiveness of various models of the STDPs when treating such common disorders as anxiety and depression, selected personality disorders, certain posttraumatic stress syndromes, and selected eating and substance abuse disorders.

In 2013, the American Psychological Association's Council, after an extensive and comprehensive review of psychotherapy research studies, concluded that the general or average effects of psychotherapy are widely accepted to be significant and large and are quite constant across most diagnostic conditions, with variations being more influenced by general severity than by particular diagnoses.

The council members asserted that the results of psychotherapy tend to last longer, and be less likely to require additional treatment courses, than psychopharmacological treatments. For example, in the treatment of depression and anxiety disorders, psychotherapy

Telegram: @medical_k

www.konkur.in

clients/patients acquire a variety of life skills that are used after the treatment termination, and generally may continue to improve after the termination of treatment. Within this picture of broad effectiveness for therapies of long duration, STDPs hold a position of distinction. Systematic review and meta-analyses conducted since 2010 of the effect of STDPs on patients suffering from mood disorders, anxiety disorders, somatic conditions, and personality disorders, concluded, after reviewing studies meeting high standards of quality, that the therapies studied were clinically effective, provided respectable effect sizes, and were cost-effective compared with the control conditions. The fact that these robust outcomes were also obtained working with patients suffering from personality disorders, who are not considered very responsive to other forms of psychotherapy, highlights the potential therapeutic outcome, and the value, of these ISTDPs, designed by Habib Davanloo starting in the 1970s.

A question stemming from a public mental health perspective is, can these interventions be made readily available to the large number of patients who may benefit from them?

In parallel to the growth of research in these short-term techniques, the use of planned, psychodynamically oriented, short-term modes of treatment in clinical settings has also grown. Hanna Levenson and colleagues, in a comprehensive national survey of psychiatrists, psychologists, and clinical social workers, found that psychodynamically oriented clinicians provided a sizable proportion of all brief therapy conducted nationally. Most such clinicians acknowledged treating many patients in brief therapy and would welcome supervisory and learning opportunities to enhance their technical expertise in STDP and ISTDP. The challenge to the field is to provide such learning opportunities to sufficient number of therapists to ensure the availability of such therapies to the large number of patients who, suffering from gravely disabling conditions, remain untreated, or undertreated in the community.

The current state of the field of STDPs can thus be described as healthy. The field has developed well-documented models of treatment and has proposed specific techniques that are often

Telegram: @medical_k

www.konkur.in

codified in research-based treatment manuals. Practitioners can count on numerous well-conducted research studies to support efficacy and effectiveness claims, and large numbers of practitioners offer short-term dynamic approaches nationwide to the growing number of patients who consult them for their psychiatric disorders and life crises.

HISTORY

The Early 1900s

The history of ISTDP traces back to Sigmund Freud, in that there is reason to believe that many of Freud's early treatments lasted from a few hours to a few months. Many such early treatments were in fact training analyses conducted with psychiatrists and other clinicians traveling from locations throughout Europe or the United States with stringent travel time limits. Freud's treatment of the conductor Bruno Walter that took place in 1906 lasted a few sessions, and the composer Gustav Mahler was treated in 1908 during a 4-hour walk through the woods of Vienna for an episode of psychogenic impotence.

As the time went on, various patient factors and technical developments may have contributed to the lengthening of the course of psychoanalysis. The increasing reliance on free association as a key technical ingredient diminished, by necessity, the analyst activity and may have diffused the therapeutic focus of the clinical situation. The use of the couch and the increasing commitment to allow for the slow development of a transference neurosis may have further contributed to the lengthening of the psychotherapeutic process.

The consolidation of the early psychoanalytic technical triad of reduced therapist activity, encouragement of free association, and the development of the transference neurosis has yielded substantial heuristic fruits and has undoubtedly contributed to the construction of the vast edifice of psychoanalytic metapsychology and theory of psychopathology. The price, however, may have been the reduction of therapeutic potency for those patients for whom the nature and

Telegram: @medical_k

www.konkur.in

extent of their resistances (particularly what Freud termed superego resistances) proved impervious to the technique of free association —thus Freud acknowledged growing pessimism regarding the power of free association to overcome such powerful resistances.

The Middle 1900s

Among early psychoanalytic practitioners, Sandor Ferenczi and Otto Rank deserve credit for attempting to create alternative techniques to enhance the therapeutic effect of psychoanalysis. In their book *The Development of Psychoanalysis,* they delineated a therapeutic position that included enhanced activity of the therapist, the active development of a therapeutic focus, and the setting of time limits—a triad that was to become the core of the technical offerings of later innovators such as Peter Sifneos, David Malan, and Habib Davanloo. These investigators were also aware that when patients acquired just intellectual knowledge, without integrated affects, such knowledge may serve as resistance, and they recommended an active maintenance of the focus on affect through the course of therapy to overcome such as intellectualized resistance. In the late 1930s, Franz Alexander, by then a prominent psychoanalytic leader in Chicago, focused his efforts on a pioneering research project aimed at making psychoanalytic treatment more effective, to specify the recovery techniques (process variables) necessary to achieve such a goal, and to shorten the duration of the average course of treatment. More than 600 patients were included in his studies, the findings of which were reported in 1946 in the book *Psychoanalytic Therapy* coauthored with Thomas French.

Consonant with the work of Ferenczi and Rank, Alexander also emphasized the importance of the therapist's increased activity and the maintenance of the therapeutic focus on the patient's emotional experience—thus his emphasis on what he called the "corrective emotional experience," an experience that he considered essential to any successful therapeutic venture. Such corrective emotional experience affords the patient an opportunity to relive, in the safe and supportive presence of the therapist, the original childhood

Telegram: @medical_k

www.konkur.in

traumatic experiences that contributed to the development of the patient's neurotic symptoms and maladaptive defenses. In his 1946 book, Alexander reported therapeutic results comparable to those of long-term psychotherapy and emphasized the fact that, besides symptomatic improvement, short-term therapies can also promote significant character changes. Of note, both his belief in the therapeutic power of bringing affect into the focus of treatment and in facilitating emotional experiences in the here and now of the therapy session (inevitably related to the transference) have been substantiated again and again in high-quality research studies.

The Contemporary Situation

Starting in the 1960s, the field of STDP underwent tremendous growth. Clinicians and researchers across the United States and the United Kingdom proposed diverse short-term models anchored in the psychoanalytic tradition. Authors such as David Malan in London, Peter Sifneos in Boston, Habib Davanloo in Montreal, and others generated models of psychoanalytically based psychodynamic psychotherapies applicable to increasingly broader populations of patients and—with significant boldness—provided transcripts, audio recordings, or videotapes of treatment sessions. These authors defined in very specific terms their treatment techniques and initiated basic research strategies to examine the outcomes of their treatments. Additional models were developed by clinicians and investigators such as Mann, Horowitz, Luborsky, Strupp, and the New York Beth Israel group (Winston, Trujillo, Pollack, Been, McCullough, Laikin, and others). The Beth Israel group, and other investigators, such as A. Abbass, have contributed seminal research studies demonstrating the efficacy and effectiveness of STDP as well as its broad applicability to patients suffering from complex psychiatric and personality disorders.

CLINICAL SPECTRUM OF STDPS

Telegram: @medical_k

www.konkur.in

This chapter will describe in more detail the models proposed by Sifneos, Malan, and Davanloo as their models (which have much in common) can be ordered in a spectrum of complexity of techniques as well as of clinical severity of the pathology of patients who can benefit from them. Sifneos's short-term anxiety-provoking psychotherapy (STAPP) initiates the spectrum and occupies its relatively less complex position as it is mainly applicable to patients suffering from psychodynamically uncomplicated conditions, which can be successfully treated using basic technical interventions (development of a treatment focus, increased therapist activity, minimal to moderate resistance, and transference work). Increasing technical complexity, and patient applicability are provided by Malan's short-term model, which can be situated in the middle range of the theoretical spectrum. Davanloo's ISTDP provides more complex interventions to reach more complicated psychopathology.

Short-Term Anxiety-Provoking Psychotherapy—Peter Sifneos

Theoretical Issues. Developed by Peter Sifneos as a result of his 7-week treatment of a patient who presented to his clinic at the Massachusetts General Hospital complaining of severe anxiety, but needed to move from Boston after a few months, STAPP has found its place in the contemporary therapeutic armamentarium as a brief psychotherapy approach for patients who, having an oedipal conflict as the basis of their symptomatology, display high motivation for change, and suffer from few characterologic complications.

Typically, the oedipal dynamics lying at the core of the patient's clinical problems have to do with the conflictual aftermath of unresolved competition with the parent of the same sex for the love and affection of the parent of the opposite sex (or their surrogate). The presence of significant anxiety and the defenses deployed by the patient to counter such anxiety make it difficult for the patient to resolve such conflicts through "living," leading, as time goes on, to the development of overt clinical symptoms, subjective suffering, and/or interpersonal difficulties. Common chief presenting complaints of STAPP patients include various experiences of anxiety,

Telegram: @medical_k

www.konkur.in

alone or in conjunction with other symptoms, grief reactions, mild-to-moderate depression, somatic symptoms, and/or interpersonal difficulties unrelated to enduring character disorders.

Techniques. As Sifneos indicates, "the technical therapeutic considerations for this kind of psychotherapy are specific and clear-cut. The therapist must encourage the development of a therapeutic alliance and must create the atmosphere where learning takes place."

Taking advantage of the prevailing positive transference feeling, staying within the specified focus, and using anxiety-provoking confrontation questions, clarifications, and interpretations, the therapist must strive to clarify with the patient the conflictual impulses and feelings underlying their psychopathology, while avoiding getting entangled in pregenital characterologic issues such as passivity, dependence, sadomasochistic or narcissistic features, and acting-out tendencies, which are often used defensively by the patient and tend to prolong treatment.

Sifneos' prescription synthesizes three core technical dimensions: the use of positive transference, the active maintenance of the focus, and the avoidance of regression. Beyond this general prescription, Sifneos provides detailed descriptions of techniques covering the process of therapy and including the following domains: selection criteria, initial assessment, early and middle phases of therapy, and termination.

SELECTION CRITERIA. Sifneos summarizes his selection criteria for STAPP as follows:

1. Presence of a circumscribed chief complaint.
2. Evidence of a give-and-take or meaningful relationship in childhood.
3. Capacity to relate flexibly to the evaluator and to express feelings.
4. Above-average intelligence and psychological mindedness.
5. Motivation for change.

Telegram: @medical_k

www.konkur.in

INITIAL ASSESSMENT. Beyond the completion of a classical psychiatric history and mental status examination necessary for the development of a criteria-based clinical diagnosis following the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5-TR), the initial assessment of patients selected for STAPP treatment must provide evidence of the fulfillment of the selection criteria and must lead to the joint development of a sufficiently explanatory psychodynamic formulation, a therapeutic focus, and a therapeutic contract. Such developments are usually the result of an active and dynamic interaction between the patient and the therapist, an interaction that optimally ends in the mutually agreed delineation of therapeutic foci that clearly and succinctly crystallize the specific psychological conflicts underlying the patient's psychological problems.

THE OPENING PHASE. The goal of the opening phase of treatment is to deepen the patient's commitment to work on the mutually agreed upon therapeutic contract as delineated in the initial interviews. To accomplish that goal, Sifneos recommended the use of techniques such as high therapeutic activity, the maintenance of the therapeutic focus, the consolidation and extension of the therapeutic alliance, the use of positive transference, and the avoidance of the defensive (and regressive) use of pregenital characterologic issues.

THE MIDDLE PHASE. From the technical point of view, the middle phase of treatment has as its goal a significant working through the patient's psychological conflicts as delineated early in the treatment in the dynamic formulation and therapeutic focus. Here the facilitation of transference-based "corrective emotional" experiences is central. As depicted by Alexander, "the key to shorter therapy lies in the ability to experience and control the transference." To accomplish this task, the STAPP therapist continues to use anxiety-provoking questions, confrontations, and clarifications as they link the emerging transference feelings with similar experiences in the patient's past and/or in other areas of the patient's present life. In this phase of therapy these interpretative links should lead to new

Telegram: @medical_k

www.konkur.in

learning and healthy problem solving. To facilitate the consolidation of such learning, the therapist needs to support the emerging evidence of such growth and continue to use supportive, clarifying, educational, and insight-promoting techniques.

THE TERMINATION PHASE. Because STAPP is designed as short-term therapy with open-ended termination, the therapist must rely on evidence of significant clinical improvement before approaching the termination phase. To the persisting controversy in academic psychotherapy as to who should initiate the terminations of the therapy, Sifneos provides clarifying answers: The therapist, being more able to discern objectively the state of resolution of the patient's original conflicts, should initiate termination discussions. In practice, however, more than half of Sifneos' patients spontaneously mentioned the possibility of ending the therapy as they experienced better moods and enhanced self-esteem and enjoyed their new problem-solving capacities.

Regardless of who initiates the discussion, termination is "in the air" when evidence is provided that points toward substantial differences in the attitudes and behavioral patterns present at the initiation of therapy, and new problem-solving skills are applied by the patient to the solution of their own conflicts. Abilities such as progressive independence in the pursuit of personal goals, increasing self-assurance, and improved self-esteem signal the emergence of new adaptive capacities liberated from the shadows of the unconscious conflicts that dominated the patient's life prior to the initiation of therapy.

Clinical Issues

INDICATIONS. Clinical experience with Sifneos' techniques suggests its application to the patient who fits the following DSM-5-TR diagnostic categories:

Adjustment disorders with depressive mood, with anxiety, and with mixed anxiety and depressed mood, generalized anxiety disorder, panic disorder, selective somatic symptom disorders, illness anxiety disorders, psychological

Telegram: @medical_k

www.konkur.in

factors affecting other medical conditions, acute stress disorder, persistent depressive disorder (DSM-IV's dysthymic disorder), and major depressive disorder.

As taught by Sifneos, beyond those diagnostic parameters, these patients should fulfill the following selection criteria: relatively circumscribed chief complaint, a history of at least one personal relationship characterized by mutuality ("give and take"), ability to interact flexibly with the therapist/evaluator, average intelligence with responsiveness to insight, and motivation for change.

LIMITATIONS. As reported by Sifneos, patients with significant character pathology, excessive dependency, multiple foci of loss, or active substance abuse may not be suitable candidates for STAPP.

COMPLICATIONS. Beyond premature abandonment of treatment, the most commonly reported complications include the development of a transference neurosis that may need additional time for resolution. Fear of termination may produce clinical regressions that can, and needs to, be handled by active interpretation within the framework of the technique. This complication is more likely to appear in those cases in which one or more early losses have not appeared in the initial psychodynamic evaluation and thus have not been incorporated in the therapeutic focus, promoting its expression through distinct behaviors in the transference, such as excessive dependency and clinging, as well as through other signs of clinical regression.

CONTRAINDICATIONS. Active dependence on alcohol or other drugs needs to be addressed independently, and a period of abstinence (30 to 90 days) should be documented prior to the initiation of STAPP. Active suicidal ideation and overwhelming interpersonal, work, or financial adversity should prompt the use of crisis intervention techniques. Once the crisis situation is resolved, the use of STAPP could be considered after a careful evaluation of the stability of the patient's psychosocial situation and the restoration of sufficient ego strength.

Telegram: @medical_k

www.konkur.in

Chris, a 31-year-old single man, sought help for a moderate depressive episode precipitated by the loss of his relationship with his girlfriend, Joanna. She had broken off the relationship after approximately 1 year, tired of Chris' erratic work ethic and emotional instability, and discouraged by his fear of commitment to the future of their relationship. This cycle of infatuation, increasing fear of commitment, and relationship loss had become a pattern in Chris' interpersonal life. His work life was plagued with similar problems. Chris lost several jobs because of serious conflicts, and threatening confrontations with his superiors. As conflicts arose at both work and home, Chris typically suffered increasing anxiety and episodic panic attacks. In the aftermath of each loss, Chris usually was stunned, sad and often endured prolonged depressive episodes at times accompanied by suicidal ideation.

DYNAMIC FORMULATION. The development and delineation of an accurate dynamic formulation is an essential clinical activity in STDP. The challenge is to construct, based on the findings of the clinical situation, a clinical synthesis that links the patient's subjective symptoms with the underlying original childhood foci that determine or drive such symptoms. These genetic foci may be related to repressed unconscious impulses (aggressive or sexual) and feelings (loss, grief, self-doubts) that may have first occurred at key developmental points, and remain suppressed and unresolved. The end result of the dynamic formulation can be represented by a dynamic holographic (Fig. 32.5–1) representation of the pathogenic sequence that links deep genetic impulses or feelings with broad dynamic forces (repetitive experiences such as irritability or ready to explode anger or habitual maladaptive behaviors such as automatic opposition to authority figure). The final step of the hologram, links those dynamic forces with their surface, conscious conflicts or behavioral manifestations such as sullen withdrawal and passivity or self-destructive angry acting out.

Telegram: @medical_k

www.konkur.in

For Chris, in the foregoing case, the dynamic hologram can be represented as follows:

Life problems: Recurrent episodes of anxiety and depression; work problems; unstable interpersonal relationships; conflict with authority figures; antagonism toward, and emotional distance from, his father, brother, and other male friends; and fears of heterosexual intimacy and of commitment.

Dynamic forces: Ongoing hostility and envy toward males, authority figures, and successful people, and compulsive and possessive craving and seeking female love objects while simultaneously having great difficulties considering fulfilling, or even recognizing their independent needs.

Genetic pathogenic foci: Unconscious loss of maternal objects precipitated by birth of brother at age 2 years; uncontrolled grief for that loss with compulsive drive to experience child-like possession of love objects; and compulsive hostility toward others perceived as rivals.

PROCESS AND GOALS OF TREATMENT. The typical clinical process in STAPP can be summarized as follows:

Objective: Resolution of Oedipal conflicts

Focus/Foci: Triangular/Oedipal

Duration: From 10 to 20 sessions, lasting from 50 to 60 minutes, occurring once a week

Termination: Open

After the evaluation phase, the typical therapy process proceeds on the strength of the therapeutic alliance optimally established during the early sessions. The efforts of the therapist in the initial phase aim to enrich the dynamic formulation through an active inquiry around the foci established in the initial formulation. This active inquiry, in the case of Chris, yielded additional confirmation of the persistence of repressed sexual feelings toward his mother and the presence of hostile feelings toward all rivals for his mother's

Telegram: @medical_k

www.konkur.in

affection. A memory suffused with very visceral feelings emerged in this phase as a result of the therapist's active inquiry. In this memory, Chris saw himself in his mother's arms in a dark room. He remembered vividly the intense pleasure of the contact with the warm skin of his mother, the texture of her clothes, and the smell of her perfume. While narrating this memory to the therapist, Chris was so absorbed in the experience that he blushed intensely while describing it to the therapist. He first giggled with delight and amazement, a look of disbelief on his face, seeking the complicity of the therapist in this timeless experience of imaginary possession, and enjoyment of his mother's body. He next described the painful termination of this moment of pleasure by his father's sudden, angry forceful, and disruptive opening of the closet door, and intense pain of the flood of light that disturbed his pleasurable absorption. After this sequence, Chris felt sad and open himself to the experience of grief at this loss of the intense and exclusive bond with his mother; a loss that in his childhood he had also after his brother's birth.

FIGURE 32.5–1. Dynamic hologram.

Feeling safe in the therapeutic situation, he was able to experience again and again, the sadness, loneliness, sense of abandonment, and rage that had been all too familiar through his childhood and that recurred as well in his present life when his romantic attachments were threatened or actually lost. The affective link between this childhood experience and his intimacy problems in

Telegram: @medical_k

www.konkur.in

the present became viscerally obvious to Chris, and the acceptance of this link enhanced his capacity to work through this essential component of his pathology. A parallel conflict appeared in the transference as the patient resented the “intrusion” of the inquiring therapist into the zealously guarded privacy of this primal fantasy of maternal possession.

OUTCOMES. In addition to his role as a clinical pioneer, Sifneos deserves additional credit for his commitment to make his work visible through the pioneering utilization of the rigorous outcome evaluation of his work. In two studies, Sifneos reported respectable clinical outcomes, which included moderate symptomatic improvement, significant enhancement of self-esteem, and positive resolution of the crisis situation that initially brought the patients into treatment.

Beyond this early evaluation, Sifneos’ approach has been studied in a modified form by many clinical researchers. The work of Arnold Winston and colleagues represents an excellent investigational effort. In these studies, two forms of brief therapy based on procedures specified in therapy manuals were used. One of them, labeled STDP was based on principles developed by Davanloo. The second one—brief adaptive psychotherapy (BAP)—used a composite of brief therapy techniques and was heavily influenced by the work of Sifneos. The results of both of Winston’s studies indicate that both treatment conditions were equally effective and obtained clinical outcomes that were significantly better than those achieved by the patients who remained on the waiting-list control for the duration of the study. Of note, the Sifneos-derived BAP technique achieved better outcomes than the STDP in measures of anxiety and phobic anxiety, whereas STDP showed significant advantage over BAP on depression subscales.

Short-Term Dynamic Psychotherapy—David Malan

Theoretical Issues. The work of David Malan flows from the interest of Michael Balint and his group at the Tavistock Clinic in

Telegram: @medical_k

www.konkur.in

London, in expanding the boundaries of psychoanalysis by training general practitioners in basic psychotherapy techniques, and in developing brief psychotherapy techniques to enrich the clinical armamentarium of experienced psychoanalytically oriented psychotherapists.

Anchored in classic psychoanalytic metapsychology and theory of technique, Malan's brilliant contributions to STDP involve both technical aspects and research insights. His contributions to technique include the focusing of the therapist's interventions on the triad of impulses, defenses, and anxiety (triangle of conflict) as it plays out in relation to the therapist and to key figures in the patient's current life and the past. In this regard, Malan advocates for a comprehensive exploration of all components of the triangle of conflict and recommends a thorough working of the impulse component of the past conflict.

His contributions to research are many. By keeping the research enterprise very close to the clinical ground and to the way in which psychodynamic clinicians actually think and behave, he has fostered the meaningful generalizability and reliability of his findings. His attempts to make outcome predictions from baseline clinical data, place him as a pioneer in research techniques that later grew exponentially in the 1970s and 1980s. A key finding of his studies is that the higher the number of interpretations linking the current behavior of the patient with the past and the transference (TCP), the better is the outcome. This finding has stood the test of time and has been replicated in numerous other psychodynamic psychotherapy studies.

Techniques. The treatment process in Malan's STDP can be summarized in the following manner:

OBJECTIVE. To work through the patient's dynamic problems by linking the patient's impulses and feelings, defenses, and anxiety in relation to each relevant psychodynamic focus, while promoting "corrective emotional experiences" with the therapist in the transference. The typical outcome of such working through is

Telegram: @medical_k

www.konkur.in

increased tolerance of interpersonal conflict (ego strength), enhanced assertion, and substantial lessening of dependence. Negative feelings and pessimism are also reduced.

FOCI. Unresolved interpersonal conflicts and suppressed impulses and feelings, including feelings of abandonment and loss, links between traumatic experiences in the past, congruent situations in the present, and lived perceptions and emotions in the transference. A patient with unresolved abandonment and separation fears may come to understand the link between this fear (based on childhood abandonment experiences) and her present day compulsive neediness and clinginess. Supported by her positive transference experience, such patient may feel confident enough to endure fears of loss and initiate assertive independence in key areas.

SELECTION CRITERIA. Motivation for psychological change, response to early tentative interpretations (trial interpretations), and ability to tolerate and work with intense feelings.

EXCLUSION CRITERIA. Inability to create emotional contact between therapist and patient, extremely rigid defenses, lack of motivation for dynamic change, and the presence of risk factors for the development of intense dependency.

Therapists working within Malan's framework used all psychoanalytic technical interventions, organized around two conceptual triangles labeled the triangle of conflict and the triangle of the person (Figs. 32.5–2 and 32.5–3). The objective of treatment is the repeated, and affect-laden, clarification of defense in the triangle of conflict, which permits access to the experience of underlying impulses and feelings when anxiety is appropriately modulated. Increased awareness of formerly repressed impulses and feelings permits their elaboration and working through as they appear in the patient's current life, the past, and the transference. As noted previously, Malan observed that the higher the number of links between experiences in the current life of the patient, the past, and the transference, the better is the outcome.

Telegram: @medical_k

www.konkur.in

FIGURE 32.5–2. Triangle of conflict.

The techniques used by Malan are the ones used in standard analytically oriented psychotherapy. In addition to the clinical material spontaneously communicated by the patient or developed through the therapeutic interaction, dreams, fantasies, slips, and associations are incorporated into the clinical work.

The clinical material is kept manageable by the efforts of the therapist to keep the therapy in focus, an objective that is achieved by following Malan's recommendation to use "selective interpretation, selective attention, and selective neglect." The therapy is terminated when there is evidence of sufficient symptomatic improvement. In most cases reported by Malan, patients also achieved substantial improvements in long-standing characteriologic problems.

Clinical Issues

INDICATIONS. Clinical experience with Malan's techniques suggests its application to the patient who fits the following DSM-5-TR diagnostic categories: *Adjustment disorders with depressive mood, with anxiety, and with mixed anxiety and depressed mood, generalized anxiety disorder, panic disorder, selective somatic symptom disorders, illness anxiety disorders, psychological factors*

Telegram: @medical_k

www.konkur.in

affecting other medical conditions, acute stress disorder. Selective separation anxiety disorders. Persistent depressive disorder, dysthymic disorder and major depressive disorder. Selected personality disorders such as avoidant and dependent personality disorders.

LIMITATIONS. The range of techniques proposed by Malan can provide treatment to patients suffering from oedipal psychopathology complicated by loss and abandonment, as long as the patients have not developed too intense, character-based interpersonal defenses or express regressive trends such as diffuse pervasive anxiety, paralyzing helplessness, extensive somatization, and the like. In his series of studies, Malan and his group predicted poor outcome in patients who failed to make contact with the evaluator, remained poorly motivated after the initial interviews, or developed intense transference-based dependency.

FIGURE 32.5–3. Triangle of the person.

COMPLICATIONS. The most common complication reported in Malan's studies relates to the inability to terminate the therapy within the 40-session upper limit. In Malan's study most of these patients went on to medium-length and long-term psychoanalytic psychotherapies but ultimately achieved delayed, but respectable,

Telegram: @medical_k

www.konkur.in

clinical outcomes. Of the 30 patients treated in Malan's second study, only 1 was reported to be clinically worse at follow-up.

CONTRAINDICATIONS. As reported in Malan's studies, there were certain absolute contraindications that eliminated patients from being considered a candidate for this treatment. They included a recent history of suicide attempts, active substance abuse, history of more than one course of electroconvulsive therapy (ECT), chronic incapacitating obsessional symptoms, and gross destructive or self-destructive acting out. Whether selected samples of these originally excluded patients would be good candidates for therapy should they respond positively to trial therapy needs to be tested in additional studies.

Telegram: @medical_k

www.konkur.in

Ana, a divorced 60-year-old woman, sought psychiatric help following a severe depressive episode lasting several months. This episode, which was one of many in her life, was especially severe in terms of loss of energy, interest, and motivation, as well as in terms of the intensity of her sadness and her wish to die. Only her profound religious convictions protected her from acting on these wishes. Ana had lost a lot of weight, had trouble sleeping, experienced many nightmares, and had difficulty with concentration. She was plagued by pervasive feelings of hatred for her mother, who was by now very old, ill, and dependent on Ana, who was unable to forgive her for having abandoned her in an orphanage when she was 5 or 6 years of age.

After an extensive assessment, the dynamic formulation of Ana's problem was represented as follows:

Life problems: Recurrent depressive episodes plagued by feelings of guilt and self-reproach; problems with men involving choosing partners who are commonly cold, distant, or otherwise unavailable; involuntary and painful emotional distance from her children, friends, and other close relationships; and unproductive and unrewarding work-life, despite considerable intellectual gifts.

Dynamics: Ambivalent relationship with her mother, whom she blames for most of the tragedies of her life; guilt and need for punishment in relation to her unrelenting hatred for her mother; and pathologic grief reaction for the loss of an idealized and more optimal relationship with her mother, the one she remembers she had prior to her orphanage placement. From this focus there flows a melancholic conviction of the inevitable failure of human relationships.

Pathogenic foci: Grief and inability to mourn the loss of her mother after she was placed in the orphanage, with attendant rage and guilt; a second pathogenic focus results from her pathologic grief for the loss of her father, who, because of severe alcoholism, had abandoned the family; a move that

Telegram: @medical_k

www.konkur.in

caused the mother to place her children in an orphanage in order to be able to work and ultimately recover their care. Unconsciously, Ana had always blamed her mother for the family catastrophe, thus "protecting" an idealized view of her father, to whom she was profoundly attached.

For Ana, the initial phase of treatment focused on facilitating, through quite intense resistance, the actual affective experience of her destructive anger toward her mother, the work through of which, made possible the appearance of a modicum of empathy with her mother's painful life situation around the time she placed Ana and her sisters in the orphanage. Next, the therapy focused on Ana's father. Deep feelings of idealization, disappointment, anger, and grief were experienced with increasing clarity and intensity, frequently via displaced feelings in the transference and almost always after overcoming considerable resistance. The last phase of treatment permitted the gradual development of realistic feelings of empathy and appreciation for her mother, experienced now without the cloud of anger or the numbed emotional distancing which had accompanied such feelings in the past. The reawakening within Ana of feelings of joy and hope, as well as professional ambition also needed support and encouragement, as such "luxuries" had been blocked in her development by her feelings of guilt.

OUTCOMES. Although Malan's carefully designed and elegant research studies would not conform to today's requirements for research in STDP, they contributed rich insights to the field. Malan reported on two different naturalistic, noncontrolled samples. The results of the initial study of 21 patients were reported in Malan's 1963 book, *A Study of Brief Psychotherapy.* A replication study involving 39 additional patients was reported in 1976. Both studies generated a wealth of therapeutic insights, which have guided the field since their publication. His findings confirmed that neither severity of baselines symptoms nor their relative chronicity predicted

Telegram: @medical_k

www.konkur.in

clinical outcome at termination, whereas the presence of motivation for insight was highly predictive of success. In terms of therapeutic process, use of transference and transference–past-present links was also found to be highly predictive of positive outcome.

Malan's proposals, both in direct or modified forms, were later thoroughly tested in efficacy studies. Leichsenring's meta-analyses included several studies using Malan's STDP as one of the study groups. Probably the most rigorous test of Malan-derived STDP principles and techniques is represented by a study by Svartberg and colleagues, which showed statistically significant improvements to patients with Cluster C personality disorder suffering from anxiety and depressive disorders. This study compared STDP and cognitive therapy and found changes in symptom distress after active treatment termination which were statistically significant only for the STDP group.

Intensive Short-Term Dynamic Psychotherapy—Habib Davanloo

Theoretical Issues. Davanloo developed his technique of ISTDP in a series of clinical research projects at the Department of Psychiatry of the Montreal General Hospital of McGill University. The initial studies (conducted between 1963 and 1974) established that excellent results could be achieved working largely through interpretations on a population of highly responsive and motivated patients suffering from relatively simple psychodynamic problems. A major naturalistic research project was then designed to broaden the base of eligible patients by testing the effect of techniques designed to deal with increasing resistance. This study established for Davanloo that the combination of transference focus and special handling of resistances could be used to achieve major breakthroughs into the patient's unconscious, leading all the way to major unlocking of the unconscious, a process found to have great therapeutic impact.

These discoveries led to the development and consolidation of his technique of ISTDP and to a new theoretical understanding of the function of the human unconscious and of the role of transference

Telegram: @medical_k

www.konkur.in

and the therapeutic alliance in the therapy of highly resistant patients. For Davanloo the key therapeutic force involves the mobilization of the therapeutic alliance through a highly specialized form of interviewing designed to deal with the patient's overwhelming resistance. The second major area of scientific concern is Davanloo's views of the centrality of the process of attachment for human development and of the importance of its disruptions for psychopathology. For Davanloo, it is the severe traumatization of core attachment bonds during development what causes psychic traumas, the pain of trauma, the mobilization of primitive rage and murderous impulses, and the guilt, grief, and character distortions that one reliably finds at the core of the neurotic processes of complicated psychoneurotic patients.

Techniques. The core of Davanloo's techniques flows from his research on the twin dynamics of transference and resistance. The central aim of Davanloo's system of ISTDP is the rapid reduction or removal of resistance through the careful application of a system of planned interventions that end—when successful—in direct access to the unconscious as a result of the breakdown of the major resistance and defense systems with the attendant mobilization of the unconscious therapeutic alliance.

This planned sequence of steps to deal with resistance is what Davanloo called the central dynamic sequence. The eight technical steps of this sequence are as follows:

1. Phase of inquiry into the patient's clinical and interpersonal difficulties.
2. Pressure over the avoided or repressed feelings.
3. Mild to intense challenge to the patient's resistance: Davanloo's "head-on-collision."
4. Detection and challenge to the transference resistance.
5. Direct access to the unconscious; usually in the form of viscerally intense, sudden eruption of vividly experienced primal and primitive rage, sadness, grief, and the dominant ascent of a deep therapeutic alliance.

Telegram: @medical_k

www.konkur.in

6. Systematic analysis of the transference.
7. Dynamic exploration of the core unconscious configuration of conflict.
8. Consolidation and preparation for working through of such unconscious configuration.

The end product of this process, when successful, involves increasing visceral experience and awareness of intense murderous rage and other deep feelings, which usually appear first in the transference and which then are focused on key figures in the patient's development and childhood trauma. As these feelings burst into open, they typically bring forth deep waves of sadness and guilt, both of which are experienced deeply and viscerally in a manner that promotes the resolution of the pathogenic foci. Following the completion of the tasks of the initial interview, the therapy enters the working-through phase. Key to this phase is the ongoing affective experience of personal reactions and conflicts. The tasks of the working-through phase include the continuation of the process of resolution of previously repressed, extensive, murderous impulses and feelings.

The transformation of pathologic grief reactions into acute grief processes facilitates their resolution and contributes greatly to clinical improvement.

The process of termination is initiated when there is evidence of symptomatic resolution and of character and functional changes. In complicated cases, mourning the termination of the therapeutic relationship becomes a significant focus and the key to the prevention of repressive dependency.

The working-through phase aims at the systematic resolution of the multiple foci of conflictual painful feeling accessed in the initial interview. The following principles apply to the working-through process:

The therapist should place emphasis on the patient's actual experience of their feelings. Feelings such as intense grief reactions, sadness, and rage followed by guilt and remorse

Telegram: @medical_k

www.konkur.in

repeatedly appear in the psychodynamic focus, facilitating their working through and resolution and promoting healthy adaptive growth.

Often, as a result of the breakdown of resistance systems, the patient experiences vivid reactivation of memories and dreams, which enrich the working-through process, as long as the therapist holds the focus on the direct affective experience of the recovered memories and dreams.

Clinical Issues

INDICATIONS. *Adjustment disorders with depressive mood, with anxiety, and with mixed anxiety and depressed mood, generalized anxiety disorder, panic disorder, selective somatic symptom disorders, illness anxiety disorders, psychological factors affecting other medical conditions, acute stress disorder. Selective separation anxiety disorders.*

Persistent depressive disorder, dysthymic disorder, and major depressive disorder. Treatment-resistant anxiety and depressive disorders and chronic pain syndromes.

Major dissociative disorder (depersonalization); social anxiety disorder; obsessive-compulsive disorder; somatic symptom disorder, conversion disorder and hypochondria.

Selected personality disorders such as avoidant and dependent, obsessive compulsive and histrionic personality disorders.

Davanloo, further characterized the core psychodynamic problems presented by patients eligible for treatment through these techniques, on the basis of a descriptive sample of close to 1,000 patients. The large majority of these patients suffered from diffuse and pervasive symptoms such as anxiety, depression, and widespread somatic complaints. They displayed severe maladaptive personality and character problems, leading to significant interpersonal and work problems and to intensely self-sabotaging and self-destructive behaviors. They had clinical histories of overt (and covert) severely traumatic experiences and presented to

Telegram: @medical_k

www.konkur.in

treatment with high degrees of major resistance. The core psychopathology of these patients was dominated by the presence of highly primitive unconscious rage often directed toward multiple figures of their past who participated in their highly traumatic development or otherwise induced repeated experiences of abandonment and loss. The widespread experience of unconscious rage often led to profound feelings of guilt and grief and commonly promoted masochistic self-destructive lifestyles.

LIMITATIONS. These techniques can provide effective treatment to a large majority of patients suffering from what had been classically called severe psychoneurotic disorder and character disorders. These patients are diagnosed today with what was formerly called Axis I disorders, such as anxiety (including panic) and major depressive disorders, and with personality (predominantly Cluster C) disorders. They represent large cohorts from among the patients who seek treatment in outpatient settings and in private practice and present a serious public mental health burden because of the treatment-resistant nature of their problems and their high utilization of health and mental health resources.

As these techniques are designed to deal with impulse (rage)-based dynamics, they may reach their limits in the growing population of patients suffering from primary self-disorders such as narcissistic and borderline syndromes (self-disorders).

The treatment of self-disordered patients needs to go beyond the resolution of their unconscious rage and secondary guilt and grief. Treatment needs to reach two key components of their disorder: their severely devalued self-images and self-representations, and, more importantly, the healthy and vital self-representations that often lie dormant and repressed under the weight of more consciously experienced negative views of self. Such healthy self-representations will make possible the healthy ego development and personal growth that can be induced by treatment.

Techniques for the treatment of these disorders have been proposed, and they are reviewed later in this section.

Telegram: @medical_k

www.konkur.in

COMPLICATIONS. The most common complication of ISTDP consists of the development of a protracted or stagnant therapeutic process as a function of the therapist's inability to break through the highly elaborate structure of resistances presented by the patient at baseline. Transference-based negative therapeutic reactions might ensue and result in a temporary worsening of the presenting symptomatic picture.

CONTRAINDICATIONS. These techniques are not indicated for the treatment of psychiatric disorders such as schizophrenia, substance abuse disorders, antisocial personality disorders, or life-threatening psychosomatic conditions.

The application of ISTDP for psychosomatic and borderline disorders requires modifications of the technique. Selected problems of patients with bipolar disorder (certain maladaptive behaviors, interpersonal problems, and pathologic grief reactions) can be treated with these techniques with positive effects on the patients' overall affective functioning.

Davanloo provided numerous detailed case reports that give step-by-step descriptions of the different phases of his therapeutic approach.

The following case was treated following Davanloo's system of ISTDP.

Telegram: @medical_k

www.konkur.in

At the time of the first interviews, John was a 35-year-old professional seeking help because of a worsening of lifelong feelings of depression, hopelessness, and impotence. He had an almost delusional conviction that he was destined to catastrophic failure and that he was helpless to change the course of such a fate. A very brilliant man, he struggled to hold back his professional ambition for fear of being perceived as arrogant. He suffered from pervasive feelings of physical and intellectual inferiority and experienced severe loneliness, with the conviction that he would never be able to marry. He believed that no worthy woman would ever show an interest in him.

John was also plagued by episodes of severe anxiety, which became intensified in conflict situations. He feared any interpersonal conflict that could lead to angry words or deeds. In his struggle to suppress any remnant of anger, he had adopted an ego-syntonic, submissive, and self-effacing character structure.

The second of two siblings raised in a middle-class family, John remembered a lifetime of submission to the capricious and sadistic acts of his older brother, who tyrannized him daily through angry words and physical violence. Neither his mother (perceived as distant, sad, and helpless) nor his authoritarian and emotionally removed father ever intervened effectively to curb his brother's relentless aggression. As early as he could remember, John's subjective experience was suffused with terror. Usually, he was afraid of triggering his brother's brutal temper. Occasionally, he feared losing control of his intense destructive impulses toward his brother. Such impulses were deeply repressed and denied.

The dynamic formulation of John's problems can be represented as follows:

Life problems: Ongoing feelings of depression, sadness, hopelessness, and loss of motivation and interest; deep loss of self-esteem, with feelings of physical and intellectual inferiority;

Telegram: @medical_k

www.konkur.in

a resignation to a life of limited relational and intellectual ambitions; fear of rejection by women and fear and avoidance of falling in love due to the subjective certainty of rejection; and subjective sense of helplessness, worthlessness, and impotence.

Dynamic forces: Struggle to suppress even minimal experience of anger in any context; suppression of assertive wishes and of ambitious hopes and aspirations, and intense guilt and self-reproaches when hoping for assertion and success.

Pathogenic foci: Powerful deep unconscious destructive feelings (including death wishes and murderous impulses) toward his older brother; and parallel destructive impulses toward John's father for his lack of emotional involvement and toward his mother for her failure to prevent the abuse perpetrated by John's older brother. These foci were sharply portrayed via a particularly violent dream that occurred in the early phase of treatment. In this dream "a serial killer, in a murderous rampage stabbed and killed several members of the same family."

GOALS OF TREATMENT. Davanloo established ambitious goals for his system of ISTDP. He asserted that he aimed at a total resolution of the patient's core psychopathology, leading to a clinical situation in which the patient was symptom free and showed demonstrable structural, character, and behavior changes.

There should be visible and stable changes in the way in which the patient is related to others and used their capacity to love and work. A key component of such progress was the patient's often new ability to be in touch with and appropriately express deep feelings.

OUTCOMES AND RESEARCH. Very few studies have been conducted rigorously to assess the efficacy and effectiveness of Davanloo's STDP. In fact, in several meta-analyses of brief dynamic therapy studies conducted between 1978 and 2004, only the studies presented by Winston and colleagues purported to test the efficacy

Telegram: @medical_k

www.konkur.in

of Davanloo's STDP when compared with an alternative dynamic therapy and a wait-list control. These studies, however, have been widely disseminated, are cited by all selective meta-analytic reviews, and are often praised for their careful scientific design and clinical implementation.

In Winston's 1991 study, 32 patients with diagnoses of personality disorder were randomly assigned to two treatment conditions, and an additional 17 patients were assigned to a wait-list control group. Both therapy conditions were brief dynamic therapies, one being an STDP based on the principles of Davanloo and a second (BAP) drawing heavily on the work Sifneos. At the end of the study, the two therapy groups obtained similar outcomes (significantly better than the wait-list controls) but showed differences in outcomes in symptomatic subscales. Davanloo-based STDP obtained better outcomes on ratings of depression, whereas the Sifneos-based BAP offered better results in ratings of anxiety. Both therapy conditions demonstrated robust and clinically meaningful effect sizes (0.70 to 1.35). An expansion of the earlier study to include 81 patients reported in 1994 obtained similar results.

In a recent report by Allan Abbass and colleagues, 27 patients diagnosed with DSM-IV personality disorders (borderline, obsessive-compulsive, and avoidant personality disorders constituted 65% of the sample) were randomized for treatment with ISTDP or to a minimal contact, delayed treatment, control condition.

The ISTDP treatment was provided as outlined by Davanloo, and treatment adherence was carefully controlled. After an average of 27.7 (range 2 to 64) sessions, the ISTDP patients did significantly better than controls in symptomatic and functional measures, and these gains persisted in long-term follow-up. Of note, the treatment sample reached the normal range on the individual symptomatic scales used (Brief Symptom Inventory and Inventory of Interpersonal Problems), had an 83% reduction in personality disorder diagnosis, and achieved large reductions in the use of medications. Just as important, these patients achieved a significant reduction in functional disability.

EMERGING SHORT-TERM DYNAMIC PSYCHOTHERAPIES

Accelerated Experiential Dynamic Psychotherapy—Diana Fosha

Theoretical Issues. Building on the work of Sifneos, Malan, Davanloo, and others, Diana Fosha proposed a new model of therapy, which she called accelerated experiential dynamic psychotherapy (AEDP). This approach integrates the technical contributions of its predecessors under the aegis of an affect-centered model of relational psychodynamics; a dynamic which Fosha has later anchored in the neurobiology of attachment and affect.

Whereas the reduction of resistance by breaking through the defense of patients constituted a central tenet of Davanloo's ISTDP, Fosha proposed an alternative route to deal with such defenses: fostering the experience of deep affects and the development of an emotional bond between patient and therapist. Such bonds, by promoting feelings of safety and connectedness in the here and now, are hypothesized ultimately to reduce the need for resistance and defensiveness and to facilitate "corrective emotional" experiences of intimacy and closeness within the patient/therapist relationship.

Fosha's AEDP places the experience of affect, in the context of an emotional relationship, at the center of its understanding of normal psychic development and of the psychotherapeutic process.

Following the teachings of Donald Winnicott and Heinz Kohut, Fosha understands psychic activity as motivated by the person wishing to maximize the integrity and vitality of self-experience and the strength of meaningful attachments. In this framework, affects are, in the context of normality, deep sources of meaning and vitality and, in turn, affect frame experiences of integrity and authenticity. However, they may also become sources of suffering and anxiety when caretakers are actively destructive (through rejection, excessive criticism, or shaming) or passively destructive (by being detached, uninvolved, or absent). Affects experienced under such

Telegram: @medical_k

www.konkur.in

painful conditions may eventually overwhelm the mastery capacity of the developing ego and may make it necessary, to ensure survival, the use of increasingly complex defense mechanisms. The basic therapeutic stance of the AEDP therapist—supportive, affirming, and emotionally engaged from the initiation of therapy—is intended to create a therapeutic environment in which defenses can be momentarily withdrawn and deep feelings can become available for therapeutic reconstruction.

Techniques. The central goal of AEDP is the mobilization (and working through) of core affects and genuine experiences. According to Fosha, the key mutative agent in AEDP is the state transformation leading to the visceral experience of core affective phenomena within an emotionally engaged dyad.

AEDP aims to facilitate affective experiences such as (1) previously unbearable emotional experiences (including grief, anger, sadness, fear, and joy), (2) self-experiences (positive or negative self-images), and (3) relational experiences (feelings of closeness or distance from others), and (4) affects associated with healing and with breakthrough feelings emerging as liberation from emotional traps. To achieve these aims, the AEDP therapist can use what Fosha calls (1) relational techniques (animated by empathy), (2) restructuring interventions, using the classical triangles of conflict and triangle of person to facilitate cognitive understanding, and (3) experimental/affective interventions (facilitating deep, genuine affective experiencing).

Clinical Issues

INDICATIONS. AEDP has been used widely with a variety of outpatients suffering from the previous DSM-IV-TR Axis I disorders (anxiety disorders, dysthymia) and Axis II disorders (avoidant, dependent, and histrionic personality disorders). For patients with more severe psychopathology, such as somatoform, dissociative, and/or borderline disorders, a positive response to a “trial therapy” dose is necessary prior to the conduct of the full therapy course.

Telegram: @medical_k

www.konkur.in

Success with narcissistic personality disorders has also been reported in selected cases.

LIMITATIONS. Exclusion criteria include all psychotic disorders, bipolar disorders, major depression, impulse disorders, marked acting-out behaviors, and substance abuse disorders.

COMPLICATIONS. No complications have been reported in the AEDP literature.

Psychoanalytic Psychotherapy for Panic Disorders—Barbara Milrod and the Cornell University Group

Theoretical Issues. The psychoanalytic psychotherapy for panic disorder proposed by Barbara Milrod and the Cornell University Group shares common theoretical underpinnings and metapsychology with classical psychoanalysis but differs in its application. For these researchers, panic symptoms carry psychological meanings, and the aim of PFPP (panic-focused psychoanalytic psychotherapy) is to uncover such unconscious meanings to achieve relief. In addition, their conceptual framework assesses continuous psychodynamic conflicts which tend to be quite specific to patients suffering from panic disorders: conflicts related to separation and the development of individuality. Anxiety is often aroused in these patients when confronting abandonment or separation threats. Conscious or unconscious anger is also a common trigger of anxiety reactions, including panic.

The theoretical underpinnings of their method (PFPP) incorporate key generally psychoanalytic precepts such as the following:

1. The role of unconscious fantasies. Unacknowledged (unconscious) rage is considered by Milrod's group to be an important part of the mental life of these patients, which—in their cases—relates to the onset of panic.
2. The common presence of characteristic defenses such as reaction formation, undoing, and denial, which are extensively

Telegram: @medical_k

www.konkur.in

used by panic patients to minimize and deny anger, and protect their bonds with others.

3. The central role of transference in organizing the patient's relationship to others, including the therapist. As children, these patients often lived in fearful dependence, plagued by concerns about rejection and/or abandonment. Such concerns fueled repeated experiences of anger, which in turn exacerbated the fear of separation and loss.
4. The sudden failure of the overburdened system of defenses may lead to the onset of acute panic.

Techniques. Emerging from classic psychoanalytic metapsychology and from the common ground of psychoanalytic psychotherapy, panic-focused psychotherapy is an active, focused, interpretative technique that—at least in research projects—can be carried out in 24 sessions conducted once or twice a week. There are three phases to the therapeutic process: (1) an initial evaluation and early treatment phase normally focused on addressing the acute panic, and its surrounding dynamics, (2) a middle phase focused on the underlying core conflicts, and (3) a termination phase usually focused on the patient's substantive conflicts with separation and independence.

Techniques of work vary with the phase of treatment, but in a complete course of therapy, most of the classic psychoanalytic techniques are used. Clarifications, interpretations of impulses and feelings, and transference interpretations are covered. Affects (related to anger, interpersonal dependence, and fear of autonomy) are also mobilized and worked through.

Clinical Issues

INDICATIONS. The central indication of PFPP is the treatment of panic disorder, and this is the venue in which panic-focused psychotherapy has established its efficacy in randomized, controlled clinical trials. Many of the patients included in the reported trials suffered comorbid depression and reported improvement of their

Telegram: @medical_k

www.konkur.in

depressive symptoms as well, which may suggest the ready applicability of this technique to the treatment of depression with whatever modifications are called for as a function of different psychodynamic configurations.

LIMITATIONS. The most common current limitation of this technique relates to its specific focus or panic disorder. This limitation, however, needs to be balanced by the awareness of the public health effect of the successful treatment of panic disorder, whose patients carry a high suicide risk, suffer high rates of medical and psychiatric comorbidities, and incur very high overall medical costs.

COMPLICATIONS. The reported dropout rate of PFPP is lower than that reported for psychodynamic psychotherapies in general.

Deterioration of clinical status, worsening of panic symptoms, and the development of comorbid depression are also possible complications.

CONTRAINDICATIONS. The presence of active substance abuse, high active suicide risk, bipolar disorder, and psychosis contraindicate the use of this technique. Cognitive impairment of enough magnitude to interfere with learning represents another contraindication.

GOALS OF TREATMENT. Building on the psychodynamic formulation of panic, which understands the disorder as mediated by conflicts related to separation and autonomy and with difficulties with the recognition modulation and expression of anger, the goals of treatment are designed to facilitate the resolution of those conflictual dynamics. Thus, the initial phase of treatment brings into focus detailed and specific exploration of the feelings surrounding the onset of panic and the personal meanings evoked as associated with the symptoms of the panic episode. Goals of the initial phase (phase 1) include providing relief from panic and help to overcome the functional limitations that the disorder may impose on the patient as a function of the use of avoidance mechanisms.

Telegram: @medical_k

www.konkur.in

The goals of the middle phase (phase 2) of treatment include highlighting and working through the core dynamics of the disorder: fear of unconscious impulses (anger and sexuality) and feelings of abandonment. The goal here is to desensitize the patient to the anxiogenic effect of angry affects and to facilitate the move from dependency to autonomy while modulating fear of loss and abandonment.

Phase 3 (termination) permits the re-experiencing of conflict about reparation and dependency directly in the therapeutic situation and in relation to the therapist, thus potentially consolidating the therapeutic work of phases 1 and 2. When the treatment is successful, patients report enhanced autonomy, less fear of anger and interpersonal conflict, and acceptance and enjoyment of independence.

OUTCOMES. PFPP has been tested in an open trial and a randomized, controlled clinical trial, both of which showed a significant reduction in panic symptoms. In the second trial, twice as many experimental psychotherapy patients met response criteria at termination than patients in the control conditions, which consisted of a cognitively enriched form of relaxation therapy. In addition, PFPP showed a significantly superior reduction in the severity of a broad range of panic symptoms as measured by the Panic Disorder Severity Scale: 73% of PFPP patients versus 39% of the controls met the response criteria for panic (40% reduction in scale score). PFPP patients also achieved a significant reduction in functional impairment.

Milrod and her group presented a manualized form of psychodynamic psychotherapy for panic disorder, which they tested in a randomized clinical trial. The treatment, consisting of an open-ended number of sessions in clinical practice and of 24 sessions in the clinical trial, is conceptualized as consisting of three phases:

Phase 1 involves the treatment of acute panic, phase 2 addresses the core dynamic conflicts that support the vulnerability for panic, and phase 3 is the termination phase. The goal of phase 1 is the elucidation of the conscious and unconscious meaning of panic

Telegram: @medical_k

www.konkur.in

symptoms with the goal of obtaining a map of the personal architecture of unconscious conflicts surrounding the panic. Common themes highlight the role of separation and dependence and problems in the modulation of sexual and aggressive impulses. Key techniques in this phase of treatment include keeping the focus on the symptoms of panic, engaging in a detailed and specific exploration of the circumstances surrounding the panic experience, and providing a firm, supportive and reassuring stance that the problem can be treated and the symptoms ameliorated.

The goal of phase 2 is the reduction of vulnerability to panic by engaging and working through (often in the transference) additional unconscious conflicts related to dependence and independence and building tolerance for instinctual experiences related to anger and sexuality.

The phase of termination, by bringing to the focus the key vulnerability of these patients (separation experienced as abandonment), provides an opportunity for consolidation of the therapeutic work. Milrod and her group addressed this problem by keeping an active focus on termination for the last one third of the duration of the therapy and by helping the patient work through such fears in the context of the therapeutic relationship.

STDP of Narcissistic and Other Self-Disorders—Manuel Trujillo

Theoretical Issues. The term narcissism has pervaded popular culture and the sociologic and psychiatric clinical literatures for many decades, depicting the increasing isolation and self-oriented individualism of affluent citizens in the United States and other developed countries.

Many features of contemporary culture mirror the narcissistic traits of individuals: the pursuit of materialistic cravings and the instrumental nature of many relationships; the seeking of success for success's sake; and the cultivation of hedonic pleasure rather than the realization of ideals. In such contexts, narcissistic personality traits may be valued, adaptive, and, therefore, preferentially fostered.

Telegram: @medical_k

www.konkur.in

Witness the success of the “Master of the Universe” meme in the late 20th century.

Freud first referred to narcissism to describe a libidinal position in which cathexes were invested in the subject’s ego and not in objects. Under those conditions, true transferences could not develop, making these patients ineligible for psychoanalysis. The clinical expression of nonobject libidinal cathexes included psychotic processes.

Dynamically, significant advances have been made over the last three decades in the clarification of the metapsychological dimensions of narcissistic disorders. Two authors, Otto Kernberg and Heinz Kohut, have advanced well-developed metapsychologies for these disorders and have proposed comprehensive techniques for their treatment through appropriately modified psychoanalytically based interventions.

There are, however, fewer attempts to apply techniques of STDP to patients suffering from self-disorders, despite the fact that such techniques have demonstrated respectable efficacy in the treatment of patients suffering from complex psychoneurotic disorders, selected personality disorders, and clinical conditions such as anxiety and depressive disorders. Patients meeting criteria for these disorders have been shown to make rapid and impressive gains, as long as their dynamic problems are related to difficulties in the management of sexual and/or destructive impulses, problems in the regulation of object loss, or complex combinations of both types of pathology. Patients suffering from extensive self-pathology are typically reported to do less well, largely because the structural underpinnings of self-disorders have not been as well understood as the constructs underlying Oedipal or attachment disorders.

A significant shift in the deep psychological understanding of narcissistic disorders is represented by the work of Kohut and summarized in his book *The Analysis of Self.* Kohut advanced a complete metapsychology of self-disorders, including (1) the superordinate position of the self as a whole system organizer to which other mental agencies (e.g., drives, ego, and superego) and mental capacities (e.g., motivation, vitality, goals, and values) are, to

Telegram: @medical_k

www.konkur.in

different degrees, subordinate; (2) and the relative independence—but rich interdependence—of the development of the self in relation to the development of the other components of the mental apparatus, for example, drives, id, ego, and superego.

Kohut described the relatively independent developmental line of the self and the various disordered responses to failures of environmental support, including parental mirroring. The subjective impact of these failures is registered through deficits and distortions of the perception of self (affecting self-esteem), the relative lack of integration of ambitions and capacities (creating grandiosity, self-effacement, and/or underachievement), or the incomplete development of appropriate, socially accepted values and ideals. For Kohut, repairing these deficits requires facilitating the development of a reparative transference of one of three types: (1) mirror transference proper, involving the use of the therapist as an admiring self-object and/or the resolution of perceived therapeutic failures via empathic interpretations; (2) idealizing transference, involving the acceptance by the therapist of the patient's unconscious needs to see them as a quasi-omnipotent object, capable of soothing and consoling and (transferentially speaking) worthy of emulation; and (3) twinship transference, which allows the patient to feel like others and develop a sense of connectedness under conditions of existential equality.

In the area of the self, and thus in narcissistic disorders, the key pathogenic phenomenon is lack of integration; that is, the inability of the mind to maintain a sense of wholeness. The signal of failure to maintain self-homeostasis is the affect of shame. Its presence indicates the inability of the self to maintain sufficient wholeness and fullness. In cases of more severe pathology, fragmentation anxiety denotes the organism's fear for its own basic integrity.

A very important theoretical and practical construct in self-psychology is the developmental process that, when successful, promotes the maintenance of a coherent, whole, optimally altruistic persona. When a "good enough" environmental fit is present, this process, fraught with complexities and opportunities for derailment, facilitates vital human functions such as (1) the slow maturation of a

Telegram: @medical_k

www.konkur.in

primal boundless, grandiose self into realistic, enduring, and resilient self-esteem, personal identity, and grounded ambitions and (2) the gradual transformation of undifferentiated, global, idealizing needs into values, ideals, and a moral compass that color and mediate each person's investment in, and involvement with, external social systems of beliefs, meaning, and action.

Narcissistic psychopathology occurs via two interrelated mechanisms: (1) the failure to complete key developmental steps along the pathway just delineated. Such failure may lead to a lack of maturation, integration, and realization of large segments of grandiose self (or idealized object image) and may create split-off (or dissociated) self-object representations, which entail potential problems for identity formation for the maintenance of self-esteem, and for the development of an appropriate and satisfying system of values, ideals, and accomplishments; (2) pathologic interrelatedness of self-development with drive-developmental processes. In this regard, the presence of significant unresolved self-developmental pathology may color drive-developmental and interpersonal processes such as separation-individuation, the ability to cope with object losses, and the resolution (or lack thereof) of triangular Oedipal pathology. This clinical situation often leads to hypersexuality (sex defending from abandonment), the sexualization of violence, and to other compulsive behaviors. Kohut, in fact, stated unequivocally that clinically significant Oedipus complexes occurred because the developing child's normal drives and conflicts were disturbed and intensified by unempathic parental responses.

Once consolidated, narcissistic psychopathology is expressed via (1) painful and pervasive subjective experience of shame, emptiness, and/or fragmentation anxiety; (2) the presence of extreme intrapsychic defenses (e.g., splitting and cognitive-affective dissociation) and interpersonal defenses (e.g., distancing, feeling extreme superiority or inferiority, intense neediness, or equally unyielding indifference); and (3) symbolic or manipulative behaviors designed to restore the integrity of self by providing soothing of vicarious experiences of wholeness via symbiotic fusion. At times,

Telegram: @medical_k

www.konkur.in

such soothing is obtained through the use of addictive drugs and or compulsive sexuality.

Techniques. Therapy can be conceptualized as a process that allows the patient—via the development, experience, verbalization, and resolution of intense transferences—to reactivate primitive, dissociated, anxiety-provoking views of self and others. Once activated, a more normal developmental pathway can be resumed in which primitive self-perceptions mature and become more integrated and healthier.

INTERVENTIONS. The paradigmatic intervention for self-problems is empathic understanding coupled with active interpretations of impulses, feelings, and self-perceptions; all in a context of pervasive use of transference. In this realm empathy involves an accurate grasp, both cognitive and affective, of what others experience and its presence creates a supportive milieu. In it, the patient can either bask in the use of the therapist as an optimum self-object or, bitterly but safely, complain about the therapist's failure while benefiting from the healing effects of the possibility of resolving the damage caused by that failure.

To accomplish this task in a relatively short-term program (50 sessions or less) requires the following:

1. **Empathy.** Accurate, empathically mediated grasp of the patient's core narcissistic vulnerabilities. For many patients, these problems are hidden behind a well-cemented wall of character defenses. Thus, these narcissistic vulnerabilities are apparent only after significant breakthroughs into the patient's unconscious rage and/or grief. For this part of the process, the ISTDP techniques developed by Sifneos, Malan, and Davanloo are crucial.
2. **Transference focus.** Active and early attention to the development of various types of self-object transferences.
3. **Activation of primitive self-states.** Early detection and reactivation (largely through active inquiry) of primitive,

Telegram: @medical_k

www.konkur.in

dissociated, grand, or grandiose self-images and the containment of defensive affects, such as dissociative anxiety, fragmentation anxiety, and pervasive sense of embarrassment and shame. A simple inquiry such as “and how do you see yourself as a person now?” can bring up a mélange of primitive, childlike, exaggerated, or minimized view of self with a poorly differentiated mixture of affects such as shame, fear, pride, and others. Once all those feelings are “in the open,” the patient can do the necessary work of pruning and shaping such personal (at times idiosyncratic) views of self in order to carve a more grounded and satisfying personal identity.

4. **Imaginary reconstruction**. A special form of corrective emotional experience called “imaginary reconstruction.” This intervention permits the soothing and healing of narcissistic wounds via the imaginary reconstruction following a painful shameful, often catastrophic experience or failure of self or of a valued other. At these moments, the therapist inquiry of an imagined optimum (not perfect, but not wounding) version of the “failure narrative” often provides balsam to the narcissistic wounds. A few such interventions are provided in the case description below.

Just as the course of an episode of ISTDP treatment can be depicted by the use of the two triangles discussed earlier, the course of an episode of treatment of a (pure or mixed) self-disorder problem can be depicted as shown in Figure 32.5–4.

The typical therapy process focuses first—and repeatedly—on the overt manifestations of defensive activities, such as character defenses buttressed by splitting and cognitive–affective dissociation. Subsequent and repeated therapeutic challenges to the defenses may prompt the emergence of anxiety or paralyzing shame, and finally lead to the reactivation of formerly repressed and distorted self-representation. Distorted negative self-images are then deactivated via this exposure because the patients can see themselves more realistically and can experience and resolve the emerging grief. Positive self-images are allowed again to flow

Telegram: @medical_k

www.konkur.in

through the barriers of dissociation and are reactivated, owned (experienced by patients as rightfully belonging to them) and appropriately linked to hopes, dreams, skills, and values. In this way, profoundly personal projects of much meaning to the patient can re-emerge as valued blueprints for purposeful and meaningful life plans and actions.

FIGURE 32.5–4. Triangle of the self.

WORKING THROUGH OF RAGE. The technique of working through narcissistic rage requires a sequence of interventions that achieve (1) keeping the focus on the rage, for example, a specific memory of rage in a patient's interaction with the patient's father, (2) reactivation of the physiologic–emotional–cognitive continuum underlying the rage response to allow the patient a simultaneous visceral and cognitive experience of the rage, (3) pressure and challenges to the defenses against rage to ensure a fuller experience, and (4) pressure and challenges to the defenses against interpersonal closeness and, especially, closeness with the therapist. As the therapist acquires, via the transference, a certain standing in the patient's emotional life, the attachment to the therapist heightens the

Telegram: @medical_k

www.konkur.in

patient's ambivalent attachment to the primary object and intensifies the patient's unconscious conflict over emotional loyalty. This is yet another source of considerable resistance and active therapeutic work. Rage toward the therapist may reach murderous proportions.

REACTIVATION OF SELF

Reactivation and Integration of Self. As patients gain mastery and knowledge of their experience of rage and the pathologic grief is lessened, they are often ready to reactivate grand and grandiose self-images, and to reinitiate and complete the reintegration of such self-images both with reality and with the person's unique set of skills and personal capacities. An enhanced sense of serenity and self-regard, a capacity for confident performance of work and play activities, and increased interpersonal empathy and closeness are usual results of such processes. The work of reactivation of primal, dissociated self-images also requires clarification and correction of multiple self-distortions.

For example, for GR—the patient to be presented next case—a rather large, athletic, and physically powerful man, the self-image of utter fragility as a premature, inhumanly small baby in danger of being trampled underfoot at any moment contaminated the way he saw himself and acted physically. His hunched-over posture made him appear considerably smaller than he actually was. As the therapy advanced, he started to derive considerable pride in his body, his physical prowess, and his dress style, for which he often sought the therapist's admiration and approval. Increasingly, his dreams and fantasy life are filled with images of grandness ("I feel like the captain of my own ship"), pride, and pleasure at his own physical, mental, and emotional characteristics.

The resolution and integration of this sequence of work required a process akin to a recapitulation of the developmental work of adolescence. Much as in late adolescence, through newly developed capacities for introspection, one takes some ownership and responsibility for one's self and destiny, patients often experience a mini-recapitulation of this developmentally appropriate sequence.

Telegram: @medical_k

www.konkur.in

There is often a lessening of the earlier dependence on external mirroring and a sense of pride and pleasure at discovering, defining, and taking responsibility for one's unique personal assets and aspects; assets that can now be used to create a life of personal purpose.

Clinical Issues

Table 32.5–1.
Diagnostic Criteria for Narcissistic Personality Disorder 301.81

A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- Has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements).
- Is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love.
- Believes that they are "special" and unique and can only be understood by, or should associate with, other special or high-status people (or institution).
- Requires excessive admiration.
- Has a sense of entitlement, i.e., unreasonable expectations of especially favorable treatment or automatic compliance with their expectations.
- Is interpersonally exploitative, i.e., takes advantage of others to achieve their ends.
- Lacks empathy; is unwilling to recognize or identify with the feelings and needs of others.
- Is often envious of others or believes that others are envious of them.
- Shows arrogant, haughty behaviors or attitudes.

Narcissistic personality disorder and selected borderline personality disorder as well as the self-disorder core of many other clinical conditions such as eating disorders, certain addictions, and others.

Telegram: @medical_k

www.konkur.in

Experienced self-psychologists recognize the following additional syndromic presentations:

Primary Self-Disorders

1. Primary, overt, self-disorder: the narcissistic personality disorder, as defined by the DSM-5-TR (Table 32.5–1).
2. Covert disorder (the hidden "mirror" image of the overt narcissist): while the overt narcissist has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements), the covert narcissist may have many of the same traits but are not easily apparent; their narcissism appears as an exaggerated sensitivity to being or feeling criticized, ridiculed, devalued, or ignored.

   While the overt narcissist is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love, and they are loud and aggressive about such claims, the covert narcissist cover such traits under a façade of self-effacement and even modesty while the potent narcissistic claims remain hidden. Often their narcissistic traits are expressed through perfectionism: nothing is good enough and they can also be self-deprecating: an indirect way to claim the appreciation of others. Covert narcissist can be as angry as the overt type when feeling unjustly slighted, but instead of exploding in expressive overt rage, the covert narcissist expresses it often in passive-aggressive ways or may generate extensive revenge fantasies and actions.

   Just like the overt type, the covert narcissist believes that they are "special" and unique and can only be understood by, or should associate with, other special or high-status people, but, often unsure of the truth of such conviction of goodness, constantly searches and critiques their own self-image or behavior in search of perfection. Such self-absorption limits their capacity for empathy.

Telegram: @medical_k

www.konkur.in

3. Mixed self-disorders: disorders that reflect a mixture of narcissistic traits and conflict/drive problems. Narcissistic vulnerabilities and traits may fuel and compound many classic clinical conditions disorders, such as anxiety disorders, depressive disorders, and eating disorders.
4. Disorders mixed with other personality disorders. Pronounced self-disorder traits may color the clinical presentation and outcome of other personality disorders, such as avoidant and dependent personality disorders.

Secondary Self-Disorders

1. Disorders in which self-esteem and self-representation may be impaired through the effect of functional biologically based illnesses such as schizophrenia and bipolar disorders as they interact with the normal development of self.
2. Disorders in which self-esteem and self-representation may be impaired through the effect of structural, biologically based disorders such as attention-deficit/hyperactivity disorder in the normal process of development of the self.

The importance of secondary self-disorders lies in the fact that, if unattended, their presence may complicate the treatment and outcome of the primary disorder and force the patient to live with unresolved unconscious, defective, and pathogenic self-images. Each clinical presentation requires different interventions, priorities, and techniques.

LIMITATIONS. In addition to narcissistic personality disorders, many other psychiatric conditions affect significant aspects of the structure and/or development of the self. Patients suffering from such disorders as schizophrenia and bipolar disorders do indeed suffer impaired self-experiences and self-representations and object representations. In these conditions, such views of self and others, develop through neurobiologic alterations that may impede the structural integrity of the self. Other patients, such as those with antisocial or borderline personality disorders, may suffer from lack of

Telegram: @medical_k

www.konkur.in

ego integration or from a structural inability to develop the minimum of empathic relatedness necessary for therapy.

COMPLICATIONS. The most common complication is the development of a relatively stable transference neurosis, which requires additional time for its resolution. Negative therapeutic reactions in response to actual or perceived narcissistic injuries have been described.

Telegram: @medical_k

www.konkur.in

GR was a 44-year-old unmarried professional man who first consulted because of unbearable anxiety, depression, and loneliness. Although periodically present throughout his life, these feelings appeared in a clinically explosive form at the end of a troubled 6-month relationship with Ms. B, a divorced professional woman who was the mother of a 10-year-old girl. Ms. B ended the relationship after a few months of sustained—if unsuccessful—efforts to please GR and cater to his many needs and demands. His escalating and often frantic demands reflected a deep and potent craving for perfectly attuned attention and responsiveness to the endless flow of his physical and emotional needs. Despite all of Ms. B's efforts (now painfully recognized by the patient), he usually treated her with a mixture of cruel devaluation and condescension, forcing her to admit, in practically every encounter, her incredible luck at being with a man with his "unique" sensitivity and passion and her pitiable incompetence at "adequately" responding to him.

Dynamically, his conscious life was dominated by the need to enact scenarios of uniqueness and specialness, in a never ending quest for positive confirmation from whomever was chosen to function as a confirming self-object. Failures in this regard met with a cascade of subjective effects such as unbearable anxiety, pervasive rage, and fury, which often led to prolonged, sadistic devaluing and attacks on the hapless offender. When such a person left GR's presence, his affect shifted to intense loneliness and profound depression, often requiring immediate medical attention.

The dynamic picture for patients like this can be represented as follows:

1. Ongoing, somewhat unstable conscious experience of entitled grandness or frank grandiosity, with large segments of the patient's adaptive behavior devoted to seeking opportunities for confirmation of the patient's grand(iose) view

Telegram: @medical_k

www.konkur.in

of self and to searching for, and holding onto, complementing, confirming self-objects.

2. Storms of primitive anxiety and despair often accompanying the experience of narcissistic traumas and self-object rejections. This may include painful episodes of fragmentation anxiety, depression, and self-devaluation and prolonged experiences of emptiness. When these subjective states coincide with serious professional, health, or financial setbacks the risk of suicide is high.
3. An unconscious life dominated by negative self-images and expectations of rejection and devaluation. Such experiences color patients' conscious fears and frequently populate their dreams.

GOALS OF TREATMENT. At the end of the evaluation phase, GR's dynamic hologram appeared to have the following configuration:

Problems

- Inability to achieve reasonable success despite evident intellectual assets.
- History of stormy failed relationships with multiple women despite a craving to achieve stability, be married, and have a family.
- Chaotic life dominated by a craving for emotionally intense professional and emotional relationships (self-object-like).

Dynamics

- Ongoing and intense need for outside emotional supplies. The need to search for the perfect (i.e., all-admiring, all-giving, and nurturing) partner dominated his life to the practical exclusion of more mature relatedness.
- Primitive rage and vindictiveness triggered by perceived or actual failure of his partners to meet his unexpressed needs.
- Ongoing professional and personal self-sabotage.

Core conflicts

Telegram: @medical_k

www.konkur.in

- Profound repressed primitive, ambivalent feelings toward the maternal object, resulting in an insoluble tension between libidinal investment and sadistic-destructive derivatives in his actual relationships with women. Thus, his relationships with women typically started on a high of idealization and, just as often, crashed in a low of violent recriminations.
- Impulse/Feeling: Ambivalence toward paternal object complicated by unresolved pathologic grief, with the consequent disruption of the development of dynamically equivalent actual adult relationships.
- Self-representations: To the degree that adaptive and realistic maturation of primal grand self-representations was delayed, the patient showed incongruent behavior: The grandiose self-images were acted out in consciousness in the form of perfectionistic demands on others while the helpless self-fed enormous self-doubts and neediness.

DYNAMIC HOLOGRAM OR ROADMAP. This dynamic hologram was obtained in the initial evaluation at a time when GR was often flooded with anger, grief, and other painful feelings. The hologram represents a roadmap for the unfolding of the therapeutic experience. For this patient, therapy will proceed through repeated runs around the triangle of impulses, person, and self. The two key pathogenic foci for him are (1) the focus of self and (2) the focus of unresolved grief for the death of his father. The pathogenic capacity of each focus reinforces the pathogenic capacity of the other. The images of helplessness and utter fragility derived from his repressed, disturbed negative self-images are generated first by identification with the failed aspects of his father's life and function as a way to maintain some bond with the father. Such a bond is also reinforced by his need to expiate guilt for his unconscious murderous impulses toward his father. The trigger for such destructive feelings relates to his father's failure to act as an adequate narcissistic self-object (optimum mirror), as his father, probably immersed in his own pervasive sense of failure, was unable to recognize GR's person, accomplishments, and inclinations.

Telegram: @medical_k

www.konkur.in

The working through of these problems will require revisits to the experience of anger and destruction in relationship to the people in his current life (C) or toward the therapist (T) and subsequently toward his father (P). Multiple TCP interpretations were made before a sense of peace and emotional understanding and a modicum of closure and closeness obtained for the patient in relationship to memories of his father. Simultaneously, expressed and covert demands for closeness, support, feedback, extra time, and extra resources showed up in the therapeutic situation. The slightest disappointment in the therapist's responsiveness to such needs, evoked feelings of desolation and devastation in the session.

The previously described technique of imaginary reconstruction allowed the patient to evoke emotionally satisfying moments of perceived optimum mirroring from the therapist, often following the expression of intense anger toward the therapist as a function of real or perceived failures on the therapist's part. After one such episode, after the patient bitterly berated the therapist for not responding in the way he "needed" during a telephone interchange, the following dialogue ensued:

CLINICAL VIGNETTE

Therapist: You were obviously very disappointed with my response. What would you have wished me to say?

Patient: You know—something warm, something supportive, like "Of course, G[. . .], she should have agreed with you."

Therapist: And how would you have felt if I said that?

Patient: Relaxed, accepted, or like I have value.

Therapist: And how do you imagine I feel toward you?

Patient: Never thought of that—I think you want me to succeed, I think [with emotional conviction] you love me!

Therapist: And how do you feel about that?

Patient: Warm—Great it makes me think of my father. I think that if he would have been able to, he definitely would have loved me, how sad!

Telegram: @medical_k

www.konkur.in

Therapist: What would he have loved especially about you?
Patient: That I am sensitive, that I am creative, that I am funny.
Therapist: Because—How do you see yourself as a person now?
Patient: Just like that: Funny, creative

The ultimate goal of the therapy is the rapid reactivation of formerly dissociated positive self-images and their fuller reintegration with such dimensions of the self as hopes, dreams, and aspirations for the future and such means of self-realization as actual skills and capacities. This aim may be succinctly expressed by paraphrasing Freud's well-known dictum "Where id was, there ego shall be" as "where emptiness is, there self will be."

Mutually agreed termination of therapy with patients suffering from narcissistic personality disorder or substantive narcissistic traits requires the fulfillment of the following criteria: Significant reduction of initial clinical symptoms and substantive lessening of the interpersonal and work dysfunctions presented at the initial evaluation. From the dynamic viewpoint, a sense of agency and self-possession often appears de novo, partially replacing the overwhelming sensitivity of these patients to the negative behaviors of others.

OUTCOMES. The outcome of the treatment of these disorders has not been tested through appropriately designed research studies. Clinicians treating many of these patients report substantial gains in symptoms, interpersonal function, personal integrity, and object-relatedness. Characteristics of the treatment process, such as short duration, enhanced activity of the therapist, development of treatment foci, use of transference, and mobilization of intense affects, have been satisfactorily researched in many studies of the efficacy and effectiveness of STDP in the treatment of severe psychoneurotic and personality disorders. These studies represent a good background for the design of future studies of the treatment of self-disorders.

By the 1950s, the randomized clinical trial became the gold standard of studies purporting to demonstrate the efficacy and

Telegram: @medical_k

www.konkur.in

effectiveness of medical interventions. Since then, these trials, which have guided the development of many such medical interventions, have slowly been introduced for verbal therapies as well. By the 1970s sufficient numbers of well-conducted studies permitted the meta-analysis by Smith, Glass, and Miller that demonstrated the general effectiveness of psychotherapy when applied to the treatment a broad range of conditions. More recently, the efficacy of psychotherapy has been demonstrated for various anxiety disorders, depression, certain personality disorders, including borderline personality disorder, and selected eating and addictive disorders.

Smith, Glass, and Miller studied the outcome of psychotherapy in 475 controlled studies that fulfilled preset criteria in terms of diagnostic validity, specification of the interventions provided in both the experimental and control conditions, and the systematic measurement of outcome. The main finding established that typical patients treated in the active experimental arm of the clinical trials were significantly better than 75% of untreated controls. The therapeutic gains reported at the conclusion of the therapy were maintained at 2-year follow-up. Both behavior and psychodynamic therapies appeared to be superior to other therapies.

No separate analysis was conducted in this review of the efficacy of STDPs. To assess the efficacy of STDP in treating specific psychiatric disorders, Falk Leichsenring and colleagues conducted a more recent meta-analysis. The review included studies conducted between 1970 and 2004 and were selected for meeting stringent criteria, such as randomized, controlled trials, therapies specified in treatment manuals, verification of treatment integrity, training of therapists to preset proficiency standards, and the use of reliable and valid diagnostic and outcome measures. Core features of the STDP selected included increased activity of the therapist, focus on the core themes and conflicts defined in the initial evaluation, mobilization of affects, and active use of transference with particular emphasis on the here and now.

In this meta-analysis, STDP yielded large and significant effect sizes for target problems (1.39), psychiatric symptoms such as anxiety and depression (0.90), and social functioning (0.80), effects

Telegram: @medical_k

www.konkur.in

that significantly exceeded those attained by controls consisting of wait-list and treatment as usual. Of note, patients in the active treatment arm of the studies continued to achieve clinical improvement between termination and 1- to 7-year follow-up, as reflected in Table 32.5–2.

Table 32.5–2.
Summary of Effect of Short-Term Dynamic Psychotherapy (STDP)

Mean Effect Site	STDP Term/Follow-Up	Usual Treatment Term/Follow-Up	Wait-List Term/Follow-Up
Target problems	1.39–1.57	0.55–0.84	0.27–NA
Symptoms	0.90–0.95	0.22–0.24	0.12–NA
Social function	0.80–1.19	0.38–0.95	0.21–NA

Outcome of STDP in Specific Psychiatric Disorders

Anxiety Disorders. Although there are far fewer studies of STDP applied to the treatment of anxiety disorders than trials of CBT, those studies provide some evidence that STDP is effective in the treatment of generalized anxiety disorder, social phobia, panic disorder, and posttraumatic stress disorder. Some of these studies included comparisons between psychodynamic psychotherapy and CBT, and in most of these the two methods of treatment were reported as being equally effective.

Generalized Anxiety Disorder. Treatments developed for GAD are represented by cognitive therapy and behavioral therapies focused on anxiety management (biofeedback, relaxation). There are few studies that include well-constructed STDP therapies in the comparison arm. The results of these few studies tend to favor CBT over dynamic interventions. One well-conducted study that included

Telegram: @medical_k

www.konkur.in

99 patients randomly assigned to CBT or analytic psychotherapy showed the effect of CBT to be superior at termination but not at 1-year follow-up.

Panic Disorder. There are few studies of brief dynamic psychotherapy for panic. Milrod's group conducted several trials of manualized PFPP. In an open study of psychoanalytic psychotherapy that included 21 patients seen twice a week for 12 weeks and followed up at 6 months, they reported remission rates of 76% for the total sample and 93% for those who completed treatment.

The Helsinki Psychotherapy Study, a well-designed randomized study of the psychotherapeutic treatment of mood disorders, included a sizable number of patients suffering from panic disorder and generalized anxiety disorder. This study compared STDP (modeled after Malan's approach) with problem-solving, solution-focused therapy (SFT). In this study, 56% of patients with anxiety disorder did not meet criteria for any anxiety disorder after 7 months of STDP, compared with 42% of those in the SFT group. At 12 months, STDP patients had experienced a 34% reduction in the Hamilton Anxiety Rating Scale, compared with a 28% decrease achieved by SFT patients.

In a second study, a randomized, controlled trial of psychoanalytic psychotherapy was compared with applied relaxation training. Subjects treated with psychotherapy had significantly greater reduction in severity of panic symptoms and manifested improved psychosocial functioning. The effect size for symptomatic improvement was a robust 0.95 and for disability improvement was 0.74. Significant reductions in the score for depression, based on the Hamilton Scale for Depression, were also achieved, with a respectable 0.53 effect size.

DEPRESSION. A sizable number of reviews of psychodynamic psychotherapy trials for the treatment of depression is available. A review by Leichsenring in 2001 comparing STDP and CBT concluded that the clinical results achieved were not substantially

Telegram: @medical_k

www.konkur.in

different between the techniques. A. A. Abbass and collaborators, in a 2014 study sponsored by the Cochrane Library, reviewed all published studies in which dynamic psychotherapy lasting less than 40 hours were included.

The authors included 33 studies involving 2,173 participants and measured symptom reductions across somatic, general, anxiety and depression domains, as well as social function and interpersonal problems. Despite the studies diversity, and except for the somatic dimension, all other measures showed substantial superiority of the STDP arm of the studies over the control conditions in the short and the long term. Effect sizes increased over the long term.

PERSONALITY DISORDERS. Personality disorders represent a major challenge for clinical practice and for research due to their heterogeneity and the high level of comorbidities they share with Axis I and other Axis II disorders.

A specific meta-analysis of psychodynamic psychotherapy applied to personality disorders conducted by Leichsenring and Leibung showed robust gains in outcome domains such as target complaints, broad-based symptoms, and social functioning but did not demonstrate large outcome differences between the STDP and alternative CBT therapies. The effect size for psychodynamic psychotherapy was 1.31 versus 0.95 for CBT.

A study by Martin Svartberg and colleagues comparing STDP to CBT for Cluster C personality disorders with anxiety and depression comorbidities reported significant improvement at termination and 2-year follow-up. At the 2-year follow-up, 56% of patients treated in the STDP group and 42% of CBT patients had returned to community standards of normal functioning.

A survey by Abbass and colleagues evaluated the efficacy and long-term effectiveness of ISTDP in the treatment of patients with DSM-IV-TR personality disorders. The study compared Davanloo's ISTDP to a minimal-contact controlled condition. The most common personality disorders included in the treatment sample (borderline, obsessive-compulsive, and avoidant) corresponded to reported prevalence rates in clinical samples drawn from broadly

Telegram: @medical_k

www.konkur.in

representative outpatient facilities. The sample also exhibited high levels of interpersonal problems, work disability, and use of psychotropic medications, thus qualifying as a severe sample. The ISTDP-treated group showed superior outcomes relative to controls in measures related to symptoms, social functioning, return to work from disability, and reduced use of psychotropic medications. Most participants (86%) no longer met criteria for any personality disorder at the completion of treatment or at the follow-up assessment.

ISTDP in Other Psychiatric Disorders. The development of manualized therapies based on the psychoanalytic psychodynamic framework has fostered their application in therapeutic trials designed to assess ISTDP's efficacy when applied to a broad range of psychiatric disorders. A study of STDP in anorexia nervosa compared it with dietary advice and found no difference in body weight at termination and 1-year follow-up, although ISTDP patients reported better social and sexual adjustment. A larger trial compared ISTDP (based on Malan's approach) with specialized family therapy, cognitive therapy, and standard psychiatric care. Within a context of modest gains, all therapy conditions performed better than the control.

Although there have been a modest number of trials of ISTDP for alcohol dependence and abuse, there is insufficient evidence to support psychodynamic psychotherapy as a robust first-line therapy for these patients. Trials with cocaine-dependent patients were also inconclusive.

A study by Woody and colleagues compared a dynamic (supportive-expressive) psychotherapy condition with CBT and with drug counseling in opiate-dependent individuals maintained on methadone. Patients in all three groups showed improvements in lessened drug use, reduced criminal behavior, and improved psychological functioning. STDP showed better results than CBT in reduction in drug use, improvement in work status, and lessening of psychological problems, whereas CBT improved the patients' ability to deal with their legal problems.

Telegram: @medical_k

www.konkur.in

In a multicenter prospective trial, 157 breast cancer patients with comorbid depression were randomized to either individual STPP (intervention group, N = 78) or "treatment as usual" (control group, TAU, N = 79). As the primary outcome measure, the authors hypothesized a higher rate of remission defined as no diagnosis of depression (Structured Clinical Interview for DSM-IV) and reduction in depression score by at least 2 points (Hospital Anxiety and Depression Scale, HADS-D) in STPP versus TAU at treatment termination. Secondary outcomes mainly refer to quality of life (QoL).

In the intention to treat (ITT) analysis, 44% of the STPP group achieved highly significantly more remission than TAU (23%). STPP treatment (OR = 7.64; $p < 0.001$) was the strongest predictor for remission post-treatment; time was also significant (OR = 0.96; $p < 0.05$). A high effect favoring STPP (d = 0.82) was observed for the HADS-D score post-treatment (secondary outcome). Regarding further secondary outcomes (QoL), analyses of covariance yielded main effects for group (favoring STPP with an effect size of at least d = 0.5) for global QoL, role, emotional and social functioning, pain, treatment side effects, breast symptoms, and upset by hair loss. STPP is an effective treatment of a broad range of depressive conditions in breast cancer patients improving depression and functional QoL. The interpretations of these findings are limited by the drop-out rate (~1/3) and by delayed post-treatment assessments. Future trials may consider stepped-care approaches, tailored to patients' needs and requirements in the acute treatment phase.

COMBINED ISTDP AND MEDICATIONS. Many trials combining specific psychopharmacological agents and various forms of brief dynamic psychotherapy and CBT have supported the superiority of the combined condition over each intervention provided alone. In the treatment of panic disorder, Wiborg and Dahl studied the effect of adding psychodynamic psychotherapy to treatment with the tricyclic antidepressant clomipramine. The addition of the therapy (a manualized blend of Davanloo, Malan, and Strupp and Binder's work) significantly strengthened key therapeutic outcomes. At

Telegram: @medical_k

www.konkur.in

termination, all patients in the combined therapy conditions were free of panic. Patients in the combined therapy arm suffered far fewer relapses at 18-month follow-up (20% vs. 75% for clomipramine alone).

Regarding depression, many studies comparing psychodynamic therapy with medication have established comparable efficacy for psychotherapy and medication and the superiority of combined therapies over the medication-alone condition.

PROCESS-OUTCOME CORRELATIONS—MECHANISM OF CHANGE. Beyond established efficacy and effectiveness for specific psychiatric disorders, therapies classifiable under the umbrella term ISTDP need to refine their knowledge regarding what specific ingredients of the proposed therapy are responsible for what aspects of the process of change that determines the outcome of the intervention. Among the ingredients mentioned in the spectrum of therapies described in this section, ingredients such as the enhanced activity of the therapist, the maintenance of a relevant focus, the mobilization of unconscious affects, and the use of the transference are most often mentioned as relevant to the therapeutic outcomes obtained.

The therapeutic efficacy of those factors has been supported by well-conducted process—outcome correlation studies and selective meta-analyses. Diener and colleagues systematically examined the relationship of emotional experience and expression and the therapeutic outcome of dynamic psychotherapy through a meta-analysis of 10 independent studies. By calculating an overall effect size of the relationship between therapist-directed focus on affect and the outcome of psychotherapy, they concluded that in the sample analyzed, such focus on affect was associated with considerable patient improvement. The overall average weighted effect size across all outcomes measured was reported as significant (r = 0.30), suggesting a 30% difference in success rate for patients who received an affective therapeutic focus.

Regarding transference, transference interpretations are generally assumed to be a key treatment ingredient for psychoanalytically oriented short-term psychotherapy. Yet, despite their theoretical

Telegram: @medical_k

www.konkur.in

importance, few empirical studies have attempted to measure the long-term effects of transference interpretations in brief dynamic psychotherapy.

Glund and coworkers conducted such a study by randomly assigning 100 patients to brief dynamic psychotherapy with or without transference interpretations. Although both treatments demonstrated significant improvement after treatment termination, patients with a lifelong pattern of poor object relations benefited more from the 1-year transference-based condition than from therapy without transference interpretations, an effect that was sustained through the 4-year follow-up period. The findings of this study suggest that transference interpretations may be especially suited to improving the interpersonal functioning of patients with prior histories of poor object relationships.

Review of the growing literature on the application of brief dynamic psychotherapy to many specific psychiatric disorders has broadened the original findings of the meta-analysis of Smith, Glass, and Miller. Beyond their conclusion that the typical psychotherapy patient is better off than the untreated control at termination of the treatment, it is now possible to assert the specific efficacy of dynamic approaches when treating anxiety disorders, depression, a broad range of personality disorders and other selected eating disorders, and substance abuse conditions. Efficacy has also been established for the combination of psychodynamic therapies with medication. The challenges for future outcome research include identifying precise and specific mechanisms of change, generating additional innovative treatments for resistant conditions, and refining the technical specificity of existing psychodynamic techniques.

Psychotherapy and Neurobiology

It is to Freud's everlasting credit that psychoanalysis transformed the current understanding of mental life by contributing, for the first time in history, a scientifically grounded theory of mind. Unfortunately, his deeper ambition—to see the grand edifice of psychoanalysis anchored in the solid foundation of neurobiology—has not yet been

Telegram: @medical_k

www.konkur.in

realized. Freud was forced to abandon such ambitions, expressed in his “Project for a Scientific Psychology,” because of the immaturity of the brain science of his time, among many other reasons. In “Beyond the Pleasure Principle” Freud asserted “The deficiencies in our description would probably vanish if we were already in a position to replace the psychological terms with physiological or chemical ones. We may expect physiology and chemistry to give the most surprising information.”

He also asserted in his paper “On Narcissism: An Introduction” that “we must recollect that all of our provisional ideas in psychology will presumably one day be based on an organic substructure.”

The absence of a sound neurobiologic base with which to link his emerging discoveries about the structure of mental life forced Freud to abandon his early ambition and to concentrate his efforts on the development of a psychoanalytic metapsychology that has stood, independent of its biologic underpinnings, for more than a century and has produced abundant clinical and metapsychological fruits.

The growth of neural science in general and of cognitive neuroscience and neuropsychology in particular affords contemporary psychoanalysis a second chance to anchor classical metapsychology in a newly evolving neural science.

The following findings are highly suggestive of potential avenues for the construction of a neurobiologically anchored psychological science. Such pathways include the capacity for verbal therapies to modulate basic neurophysiologic brain functions and alter serotonergic function, modify synaptic plasticity, and changing the activation of key brain circuits in areas such as the anterior cingulated cortex, various limbic structures, the prefrontal cortex, and other brain centers that play key roles in the processing of key emotions and views of self and others.

Psychotherapy and the Modulation of Brain Function. The work of Kathleen Shear in the early 1990s demonstrated that the application of CBT to patients suffering from panic disorder appeared to reverse their pretreatment vulnerability to lactate-induced panic, raising the possibility that CBT, at a minimum, modulated the biologic

Telegram: @medical_k

www.konkur.in

cascade of events that trigger a panic episode in vulnerable patients following the infusion of sodium lactate and thus providing evidence of the biologic effect of talk therapies.

EFFECTS OF VERBAL THERAPIES ON KEY NEUROTRANSMITTERS: SEROTONIN. More evidence for the robust biologic effects of verbal therapies was subsequently produced by L. R. Baxter Jr. and his collaborators. In a study published in the Archives of General Psychiatry in 1992, Baxter investigated local cerebral metabolic rates for glucose in patients with OCDs before and after treatment with either fluoxetine or behavior therapy. After treatment, the investigators observed significant reductions in glucose metabolic rates in the head of the right caudate nucleus, a reduction not observed in nonresponding patients or in normal controls. In considering how behavior therapy could produce brain function changes similar to those caused by neurochemically specific drugs, the authors invoked the findings of Eric Kandel, who demonstrated, in the sea slug Aplysia the changes at synapses that use serotonin to mediate learned changes in stimulus-response behavior.

It is thus possible that both medication and behavior therapy achieve their therapeutic effect via the modulation of the availability of serotonin to the synapse. Although medication is reported to act by blocking the reuptake of serotonin, behavior therapy—after all, a specialized form of learning—may achieve its therapeutic effect by enhancing the functional availability of serotonin at the synapse level.

Also in the late 1990s, Heimo Viinamäki demonstrated, via single-proton emission computed tomography, the normalization of serotonin transporter densities in the medial prefrontal cortex, midbrain, thalamus, and striatum in a 25-year-old patient suffering from depression and personality disorder who received 1 year of once-a-week psychodynamic psychotherapy.

Psychotherapy and Synaptic Plasticity. A study by Arthur L. Brody and colleagues demonstrated that subjects with major depressive disorder had regional brain metabolic abnormalities at

Telegram: @medical_k

www.konkur.in

baseline that seemed to normalize equally with the application of either of two forms of treatment: the antidepressant paroxetine and interpersonal psychotherapy (ITP). In testing the hypothesis that in subjects with major depressive disorder, metabolism would (with treatment) increase in the dorsolateral prefrontal cortex (DLPFC), and decrease in the ventrolateral prefrontal cortex, the authors found that both paroxetine and ITP normalized the metabolic abnormalities defined at baseline. Specifically, both groups showed decreases in prefrontal cortex and left anterior cingulate gyrus metabolism, and increases in left temporal lobe metabolism. In discussing the potential mechanisms of action of ITP the authors invoked changes in synaptic plasticity through learning-induced retraining of implicit memory systems.

Because of ITP's special focus on improved socialization, areas of the brain associated with that function may undergo an attenuation of neuronal connectivity during such treatment. Just as signs of distress in socially isolated animals correlate with increased metabolic activity in the cingulate cortex, improvements in the socialization of depressed patients achieved through ITP may lead to reductions in the activity of the anterior cingulate cortex (ACC) and a corresponding amelioration of depression-induced negative evaluation of self and others.

A more recent study by S. Saxena and collaborators reported findings that establish the intriguing possibility that psychotherapy (CBT in their experiment) may share with medication some of their effects in brain physiology while producing their own specific effects in addition. In seeking to elucidate the nature of the brain response to brief intensive CBT for OCD, Saxena obtained positron emission tomography (PET) brain scans of patients suffering from OCD before and after a course of 4 weeks of daily intensive CBT supplemented by disorder-specific homework assignments, and compared the brain scans of patients undergoing therapy, with the brain scans of untreated controls. Treated patients, as expected, showed significant decreases in thalamic metabolic activity, and, unexpectedly, they also showed a significant increase in right ACC activity, a response that the authors considered necessary to explain the patients'

Telegram: @medical_k

www.konkur.in

response to CBT, as well as the relative rapidity and robustness of such responses. In contrast to the effect of pharmacotherapy on brain function, augmentation of dorsal ACC activity maybe a primary mechanism of action of CBT for OCD.

It is known that subregions within the ACC have different functions. A critical such function, which may mediate the effect described here, involves the conscious regulation of emotion via re-evaluation of negative emotions, suppression of excessive arousal, and suppression of amygdala-mediated negative emotionality. These effects, specific for the CBT arm of the study, tended to occur rather rapidly and were correlated with treatment response at 4 weeks.

The biologic relationship between negative affects and their modulation is central to disorders such as anxiety and depression, and it is a core paradigm that governs the psychotherapeutic treatment of these disorders. A central task of psychotherapy involves the repeated re-examination of painful memories, the experience and expression of the negative emotions associated with those memories, and the acquisition of a modulated soothing perspective. Such a sequence has also been studied in normal subjects, on whom the process of memory reappraisal has been found to be associated with improved mood, increased activity in prefrontal cortex subregions, and decreased activity in the amygdala and orbitofrontal cortex.

The results of studies examining the functional neuroanatomy underlying the neurobiologic effects of verbal therapies are summarized in Table 32.5–3.

Brain Structures Key for Psychotherapy

The Amygdala. Although every region of the brain may participate in any mental process, selected regions may have special relevance for the health (or disorder) of key mental functions and for the treatment of such problems through psychotherapy. The amygdala is probably the brain structure most commonly understood by clinicians as essential to the experience of emotions, emotional dysregulation and, conversely, emotional modulation through psychotherapy. It tends to show elevated activity in depression and posttraumatic stress; its dysregulation worsens in the presence of reduced prefrontal cortex activity (which supports key ego-functions) and improves through various means including verbal therapies. This dyad: amygdala, frontal cortex drives much of what is adaptive in humans and is capable of creating just as much emotional pain and dysfunction when it overwhelms human prudence and judgment.

Telegram: @medical_k

www.konkur.in

Prefrontal Cortex. Within the frontal lobes, in addition to the already mentioned ACC, the dorsomedial prefrontal cortex (DMPFC) is central to the exercise of top-down cognitive modulation of fear and other emotions, and to paying attention (self-awareness) to one's own (and other's) emotional responses facilitating mentalization and empathy. It executes many of the functions traditionally ascribed to the ego and to the normative superego. It also supports object relationships. It is hypoactive in depression. As long as it remains hypoactive, it limits the potential success of psychotherapy. Even without the availability of imaging technologies, the wise psychoanalytic clinicians of yore treating such patients, often insisted on affording them an initial period of therapy designed to "build up the ego," largely through being supportive, providing empathy, and supporting the patient's own efforts for tender loving self-care. Exercise however minimal in the early stages, rest, proper nutrition (protein, minerals, etc.) help as well. If necessary, treatment with stimulating antidepressants rapidly refills the empty "battery."

In the authors' own practice, they have been able to detect through neuroimaging (SPECT) significant under activity in the DMPFC in a sizable number of patients who became "stuck" in short-term therapy after an initial period of rapid progress, and who could resume their expected progress after the SPECT guided treatment of detected neurobiologic dysfunctions.

The Dorsolateral Prefrontal Cortex. A close neighbor of the DMPFC reviewed above, the DLPFC provides, under normal conditions, the basic infrastructure of the person's executive functions.

Attention, concentration, control of effort, relational processes, working memory, emotional memory, and many other functions under its control, are absolutely essential for successful adaptation to function and to people. It can also be hypoactive in depression and may contribute to the experience of loneliness, social isolation, loss of interest, and low standards of performance. In geriatric depression, the poor concentration, inability to focus, and no desire and no capacity to get much done raises the question of the

Telegram: @medical_k

www.konkur.in

differential diagnosis of dementia versus depressive pseudo dementia. Imaging studies showing hypoactive DLPFC without the widespread frontotemporal or temporoparietal underactivity usually present in true dementia, points toward a diagnosis of depression.

Neuroimaging and Basic Psychodynamic Principles

Imaging of Core Psychoanalytic Constructs. Of the many challenges that lie ahead as psychiatry and psychoanalysis continue their march toward becoming true science-based, biopsychosocial disciplines, two are really within the reach of currently emerging science.

The first challenge consists of the need to delineate the brain systems which underlie normal psychological functions, and which may signal disorder when functioning outside of defined ranges. Validated research findings are emerging, for example, which enable one to know how the temporal lobes and thalamus act in concert to modulate mood and to restrain wild fluctuations of mood in response to every day moderately challenging stimulus. Key research findings provide information as well, how the orbitofrontal cortex facilitates (or inhibits) impulsive activity, depending upon its functional state, and what conditions may lead to poor impulse control in a particular single event or situation, in response to a particular class of stimulus (sexual stimulation, risk taking in gambling) or as an expression of enduring personality characteristics.

The second fascinating task is represented by the need to re-evaluate, and if necessary reformulate, core psychoanalytic constructs, which were formulated by Freud while he waited for a robust brain physiology that would help trace neural activity as it was converted into basic mental function. As he humbly said: “The deficiencies in our description would probably vanish if we were already in a position to replace the psychological terms with physiological or chemical ones. We may expect physiology and chemistry to give the most surprising information.”

As summarized by Bradley S. Peterson and other investigators, imaging technologies can be used to develop experimental

Telegram: @medical_k

www.konkur.in

paradigms that may permit the understanding of the neural basis underpinning central theoretical constructs of psychoanalysis.

Drives and Instincts. The classical Freudian tenet that humans, as well as all living organisms, seek to maximize pleasure and minimize displeasure has been expanded by modern neuroscience into a complex theory of affects and rewards that describes numerous emotional systems served by different neural substrates. Such neural substrates, under the label pleasure, can discern and delineate and quantify various reward-systems and can help the organism to select which behaviors it enacts (or avoids) when a particular neural circuit is activated or inhibited. Thus, such circuits—and their attendant neurotransmitter(s)—may direct or even compel the organism to seek extremely risky behaviors, if driven by a severe enough “dopamine deficiency” state for example.

The nucleus accumbens and related limbic circuitry contribute to the “final reward equation” by assigning values of pleasure or displeasure to affective experiences, and the alerting/arousal system recruits the reticular formation, thalamus, amygdala, and cortex to the task of assigning personal meaning and salience to those affective experiences. Different emotional states are, in this paradigm, the result of complex and distinct interactions between the reward/pleasure systems (which promote appetitive drives) and the activation of arousal systems that assign priority to the pursuit of certain objects or activities over alternative behavioral choices. Imaging studies have shown increased activation of the nucleus accumbens and the orbitofrontal cortex while experimental subjects experience the euphorigenic effects of certain drugs, whereas the intense dysphoria experienced during abstinence correlated with metabolic underactivity of the same circuits.

As these investigations go forward, they are likely to yield a more refined theory of affects, drives, and emotions on which to create a modern psychoanalytic metapsychology and a theory of techniques built on hypotheses that can be tested in controlled studies. The role of the ego and superego as mediating agencies in the modulation of drives is as central to psychoanalysis as Freud’s theory of drives.

Telegram: @medical_k

www.konkur.in

In this area, modern neuroscience in general and neuroimaging in particular are generating seminal insights.

The relevance of frontostriatal systems is key to understanding how individuals plan, execute, and monitor goal-directed behaviors by selecting from the innumerable choices presented to them by the environment, as well as by their own perceptions, affective experiences, memories, and cognitions. Neuroimaging studies indicate that the ACC and prefrontal cortex are involved in the top-down regulation of the capacity for self-regulation through their influence on broader brain regions such as temporal and parietal cortices and the basal ganglia. Neuroimaging studies of disorders of self-regulation, such as attention-deficit disorder and bipolar disorder, have established the existence of functional disturbances of cortico-striato-thalamo-cortical activity.

These discoveries have direct clinical application as well; witness, for example the very positive clinical impact of adding anticonvulsant mood regulators to the treatment mix of patients suffering from anxiety or depressive disorders or even attention-deficit disorder, when neuroimaging determines the presence of temporal lobe over or underactivity. Under such conditions, pure antianxiety, antidepressant, or attention focusing treatments are not sufficiently effective because of the severe mood disruption precipitated by temporal disorganization.

Memory is also a core player in psychoanalytic discourse. Neuroscience research has described numerous memory systems with diverse distributions in the central nervous system. A key distinction for psychoanalysis is that between declarative and procedural memory systems. Declarative (explicit) memory is mediated by the medial temporal lobe and the hippocampus and stores conscious memory for people, places, and things. Procedural memories, on the other hand, are completely unconscious and are evident only in behavioral performance rather than conscious recall. Procedural memory involves the striatum (mediating the acquisition of skill and habits), the neocortex, the amygdala (facilitating conditioned emotional response), and the cerebellum.

Telegram: @medical_k

www.konkur.in

Many investigators have advanced the idea that a part of the unconscious (the procedural unconscious, which maps onto procedural memory) is central to key processes of psychoanalytic therapy. Early attachment relationships, for example, are internalized and encoded through procedural memory and unfold in the therapeutic process in the form of transference. Psychotherapy, in this context, represents the potential for the development of a new primal attachment relationship that may create the conditions necessary to change attachment-related, implicit procedural memory as new interactions with the therapists are internalized by the patient in corrective self-object representations. Such maybe the deepest meaning and therapeutic value of the concept of “corrective emotional experience” advanced by Franz Alexander in the 1940s and of the “moment of meaning” developed by Sanders and Stern to describe moments in the interaction between patient and therapist that break the impasse of a transference-based pattern of relatedness and advance the therapeutic relationship to a new level.

Neuroimaging and the Prediction of Outcome

The most persuasive outcome predictions have developed out of neuroimaging studies of depression. In one such study, increased activity in the rostral ACC predicted a positive response to treatment, a finding that has been replicated in other studies.

The anterior cingulate performs many functions related to conflict resolution and response to basic emotions. The central region of the cingulate (rostral subregion) may be recruited to resolve conflict between emotional stimuli or between conflictive cognitive mental contents. Thus, patients with higher pretreatment levels of activity in this area of the cingulate may be in a better position to resolve their pathogenic conflicts.

In studies related to the prediction of outcome of treatment in OCD, the orbitofrontal cortex is a key area. Neuroimaging studies have shown that lower pretreatment levels of activity predicted a good response to pharmacotherapy, whereas higher pretreatment levels or activity predicted a better response to psychotherapy.

32.6 Individual Psychodynamic Psychotherapy and Cognitive-Behavioral Therapy for Psychosis

MICHAEL D. GARRETT, M.D.

This chapter reviews the individual psychodynamic psychotherapy (PDTp) and cognitive-behavioral therapy (CBTp) of psychosis. It is organized historically, first describing clinically based psychoanalytic theories developed in the last century, then covering the newer, more research-based CBTp approaches that have evolved in the past 25 years, and finally suggesting the practical integration of both bodies of knowledge.

There is much overlap in these approaches, and there are some significant differences. Both place central importance on a close, collaborative therapeutic relationship, active listening, and a technique guided by psychological theory. PDTp, framed in a theory that assumes an open-ended receptive technique, places greater emphasis on psychological conflict, dissociated affect, fantasy, and the patient's past, while CBTp, employing a more structured technique, places more emphasis on cognition and behavior in the patient's present life. Each treatment pivots on a different foundation aiming to arrive at a similar place. PDTp seeks to bring insight and reduce suffering in the present by showing patients how psychotic symptoms are disguised expressions of emotionally charged experiences from the past. CBTp seeks to reduce suffering by marshalling the patient's capacity to examine evidence to change delusional beliefs. PDTp therapists focus on the emotional truth of psychotic symptoms; CBTp therapists focus on their literal falsity. These approaches meet and can be integrated where the heart meets the mind. Both may be of value to the same patient; at different times in treatment, patients with different needs may benefit from either approach separately or in combination.

We begin with two clinical vignettes, one of a man with psychosis treated with PDTp and one of a woman treated with CBTp. Both had a

Telegram: @medical_k

www.konkur.in

similar core psychological schema: abused as children, they were left with a psychological legacy of fear, need, rage, and expectations of mistreatment and abandonment that made it very difficult to establish stable, satisfying adult relationships.

First the patient treated with PDTp.

THE MAN WHO CHOKED PEOPLE

Bertram Karon was invited to provide psychotherapy for a man with chronic psychosis, who had been hospitalized for 10 years, a man with a history of unprovoked violence against other people in the hospital. The patient was grossly incoherent, and when he became coherent, he stuttered very badly. Review of his chart revealed that he came from a poor family, his father was an alcoholic, he had developed the stutter as an adolescent, and he had reported to sick call in the Army with a venereal infection of his mouth just before his first assault on a stranger. He would creep up behind other patients and choke them, but he had never killed anyone, as he would drop his victims when he had rendered them unconscious. After establishing rapport with the patient, in the first session Karon discovered that when he was a little boy, his mother, for minor offenses like not eating, would put a cloth around his neck and choke him. After the patient had revealed this piece of history to the therapist, he stopped choking other patients.

The patient began a subsequent therapy hour by yelling, “Why did you do it to me, Dad?” Exploring the psychotic transference, Karon learned that the patient’s alcoholic father had come home drunk one day and anally raped him. The patient’s terrible stutter was revealed to have an extraordinary cause. Latin words were discernable in the middle of his stutter. When asked if he had been an altar boy, he said, “You swallow a snake, and then you stutter. You mustn’t let anyone know.” He was extremely ashamed and guilty at having been compelled to performed fellatio on a priest. The therapist offered direct reassurance that what he had done was all right, and said, “Anyone as hungry (for love) as you were would have done the same thing.” At that point the stuttering stopped. When he started to stutter in later sessions, it was only necessary to repeat this interpretation, and the stuttering immediately ceased. As a boy the patient had turned from his mother who choked him to a father who raped him to a priest who sexually abused him. This succession of horrors drove him out of his mind. Yet his hospital record contained not one word of this history, and 10 years of confinement and treatment as usual had done nothing to allay his primary symptoms. This case illustrates how seemingly bizarre symptoms can be understood to have meaning, and how

Telegram: @medical_k

www.konkur.in

psychotherapy can ameliorate them. There are many such reports of successful psychotherapy scattered through the literature.

Now the patient treated with CBTp by the author.

Telegram: @medical_k

www.konkur.in

THE WOMAN WHOSE CAT SOUGHT TO MURDER HER

The patient was a 40-year-old woman who had made several serious suicide attempts. She reported feeling depressed, hopeless, and terrified when she came to believe that her cat was planning to murder her in her sleep. In the weeks prior to the emergence of this delusion she had been feeling unusually needy and had begun telephoning her boyfriend at work many times a day, until he began to set limits on the phone calls. She interpreted this as meaning he no longer loved her. She blamed her cat for the loss of his love.

At night when she and her boyfriend went to bed, the cat would snuggle up between them, which the patient experienced as the cat "coming between" her and her boyfriend. The boyfriend showed the cat affection, which indicated to the patient that the cat's plan to steal her boyfriend's love was working. She believed the cat planned to murder her in order to have her partner all to itself. The psychodynamic meaning of the delusion was readily apparent. Having been abused as a child and hungry for love, she felt a compelling need to be in sole possession of her boyfriend's affection.

The therapist inquired about the details of how the patient imagined the cat would kill her. The patient responded as though this should be perfectly self-evident. "You see it all the time on TV! Lions and tigers bite their prey in the neck. They bite the jugular!" The patient expected the cat to bite her jugular when she was asleep. While respecting the patient's conviction that the attack was inevitable, the therapist inquired in an off-hand manner if the patient knew where her jugular was located. She said she knew it was somewhere in the neck but did not know exactly where. The therapist commented, again in an off-hand manner, that the cat would have to have a much more precise knowledge of human anatomy than she did. While speculating where in the neck the jugular was the patient acknowledged that her being overweight and quite thick in the neck would make it especially difficult for her cat to locate her jugular. The therapist opined that the cat would certainly have one and only one chance to attack her precisely at the jugular, because as soon as she felt the cat's teeth on her neck she would surely awaken immediately and throw the cat off, compress the bite on her neck, and call an ambulance. The patient returned the next session less anxious and less depressed. When the therapist

Telegram: @medical_k

www.konkur.in

explored her change in mood, she said, “I still believe my cat plans to kill me, but I no longer believe she has the means to do it.” This positive shift in mood and decrease in depression, while not resolving the delusion entirely, was a significant gain obtained in a single session. The psychotherapy then continued to explore her relationship with her boyfriend.

Chronic psychosis is the cause of enormous suffering and individual disability. In contrast to significant advances in the treatment of heart disease, cancer, and stroke that have dramatically improved quality of life and life expectancy, most chronically psychotic patients remain functionally disabled their entire lives and live 15 to 20 years less than the general population. While medication is undoubtedly helpful to some patients at some times in some ways, compared with other branches of medicine, therapeutic outcomes in the treatment of chronic psychosis leave room for improvement. Enter and add psychotherapy.

Psychotherapy (broadly defined) is a disciplined professional interaction between a trained psychotherapist and a patient that aims to improve the patient’s quality of life by exploring the patient’s thoughts, feelings, and behaviors, with the goal of facilitating new possibilities for emotional growth and more adaptive thinking and functioning. This chapter will assume that the reader has at least some passing familiarity with such essential concepts in PDT as the existence of unconscious mental processes, unconscious fantasy, transference, and the therapist’s interpretation of psychological meaning, and CBT concepts including the existence of cognitive biases in thinking and the A-B-C cognitive sequence in which an activating event is followed by a belief about the meaning of that event, which in turn leads to an emotional and/or behavioral consequence.

Although psychotherapy is widely practiced in the treatment of non-psychotic patients, psychotherapy has for decades taken a back seat to pharmacologic treatments for psychosis. The reason psychotherapy for psychosis is so little practiced is not that psychotherapy has no value. Research to be cited in a later section of this chapter demonstrates its efficacy. Why has psychotherapy lagged so far behind medication as a frontline treatment? In the author’s view, the following issues have contributed to marginalizing psychotherapy for psychosis.

Telegram: @medical_k

www.konkur.in

1. The biggest obstacle to providing psychotherapy to patients with psychosis is the widespread belief that psychotherapy is of no value. The stunning initial successes in the work of pioneers like Harry Stack Sullivan, Frieda Fromm-Reichmann, and Silvano Arieti and the solid evidence base for CBTp should have put this mistaken idea to rest, but few people have been trained in these approaches. It is not surprising that approaches that are helpful to other patients are insufficient with patients suffering from psychosis and have left clinicians with feelings of inadequacy, failure, and pessimism about therapy for psychosis.
2. The same symptom picture might be diagnosed as “brief reactive psychosis” or “schizophrenia” depending solely on length of illness. This convention implies that schizophrenia is, by definition, a bear of a disease that never gets better. Such fatalism embedded in diagnostic practice allows clinicians to be complacent about poor outcomes rather than to press hard for better treatments.
3. Understanding the psychology of psychosis requires the clinician to empathize with levels of anguish not often encountered in everyday life. Clinicians may take for granted that psychotherapy can help patients with non-psychotic depression and anxiety because they know from personal experience that talking things through with the right person can help, but when they see little connection between ordinary mental life and psychotic symptoms, the utility of talk therapy for psychosis may not be intuitively obvious.
4. The introduction of the neuroleptic drug chlorpromazine (Thorazine) in 1954 led to the dramatic amelioration of acute psychotic symptoms in many patients. The observation that effective neuroleptics diminish dopamine transmission led to the dopamine theory of schizophrenia, which added credibility to the idea that schizophrenia is simply a brain disease, and as such is more likely to respond to medication than to psychotherapy.
5. The obvious efficacy of neuroleptics in relieving some psychotic symptoms fueled a backlash against the unfortunate hypothesis that the “schizophrenogenic mother” was the cause of psychotic illness, but this needed course correction went too far in the other direction, lending support to the idea that psychological factors are of little importance.
6. Freud did not believe that psychotic patients formed a transference that could be analyzed in a conventional psychoanalytic treatment, and so had no faith in the efficacy of psychoanalysis, at least as he

Telegram: @medical_k

www.konkur.in

practiced it, for psychosis. With some notable exceptions, the psychoanalytic community mirrored Freud's attitude and largely abandoned the care of the severely mentally ill.

7. PDTp failed to establish itself not only because it was crowded from the scene by biologic treatments, but because a classical psychodynamic approach is rarely effective without a modification of technique. Psychodynamic therapists have paid too much attention too early to the unconscious psychological meanings of psychotic symptoms, and too little attention to the patient's conscious experience of the psychotic symptoms. Pioneers of PDTp have often been mythologized as exotically talented clinicians who could do what the average well-trained clinician could not. In fact, doing effective PDTp and CBTp is well within the range of most clinicians in public clinics when they are provided with specialized training and supervision.

The time has come to give renewed consideration to the place of individual psychotherapy in the treatment of psychotic individuals. Not only is individual psychotherapy often effective, but there is also mounting evidence of the limitations of neuroscience and psychopharmacology. A recent review by a group of prominent neuroscientists (Stephan et al., 2016) concludes "… few, if any, breakthroughs in basic scientific research have led to substantive improvements in psychiatric clinical practice." What is psychiatry missing? The CATIE study found that newer medications are not decisively more effective than older drugs and cause serious side effects of their own, including metabolic syndrome and diabetes. Two recent studies suggest that structural changes in the brain correlate not only with total period of untreated psychosis but also with total exposure to neuroleptics, that is, both psychosis and the drugs used to treat psychosis may damage the brain. A recent review of the traumagenic neurodevelopmental hypothesis suggests that the brain changes typically attributed to a primary brain disease may reflect changes in the hypothalamic-pituitary-adrenal axis and dopamine system in response to psychological trauma. These studies suggest that psychiatrists should aim for the lowest dose of medication possible for the shortest period of time. Psychotherapy may help to achieve this goal.

In the author's experience, effective psychotherapy can reduce the necessity for dosage increase, poly-pharmacy, and inpatient admission. Consider an example that illustrates the possibilities for combining medication and psychotherapy.

THE WOMAN WHO HAS NEVER BEEN RE-HOSPITALIZED

A 30-year-old woman with a chronic paranoid psychosis with a 6-year history of treatment as usual, with 3 to 4 hospitalizations a year and intermittent homelessness, was referred to the author for psychotherapy. She had failed multiple neuroleptics including clozapine (Clozaril) and was being prescribed a high dose of aripiprazol (Abilify) at the time of initiating psychotherapy. In the course of a 5-month, once-a-week CBTp treatment, the patient understood for the first time that her belief that she was being pursued by thugs, her conviction that she was being monitored through a computer chip in her body, and her experience of "voices" telling her she was a child abuser were all manifestations of an illness (the convention "voices" will refer to verbal auditory hallucinations). Aripiprazol was titrated downward to a lower dose but could not be stopped without a flare-up of psychotic symptoms. She attends session every other week and has never been readmitted. During her 18 years in treatment she suffered two significant recurrences of paranoid ideas and ideas of reference, both of which were worked through psychotherapeutically without recourse to increased medication or hospitalization.

HISTORY

In the interest of brevity, one can divide the history of PDTp after its beginnings in the early 1900s into two schools, a European Kleinian School heavily influenced by the ideas of Melanie Klein that was active in the first half of the 20th century, represented by Hannah Segal, Wilfred Bion, and Herbert Rosenfeld, and an American Interpersonal School based on the ideas of Harry Stack Sullivan that has been influential from the mid-20th century on, represented by Harry Stack Sullivan, Frieda Fromm-Reichmann, Silvano Arieti, and Harold Searles. See the review by Michael Stone for a more comprehensive listing of contributors. The history of CBTp, which began in the early 1990s, will be covered in a later section, "Cognitive-Behavioral Therapy for Psychosis."

Psychodynamic thinking about schizophrenia began at the Burghölzli Mental Hospital in Zurich, Switzerland when Eugen Bleuler, M.D. became Director in 1898. He emphasized the importance of psychological

Telegram: @medical_k

www.konkur.in

"complexes" in the formation of psychotic symptoms. Carl Jung worked there during Bleuler's tenure. Jung recalled that most psychiatrists at the time paid attention to diagnosis but ignored the meaning of psychotic symptoms.

Jung described a psychotic woman who had spent many years in the hospital and made stereotyped, repetitive, seemingly meaningless gestures. He read her chart and found an entry that was years prior describing these gestures as a "cobbler's motion," that is, like the movement a cobbler would make drawing a thread through leather in a shoe he was holding between his knees. The patient died shortly after Jung met her, and her elder brother came for the funeral. Jung asked him, "Why did your sister lose her sanity?" The brother told Jung that she had been in love with a shoemaker who had not wanted to marry her, and when he rejected her, she had "gone off the deep end." Jung concluded that the shoemaker's movements represented the heartbroken patient's identification with her beloved cobbler, a way of keeping her sweetheart with her psychologically despite his having rejected her in reality. In short, he broke her heart, she lost her mind, and she remained "married" to him in gesture until death did her part.

Paul Federn was one of the few analysts in Freud's circle with significant experience treating psychotic patients. He emphasized the concept of the "ego boundary," a fundamental idea in the psychoanalytic theory of psychosis. Federn believed that the fundamental problem in schizophrenia was that the ego boundary that ordinarily separates thoughts and feelings from perceptions is faulty, allowing the content of the unconscious to spill into consciousness, where it is perceived as reality.

THEORETICAL ISSUES

In both psychodynamic and CBT literature on borderline personality disorders (e.g., work by Kernberg, Fonagy, Meares, Linehan, and Young), one finds research-based efforts emphasizing specific deviations from ordinary psychoanalytic or cognitive-behavioral treatment required for that population. Although there is a small, clinically based psychoanalytic

Telegram: @medical_k

www.konkur.in

literature on “supportive therapy” and treatments of schizophrenia, comparable refinements of theory and technique have yet to be fully realized and widely practiced in the treatment of individuals with psychosis.

As clinical technique should derive from research-supported theory, let us turn to the psychodynamic theory of psychosis. Despite disagreements about the relative importance of biologic and psychological factors in the etiology of psychosis, there is substantial agreement among psychodynamic theoreticians about its fundamental psychology: *Psychotic states represent the intrusion into adult mental life of primitive psychological processes that are ordinary in childhood; these early processes normally recede from consciousness by the time a person reaches later childhood (the “latency” period) but they re-emerge in psychosis*.

These intrusions of early mental life are of two sorts. First, individuals in psychotic states utilize *primitive cognitive processes* similar to those operative in the first years of life. Instead of thinking a thought and expressing it in verbal symbols, or feeling a feeling that is subjectively located within the psychological boundary of the self, psychotically disturbed individuals experience a body sensation or experience a distorted perception of the outside world that expresses feelings and thoughts that a non-psychotic person would express in words. For example, instead of thinking the thought, “I am a bad person” a psychotic individual might *perceive* a “voice” saying, “You are a bad person.” Federn called this failure to distinguish between subjective experience and perceptions of the outside world a *breakdown of the ego boundary*. This confusion of thought, feeling, and perception plays a significant role in the formation of ideas of reference, hallucinations, and delusional beliefs.

Second, *primitive object-related phantasies* (more on this language later) that ordinarily operate in the first years of life re-enter consciousness in psychosis and dominate the person’s experience of relationship with other people and the world, shaping the content of delusions and hallucinations and the narratives that patients construct to explain their lives. For example, while normal children might play at being king or queen, treating their parents as vassal subjects while resisting efforts to spoil the fun and expose the game as play-acting, people with schizophrenia might make a literal claim to being a king or queen,

Telegram: @medical_k

www.konkur.in

insisting that family members and clinical staff bow to their will, and resisting efforts to characterize their belief as illusory.

What remains unconscious in psychosis and in non-psychotic conditions, respectively, is different. The psychotic person, while closer to primitive childhood mental life, is not consciously aware of using archaic mental processes to keep painful thoughts and feelings about real life outside conscious awareness.

Although there is widespread psychoanalytic agreement about the intrusion of primitive psychological processes in psychosis, historically there has been disagreement about how to deal with these intrusions psychotherapeutically (see Table 32.6–1). Because Federn viewed the psychotic process as a defect in the brain's ability to invest internal mental events with sufficient "ego feeling" to mark them as belonging to the self, he advised clinicians not to encourage the emergence of unconscious material and to harbor no ambition to interpret unconscious processes. Instead, they should attempt to compensate for the patient's defective ego boundary by supportive reality testing. His approach is echoed in current-day psychosocial programs such as day hospitals, supportive housing, and employment arrangements that center treatment in a clinical team rather than a single therapist. Federn's concern that exploratory psychodynamic treatment might undermine the reality-testing of psychotic individuals is mirrored in the empirically unproven belief of some in the 1980s that psychotherapy for patients with psychosis is ineffective or even harmful.

Followers of Melanie Klein, in contrast, advocated a direct interpretation of primitive thinking with no modification of classical psychoanalytic technique. They regarded the "psychotic transferences" that then emerged in treatment as important opportunities to make interpretations revealing the unconscious ideas dominating patients' experiences.

Also, in contradiction to Federn's ideas, analysts in the American Interpersonal school of Harry Stack Sullivan sought, above all, to establish trusting relationships with patients that would facilitate their ability to open a dialogue. They did not encourage the development of a psychotic transference, however, nor regard it as the essential focus of therapeutic change. Rather, they would interpret transference distortions when they interfered with the therapeutic alliance. Sullivanians made interpretations at the interface between patients' subjective experiences of painful situations in childhood, latency, and adolescence and the meaningful

trusting relationship with the patient.

THE PSYCHOLOGY OF PSYCHOSIS

These pioneers, despite their differences, all tried to reduce the apparent distance between psychotic processes and ordinary human psychology. If one can't understand psychotic states psychologically, how can one hope to treat them psychologically? How can one relate the seemingly bizarre symptoms of psychosis to ordinary human psychology, and in so doing forward a psychological theory of psychosis and a rationale for psychological treatment? Addressing these questions begins in an understanding of the psychology of young children that can be inferred from direct child observation and clinical experience.

The experience of newborns and infants under 4 months old, as best we can determine, consists of isolated fragments of somatic sensations associated with perceptual images that have not yet been integrated within the boundary of an organized self. The newborn does not know yet that the hand in its immediate visual field of vision is *its* hand. Children do not recognize themselves in a mirror until roughly 18 months. Very young children do not know that sensations are part of their own personal subjective experience. As development proceeds, consciousness moves beyond somatic perceptions to increasingly complex "mentalized" forms of experience, allowing for symbolic representations, verbal thought, and conscious and unconscious phantasy.

Klein came to believe that early in life, experiences are organized and represented mentally in "phantasy" as *internal object relationships* between psychological "objects," where the self and an "other" (the *object* of the child's interest) are connected by an affectively charged link: the self is doing something to the object, or the object is doing something to the self. This chapter adopts her use of "phantasy" to refer to primitive unconscious phantasies, and "fantasy" to refer to conscious daydreaming. Given that human beings are fundamentally interdependent social animals, it is not surprising that human phantasy is organized in an object-related form. In object relations theory the primitive self defends against painful mental experience by splitting into two primal psychological

Telegram: @medical_k

www.konkur.in

objects, a pristine self that attempts to preserve its freedom from pain by identifying itself with a natural state of being phantasied to be pain-free, and a persecutory object that is causing the pain by intruding upon what would otherwise be the satisfactions of the primitive self. In this construction, human suffering does not arise from internal conflict, but is rather caused by persecutory attacks of elements experienced as outside the self.

This basic tendency to split off the pristine self from a persecutory object is apparent in childhood stories and their adult derivatives (Superman is all good; he does not cheat on his taxes. Lex Luther is all bad; he doesn't spend weekends volunteering at soup kitchens for the homeless). This psychology leaves many residuals in adult mental life. For example, during a headache we may say, "My head is killing me." We are imagining two psychological objects, a "me" that in its natural state would be headache-free were it not for the murderous activity of the head, and a "head," a persecutory object intruding pain into the otherwise pain-free "me." In psychotic illness, this split between the self and a persecutory object becomes the basic psychological structure of a paranoid delusion. The fundamental tendency to split the mind into contrasting mental representations of self and persecutory object is the source of the ubiquitous human tendency to blame others for our failings and sorrows; for example, the train is responsible for my lateness (not my failure to leave early enough); a particular ethnic group is responsible for society's social ills, and so on.

Child observation suggests that phantasy begins pre-verbally. Susan Isaacs described a 20-month-old child with delayed speech development who saw her mother wearing a shoe with a loose sole that was flapping about. The child screamed in terror, and for a week would shrink away if she saw her mother wearing any shoes at all. At 2 years 11 months, when she was able to express herself verbally, she suddenly asked in a frightened voice, "Where are Mummy's broken shoes?" Her mother reassured her that she had sent the frightening shoes away, to which the child replied "They might have eaten me right up." The child at 20 months had seen the shoe as a threatening mouth but could not express this phantasy verbally. Her conception of the shoe as a dangerous mouth can have no other origin than her psychology. Her oral aggressive impulses were projected outside the self and experienced as though residing in the shoe. In this phantasy, the internal danger posed by the child's aggression

Telegram: @medical_k

www.konkur.in

is transformed into a danger threatening from outside the self; that is, an intra-psychic conflict has become an interpersonal problem between two internal objects, with the persecutory object experienced as located in the outside world. A similar process happens in psychosis, when a man in a state of great internal turmoil conceives his difficulty as an external threat from the Mafia or CIA.

In the first 3 years of life, the child's conception of the world is dominated by projected elements of its own mental life; for example, the shoe is a mouth. This developmental period can be characterized as a two-person psychology in which the child feels inherently related to particular persons. Young children live in a psychic world in which what they feel and think is experienced as real. The girl who was frightened of the shoe was not telling her mother "I am having a phantasy that your shoe is a scary mouth, but I know it is just a shoe." Rather, she *saw* the shoe as a threatening mouth. The child's state of feeling *is* the child's reality during this early phase, and its perception of the world is conditioned by its emotions. This is also the case in psychosis.

Peter Fonagy and Mary Target distinguish two modes of cognitive functioning in young children, the stage of "psychic equivalence" in which whatever is psychically experienced is felt as real, and the "pretend mode," in which ideas are representational but their correspondence with reality is not examined, allowing children to play at pretend games. Consistent with the preoccupations of young children, the primitive object-related phantasies that predominate in the first 3 years of life often have oral and anal themes, such as shoes that bite. The child's experience of eating becomes the body-based metaphor for the psychological processes of *introjection* and *identification*, via which aspects of the environment are taken into the self; defecating becomes the body metaphor for *projection*, in which aspects of the self are extruded and deposited in mental representations of psychological objects outside the self.

In effect, in the service of defense, the mind appropriates the body processes of taking in and pushing out content and transforms these processes into psychological defenses. At this maturational stage, the mind is like an open international border where heavy trucks rumble back and forth day and night, exporting projected psychic content and importing it back again after it has been modified by the external environment. Residuals of these early, body-grounded mental processes remain in adult

Telegram: @medical_k

www.konkur.in

metaphors such as “That’s food for thought!”, where the comprehension of an idea is conceived as the ingestion of a satisfying food, a sort of mental “good breast” experience. When we say, “I had to swallow my pride” we mean “I didn’t abandon my pride. Rather, I temporarily hid it in an interior body space from which it can safely re-emerge when the coast is clear.”

If young children are to achieve a firm sense of being real in a real world, they must grow out of their experience of the world as projected fragments of the self. How does this happen? Donald Winnicott, a practicing pediatrician and psychoanalyst, described how a secure attachment to an empathic mothering figure becomes the developmental base for a child’s experience of reality. Winnicott’s “good-enough mother” responds empathically to the child’s authentic strivings while not imposing an alien agenda on the child’s gradually emerging unique identity. The child’s earliest experience of the external world is its encounter with the mother’s body, especially the breast. The empathic mother, attuned to the baby, learns to read the infant’s communications so as to feed the baby when it is hungry, and change the diaper when it is wet, and not the other way around.

As described by Winnicott, we can fancifully imagine the baby’s experience of hunger and feeding as, “I was feeling uncomfortable just now. I was starting to imagine something that would eliminate the discomfort when suddenly, as if by magic, the breast appeared. Then I knew I was trying to imagine something like a breast all along. I am of this world. I am in sync with this world. The world sees my existence.” The empathic mother delivers the real world to the child at an opportune moment of need and thereby builds a bridge between the child’s psychic reality and the real external world.

Children who find sufficiently resonant correspondences between their mental states and the outside world turn toward reality and begin to feel real in a real world. A child whose authentic stirrings are not met empathically may turn inward and begin living as a “false self” that merely reacts to the impingements of others rather than expressing its authentic nature. If the world returns no resonant ping to a child’s sonar probe, the child adapts to living in a dead world that appears to not know the child’s true self is alive. In some family systems, the child is recruited to fulfill the psychological needs of others in the family, in which case the family environment impinges upon and distorts the development of the child’s authentic individuality. This impingement beggars the self, leaving the

Telegram: @medical_k

www.konkur.in

child little base from which to build a sustaining sense of interpersonal competence and independence, a state of vulnerability that can predispose to psychosis.

Some children suffer not only impingements of their authentic identity but overt abuse. Research in the last two decades has shown that adverse life experiences in childhood or young adult life, including sexual and physical abuse, physical and emotional neglect, and being bullied, are associated with a two- to threefold increase in the incidence of psychosis in adulthood. The fact that the risk for delusions has been seen to increase more than 10-fold in people who have been raped and who also manifest symptoms of PTSD suggests that what is typically diagnosed as schizophrenia may, for many people, be a form of complex PTSD in individuals biologically predisposed to the neuropsychological aberrances observed in psychosis. Auditory hallucinations appear to have a particular association with sexual abuse. Several research studies that have looked for links between trauma and the content of psychotic symptoms have all found that the content of psychotic symptoms often reflects the historical details and themes of abuse particular to the individual. For example, Corstens and Longden found that in 94% of 100 cases of auditory hallucinations, it was possible to clearly formulate the underlying emotional conflicts resulting from trauma that was embodied in the voices. Such links between the content of psychotic symptoms and trauma have important implications for the psychotherapeutic treatment of psychosis because they demonstrate that psychotic symptoms should not be regarded as meaningless products of a broken brain but rather displaced and distorted memories of traumatic experiences that have reshaped the psychotic person's experience of their social reality.

In secure, empathic environments, the primitive unconscious phantasies of early childhood fade over time, but when the social environment impinges upon a child's authentic self when these phantasies are active, they do not fade. Cumulative disappointments give rise to painful conscious fantasies and unconscious phantasies that are reinforced. These will influence how later life experience is perceived and given meaning, and may leave people with such experiences feeling they have no space for tolerable living. What others have described as the pre-psychotic child's difficulty with separation and individuation from a symbiotic relationship with the mother can be viewed as a massive impingement of caregivers on the authentic independence of the child.

Telegram: @medical_k

www.konkur.in

Recall the little girl who was frightened that her mother's shoe would eat her. Oral experiences are important to young children, who often phantasize about biting and eating, and being bitten and eaten. Frightening oral themes of this sort appear in fairy tales and also in psychotic delusions. In "Hansel and Gretel," a famine descends upon the land, and a terrible mother plans to leave her two children to die in order to conserve the limited food supplies for herself. The children narrowly escape being eaten by a witch. Little Red Riding Hood and her grandmother are both eaten by a wolf who has assumed the grandmother's clothing.

Compare the internal world of a psychotic man from a chaotic family with a drug-addicted mother and absent father, who suffered a delusion composed of primitive oral phantasies. He reported that he had developed a cancer when at birth his mother touched his penis (the mother has put a "persecutory bad object" into him in the form of the cancer), and that this cancer now coated all his internal organs (the "bad object" is about to engulf him). Because he feared that medication would disturb a delicate balance between his organs and the cancer, giving the cancer the upper hand, he refused all pharmacologic treatment. In phantasy, taking medication would destabilize his resistance to the persecutory object. This man was frozen in a state of terror in which he feared his true self would disappear inside a bad object (the cancer) and be annihilated. In effect, his delusion is a horrifying version of "Hansel and Gretel" and "Little Red Riding Hood" with no happy ending, a personal fairy tale with a readership of one.

Telegram: @medical_k

www.konkur.in

Similarly, a 30-year-old man with two prior psychotic episodes reported in a first psychiatric consultation an intense anxiety he associated with his belief that a terrible drought was about to occur, which had led him to fill his apartment with many gallons of stockpiled water. At the end of the consultation, the patient said, “You have asked me a lot of questions. Can I ask you some questions?” The therapist said he would be happy to answer any questions the patient had relating to his treatment. The man then asked how old the therapist was, was he married, did he have children, and where did he live? Before offering any answer the therapist stated, “I am wondering why it is important for you to know the answer to these particular questions.” The patient responded in a matter-of-fact tone as though the reason were perfectly obvious. “If I am to model myself after you, I must know everything about you! I must know details.”

A primitive phantasy of being deprived of essential oral supplies, akin to the famine of fairy tales, emerged in his delusion of an impending drought. He imagined his relationship with the therapist as equivalent to swallowing him whole; that is, indiscriminately absorbing attributes of the therapist’s identity into himself. Before swallowing the therapist and taking on his identity (just as the wolf swallowed Little Red’s grandmother and assumed her identity) the patient sought to determine in detail what the therapist was made of, so as not to ingest a toxic persecutor inadvertently. Indeed, the devil is in the details. In psychosis there is regression to Fonagy’s “psychic equivalence” mode, in which what is felt to be real is experienced as being real.

Segal called this cognitive process “symbolic equivalence”; other writers have referred to “concrete thinking” or the experience of projected parts of the personality as “things.” Segal describes a women who, when non-psychotic, wrote a story depicting her mother and the analyst as being *like* a Lancashire witch (a fantasy), but when psychotic, believed the analyst *was* a Lancashire witch (a concrete metaphor that constitutes a delusion). Franz Kafka’s famous story *The Metamorphosis*, in which Gregor Samsa comes to experience himself as a monstrous insect, can be viewed as a psychotic sequence beginning with Samsa’s feeling of being a nobody, an anonymous functionary in an industrial society, thus being *like* an insect, then experienced as the concrete metaphor that he *is* an insect. In the

Telegram: @medical_k

www.konkur.in

“psychic equivalence” mode, if two people or things share a common attribute, they are experienced not as being similar, but as being the same.

This primitive mode of psychic functioning can be observed in young children trying to figure out what categories different objects belong to. One imaginative 3-year-old who was delighted to receive a paper origami bird requested “More ohwogamee!,” but burst into tears when offered an origami flower. “That not ohwogamee!” Are all instances of “ohwogamee” avian? Does a folded paper bird belong to the category “paper” or “bird”? In psychosis, instead of figurative metaphorical thoughts of the “X is like Y” variety that form a basis for consensual symbols, individuals aggregate disparate objects and people that share some quality of emotional significance to themselves in a single identity, like a child sorting experience according to categories different from those of most adults.

Such “X = Y” statements, when reported to clinicians, are seen as delusions. For example, a man diagnosed with schizophrenia reported that a nurse’s aide on the inpatient unit, who had a last name with four letters in common with his mother’s name, was in fact his mother in disguise. This primitive type of cognition forms a basis for a variety of delusional beliefs and ideas of reference in psychosis.

In his description of what others have called “concrete thinking,” Arieti describes how in psychosis, thinking regresses to “paleologic” or “predicate logic” (according to the Von Domarus principle), where parts or attributes of a person or thing become equated with the whole. This regression in psychosis has a psychodynamic purpose. When people in psychotic states try to think about their lives and feelings, clear thinking that maintains discernable symbolic emotionally charged connections between thoughts and events can be unbearably painful. Concrete thinking damps down the symbolic emotional resonance of thought, thereby blurring its clarity and emotional significance, making it harder for the patient to think clearly to a painful endpoint.

Concrete thinking also turns attention away from intolerable internal experience, outward to the perception of concrete objects and external entities. But the suffering that the patient wishes to avoid nevertheless persists in disguised form, hidden in plain sight in the suffering associated with psychotic symptoms. A psychotic person continues to suffer mightily, but achieves a modicum of relief by displacing the suffering away from the

Telegram: @medical_k

www.konkur.in

core interpersonal relationships that gave rise to the pain and projecting it outward into mental representations of the real world.

For example, a psychotic woman who was conflicted about her wish for a life insurance payout following her husband's death developed a delusion that her father-in-law intended to kill her to steal the money. Hospital staff were unable to confirm the existence of any insurance policy, and there was no evidence the father-in-law wished her harm. She reported seeing a red car drive by her home and concluded that the driver was her father-in-law (who had a red car), circling in the neighborhood with plans to kill her. Her paleologic equation of any driver of any red car with her father-in-law degraded her ability to think clearly in her bereavement. Instead of feeling her pain over her husband's failure to provide a comfortable inheritance for her, she dealt with her guilt over her wish to profit from her husband's death by becoming preoccupied with an external danger. Greed and murderous feeling have gone missing from her mind and reappeared in the imagined mind of her father-in-law.

In the 4th and 5th years of life, the "psychic equivalence" and "pretend" modes evolve into a more fully developed "theory of mind," in which the child can distinguish between dream images, thoughts, and real things, and appreciate that others may have thoughts and feelings that different from those of the child. The stage is set for the three-person psychology of Freud's oedipal period, where the child registers the parents' relations to each other and also begins relating to a wider network of people. Table 32.6–2 depicts the normal course of development of children: mental life before age 3 is dominated by primitive phantasies and metaphors for body processes, especially taking in external objects and extruding internal ones. As the child grows up, the fantastic, primitive two-person psychology of early childhood is gradually replaced by more realistic mental representations of others.

Examples of the disappearance of fantastic conceptions of the world in favor of more realistic representations include the disappearance, normally around age 8, of beliefs in Santa Claus, the Easter Bunny, and the Tooth Fairy. Just as the Wizard of Oz is revealed as an ordinary man operating a hand crank, not a phenomenal being wielding a magic wand,

Telegram: @medical_k

www.konkur.in

such entities become understood as parental inventions. This change is shown in Table 32.6–2 as the gradual increase of more realistic mental representations of others, progressing through latency and adolescence into young adulthood.

phantasies re-emerge in young adulthood.

The psychotic man who feared a drought:

"If I am going to model myself after you, I must know everything about you."

THE IMPACT OF LESS THAN OPTIMAL FAMILY RELATIONS IN SOLIDIFYING PRIMITIVE UNCONSCIOUS PHANTASY

Tolstoy's observation that "Happy families are all alike; every unhappy family is unhappy in its own way" might be rephrased here as "Happy children are all alike, but unhappy children who are vulnerable to developing a psychotic illness are each unhappy in their own way." Because the failures in development that make people vulnerable to psychosis can take many forms, the roads to psychosis are as varied as there are different patterns of troubled development. Just as no single gene has been identified to account for all instances of psychosis, no single psychological dynamic has been implicated in all cases of psychosis. There are many fault lines along which the mind can shatter. In some cases there is a massive failure in the early caretaking environment that ushers in the psychosis, or an evident trauma such as physical or sexual abuse, rape, or persistent bullying at school, but in many cases no such massive trauma is apparent.

In ordinary mental life a person might remark in response to a severe upset, "I almost lost my mind!" implying they felt like they were approaching the abyss of madness without falling in, but close calls of this sort fail to convey the profound alteration of a psychotic person's relationship to reality. Individuals who have suffered too grievous hurts in life culminating in a succession of social failures may not be able to step back from the abyss. Some autobiographical accounts of psychosis describe a near voluntary letting go of reality, a surrender to the enveloping tide of psychosis in the face of the seeming impossibility of meeting the ongoing demands of everyday life. To grasp the enormity of this transformation the average person might ask how much pain they would need to be in to wake up one morning and decide to not go to work,

Telegram: @medical_k

www.konkur.in

to renounce the prior premises of family life with one's partner, children, friends, and extended family, to live instead in a private world where one's urgent concerns cannot be shared with anyone for fear of being labelled crazy. The high incidence of psychosis in abused children suggests that mistreatment by caregivers results in a legacy of pain sufficiently intense to drive a person to abandon a consensual reality in which they are unable to live. In her book *I Never Promised You a Rose Garden*, Joanne Greenberg describes in detail such a flight from and return to reality over the course of her psychotherapy.

Arieti observed the so-called "schizophrenogenic mother" in less than 20% of families, and found that most parents of children who became psychotic were loving and concerned. Karon makes the important point that psychological processes in parents that may predispose to psychosis in children often operate outside the parents' conscious awareness. The caregivers fail to give the child what is needed but do not harm the child intentionally; in such cases both child and parent may be victims of the parent's unconscious psychology. In most cases, the erosion of good-enough development occurs gradually, one disappointment at a time, one failed interpersonal exchange after another, until the young person's psyche can no longer hold on. After having failed to achieve a positive standing in the peer group despite repeated efforts to do so, the about-to-be psychotic person one day surrenders and says simply, without much fanfare, "I'm done. I give up."

In her account of her psychosis and psychotherapy with Fromm-Reichmann in her book *I Never Promised You a Rose Garden*, Joanne Greenberg describes her mother and father as loving parents desperate to help her, but not knowing how. In her case, her psychosis issued from the accumulation of many factors—her younger sister's birth, traumatizing urologic surgery at age 5, the impinging presence of her charismatic, demanding maternal grandfather (who to a great extent defined her parents identities and accordingly hers), a move away from a familiar neighborhood where she felt safe, and the anti-semitic bullying she encountered in summer camp.

Telegram: @medical_k

www.konkur.in

Greenberg describes her retreat from the real world, where she found it impossible to live, into a psychotic world she called Yr, inhabited by a host of magical delusional characters with their own language, personas as beautiful, compelling, and terrifying as in any fairy tale. She hears the “voice”of a hallucinated being named Anterrabae, who says to her “Bird-one, you are not of them.” Which confirms her conclusion that she is impossibly misfit to the real world. As she descends into psychosis, her sense of self disintegrates, and her mind drifts away from verbal thought that would require her to think clearly about her pain, toward a succession of images and sensations characteristic of the pre-verbal mental processes of early childhood.

www.konkur.in

A black wind came up. The walls dissolved and the world became a combination of shadows. Seeking for the shadow of firm ground on which to stand, she was only deceived again when it warped away like a heat mirage; she looked toward a landfall and the wind blew it away. All direction became a lie. The laws of physics and solid matter were repealed and the experience of a lifetime of tactile sensation, motion, form, gravity, and light were invalidated. She did not know whether she was standing or sitting down, which way was upright, and from where the light, which was a stab as it touched her, was coming. She lost track of the parts of her body; where her arms were and how to move them. As sight went spinning erratically away and back, she tried to clutch at thoughts only to find that she had lost all memory of the English language and that even Yri was only gibberish. Memory went entirely, and then mind, and then there was only the faster and faster succession of sensations, unidentifiable without words or thoughts by which to hold them. These suggested something secret and horrible, but she could not catch what it was because there was at last no longer a responding self. The terror, now, could have no boundary.

How can we conceive of the ways adverse experiences trigger psychosis? To be psychologically significant, an event must, by definition, have personal meaning for an individual, whether that meaning is good or bad. Because the unconscious phantasies laid down in childhood become the foundation of the adult's system of meanings, inferences about significant life events are inevitably linked to, and elaborated by, unconscious phantasy. We pass a test, and the world appears to welcome us; we fail a test, and the world turns away, and so on, in the ongoing, never-ending cascade of meaning that is the human psyche. Unconscious phantasy always operates in the background of conscious experience,

Telegram: @medical_k

www.konkur.in

inevitably shaping our thoughts, feelings, and actions over the course of an ordinary day. Most such phantasy is not experienced as an ego-dystonic intrusion, but rather as a source of value, meaning, and goal-directedness.

When we have a sense that we are *overreacting* to an event, we know we are experiencing the intrusion of an unconscious phantasy that is emotionally coloring our view of the event. We know that what has just happened is somehow not as bad as we have felt it to be. With cognitive effort, and in a brief time, we can usually temper our overreaction. The unconscious phantasy that lent its overcharged emotions to the experience fades, and we go on with our day. But when a traumatic event or succession of events kindles powerful emotions that resonate with primitive unconscious phantasies that have been reinforced by early failures of development, we may become convinced that a scene expressive of our primitive unconscious phantasies is actually happening now, in reality. Any feeling person can empathize with the reactions of helplessness, rage, fear, and betrayal of someone raped by a parent or sexually abused by a priest—or both, as was true for Karon's patient.

But in psychosis, the enormity of what has happened goes even deeper. A child who desperately wants a parent's love and needs the parent's protection with the intensity that only a vulnerable child can feel, who is instead used like a condom and thrown away, may not be able to bear such events within an integrated experience of self. As the trauma resonates with the deep object-related phantasies of early childhood, the mind begins to vibrate with pain, then shake, then fall apart into pieces. At the deepest levels of the psyche, where the most joyous phantasies of loving others should ordinarily reside and give hope at times of adversity, a sort of wholesale genocide of good psychological objects occurs. The psychotic person's mind then becomes a fragmented collage of fantastic figures that tend to be all good or all bad.

This experience of one's worst unconscious anxieties coming true is accompanied by a pervasive terror that has been termed *annihilation anxiety*. On the brink of psychosis, the self sees itself beginning to fall apart and disintegrate. As individuals descend into the "psychic equivalence" mode, where what they feel is experienced as real, primitive unconscious phantasies surface in consciousness as delusions, hallucinations, or other psychotic symptoms, whereby the psychotic person's thoughts and feelings are expressed in a psychotic "fairy tale," in

Telegram: @medical_k

www.konkur.in

idiosyncratic concrete metaphors, and in altered perceptions of other people and the outside world.

The author once supervised the psychotherapy of a young woman, Samantha, who routinely sat down to what on the surface was expected to be a warm family dinner where one might be expected to say such things as “How was school today?” or “Can you pass the potatoes?” knowing that within three hours her father would likely be raping her. When she was unable to bind this experience within an integrated view of herself and the world, her mind fell apart, first into two pieces in addition to the self, and later into four. She began to hear the ‘voice’ of a “good angel” on her right shoulder, and a “bad angel” on her left. The bad angel urged her to kill herself, the good angel to stay alive. As she descended further into psychosis, she came to hear three distinct “voices,” that of “Darryl,” who combined traits of her violent father and a fantasied older brother who might have defended her; “Baby,” who cried and was weak, who represented the needy child who had been betrayed; and “Tamika,” who was brash, irreverent, street-wise, so tough she could not be hurt. She described how the Tamika “voice,” like a professional wrestling match where one wrestler tags off to another, would command her to take certain actions when she felt at a loss as to what to say, feel, or do. Her psychotherapist established a trusting rapport, which over time allowed her to put Humpty Dumpty back together again. Samantha came to understand that the states of mind composed of her cast of hallucinated characters were aspects of her own feelings. Darryl’s violence and Tamika’s indifference evolved into a confident self-assertiveness that allowed Samantha to stand up for herself without need for recourse to auxiliary internal objects.

Here are examples of how different family constellations may predispose to psychosis by impinging upon the good-enough development of children, leaving them unhappy in their own way. In good-enough development, parents support independence when the growing child shows this developmental striving but allow dependence when needs for reassurance and security are paramount, as is particularly apparent in the practicing and rapprochement phases of development

Telegram: @medical_k

www.konkur.in

described by Mahler. If we keep this empathically alternating relationship between parent and child in mind as a central arc of development that leads from the nuclear family out eventually into the adult world, the disturbances that predispose to psychosis can be viewed, broadly defined, as a disturbance in the child's separation and individuation from the parent; i.e., a failure in the child's becoming an authentic, self-inhabiting person.

In the severe cases of childhood onset psychosis, florid acute psychosis in adults, and severe chronic psychosis, individuals may literally not know where other people end and they begin. More often, however, the disturbance is less dramatic but nevertheless profoundly important. Some parents need their child or imagine their child to be someone other than who the child authentically is. They impose their own mental representation of an internal object on the identity of the child. Rather than discovering who the child is as the child's identity unfolds, they decide who the child is and require the child to inhabit that identity as a condition of relating to the parent.

The father of a son might have wanted a daughter to avoid the competitive feelings he might experience with a son. Or a mother with an inadequate relationship with her husband may want an enmeshed relationship with a child who will remain dependent upon her, allaying the mother's loneliness and separation anxiety. Or a father may have wanted an athlete, but the son prefers to draw, or a mother who has lost a child in infancy may subtly communicate to another child in the family the parent's wish that it had been the other child who had died, or the next child born may be viewed as a replacement for the dead child, and so on. The possibilities for mismatches between the child's authentic identity and the imposition of a parent's need are many. These sorts of stories routinely emerge in the individual psychotherapy of psychosis.

Theodore Lidz described two basic patterns in which the psychology of one or both parents impinges upon and dominates the development of the child, patterns he termed the "skewed" and the "schismatic" family, respectively. The former serves the needs of one of the parents, most commonly the mother. The other parent and the children accept the dominance of one parent's needs, knowing that servicing them is necessary to the parent's psychological survival and therefore the survival of the family. In the latter, both parents attempt to impose their own differing and distorted view of the world on the family, and no consistent

Telegram: @medical_k

www.konkur.in

consensus is achieved. When two very different parental agendas are imposed upon the identity of the child, the child has difficulty forming a stable identity.

Arieti described a psychotic patient who grew up in a schismatic family environment. His father was a war hero killed in World War II. The father's loss so crippled the patient's mother that she was unable to invest emotionally in her son. The patient translated this seeming lack of interest into a feeling of his being a bad person. His maternal grandmother, however, encouraged him to believe he was an exceptional person who would grow up to be a hero like his father. In the face of these two contradictory imposed identities, the patient grew up with no core identity and no realistic self-esteem, a condition that left him vulnerable to psychosis.

Another patient, Jason, grew up in an atmosphere of constant bickering and fighting between his parents, who frequently urged him to take sides. The parents, who divorced when he was 16, forced him to decide which parent he wished to live with, making no effort to arrange amicable joint custody. He chose his father, who promised Jason a motorcycle when he was 18. The father had little interest in his son except to demonstrate the son's preference for him over his wife. Jason soon became disenchanted and one evening returned to his mother's house, hat in hand. At first, she barred him from her home, haranguing him about how he had betrayed her by choosing his father, saying he must live with his choice. She eventually relented and allowed him in, but she said, amidst angry declarations of what a monster the father was, that nothing would please her more than to read in the newspaper that Jason's father had been murdered. Jason got the message: The price of his return was to be his father's life. He was psychotic by daybreak. Both parents viewed Jason as belonging either to themselves or to the other parent, and if the other parent, their mental representation of Jason was infiltrated by their hatred of their ex-spouse.

www.konkur.in

Karon describes a mother–child dyad in which an insidious mismatch arose around feeding. A psychotic man who went on hunger strikes and believed he was being poisoned reported, “The Athenian girls are laughing at me. They say their breasts are poisoned.” There was, at first pass, no apparent trauma in the patient’s history. His mother, who had breast fed him for a year and weaned him gradually, asked her son, “Did I give you enough milk?” He replied cryptically, “The cow gave her calf milk and then kicked it. She shouldn’t do that. It’s something that happened hundreds of times in the history of the world.”

Karen inferred that the cow represented his mother, the calf represented the patient, and the history of the world represented his life history. Thus, the patient was complaining that every time his mother fed him, she got angry or “kicked” him. This pattern was apparent in their relationship as adults. If the mother cooked a meal and he ate it, they quarreled afterward. If she cooked and he was on a hunger strike, or if someone else cooked, there was no quarrel. When the patient was a child, his need to be fed produced anxiety in the mother, which made her angry. The same sequence occurred in their adult relationship, in which she would find pretexts for a squabble after feeding her son.

The essential aim of PDTp can be stated rather simply in relationship to the theory outlined above. The therapist tries to help patients tell their stories, to say what has happened to them in their lives and how this has made them feel, and what thoughts and feelings are currently being expressed in the psychotic symptoms. In this sense each patient’s psychotic symptoms are a Rosetta Stone by which one person’s emotional life can be translated into simple human terms.

TECHNIQUE

As noted, most psychoanalytic theorists would agree that psychotic mental states represent the intrusion of primitive psychological processes into adult waking life, and that those processes were originally most

Telegram: @medical_k

www.konkur.in

clearly explicated by Melanie Klein and her followers. Although Kleinian analysts made brilliant contributions to the psychoanalytic understanding of psychosis, their way of working using classical psychoanalytic technique has no direct application in the public mental health sector. But if one regards psychoanalysis as a body of ideas applicable in a variety of settings, not as a specific clinical technique, Kleinian ideas are a compass in psychotic chaos, invaluable tools for understanding the psychotic process and guiding care wherever it occurs with whatever technique is applied. We begin with a short review of Kleinian technical ideas, as they illuminate some general principles of therapy for psychosis, followed by the recommendations of therapists of the American Sullivanian School.

The European Kleinian School

Segal describes the treatment of a chronically psychotic man with multiple delusions and hallucinations who believed that he was a prisoner, not a mental patient, and that the world had been changed and was being destroyed. His two core delusions, that he was in prison and that the world was changing, were connected to primitive internal object-related phantasies. He complained that he was being given plenty to eat in the hospital, but not enough to do or think about, which led him to believe his head, arms, and legs were shrunken while his stomach had become huge. Instead of saying he was bored and that he felt like he was being force fed, he expressed these sentiments in a somatic delusion (a concrete metaphor). Because in the hospital he thought about little else than eating, he believed the world was obsessed with eating, to the point that people had neglected to plant new crops, which would lead to famine and the destruction of the world. After Segal consistently interpreted his primitive object-related phantasies and analyzed the psychotic transference, within a year all his delusions disappeared.

Wilfred Bion extended the work of Freud, Klein, and Segal in novel ways with his concept of *attacks on linking*. In psychosis, individuals turn away from painful realities by internally undermining (attacking) the connecting links between memories and verbal thoughts that give experience meaning. Instead of thinking a verbalizable thought, psychotically disturbed individuals project the part of their cognitive apparatus that would ordinarily maintain a conscious awareness of reality outside the self into what Bion called a “bizarre object.” The familiar computer chip in the brain, a common delusion, is a “bizarre object.” The

Telegram: @medical_k

www.konkur.in

person's cognitive capacity to observe reality has gone missing from the person's mind and has been projected into a mental representation of the chip. The chip operates within the person's body but is separate from the person's ability to think. The capacity most often projected into the chip is that of monitoring thoughts and transmitting them to an external agency such as the FBI, in which case the chip has taken over one's capacity to know one's own thoughts and evaluate them.

Herbert Rosenfeld believed in the importance of analyzing the psychotic transference. In his experience, primitive phantasies of intruding upon others or being intruded upon to the extent of annihilating the self are common in the psychotic transference. He describes a patient who feared that one day she would begin to speak in a strange voice that belonged not to her but to Rosenfeld. In keeping with Klein's emphasis on primitive body-related phantasies in which children imagine taking something out of or putting something into the mother's body or having the same done to themselves, Rosenfeld interpreted the negative psychotic transference to this woman, telling her she feared that he was going to force himself into her body and her mind and take control of her thoughts so as to cause her to lose her identity entirely.

The American Interpersonal School

Harry Stack Sullivan's ideas about the etiology and treatment of psychosis are important not only because they are persuasive but because of their simplicity. Sullivan believed that disturbances in the early mother–child relationship predispose to psychosis. According to Sullivan, all human beings have basic needs for *security* and *satisfaction*. His concept of security roughly parallels current concepts of secure attachment, positive self-esteem, and associated expectation of esteem from others. His concept of satisfaction roughly corresponds to Freud's conception of drive satisfaction, including the gratification of sexual needs. In order to achieve security and satisfaction, children must cultivate sufficient interpersonal competence to ensure that these basic needs are met in childhood, latency, adolescence, and adulthood.

According to Sullivan, when an infant's need for maternal care makes the mother anxious, this anxiety is communicated to the child, undermining the child's capacity to feel secure and to develop the interpersonal competence necessary for independent living. This failure of relatedness arises in interactions with the small group of people that

compose the child's core care-giving environment. He considered the developmental milestone of having a "chum" during latency to be an important marker of mental health, as it signals the growing person's ability to establish a stable and gratifying relationship outside the nuclear family.

Sullivan died at 57 before ever writing a comprehensive manual for technique. His recommendations are scattered throughout his writings.

Much of his initial work with psychotic patients was done on a special 6-bed inpatient unit that he designed at Sheppard Enoch Pratt Hospital, where without medication, he reportedly achieved an average 85% recovery rate for acute psychosis. Consistent with his theory, he placed a significant emphasis on the quality of interpersonal contacts in the ward milieu. He took care to alert ward staff to the exquisite sensitivity of psychotic patients, encouraging them to spend considerable time fostering a relationship in which the patient could feel secure. Believing that his patients felt interpersonally incompetent in their family settings, he placed them in a humane environment in which all patients could feel like valued members of the community. He resisted objectifying diagnoses while teaching that, however strange their symptoms, people with psychosis should be considered "more simply human than otherwise." (In a similar vein, CBTp recommends the psychotherapy technique of *normalizing* to emphasize the continuity between psychosis and ordinary mental life.)

A central aim in Sullivan's approach was to reconstruct the chronology of the onset of the psychosis, so as to impress upon patients that whatever psychotic reaction had befallen them was the result of their profound disappointments in life experiences with a small number of people. Sullivan cautioned that it is extremely important to use simple, clear language because people in psychotic states have difficulty communicating in consensually familiar verbal symbols. Talking in too complex or fancy a way would be, in his words, "asinine behavior." With hebephrenic patients who had retreated into an autistic self-involvement, or paranoid patients with fixed delusions, he sought to revive a state of confusion present in an earlier phase of the psychosis. This goal is similar to the CBTp aim of encouraging a state of uncertainty in patients about their delusional beliefs. The therapist must spend sufficient time with the patient to let the treatment unfold. When the patient is not communicating clearly, the therapist should welcome the attempt to communicate but not pretend to understand what is still confusing.

Telegram: @medical_k

www.konkur.in

Sullivan offers occasional examples of his work with patients. A psychotic man who had been severely disappointed in love said of the woman who had rejected him, she is “of the past” and “out of my mind” and someone “of no importance.” Sullivan took advantage of this moment of denial to say something along the lines of, “Nonsense! You are happy with her.” Having startled the patient into alertness, Sullivan continued, “and there is no reason on earth why the pleasure you had in her company should be thrown away just because the relationship didn’t last forever.”

If all goes well enough on the inpatient service and some degree of human contact can be re-established, allowing some degree of social recovery, the patient can be treated as an outpatient. Sullivan believed the training, experience, and personality traits of the therapist were crucial to a positive outcome. (Training and experience do matter, a fact often lost in RTCs of PDTp.)

Frieda Fromm-Reichmann worked closely with Sullivan. She distinguished *psychoanalytically oriented psychotherapy* from classical psychoanalytic technique and believed that even the most psychotic patients were capable of some degree of interpersonal relatedness. Her success as a clinician stemmed from her warmth, humility, and exquisite psychological intuition. She stressed that when the therapist inevitably disappoints the patient in some way, it will likely be experienced as a repetition of early traumas, and will provoke anger and intense hostility that can be understood and worked through. She emphasized how lonely psychotic people are, noting that in spite of their retreat from the real world, people in psychotic states nevertheless retain some dim notion of the unreality of their substitute delusional world. A longing for human contact and understanding remains, yet patients are afraid to admit this to themselves or to the therapist for fear of further disappointments.

Fromm-Reichmenn emphasized that to establish trust, the therapist must treat patients with kindness and consideration, without infantilizing them. She would explain to them that symptoms were ways of remodeling life experiences in consequence of, or in accordance with, their thwarted past or present relationships. She recommended telling hallucinating and delusional patients that the therapist does not see, hear, and believe the same things the patient does, but that the two parties can investigate

Telegram: @medical_k

www.konkur.in

together the reasons for the differences in their experiences. She wanted patients to become aware of and to grieve the losses they had sustained in early life without distorting them symbolically as psychotic symptoms. This approach is reflected in the title of Greenberg's book *I Never Promised You a Rose Garden*. Interestingly, at one point in Greenberg's psychotherapy Fromm-Reichmann used CBPp like technique to array evidence against her patient's belief she had tried to kill her sister.

Silvano Arieti won the National Book Award in Science in 1975 for his seminal work *Interpretation of Schizophrenia*. This 756-page book is arguably the most comprehensive and coherently organized text currently available on PDTp, with Karon and VandenBos's *Psychotherapy of Schizophrenia* a close second. Sullivan, Arieti, Fromm-Reichman, and Karon share much in their clinical style, an approach which might be called an *interpersonal interpretive technique*. What follows is a description of this technique following Arieti's outline of three phases of treatment, written as an amalgam of his approach and others.

Interpersonal Interpretive Technique

Arieti conceptualized PDTp as proceeding in three stages. First, the *engagement* phase, in which the therapist attempts to connect with a person who has largely withdrawn from social contact and consensual reality. Next, a phase that focuses on showing patients how they express themselves in a variety of *psychotic mechanisms*, such as hallucinations, delusions, and ideas of reference. Specific techniques are required to bring the thoughts and feelings experienced as perceptions back within the boundary of the self, where they can be experienced as mental events and examined in more traditional psychodynamic fashion. CBTp techniques that can be a stand-alone practice can be extremely useful in this second phase, about which there is more in the CBTp portion of this chapter.

Third, when patients have learned to identify the psychotic mechanisms that disguise their thoughts and feelings, they can begin to reclaim their inner life as the therapist interprets the meaning of symptoms in relationship to disowned emotions, memories, distorted thinking, and current life events. The therapist attempts to help the patient see his psychotic symptoms as meaningful reactions to problems in living, without accepting the psychotic distortions or promising the patient compensation

Telegram: @medical_k

www.konkur.in

or an ideal world. These three phases of treatment will now be described in more detail.

Engaging the Patient and Establishing a Therapeutic Alliance. Establishing a trusting emotional relationship with a patient suffering psychotically is the first and most important step in the psychotherapeutic process. The patient is caught in a devilish version of Schopenhauer's porcupine dilemma, in which too much closeness with other human beings brings the prick of the quill, and too much distance the chill of a cold that withers the spirit. Having found that attempts to relate to others have in the past occasioned intense anxiety and repeated interpersonal failures, the psychotic person withdraws from consensual reality and ordinary social contact into a solitary delusional world. Patients who can be engaged in psychotherapy must find a way to set the value of a relationship with the therapist against the unaltered continuation of their psychotic existence.

All clinicians, whether in psychiatry, internal medicine, or surgery, will see in their patients a balance of health-promoting factors and pathology. The clinician will not know all the variables involved, or their ultimate strength in the clinical equation defining outcome. The same is true in the initial engagement phase of therapy with patients suffering psychosis. The therapist cannot always know beforehand how the need for human contact will play out against the patient's aversion to the real world. Patients who lack basic trust will approach all relationships, including a relationship with the therapist, with trepidation. When a person's development has been significantly impinged upon by others, the patient may experience being influenced by the therapist in any way as an impingement.

Telegram: @medical_k

www.konkur.in

For example, a psychotic woman revealed after months of psychotherapy that she did not think about what the therapist said during the sessions; instead, she tried to memorize the therapist's words so that she could digest them later, alone, when she felt she could exert more control and avoid the therapist's ideas taking over her mind. Patients who have had a symbiotic relationship with their primary caregiver may adopt an opposite course and rush to fuse with the therapist's identity in an attempt to reserve no mind of their own with which to feel their own pain.

The minimum conditions for psychotherapy require the patient to be able to attend sessions, whether as an inpatient or outpatient, and to curtail violent behavior directed toward themselves, the therapist and others. The therapist cannot allow socially intolerable behaviors such as stealing from the therapist, inappropriate touching, or significant disruptions of the therapist's life. A minority of patients, even when properly approached, are too damaged or too terrified to engage in treatment, at least within the parameters of the current mental health system. The therapist needs to strike a flexible balance between authoritarian controls over the patient's behavior and sitting passively by while the patient contemplates some ruinous action.

Confidentiality should be discussed early in treatment. With respect to parents, significant others, and public authorities, the therapist should explain that the treatment will remain confidential except when the therapist believes that the patient presents a clear danger to self or others, in which case the therapist may need to contact family, friends, or the authorities. If a patient cannot allow the therapist to call in help if need be, the patient may be best treated in a more structured clinical setting. The therapist can share a draft of insurance forms, psychosocial summaries, and disability applications prior to releasing confidential information.

Patients with psychosis don't necessarily expect to have rewarding conversations with mental health professionals. They may find that the delusions and hallucinations that are the most compelling concerns in their lives may be brushed aside as "imaginary" by others.

Telegram: @medical_k

www.konkur.in

After establishing rapport with his therapist, a psychotic man acknowledged that the most important relationship in his life was his ongoing dialogue with a female “voice” he believed to be the voice of God. He said, “I never tell the doctors much at all about God. I know what they are going to think! They will just think I am crazy. They don’t want to talk. They are just Haldog (*sic*) terrorists. So I take the medication and then after a while they let me go, and I stop taking the medication after I leave. I trust you. Maybe I shouldn’t, but I do. There is something about your way of speaking, something about your manner, that makes me trust you.”

Establishing rapport is not a mechanical matter of technique, but fundamentally *it is a matter of the heart*. The therapist’s relationship with the patient will reflect what the therapist genuinely thinks and feels about the psychotic person. Just as children readily discern when meeting an adult for the first time whether it feels safe to proceed, psychotic individuals will know by the therapist’s words, gestures, facial expressions, and tone of voice, whether the therapist’s greeting is a well-intentioned but generic professional posture, or whether the therapist is motivated by an affectionate, abiding respect for the patient’s individual personhood. Patients must know that they are truly seen by the therapist as discrete individuals. Unlike non-psychotic patients, who can explore their fantasies about who the therapist is, the psychotic patient cannot wait to know, for fear of the worst. Adrift in a sea of madness, the psychotic patient must find something real in the therapist to hold on to that is sufficiently reassuring to allow the patient to risk connecting.

Telegram: @medical_k

www.konkur.in

Greenberg illustrates the sensitivity of psychotic patients to the therapist's true feelings in her description of the reaction of inpatients to a conscientious objector who was unhappily assigned to the hospital as a therapy aide in lieu of military service. The patients sensed that he was frightened of them and that he defensively held them in contempt. "His rigid fundamentalist beliefs made him see insanity is a just desert for its victims, as God's vengeance, or as the Devil's work, and sometimes as all three at once. As the days passed, his fear waned in time and his righteous wrath was at hand. … Against his loathing, the sick fought in their sick way. The literate rewrote the Bible or ridiculed its passages to make him horrified. Constantia made flagrant sexual advances to him. And Debra made a few pointed observations about the similarity between psychotics and religious fanatics."

The seeming failure of people around them to see the world as they do leads psychotic patients to believe that at best the therapist will not understand, and at worst the therapist is directly involved in the patient's delusions. The therapist's attempt to communicate effectively is paramount. Initially the therapist should not ask the patient any complicated questions, because a person who is desperately fighting for psychological survival will be unable to attend to the therapist's queries. A patient's wish to talk to the therapist is a good sign, no matter the subject. When the patient is unable to talk directly about the psychosis, the therapist should encourage the patient to talk about something else.

When the therapist does not understand what the patient has said, the therapist should not pretend to understand, but rather say the therapist is trying to understand but is not yet certain what the patient is trying to say. When the patient cannot or will not speak, the therapist must be able to tolerate periods of silence, but the therapist should not allow protracted silence to develop. Based on whatever the therapist knows about the patient, the therapist can keep talking, musing, meandering, speculating, allowing the patient to feel the therapist's effort to communicate. The therapist should be emotionally engaged, firm, honest, and familiar in his manner as opposed to emotionally distant.

The therapist need not withhold direct reassurance. Arieti describes his approach with a patients with post-partum psychosis. "In many cases, I

Telegram: @medical_k

www.konkur.in

have told the patient that she is in great distress because she rejects the baby, she feels guilty about it and believes that the baby is going to suffer. I have reassured the patient by telling her that she must accept the fact that she rejects the baby and that the baby will not suffer. Adequate provisions are being made for the baby. We shall eventually discover why she feels this way and her feelings will change. In the meantime, she cannot feel guilty because she can't help rejecting the baby. I have found that even very disturbed women understand these explanations, partially or totally, and are relieved by them." Karon routinely reassured terrified patients saying, "I will not let anyone kill you."

The therapist should ally with the non-psychotic part of the psychotic patient's personality that remains capable of standing outside the psychosis and reflecting on it, thin ledge along a deep chasm though this foothold may be. The therapist should not collude with the patient's delusional beliefs, nor should the therapist side-step the issue of the patient's being ill, though the matter of what to call the patient's condition must be handled with finesse. The patient's condition may have been called "schizophrenia," "mental illness," "bipolar disorder," or "a chemical imbalance." It is important to understand the labels that have been applied, the meaning of these descriptors to the patient, and what words the patient might use to describe what is going on. How the label is worded shapes patients' self-image and the way they believe the therapist will see them. Patients will sometimes talk comfortably, for example, about an "emotional breakdown" while being allergic to the word "schizophrenia."

Telegram: @medical_k

www.konkur.in

A woman with a delusion about a man at her church was willing to consider that she might be mistaken about his intentions toward her, but she was absolutely certain that the label “schizophrenia” did not apply to her. She had looked up “schizophrenia” on the Internet and had taken away the idea that “schizophrenics imagine things that are not real.” This could not possibly apply to her, she thought, because she had no doubt that the man at church had in fact said certain things to her, as indeed he had. Although she granted that she may have misinterpreted what he said, she had certainly not *imagined* him saying what he said. She had understood the diagnostic label “schizophrenia” to apply to people who imagined things that never happened rather than people who misinterpreted things that did happen. The fact that her doctors had given her a diagnostic label that she believed clearly did not apply to her led her to conclude that they must have some malicious purpose. The therapeutic alliance foundered until this issue was identified and worked through.

Although it would not be accurate to characterize psychosis as a freely chosen, alternative way of living, people who have recovered from psychosis and written autobiographical accounts of their illness describe needing to give up on an impossibly painful real world and to surrender, subjectively voluntarily, to psychosis. Greenberg describes her escape from the real world into her delusional Yr, where in her mind she lived apart from the pain of the real world for years. Fromm-Reichmann stood patiently at the boundary between Yr and the real world, encouraging Greenberg to step across the boundary back into reality when she could, accepting Greenberg’s need to step back into Yr when she needed to.

People with psychotic illnesses may feel they have less to lose than non-psychotic individuals because they have already lost so much. Having already given up on life, such patients may feel freer to tell the truth about what they think has been going on in their core relationships, including with the therapist. When a patient with a psychotic condition comments accurately on something the therapist has said or done, the therapist must acknowledge the truth of the perception. As Arieti put it, “… on the one hand [the psychotic person] is very sensitive and is capable of seeing through a situation to perceiving the truth even more so than the

Telegram: @medical_k

www.konkur.in

normal person; on the other hand, what he does with what he sees is so distorted that it will increase, rather than decrease, his difficulties."

If attempts to engage the patient are successful, the clinician may recognize a "breakthrough" from the profound isolation of psychosis.

Arieti quotes a patient who describes such a breakthrough moment. "There was a reading room on the ward, with a piano and magazines. I went there and I looked at the cover of a magazine. The nurse stepped in. I had never seen her before. She started a conversation with me as if I were a normal person. I told her with tremendous emotion, "You're the first person who has broken through to me." She was not on guard. I was not on guard. She was an ordinary girl. She made me feel communication with people was worthwhile. Before that nothing was worthwhile. People were hateful."

Identifying Psychotic Mechanisms. Arieti distinguished between *psychotic mechanisms*, meaning the form the symptom takes, and the content and psychodynamic meaning of the psychotic symptom. For example, auditory hallucinations may be similar in form from patient to patient but different in content and personal meaning. Arieti helped patients recognize when these psychotic mechanisms were operating in their minds. CBTp-like techniques were thus essential to Arieti's method. Through a process that CBT therapists would now call "guided discovery" of a cognitive bias, Arieti helped patients understand that they heard "voices" when they *expected* to hear them: "A patient goes home after work and expects the neighbors to talk about him. As soon as he expects to hear them, he hears them. In other words, he puts himself in what I have called *'the listening attitude.'*" The patient comes to see that there is an internal mental contingency to what would otherwise be experienced as an external event. A similar realization happens when patients in CBTp understand that their "voices" follow stress or lack of sleep.

Even after recognizing that their expectation of abuse leads them to imagine an abusive attitude in strangers, or to trigger critical "voices," patients may remain puzzled as to why specific charges have seemingly been brought against them. They have no conscious awareness of ever having had thoughts about themselves of the sort given voice in the attack. Klein's ideas about primitive splitting and projection are extremely

Telegram: @medical_k

www.konkur.in

useful in understanding and working with this state of mind. In psychosis, repudiated thoughts and feelings literally go missing from the patient's mind and reappear as infiltrations of the patient's perception of reality. The patient who reports being unaware of ever having any thoughts similar to the persecutory charges is telling the truth. Arieti offers the example of a woman who heard "voices" telling her she was a prostitute, who was puzzled because she had no conscious awareness of thinking such thoughts about herself, until in PDTp she became aware of a variety of sources of poor self-esteem that had condensed in her mind into the "prostitute" charge.

Arieti approached ideas of reference and delusions with a technique similar to his approach to auditory hallucinations, by helping the patient identify what he called a "referential attitude." A man enters a public park feeling a vague, abstract sense of foreboding. Once in the park he notices children running in a direction opposite from him, and he jumps to the conclusion that he is being perceived as a child molester and the children are running from him. What Arieti called a "referential attitude," CBT therapists would call a jumping-to-conclusions bias and a self-referential bias.

Arieti taught patients to recognize the vague antecedent referential attitude that preceded and became concretized in ideas of reference. PDTp attempts to reverse this sequence, to move from the perception of concrete exterior events to the mental interior of more specific thoughts and feelings, and finally to the developmental origins of these feelings.

For example, Arieti describes a patient who believed she was getting Morse code messages she could feel when she palpated pulsations in her wrist that gave her directions about what to do and not to do to remain safe. Arieti interpreted that that she was actually giving herself advice, but she needed to experience the directives as originating in some august authority outside herself. He related this symptom to her parents never having provided the confident guidance she needed to grow into an independent person.

In some cases, the patient's delusions reflect a sensitive awareness of an actual social reality. Arieti calls this a "punctiform insight."

Telegram: @medical_k

www.konkur.in

He gives the example of a compliant woman who was in fact being overworked and taken advantage of by her employer, who received a present of yellow roses from her boss for her birthday. She associated the color yellow with jealousy and in a turn of “paleologic,” she decided that yellow roses had been selected to show her that her office-mates knew she was jealous of the boss’s wife. Arieti interpreted that she was in a state of anxiety at work relating to her self-doubts and poor self-esteem, and that she had used a special type of thinking to express her feelings of unworthiness, in which she attributed her thoughts about herself to others. The boss did in fact appear to be hostile and demanding, and it did in fact appear she was being exploited, but her punctiform insight into this social reality had been expressed in a widening circle of paleologic ideas of reference in which the entire social surround was seen as being hostile.

Interpreting the Relationship Between Psychotic Symptoms and the Patient’s Current and the Past Life. Assuming that the therapist has been able to engage the patient and has made progress in the second phase of treatment in helping the patient to identify psychotic mechanisms and not regard their content reflexively as reality, the therapy can turn gradually toward a more traditional psychodynamic approach. Trauma and impingements upon the good-enough development of an authentic independent self have left the psychotic person with a socially incompetent personality incapable of meeting the person’s adult needs for security and satisfaction. Painful, repressed elements of the person’s mental life have so distorted the psychotic person’s mental representations of other people and reality that it has become impossible for the person to form gratifying relationships with others. Psychotherapy offers patients the opportunity to re-think these distortions so as to do better with other people and have a second chance at finding their lost authentic self.

The therapist tries to create a psychological holding environment in which, session by session, the patient’s authentic thoughts and feelings can emerge in treatment. Week after week, the patient speaks to the therapist of thoughts, feelings, and actions, and the therapist helps the patient by interpreting the unconscious meaning of the patient’s productions, including especially the patient’s psychotic symptoms. The patient may say things that are fragmented and initially incomprehensible. The therapist must gather up these mental shards over time to make

Telegram: @medical_k

www.konkur.in

coherent sense of what the patient is saying. The therapist's genuine concern and ability to bear empathic witness to the patient's emotional life provides a corrective emotional experience that offsets a childhood environment that failed to bear witness to the child's true self.

The third phase of PDTp, while similar in broad outline to work with non-psychotic patients, poses unique challenges. The non-psychotic person in psychotherapy has the challenge of trying to find links between an affectively charged experience in the present and an affectively charged experience in the past; such patients come to see that the way they are feeling in the present is an expression of a childhood state of mind. Once non-psychotic persons can see that the possibilities of the present have been constrained by the past, they can work themselves free of the past and return to the full possibilities that life offers in the present. The psychotic person's task in PDTp involves an additional intermediate step that the therapist must help the patient accomplish. In psychosis, affectively charged experiences from the past are experienced as altered perceptions of the outside world that are elaborated in delusional accounts of reality. The psychotic person in psychotherapy must first translate a current perception, or a belief regarded as a real perception of the objective world, into an affectively charged thought and/or feeling about people and the world and then link that affectively charged experience with an affectively charged experience from the past.

Consider, for example, a typical sort of session that might be occurring in any number of public clinics across the country.

Telegram: @medical_k

www.konkur.in

THE MAN WITH PEOPLE INSIDE HIM

The author supervised a social worker who had been seeing a 22-year-old man who had become psychotic at the age of 17 for supportive sessions once a month. He had been tried on adequate doses of several neuroleptics with no seeming impact on his core delusion that people he did not know were having sex inside his body, an experience he found very distressing. The patient reported vague somatic sensations that he took as indications of the movement of other people's bodies inside his body. The therapist was encouraged to see the patient more often and to take a careful developmental history, which he did.

Lo and behold, the therapist discovered that the patient had been seduced into an ongoing sexual relationship by his older sister when he was 8 years old, a fact not known previously, which appeared nowhere in the patient's chart. In supervision, the author suggested that the therapist might consider the patient's perceptions of movements inside his body as a kind of sexual daydream in which the patient was experiencing his thoughts and feelings as perceptions. Following up on the history he had obtained, the therapist remarked to the patient in an offhand manner that most young men his age have fantasies about sex from time to time and asked if it was possible that his sense of movement inside his body, which he thought was sexual activity, might be a form of sexual daydreaming?

The patient took readily to this suggestion. As if to say "Now that you mention it," he shared with the therapist for the first time some doubts he had about his delusion. He was at a loss to understand how the people having sex entered and left his body without leaving scars. He acknowledged that when he imagined what the woman inside him might be like, he imagined her as having some of his sister's attributes. After exploring his memories, thoughts, and feelings about his relationship with his sister in four subsequent sessions, the body sensations faded, his delusion receded, and his interest turned to how he might get a job.

In psychoanalytic terms, his sister's early sexual overstimulation was an impingement upon what should have been a slower, more natural development of his sexuality. At age 8, he was not emotionally prepared to reject his sister's advances, nor was he able to absorb

Telegram: @medical_k

www.konkur.in

them emotionally. Unable to integrate these highly charged experiences within his latency age identity, he found them persisting in the form of unabsorbed introjects that he experienced as moving around inside his body. Consistent with primitive object-related phantasy that imagines the movement of internal objects in and out of the body, the patient believed that two people were moving in and out of his physical self. This is an example of the meat-and-potatoes sort of psychotherapy work that can occur in public clinics where earnest, well-trained clinicians are supervised by a clinician with more experience doing PDTp or CBTp.

The therapist will want to accumulate a chronology of significant life events and interpersonal relationships with the aim of relating this history to the patient's psychotic symptoms. It will likely not be possible to take an orderly history in a single sitting. In modern treatment-as-usual, the life histories of psychotic patients are sometimes reduced to a clinical shorthand that may be adequate for pharmacologic treatment but fall short of what is needed for PDTp. For example, one might read in a chart, "This is the fifth psychiatric hospitalization for this 26 y.o. Male with a diagnosis of chronic paranoid schizophrenia who presents with auditory hallucinations telling him to kill himself that recurred 10 days after he stopped taking his neuroleptic." This sentence contains enough information to sketch out a bare-bones pharmacologic plan: re-start his medication because it worked before and discharge him when the "voices" abate. A good clinical service will address the questions "Why five admissions?" and "Why did he stop his medication?" although important issues like these are difficult to work through in a 10-day admission, and this focus is often entirely lost in the transition to outpatient services. Rarely will the origins of the patient's self-hatred, so intense as to be expressed in a "voice" telling him to kill himself, be a central concern. Rarely will his self-hatred be the focus of a treatment plan that includes PDTp or CBTp as the treatment of choice to explore this issue.

While helping the patient translate altered perceptions and concrete metaphors into more ordinary human thoughts and feelings, the therapist must also help the patient deal with the strong affects that in the first place drove the patient's thoughts out of the patient's mind and into the patient's perceptions of the outside world. Repressed affects that commonly emerge in PDTp include intense terror, rage, shame, guilt, longing,

Telegram: @medical_k

www.konkur.in

loneliness, despair, and self-hatred. Andrew Lotterman advocates the therapist's occasionally disclosing the therapist's feelings to the patient as a way of modeling how a person can contain and verbally express distressing affects. For example, if the patient were to arrive quite late for a session, the therapist might say simply, "I was worried when you weren't at our appointment on time." The therapist's modest, measured disclosure of the therapist's feelings helps the patient to keep in mind the person the therapist really is.

In psychosis, affect may cease to operate as a signal-triggering defense but may course through the patient's mind like a runaway train, becoming traumatic in its own right. The patient can be taught that no emotion, no matter how strong or seemingly out of place, is entirely irrational. If angry, it is likely the patient has felt hurt, though the hurt may not be conscious, may relate to something in the past, or be symbolic in nature. All felt emotion is real in the sense that it is really experienced, and all emotion is commensurate and in proportion to the mental events that aroused the emotion. The therapist can aim to say, "Given your experience of those events, it is not surprising you felt as angry [frightened, needed, guilty, etc.] as you did." In keeping with the playground adage, "Sticks and stones can break my bones, but words can never hurt me," the patient can be encouraged to understand that emotion alone does not harm.

Psychotic individuals inevitably suffer from poor self-esteem, and more often from self-hatred. People who has not felt their existence empathically recognized, who enter adolescence and young adulthood lacking the social competence to meet age expectable goals in social interaction will judge themselves to be a failure and a lost cause. Many delusions directly reveal patients' poor self-esteem, as when they think they have a vile odor, or skin eruptions, or are harangued by "voices" telling them that they are worthless and should kill themselves to spare the world their presence.

Telegram: @medical_k

www.konkur.in

For example, a young man who regarded it as his duty to lead his family out of poverty and set a positive example for his siblings believed he was a total failure after this younger brother was killed in a drug-related slaying. The patient came to believe that dogs in the neighborhood were looking through his clothing, and with their eyes were mocking his puny body. This man's self-hatred had gone missing from his own mind and reappeared in the mocking eyes of the dog. The therapist's devotion of considerable time and effort on the patient's behalf can go a long way to shore up self-esteem. Unfortunately, it is difficult to spend much time with patients in current care delivery models.

As the patient comes to doubt that his problems are caused by a delusional persecutor, the patient may mount an anti-parent campaign with a similar accusatory theme. Descriptions of parents that first emerge may be malignantly distorted images of the parents, infiltrated by primitive projections quite at variance with the therapist's impression of the parents upon meeting them. Because the patient has come to give some credence to what the therapist says, the therapist can point out distortions in current events related to the parents. For example, a psychotic man, who had come to understand that his perceptions of what his students said in the classroom were distorted, accused his parents of tormenting him by the off-hand mention at family dinners of the names of his prior homosexual lovers. In the course of therapy, he acknowledged that his parents could never have been aware of the existence of the lovers in question and so could not have known their names. He was able to see that events similar to the "voice"-hearing intrusions in the classroom were happening around the family dinner table.

When over time, the therapist has come to a more measured view of the patient's development, the therapist should acknowledge the very real limitations of the parents and the hurts they inflicted. In some cases, the patient may be told that despite the parent's actions being hurtful, there is no clear evidence the parents intended to hurt the patient in the way they ultimately did. In keeping with Klein's conception of the *depressive position* as including complex, integrated images of other people that tolerate ambivalence, the therapist endeavors to help patients away from

Telegram: @medical_k

www.konkur.in

the *paranoid-schizoid position* to the more mature *depressive position*, where they can see their parents as having both good and bad traits.

Patients can also be shown that their behavior may reinforce negative interactions with parents that foreclose the possibility of making whatever connection might be possible. As is true in the psychotherapy of non-psychotic individuals, patients with psychosis must learn that they will not get what they want by putting their parents on trial with the expectation they will now make good on what was missing in childhood. Patients must face the necessity of going out into the world and finding their own adult satisfactions. When Greenberg ("Deborah" in her book) complained to her therapist about how hard it was to live in the real world, Fromm-Reichmann responded, "I never promised you a rose garden," from which the book took its title.

Telegram: @medical_k

www.konkur.in

Over the many months of her treatment, Greenberg worked to understand the meaning of her psychotic symptoms in terms of her life experience. Well into treatment, she revealed to her therapist that she believed herself to be a Japanese soldier. She knew about the "Japanese menace" in World War II and had heard the phrase on the radio, "If you aren't with us, you are against us." Socially estranged from her peer group, she heard her "voices" repeating, "You are not of them," which she took to mean that people thought of her as they thought about the hated Japanese soldiers. Instead of feeling *like* a Japanese soldier (a figurative metaphor), in her delusion, she believed she *was* a Japanese soldier (a concrete metaphor). As she imagined herself into the identity of the hated Japanese soldier, her urologic surgery at age 5 became a soldier's war wound, and the soldier's wish to escape was her wish to escape from a painfully overwhelming real world. At a point late in her treatment, when Greenberg had recovered her will to live, she made an additional discovery regarding the Japanese soldier. Greenberg writes:

"It's a description of … why … why, it's grandfather!" Deborah [Greenberg] cried, having unearthed the familiar tyrannical Latvian to whom she had given such an unrecognizable mask. It was a description of him and it fitted him better than height or weight or number of teeth. Dr. Fried [Fromm-Reichmann] then said, "Coming to see this … does it hurt so much?" Deborah replied, "A good hurt." Then Dr. Fried continued, "The symptoms and the sickness and the secrets have many reasons for being. The parts and facets sustain one another, locking in and strengthening one another. If it were not so, we could give you a nice shot of this or that drug or a quick hypnosis and say, Craziness, begone!' and it would be an easy job. But these symptoms are built of many needs and serve many purposes, and that is why getting them away makes so much suffering."

In addition to disclosing emotions, Lotterman advocates structured modifications of free association that he calls “naming” and “enlargement” that can help the patient get in touch with repressed emotions and put them into words, as well as role playing, in which the therapist might say “Imagine you are a poet trying to put your feelings into worlds.” For example, when a patient offers a vague description of a feeling state such as “I felt bad,” the therapist might encourage the patient to linger over the statement to name more specifically the emotions involved. The therapist may note a particular phrase that appears to have a significant emotional valence, as when a patient said her feelings had been “interred. “When the therapist drew her attention to this word, she at first dismissed it as just an expression, but when encouraged to stay on point and enlarge her associations to the word, she began to talk about how cut off from people she felt and how hopeless she felt about anyone ever discovering her; that is, about her ever being disinterred.

At the beginning of treatment, the relationship with the therapist as a supportive real presence is paramount. As awareness of psychotic mechanisms increases and examination of the patient’s family relationships proceeds, treatment may pay more attention to transference distortions. For example, a patient who believed she had an offensive odor recalled that the therapist had opened the window to his office when she arrived—to air the stink out of the room, she assumed. She believed that the therapist and most strangers on the street thought she had a bad smell. The therapist was able to point out that he had actually *closed* the window to shut out noise from the air well, but she had distorted her memory of his actions in keeping with her negative expectations. The patient was able to work through her conviction that the therapist thought she had a bad smell (but withheld telling her because he didn’t want to hurt her feelings).

At the beginning of treatment, the therapist strives to be a trusted supportive parental figure who offers a sincere commitment to provide whatever support is needed for the patient to survive. Later in treatment, the therapist may move toward a more demanding stance that conveys the expectation the patient will be able to live in the real world. As is true

Telegram: @medical_k

www.konkur.in

in the back-and-forth movement between dependence and independence in childhood, the patient may resent and resist such encouragement. The therapist must go slowly, showing the patient that the expectation of independence is an expression of confidence.

Aside from the fear of psychosis that may inhibit a therapist's close work with psychotic people, and aside from feelings in the countertransference that can provide clues to the patient's pre-verbal states, several other forms of countertransference reactions may arise during the course of treatment. Therapists may feel so deeply gratified by the intimately meaningful reward of the work that they do not recognize that a patient has made significant progress toward termination. Or they may become so habituated to a patient's peculiarities that they fail to recognize the pervasiveness of a patient's psychosis. Or they may experience a diminished interest in a patient as the person becomes less psychotic. There is little idle chit-chat in work with people who suffer from psychosis. Therapists may find the courage and raw vitality in psychotic patients an appealing environment in which to work, especially when compared with the deeply defended "normalcy" one often encounters working with personality disorders.

As in any psychotherapy, the patient changes not only from insight but from internalizing aspects of the therapist. The patient may identify with the therapist's accepting attitude such that the patient's excessively harsh superego is softened. The patient may take the relationship with the therapist as a model of how a human relationship might be. When therapy succeeds in reducing a patient's distortions of reality, expressed in psychotic symptoms, and when the relationship with the therapist provides a sufficient basis for self-esteem, the patient can get on with the sometimes difficult business of adult living. After all, the therapist never promised the patient a rose garden—just a better chance at living.

Cognitive-Behavioral Therapy for Psychosis (CBTp)

Cognitive-behavior therapy, as first described by Aaron Beck in 1979, was not applied to the treatment of psychosis in earnest until the early 1990s. The first comprehensive textbook of CBTp appeared in 1996, and many have appeared since. Interventions shifted from the primarily behavioral focus in token economies to cognition in psychosis, and a vibrant several decades of clinical research and refinement of technique ensued and continues. If behavioral therapy evolved into cognitive-behavioral therapy,

Telegram: @medical_k

www.konkur.in

and, as it appears to headed, CBTp evolves into “affective cognitive-behavioral theory,” CBTp and PDTp will lie in closer proximity.

A basic tenet of cognitive theory is that a person’s beliefs about events mediate between those events and the emotional and behavioral consequences that follow them. This paradigm is summarized in the A-B-C sequence familiar to all cognitive therapists, in which “A” is an activating event, “B” is a belief about the meaning of that event to the individual, and “C” is the emotional and behavioral consequence of that belief. Assuming that emotional distress and maladaptive behavior are a consequence of delusional beliefs, CBTp researchers set out to determine how delusional beliefs and beliefs about “voices” arise, hoping to find ways to help patients change these beliefs and reduce suffering. The subsequently evolved “CBT triangle,” which depicts reciprocal links between cognition, affect, and behavior reinstates the importance of emotion in symptom formation in CBT theory, a view that has always been central in PDTp.

Their research revealed that a number of cognitive biases found in ordinary people were exaggerated in people with psychosis, including attributional bias, self-referential and attentional bias, a tendency to jump to conclusions, dichotomous thinking, belief inflexibility, and theory of mind deficits. A cognitive model of psychosis emerged, in which prior expectations were seen to shape the cognitive processing of an external life event or an internal event like hearing a “voice.” Informational events that have the qualities of being expected, external, clear, common, neutral in affective significance, voluntary, public, and irrelevant to the person, may be ignored. But when, as is often the case with psychotic experiences, an event is unexpected, internal, ambiguous, unusual, affectively loaded, involuntary, private, and personally relevant, the event proceeds to further cognitive processing according to the individual’s information-processing style under conditions of high emotional arousal. Delusional people tend to have a cognitive style that focuses on current stimuli as opposed to past regularities of experience, and they tend to make rapid, overconfident judgments that are lacking in nuanced cognitive complexity.

Descriptions of the cognitive biases operating in psychosis allowed clinicians to tailor CBTp interventions to research findings. Through a process of *guided discovery*, patients can be shown that their belief is not the only possible explanation for events. Patients were taught to identify the cognitive biases operating in their own thoughts and to question the

Telegram: @medical_k

www.konkur.in

conclusions that followed from these biases. Many of the cognitive biases revealed by empirical research are known in the psychoanalytic clinical literature by different names. For example, Klein's idea of a primal split, in which the self is identified with good elements of the psyche and bad elements are projected into a persecutory object, is a description of what CBTp therapists would call an "attributional bias." What Freud described in 1926 in *Inhibitions, Symptoms, and Anxiety* as a constriction of the ego in the service of defense, CBTp would call a "safety behavior." There are many such crosswalks between psychoanalytic and cognitive theory. It may be reassuring to experienced clinicians to find that the psychoanalytic and cognitive-behavioral traditions have found their way to many of the same ideas and that CBTp has demonstrated the value of those ideas in empirical research.

Clinicians and researchers continue to develop new modes of treatment. In a so-called "third wave" of clinical interventions, new types of therapy emerged after CBTp gained acceptance. Over time, early attempts to mitigate suffering by changing beliefs has made room for more meta-cognitive approaches; that is, helping patients change the way they think about their own thinking. These innovative techniques include, among others, mindfulness-based approaches that draw upon the wisdom of Eastern traditions to foster a more accepting attitude toward suffering, with an emphasis on kindness and compassion. In contrast to traditional CBTp, which might encourage patients who are hearing distressing "voices" to turn their attention away from the "voice" and to change their beliefs about the "voice," a mindfulness approach would encourage them to adopt a more tolerant, more meditative, less emotionally reactive response to the presence of the "voice."

Acceptance and commitment therapy (described elsewhere in this textbook) does not have the primary aim of changing beliefs, but rather hopes to encourage patients to identify and keep clearly in mind their personal values, and to act on these values rather than acting on the prompt of a psychotic symptom. Compassionate mind training aims to help patients increase self-esteem by resisting self-critical elements in their personality more effectively. For example, the "two chair technique" allows the patient to imagine sitting in one chair while conducting a dialogue with an inner "bully." This technique echoes the voice dialogue approach developed in the late 1980s, and Gestalt approaches

Telegram: @medical_k

www.konkur.in

promulgated earlier, and is in keeping with a fundamental goal of most PDTp: diminishing the impact of an overly punitive superego.

CBTp offers a variety of effective interventions that can be used in their own right that can also be integrated with PDTp to help patients recognize the operation of distorting psychotic mechanisms. This sets the stage for more effective PDTp work if the patient needs wants and can use this treatment approach. Like psychodynamic approaches, CBTp therapies are too richly diverse to summarize. There follows a description of how a more traditional CBTp might be conducted in the following sequence: (1) engaging the patient; (2) eliciting the patient's story; (3) introducing CBTp with an emphasis on coping mechanisms; (4) reviewing the three treatment models underlying CBTp; (5) applying these models to the patient's experience; (6) challenging beliefs and re-formulating the patient's personal life narrative; (7) maintaining contact and employing "booster sessions" as needed.

Engaging the Patient in CBTp. The therapist should pay attention to how the patient came to be referred. Was it the patient's idea or someone else's? What is the patient's understanding of the purpose of the meeting? Does the patient have any specific anxieties about the meeting? Patients may wonder why the therapist is offering to see them more frequently than they expected. One patient joked, "Do you have a new supervisor?" The therapist might say, "If it is okay with you, we can meet a few times and talk about what has been happening in your life and see if we can figure out a way for things to be less distressing." Does the patient have an immediate, overriding concern that must be addressed before the patient can focus on the therapy? A patient who is worried about being evicted from home or who doesn't have enough to eat will have difficulty paying attention until these needs are addressed.

The therapist will want to know about prior interactions with the mental health system, particularly those that have been notably problematic for the patient. Allowing the patient a virtual "panic button" that the patient can activate if the patient gets overly anxious in the session may be helpful. The therapist can ask occasionally, "How are we doing so far?" The therapist must be sensitive to the fact that the patients may believe they are putting their life at risk by even talking with a therapist. If the patient is reluctant to talk about what the therapist sees as psychotic symptoms, the therapist can find something else the patient is willing to discuss. In

Telegram: @medical_k

www.konkur.in

summary, as was emphasized by the American Sullivanians, contemporary CBTp therapists establish a relaxed conversational manner that levels the power relationship between patient and therapist.

Elicit the Patient's Story. It is vital to ask what the patient thinks is happening and why. What evidence does the patient have for a problematic idea? The patient will often point either to one seminal event that fostered the delusional belief, or to a series of events given meaning by ideas of reference, in which case the patient may have pondered, "If this happened once or twice, it might be a coincidence, but it has happened over and over again, so there must be something going on." It is extremely important to elicit any aspects of the patient's experience about which the patient feels confused, as these doubts can often serve as a useful base to explore alternative explanations of the patient's experience.

For example, a man who had no doubt that he was an angel reported he had had an experience when he was being taken to the hospital that made no sense to him. The ambulance had passed children playing in school yard. He saw a good aura around the heads of some of the children, and a bad aura around others, but he knew there must have been something wrong with his perception because he believed all children were innocent and good. To encourage a therapeutic alliance based on evaluating data, the therapist might ask such a patient to rate his degree of preoccupation and conviction regarding a delusion on a 1% to 100% scale. If the patient reports being 99% certain of the delusion, the therapist might quip, "So we can work with the 1%."

Because the wish to reduce distress drives treatment, the therapist must determine what the patient finds most distressing about the current situation. While a diagnostically oriented clinician might aim at eliminating symptoms like "voices," the patient may be initially unconcerned about the "voices" and yet quite distressed that the patient's family regards them as imaginary. The therapist will want to establish rapport by empathizing with the patient's beliefs and feelings from the patient's point of view. The therapist might say, "Having heard what you went through, I can see why

Telegram: @medical_k

www.konkur.in

you came to the conclusions you did. When you first noticed strangers in your neighborhood looking at you, you concluded that you were under surveillance. I can see how that made sense to you at the time." The therapist may go on to ask what other people think about the patient's belief. What does the patient's family say? Does anyone share the patient's point of view?

The therapist can record the patient's life history on a *timeline* sketched out along a horizontal line on paper and add to the timeline as history accumulates. Putting the patient's history down on paper will frame the therapeutic alliance around a shared data set. In many cases, the timeline will be the first occasion the patient has ever constructed any organized, linear sequence of personal history. Life events that psychotic individuals have trouble connecting in their minds can sometimes be connected on paper by noting their physical proximity on the page. For example, the therapist might say, "We marked your parent's getting divorced right here when you were away at school, and I see the 'voices' started up a short time after that."

Temporal sequences, and therefore causal links, can often be better established on paper than in the flow of conversation. The use of paper also gets the patient used to working with diaries and documents in homework assignments. At a later time in treatment, it will be extremely useful for the therapist to draw two columns representing alternative beliefs so that evidence for and against each belief can be arrayed in each column. It is important to inquire about a history of physical or sexual abuse or bullying, but it is wise to establish some rapport with the patient before venturing into this territory. Even when the patient has been abused, the patient may not tell the therapist early in treatment. Substance abuse is usually more easily acknowledged.

If the patient hears "voices," the therapist should inquire about the identity, purpose, and power relationship to the patient, the consequences of non-compliance with the "voices," and whether the patient regards them as omnipotent or omniscient. As noted earlier, the therapist should inquire about what diagnosis the patient has been given, by whom, and what it means to the patient. The therapist will want to know what the patient's daily life is like and what relationships are important to the patient. The therapist should consult the chart and collaterals for additional information and, of course, screen for danger to self or others.

Telegram: @medical_k

www.konkur.in

Introduce the Principles Underlying CBTp With an Initial Emphasis on Coping Mechanisms. After the therapist has constructed a comprehensive timeline and identified the primary sources of the patient's distress, goals for treatment with the patient can be addressed. The fundamental aim is to reduce distress rather than necessarily eliminate symptoms. Goals might include an increased understanding of what triggers psychotic symptoms, improved coping with residual symptoms, reduction in stress related to delusions and hallucinations, and maintaining gains and preventing relapse. The therapist should inquire as to what coping mechanisms the patient currently uses.

If a patient has abandoned hope of coping, this may be a grave sign. The therapist may ask patients if they would be interested in learning how other patients cope with distressing experiences. Most will say yes. This conveys the implicit message that what is happening to the patient has happened to other people: the patient is not alone. Most coping techniques involve the re-direction of attention away from distressing symptoms or toward more rewarding interests. Patients may distract themselves by listening to music, or practice focusing away from symptoms and on to pleasant imagery. The therapist can go through a list of possible coping techniques with the patient and choose several to try as a homework assignment. Coping cards that the patient can carry are useful. By highlighting the patient's coping capacity, the therapist underscores that symptoms are not entirely outside the person's control.

The therapist can explain the three basic models underlying the CBTp approach: (1) the stress/vulnerability model that emphasizes the importance of stressful life events in the genesis of distressing experiences; (2) the continuum model that finds analogies to psychotic symptoms in ordinary mental life, and 3) the A-B-C model noted earlier. The therapist should be fluent in each of these models and be able to explain them clearly to the patient. The stress/vulnerability model is a good place to start. The therapist should avoid appearing to be an expert lecturing the disempowered student. One might say, "Everyone experiences stress at some point in life. Stress can result in worries and a lack of sleep. I have certainly felt the effects of stress myself."

Discuss the Normalizing and A-B-C Models in More Detail. *Normalizing* psychotic symptoms equalizes the power relationship between the patient and therapist, which encourages a good-faith

Telegram: @medical_k

www.konkur.in

exploration of the patient's symptoms without the serious risk that the patient will feel diagnostically stigmatized. The patient will hear the therapist saying, "We all have a bit of what you have, though you have more than most." Normalizing encourages patients to place their symptoms in a psychological realm rather than regard them as problematic realities. The therapist should be prepared with a variety of personal examples of psychosis-related mental events that can be shared. One might normalize hearing "voices" by describing hallucinations of everyday life, such as hearing one's name on the street when no one is speaking, or by describing how "voice"-hearing is a variant of the self-talk and internal dialogues everyone engages in from time to time, as when we say to ourselves sub-vocally, "You idiot!", or when, on a diet, we say to ourselves "Who are you kidding! You don't need dessert!"

Although affect and cognition interact in a dialectic manner, it is useful to teach patients the A-B-C model that emphasizes beliefs. This can be taught first in abstract outline, then from the therapist's personal examples, then from mundane examples from the patient's experience, and eventually in relationship to the patient's core delusional beliefs. The A-B-C model can be used to analyze a relatively neutral event in the patient's life. This gives the patient and therapist practice with the concept. The patient is invited to examine a distressing "A," ideally an event about which the patient already expresses some doubt.

As the patient and therapist begin to use the A-B-C model to examine the patient's core psychotic experiences, the therapist can return to normalizing to emphasize the range of beliefs and perceptions that occur in ordinary mental life. The author sometimes tells patients the story of how in dim light, he 'hallucinated' the image of a black dog curled up on a bed that turned out to be a black sweatshirt thrown on the bed in such a way that the arms of the sweatshirt looked like the folded legs of a curled up dog. This example illustrates how we sometimes "see" what we expect to see.

Apply These Models to the Patient's Experience and Begin Investigating Core Psychotic Beliefs. The therapist can with advantage adopt a "Columbo-style," off-hand way of talking. "Columbo" was a detective on television, played by Peter Falk, who spoke in a casual manner that belied what he knew. The therapist fosters a therapeutic alliance not based on the therapist's claim to know what is in the patient's

Telegram: @medical_k

www.konkur.in

mind, but on the joint investigation of data consciously available to both patient and therapist. The treatment team consists of Watson and Crick sitting side by side, rather than Freud sitting behind Dora (one of his first patients).

The A-B-C model can be used to examine core psychotic experiences. The therapist can put two columns down on a piece of paper to examine alternative theories. First, the therapist and patient clarify the "A": What precisely did the patient experience? What precisely did the patient hear? The patient may have actually experienced only a muffled sound but later concluded it was a threat. An "A" may be a mental event, like a "voice," or an external event, like the glance of a stranger. Patients often merge the "A" and the "B" such that the event and the patient's belief about an event are simultaneous equated experiences. CBTp aims to separate the "A" from the "B" so that the patient's beliefs can be examined. The therapist might say, "If your explanation for 'A' is correct, your reaction is understandable. If there is any other way of understanding what is happening to you that would be less distressing, it would be important for us to discover it. Let's look at the evidence and see what we can figure out."

A rich toolbox of CBTp techniques has been developed to examine beliefs; for example, the practice of rating the patient's degree of conviction on a scale from 1% to 100%. If patients can be made aware of their convictions changing, the therapist can point out that while facts don't change, beliefs do, thereby categorizing the delusion as a belief rather than a fact. Other techniques include rating the likelihood of a belief, rating the value of the evidence, agreeing to disagree about final conclusions pending further assessment, peripheral questioning, informational handouts that increase real-world knowledge, googling topics during the session, inference chaining ("If this turned out to be true, what would it mean to you? Which explanation would you prefer to be true?"), homework assignments and diaries, reality-testing experiments, and self-esteem-building exercises.

Challenge Delusional Beliefs and Re-Formulate the Patient's Personal Life Narrative. On the basis of their joint investigation, the therapist can offer a tentative formulation based on the stress/vulnerability, cognitive, or biopsychosocial model that leads to a more adaptive alternative belief. A formulation using the stress/vulnerability model might
